Both schizophrenia and major depressive illness have a well-established genetic component. In fact, there are some adoption studies in which rates of schizophrenia were found to be equally high for adopted and nonadopted children ([Gottesman and Shields, 1982](#)). This finding has been taken to mean that a genetic predisposition accounts for much of the disorder seen in children. However, other data suggest that the more severe the parental disorder, the more likely a child is to be placed for adoption ([Sameroff and Zax, 1978](#)). This would indicate that children given up for adoption cannot be readily compared with those who are kept by their original families.

More recent work by Plomin and Daniels introduces the concept of shared and nonshared environmental influences ([Plomin and Daniels, 1987](#)). Plomin and Daniels developed this concept in response to their work on adopted children and twins. In particular, they documented that children living in the same family may nevertheless perceive their environment quite differently. For example, one child may have been influenced by the musical activities she shared with her father and may report her home to have been peaceful. Her brother, in contrast, may have focused on the verbal battles between their parents, grown up feeling rejected, and become a disturbed youngster. Since then, these authors have advanced the precision of measuring the environmental and genetic contributions to specific behaviors or psychopathologic conditions in children. For example, the shared environmental influences are determined by comparing the correlation of a behavior between

adopted children and their adopted siblings with children in other households, using the formula  $E_{NS} = 100 - h^2 - E_S$  where  $E_{NS}$  is the nonshared environment,  $h$  is heritability, and  $E_S$  is the shared environment. This formula suggests that the bulk of the environmental component is nonshared, whereas the shared environment, which includes parental behaviors, accounts for much less of the variance for most disorders ( [Plomin, 1994](#)).

In summary, there is good evidence that children are adversely affected by parents with a psychiatric illness. However, their vulnerability is primarily related to the overall number of stresses the child is exposed to, the pervasiveness with which each parental illness affects the actual caretaking practices of the parent, and by the children's genetic risk status. Thus, personality disorders in parents showing a pervasive and chronic course are more difficult for children to cope with than, say, an intermittent psychotic illness in the parent. Age and sex differences in susceptibility also exist but vary in developmentally expected ways.

## DEPRESSION IN PARENTS

Of all mental illnesses, depression in mothers has received most attention in the literature ( [Rutter, 1986](#)). Because the incidence of this condition among young women is at least 9% ( [Boyd and Weissman, 1981](#)), it potentially affects a large number of children. In fact, there are reports that the rate of depression in nonworking mothers of preschool children may be as high as 40% ( [Richman et al., 1982](#)). Both Richman and her group and Boyd and Weissman defined depression according to criteria of the ninth edition of the *International Classification of Diseases* ( [World Health Organization, 1977](#)), that is, exclusive of postpartum depression, known as "maternal blues," which occurs in more than 80% of women and is usually self-limiting ( [Stein, 1982](#)). However, it includes persons who, by criteria of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* ( [American Psychiatric Association, 1994](#)), have a single or recurrent episode of major depression (296.2 or 296.3), bipolar disorder, depressed (296.5), or dysthymia (300.40), with all the ensuing differences in each condition's genetic vulnerability.

The effects of maternal depression on children have often been described ( [Beardslee et al., 1993b](#); [Coghill et al., 1986](#); [Cox et al., 1987](#); [Cytryn et al., 1984, 1986](#); [Field, 1988](#); [Gershon et al., 1982](#); [Puckering, 1989](#)). Findings suggest that these children display a wide range of behavior-management problems. Although some appear depressed, especially when parental depression occurs early in the child's life ( [Hammen et al., 1990](#)), others show conduct disorders or hyperactivity ( [Orvaschel et al., 1988](#)).

More important, data from [Richman et al. \(1982\)](#), [Coghill et al. \(1986\)](#), and [Cox et al. \(1987\)](#) show that many children tend to maintain their abnormal behavior even after remission of the mother's depressive illness. For example, Richman and colleagues report that 58% of the 3-year-old youngsters in their study still showed behavior problems at the age of 8 years, even though maternal depression had remitted.

There are some suggestions from a large twin study ( $n = 315$ ) that nonclinically depressive symptoms yield a heritability estimate of 20%, a shared environmental estimate of 27%, and a nonshared environment estimate of 53% ( [Eley and Stevenson, 1995](#)). However, when adolescents on the high end of the continuum of depressive symptoms were analyzed separately, genetic factors accounted for much more (59%) of the variation. In another study, children aged 8 to 11 years showed a high shared environmental variation (60%) and low heritability (18%), whereas in the older group (aged 11 to 16 years), depressive symptoms were primarily accounted for by heredity (78%), with the shared environment explaining only 4% of the variation. Other findings suggest that children of parents with bipolar disorder are at significantly higher risk of showing disturbed behavior than those whose parents have a unipolar illness (20% versus 43%). Children with two affected parents show a far higher morbidity than those with one affected parent (74% versus 24%) ( [Gershon et al., 1982](#); [Puig-Antich et al., 1985](#); [Weissman et al., 1987](#)).

It has also been found that parents who have experienced a single depressive episode versus multiple depressive episodes exhibited few differences in their behavior toward their children, but mothers who in addition to their depression were also diagnosed with a personality disorder had the most severely compromised children overall ( [Radke-Yarrow and Klimes-Dougan, 1997](#)). The same authors also reported in a later article ( [Klimes-Dougan et al., 1999](#)) that children of depressed mothers are also more likely to report suicidality than the children of well mothers. This finding underlines the growing body of literature that shows that suicidality also runs in families ( [Brent et al., 1996](#)). In fact, in a large twin study by [Statham et al. \(1998\)](#), the heritability of serious suicidal attempts was 55%. Within that context, familial depression and suicidal attempts appear to be separately transmitted in families.

Obviously, the children of depressed parents are subject not only to genetic risk but also to a highly stressful environment. Studies examining the parenting style of depressed mothers have focused on direct mother-child interactions. For example, [Richman et al. \(1982\)](#), in a longitudinal prospective study of nearly 200 children evaluated at ages 3, 4, and 8 years, found a high correlation among maternal depression, the frequency the child was read to at home, and his or her reading age measured at age 8 years. This correlation was particularly prominent in boys. In another study, children who, at 2 years of age, had received little reciprocal cognitive stimulation from their depressed mothers performed poorly on cognitive tasks in school at 5 years ( [Meadows and Mills 1987](#)). Likewise, in the foregoing study of depressed mothers by Radke-Yarrow and Klimes-Dougan, children were most affected when their mothers had an associated diagnosis of a personality disorder that behaviorally translated into more critical, irritable interactions and psychological unavailability that was much more severe than in the purely depressed mothers ( [DeMulder et al., 1995](#)). Nevertheless, the literature suggests that, overall, depressed mothers are more preoccupied with themselves and consequently are less sensitive to the needs of their children ( [Billings and Moos, 1983](#); [Cox et al., 1987](#); [Field, 1984](#); [Zekoski et al., 1986](#)). In particular, they are said to stimulate their babies less, that is, use fewer questions, explanations, and suggestions ( [Cox et al., 1987](#)), and have a less consistent attitude toward disciplining. They are also less able to compromise ( [Kochanska et al., 1987](#)). Moreover, there is increasing evidence that, at least in mothers of infants and toddlers, the pharmacologic treatment of mothers does not have clear beneficial effects for the children (Panikkar, 2000). This may be related to Radke-Yarrow's observation that there remain "residuals" of the depression in many of these mothers that are sufficient to compromise at least some socioemotional aspects of young children's development. Furthermore, data by Sameroff and his colleagues indicate that depressed women more often marry or live with depressed or otherwise psychiatrically disturbed men than do women with, for example, obsessive-compulsive disorders ( [Sameroff et al., 1993](#)); that is, assortative mating takes place in this population. The same group of investigators found that overall family functioning is the most powerful mediator of the mental illness variable and is a better predictor of future child mental health than are the details of postpartum and lifetime histories of parental depression ( [Dickstein et al., 1998](#)). Families are compromised only when mothers are symptomatically depressed and not when they are between depressive episodes. However, it seems to be true that depressed mothers overall show a wide variety of interactional patterns, and some of them appear warm and very involved with their children even when these women are depressed ( [Cox et al., 1987](#)).

Another important area of research has been the relationship between maternal depression and children's attachment patterns. It appears that an increased number of children of depressed mothers (65% versus 35% in control populations) display an insecure attachment pattern when they are tested on the Ainsworth Strange Situation Paradigm at 12 or 18 months ( [Radke-Yarrow et al., 1985](#)). However, a similarly high rate of insecure attachment patterns is found among children who live with a wide variety of psychologically compromised parents, such as parents with anxiety or personality disorders ( [Benoit et al., 1989](#); Benoit et al., 1992; [Minde et al., 1990](#)).

Other studies have focused on the children and, here again, on their self-concept as a mediating variable in the intergenerational continuities of depression. Thus, [Jaenicke et al. \(1987\)](#) found that children at risk of depression had a more negative self-concept, a finding these authors thought to be related to the degree of blame and criticism they received from their mothers. [Hammen et al. \(1987\)](#) singled out negative self-concept as a cognitive mediator for later experiences, which then confirm a basically depressive predisposition.

In summary, it appears that parental depression is a significant risk factor for the mental health of children. The abnormal behavior in these youngsters is not limited to depression but can encompass a wide range of both introverted and acting-out behaviors. Although genetic factors seem to be important, the children's interpersonal experiences also affect their attachment patterns, self-esteem, and cognitive style, which, in turn, contributes to and maintains later depressive symptoms.

## OTHER PSYCHOSOCIAL ABNORMALITIES IN PARENTS

There are two other groups of parents whose maladaptive behavior toward their children has been thoroughly examined by mental health researchers. These are antisocial and abusing parents. Although some of their parenting characteristics resemble those of parents who show a personality disorder or other psychiatric disability, and although some antisocial parents also abuse their children more often than do parents who are not antisocial, these two groups display sufficiently distinct patterns of disordered parenting to warrant separate reviews.

### Antisocial Behavior in Parents

Many investigations document that antisocial behavior in parents is often associated with externalizing disorders in children such as delinquency or conduct disorders ( [Hinde, 1980](#); [Le Blanc and Loeber, 1993](#); [Loeber and Stouthamer-Loeber, 1986](#); [Wadsworth, 1979](#)). This has been true in different ethnic and cultural groups ( [Minde and Nikapota, 1993](#); [Rohner, 1975](#); [Werner, 1979](#)). [Loeber and Stouthamer-Loeber \(1986\)](#), in a metaanalysis of those studies, find that data cluster around four risk

factors: conflict, neglect, deviant values, and marital discord.

#### *PARENT-CHILD CONFLICT*

Investigations of parents of children with externalizing disorders identify two ways in which ineffective parenting strategies can contribute to such difficulties. Some investigators label ineffective parenting to be a precursor to child misbehavior ( [Pettit and Bates, 1989](#); [Shaw et al., 1994](#)), whereas others focus on ineffective parenting as a response to these children's conflictual behaviors ( [Patterson, 1982](#); Patterson et al., 1993). Typically, both types of studies support the view that these parents rely on negative, insensitive, and harsh strategies rather than positive ones such as reasoning, negotiation, and compromise ( [Campbell, 1995](#); [Kochanska and Aksan, 1995](#)). Investigators also agree that parents are usually aware of and are displeased with their child's disobedience but are unable to set adequate limits or to employ constructive and nonaggressive ways of disciplining. As a consequence, the child's behavior fails to improve, and this leads to an escalation of maladaptive parental attempts to take control, to a point at which parents and youngsters see each other as enemies. The basic deficit underlying this pattern seems to be parental insensitivity to the child's emotional needs, especially the need for structure and regulation. The children feel rejected, and this feeling, together with nagging and coercive discipline, is directly related to later delinquent behavior. In contrast, competent parents use preemptive rather than reactive strategies to handle conflict in their preschoolers, and this single difference in parenting best distinguishes children who show conduct problems 2 years later from those who do not ( [Gardner et al., 1999](#)).

#### *NEGLECT AND DEVIANT VALUES*

[Loeber and Stouthamer-Loeber \(1986\)](#), in reviewing available studies, concluded that the lack of parental supervision and the absence of parental involvement with their children are both significantly correlated with the development of later conduct disorders. It appears that lack of parental supervision is also strongly associated with delinquency ( [Wilson, 1987](#)). Delinquent children, in turn, often come from homes with no or few house rules, inadequate disciplining, and little parental monitoring of delinquent behaviors ( [Patterson, 1982](#)).

Moreover, parents who exhibit antisocial behaviors themselves also tend to condone abnormal behavior in their children and therefore may serve as models for deviant activity or problem solving ( [West and Farrington, 1973](#)). Support for this concept comes from the observation that delinquency in children is more strongly associated with a parent's current rather than past criminality or delinquency ( [Robins et al., 1975](#)).

#### *MARITAL DISCORD*

As is common in families in which a parent has a specific psychiatric diagnosis, families with antisocial members show much family discord, a powerful predictor of child adjustment ( [Rutter and Giller, 1983](#); [West, 1982](#)). In fact, there is abundant evidence that children in these families are exposed to both frequent and prolonged quarreling among their parents and temporary separations because of arguments, as well as to abuse of alcohol and drugs (Cummings and Davies, 1996).

In general, investigators and clinicians report that marital discord has both direct and indirect negative effects on children. The "direct" negative effect is that children copy the parents' angry, impulsive, and violent behaviors and thereby fail to learn appropriate social interaction skills, such as compromising, necessary for successful peer relationships. More recent work also suggests that children may respond to marital conflict with disturbances of affect regulation and increases in heart rate and blood pressure ( [Lieberman and Van Horn, 1998](#)).

In addition to these direct effects of marital conflicts are "indirect" consequences, mediated through the father-child or mother-child relationship. For example, mothers in high-conflict marriages are less warm and are more erratic in their discipline, and they frequently use guilt- and anxiety-inducing techniques ( [Fincham et al., 1994](#); [Harrist and Ainslie, 1998](#)). Fathers in such situations also withdraw more from the parenting role and show more negative interactions with their children than do fathers in low-conflict marriages ( [Doherty, 1998](#)). Finally, parents in such conflictual relationships are more often depressed, and this is also linked with impaired family functioning.

#### **Child Abuse**

By definition, child maltreatment is the most telling syndrome associated with deviant parenting. As is shown in [Chapter 100](#) and [Chapter 101](#), child abuse is a complex problem that cuts across all classes of society, although it is more commonly seen in poor families ( [Pelton, 1978](#)). Official sources claim that in 1995 there were about 1 million substantiated reports of child maltreatment and 1,000 child fatalities resulting from abuse and neglect in the United States ( [U.S. Department of Health and Human Services, 1997](#)). Children 3 years old and younger comprised 77% of all child fatalities. Life prevalence rates of sexual abuse are estimated to be as high as 62% for girls and 31% for boys ( [Dubowitz, 1986](#)).

Although these figures appear horrendous, the reader should be aware of significant differences in the definitions of abuse, among other things, because of the preconceptions of individual professional groups and differing community values ( [Barnett et al., 1993](#)). The definition can also include qualitative, as well as quantitative, aspects of abuse. For example, physical or sexual abuse may happen once or repeatedly (i.e., are experienced as one or more events), or there may be an ongoing abusive relationship between a caretaker and a child ( [Glaser and Prior, 1997](#)).

What, then, are the parental behaviors associated with abuse? Direct answers are difficult because the maltreatment of a child is usually not just a function of parental deviance but the result of an interaction between child and parent ( [Cicchetti and Risley, 1981](#)). Furthermore, because of its generally low incidence per individual, unique characteristics of abusers cannot be readily identified. However, in many cases, abusing and neglectful parents have been adversely affected by their own past experiences ( [Harmer et al., 1999](#)), and they often live in suboptimal physical and social conditions ( [Boyce et al., 1998](#)); these factors make them less tolerant toward children with a difficult temperament or a chronic illness. Abusive parental behaviors therefore are seen as a consequence of an interaction between parental stresses and available supports ( [Belsky and Vondra, 1989](#)). One can also argue, as [Rutter \(1989\)](#) does, that child maltreatment reflects primarily a substantially abnormal pattern of parenting that may lead to such manifestations as physical or sexual abuse, failure to thrive, or even to deliberately created iatrogenic illnesses such as are seen in the Munchausen by proxy syndrome. Authors who have studied the parental contribution to abuse describe both personality factors and psychological disturbances:

#### *PERSONALITY FACTORS*

There is reasonable evidence that psychological maturity and parental competence are correlated, and it is more often younger and less mature mothers who abuse their children ( [Ragozin et al., 1982](#); [Unger and Wandersman, 1985](#)). This finding has been documented in a longitudinal study of 267 economically deprived families, in which those who abused their children early on had lower scores on scales assessing locus of control and higher scores on aggression, suspicion, and defensiveness ( [Brunquell et al., 1981](#)). In an investigation of 570 German families with abusing parents who came from diverse social classes, [Engfer and Schneewind \(1982\)](#) found the abusing parents to report very unfavorable socialization experiences in their own past. This experience, in turn, was related to heightened irritability and nervous tension as well as family conflict, leading to frequent angry outbursts and harsh punishments of the children.

#### *PSYCHOLOGICAL DISTURBANCES AND INTERGENERATIONAL TRANSMISSION OF MALTREATMENT*

There has been a long-held belief in the scientific literature and popular press alike that the majority of abused children will become abusing parents ( [Friedrich and Wheeler, 1982](#)). Reports emphasizing such continuities are usually retrospective, that is, based on studies of parents who had abused a child and who then reported about their own backgrounds ( [Steele and Pollock, 1968](#)). Investigations using an epidemiologic and prospective approach found a much lower rate of intergenerational transmission of maltreatment. For example, in one prospective study ( [Hunter and Kilstrom, 1979](#)), in which 282 parents of newborns admitted to an intensive neonatal care unit were interviewed and were followed for 1 year, only 18% of mothers who had reported abuse in their own childhood repeated it with their children. Similar figures have been presented by other investigators ( [Kaufman and Zigler, 1987](#); [Strauss, 1979](#)).

The mechanism of transmitting maltreatment from one generation to the other has not yet been established ( [Egeland et al., 1988](#); [Kaufman and Zigler, 1989](#)). Some authors claim that abusive parents teach their children that aggression is an appropriate way of dealing with conflict ( [Burgess and Youngblade, 1990](#); [Hertzberger, 1983](#)). Proponents of attachment theory suggest that children in abusing families develop representational models of the world that are so traumatic that they cannot be remembered in an integrative fashion and therefore cannot serve to prevent a repetition of these behaviors in the next generation ( [Bowlby, 1980](#); [Sroufe and Fleeson, 1986](#)). A maltreating caregiver therefore is both frightened and frightening, and his or her current attachment model is characterized by a lack of resolution of loss or trauma, resulting in contradictory and unintegrated mental contents. There is some support for this concept from studies that prospectively followed abused

children and found that most fit the D (disorganized) category of attachment ( [Lyons-Ruth and Block, 1996](#)). [Crittenden \(1981\)](#) adds an A/C category (describing a mixture of dismissive and overinvolved behavior) to the traditional attachment ratings and has evidence that this combined category is found in more than 80% of abusing caretakers. It is interesting that [Cummings et al. \(1994\)](#) also find that physically abused boys are more behaviorally reactive to interadult anger than comparison subjects. This finding implies that greater anger and aggression experienced across various family subsystems (e.g., parent to child, parent to parent) have a cumulative effect and sensitize rather than habituate children to hostility in others. This also means that attachment can have an important mediating role both in increasing and decreasing the likelihood of abuse.

Belsky (1984, 1993; [Belsky et al., 1984](#)), who has developed the most comprehensive model of abuse to date, suggests that low self-esteem, poor interpersonal skills, and a low intelligence quotient (IQ) provide a matrix that often leads to marriages to deviant and unsupportive spouses. This situation, in turn, creates marital discord, which leads to poorly behaving children whose behavior irritates their parents and causes them to commit abuse. [Quinton et al. \(1984\)](#), [Quinton and Rutter \(1985\)](#), and [Dowdney et al. \(1985\)](#), in a study that assessed parenting capacities of 89 women raised in institutions, also demonstrate that both assortative mating and marital discord provide an important link that continues poor parenting from generation to generation. They also point out that even among these very high-risk women, 40% had no difficulties in psychosocial functioning, and only 18% had their children placed into care, although almost half of these mothers had later children whom they managed to parent well. This finding suggests that many poorly parented persons will nevertheless be able to move from a deviant life path into a more integrated and positive developmental trajectory.

In summary, much evidence points to the association between antisocial and abusive parents and later psychopathology in children and adolescents. However, here again, we do not find a parenting style that is specific to a particular disorder in the caretaker. Rather, we observe that such parents neglect their children, dismiss their need for sensitive understanding, or behave in ways that generally fail to support their children's overall social and emotional development.

## ORIGINS AND CLINICAL MANIFESTATIONS OF DISORDERED PARENTING SKILLS

The final segment of this chapter is devoted to the discussion of the substantial literature that examines how specific maladaptive parenting patterns come about and to what degree specific parental actions or strategies become associated with behavioral difficulties in the children. A better understanding of these pathways is clearly important to facilitate remedial efforts.

In the search for meaningful general dimensions of problematic parent-child interactions, two categories have been conceptualized most clearly. One is characterized by emotional detachment and lack of involvement (i.e., too little control), and the other is characterized by excessive control through hostile harsh disciplining and overt maltreatment.

## PARENTS WHO SHOW EMOTIONAL DETACHMENT AND LACK OF INVOLVEMENT ARE UNRESPONSIVE AND INSENSITIVE

Parents whose behaviors fit this category make children feel misunderstood, rejected, or emotionally abandoned in the sense of attachment theory ( [Sroufe, 1983](#)). The association between parental detachment early in life and later psychological disturbance has often been made. For example, work by Minde and his colleagues shows that a mother's sensitivity to the social cues of premature twins within the first 3 weeks of life predicts which one of the twins will be preferred by her 4 years later ([Minde et al., 1990](#)). Rutter and colleagues, in their study of parenting abilities of women reared in institutions, also showed that among women placed in care before the age of 2 years, a much higher proportion had a personality disorder than did those whose primary attachments were disrupted after the age of 2 years (32% versus 5%). These authors also assessed the degree to which parental disorder determined when the separation took place and found that children who were placed in institutions in early infancy were more likely to have had parents who abused "hard" drugs or alcohol or who had a criminal record. Yet their own later parenting competence was less predicted by their parents' deviance than by the age of placement, with placement at a younger age predicting poorer parenting later in life. Most important, 80% of the girls who were admitted to an institution before the age of 2 years and who remained there until at least age 16 years were poor mothers, whereas only 30% of those who returned home before age 16 years showed poor parenting skills. This occurred even though many of these girls returned to families that experienced severe social disadvantage and marital discord. Of the girls who were placed after the age of 2 years, 45% also showed significant problems in their parenting skills later on, and those who returned home did not differ from those who remained in the institution during all of their childhood. The reason was thought to be the degree of active hostility, rejection, and punitiveness the children encountered on returning home ( [Rutter et al., 1983](#); [Rutter and Quinton, 1984a](#)).

One other longitudinal study highlights the crucial importance of parental sensitivity and care for normal development. Tizard and her group studied a sample of 65 children who had been placed, shortly after birth, in well-run institutions in Britain. Twenty-four of these children were adopted by the age of 4 years; others remained in institutions longer. Most had returned to some type of family by the age of 16 years. In an earlier article, [Tizard and Hodges \(1978\)](#) emphasized that most of the early-adopted children (before age 4 years) had developed good, stable, affectionate relationships with their adoptive parents, whereas those adopted between the ages of 4 and 8 years showed poorer relationships with peers and others. At age 16, they found that the children who were returned to their biological parents (the restored group) sometime after the age of 2 years showed a far higher rate of serious psychiatric disorders than did those who had been adopted early, partly because the former group had lived in a highly disadvantaged environment after their return home ( [Hodges and Tizard, 1989b](#)). However, 12 years later, even the successfully adopted children were more indiscriminately friendly, had fewer close peer relationships, and confided less in others than did the controls. At the same time, their academic performance was not affected ([Hodges and Tizard, 1989a](#)), a finding suggesting that the lack of sensitive early caretaking had left a mark on the quality of social relationships these youngsters had in late adolescence but not on their academic functioning.

Data by [Rutter et al. \(1998\)](#) and [O'Connor et al. \(2000\)](#), reporting on 111 Romanian children who were adopted by British families after a variable stay in highly neglectful institutions, confirm that children who were adopted into caring homes before 6 months ( $n = 58$ ) despite severe initial delays (mean Denver score of 56.8) showed good cognitive recovery by age 4 years (mean Denver score of 115.7). This was not true for the children who were adopted between 6 and 24 months, because their scores at 4 years old were significantly lower (mean, 96.7). More important, however, both early- and late-adopted children showed symptoms compatible with a severe attachment disorder (e.g., indiscriminate approach to strangers, lack of checking back with a parent) and an inability to conceptualize the feelings and thoughts of others as described by [Fonagy and Target \(1998\)](#). However, here again, the rate of disorder in the early adoptees was far lower (7%) than in the late-adopted children (22%), although the number of children exhibiting mild disturbances was similar in the two groups (37% versus 39%). These patterns remained quite stable during the subsequent 2 years. There was also a significant correlation between attachment disorder behaviors and hyperactivity at age 6 years ( $r = 0.42$ ) ([O'Connor et al., 2000](#)).

It therefore seems that a caretaker's severe lack of involvement and responsiveness toward a child's emotional needs has both cognitive and emotional consequences, at least in a minority of children. Moreover, although it appears that later adequate caretaking can repair cognitive shortcomings, this is not necessarily true for the social and emotional development of such children, many of whom are left with behaviors that may compromise their later ability to parent their own children.

## Parents Who Exert Control Through Hostile, Rejecting, Harsh Discipline and Overt Maltreatment

The manner in which parents control the behavior of their children has long been seen as an important predictor of children's later social and intellectual competence ([Maccoby and Martin, 1983](#)). Research has broadened the concept of *control*, which now includes not only the parents' use of discipline and punishment but their overall monitoring of behavior, handling of conflict, and their emotional style of coping ( [Dowdney et al., 1984](#)). Thus, control now not only relates to the degree of power a parent uses in disciplining children but also includes a democracy versus autocracy dimension.

The relevance of this distinction has been shown in numerous empirical studies. Briefly, Baumrind ( [1967, 1971, 1989](#)), in response to the work of [Baldwin \(1955\)](#), developed a tripartite division of parenting styles in which she contrasted authoritarian, permissive, and authoritative categories. Authoritarian parents, in a prospective study involving 134 children, are observed to be controlling and autocratic. They praise and blame without giving clear criteria for acceptable conduct, display anger readily, and are not very involved in their children. Their children, in turn, are passively hostile, anxious, timid, unhappy, and have little self-esteem ([Loeb et al., 1980](#)). They also score low on measures of conscience; that is, they have not developed a successful way of internalizing societal values ( [Hoffman, 1975](#)). Finally, [Dornbusch et al. \(1987\)](#), using a sample of 8,000 children from different ethnic regions, find that the association between low self-esteem and authoritarian parenting holds true in all social classes and among all ethnic groups and, more important, also influences academic achievement. [Steinberg et al. \(1989\)](#) confirm these results and document that children who live in authoritarian families are not only affected in their emotional development but show academic difficulties at least up to the age of 17 years.

Then there are the permissive parents who employ a low level of control, either because they adopt a democratic philosophy and trust their children or because they are not very interested in taking on child-rearing responsibilities and provide little or no active guidance ( [Lamborn et al., 1991](#)). Their children tend to be disorganized,

lack a sense of competence and purpose, and do not apply themselves academically.

The third style of parenting, called authoritative, combines parental warmth and acceptance or involvement with a certain degree of control or strictness. This seems to give the children a feeling that their parents take them seriously and would help them if they need assistance, but that they also have clear expectations of acceptable behaviors that would be enforced. In follow-up studies, authoritative parents have children with the best behavioral outcome and highest school achievement, at least up to late adolescence ([Steinberg et al., 1989](#)). It is remarkable that these children also internalize parental values most readily. This has puzzled investigators because the strong external controls imposed by authoritative parents would be expected to undermine the internalization of moral values, as happens in children of authoritarian parents. Although the debate is ongoing, some investigators suggest that overall parenting is divided into “parenting practices,” which provide the content such as spanking or insisting that children do their homework, and “parenting style,” which refers to the emotional climate such as tone of voice, body language, or display of temper. The authoritative parent communicates feeling comfortable with being in control but at the same time also recognizes and respects the child's wishes and need for separateness. Control can then be seen here as one way to get the child's attention, an essential prerequisite for any effective parenting or disciplining. This is not what an authoritarian parent communicates.

Nevertheless, there is evidence that these constructs do not work for all children equally well ([Darling and Steinberg, 1993](#)). For example, African-American parents who use some aspects of authoritarian child rearing (e.g., are more controlling, more critical, and more inclined to value conformity than independence in their children) have better-adjusted youngsters than those exercising permissive or authoritative child-rearing patterns. This finding confirms the clinical observation that optimal child-rearing techniques may differ among families living in different cultures and socioeconomic circumstances ([Baldwin et al., 1993](#)).

Although these investigators explore the parents' child-rearing styles, others ([Grusec and Goodnow, 1994](#)) study the conditions that determine the child's willingness to comply with or accept a parent's rules or values. Grusec and Goodnow claim that three relationship values—warmth, protection, and mutual compliance—are the primary sources for the development of moral values. This means that for these authors, concepts associated with secure or insecure attachment patterns are important building blocks for the development of children's prosocial behaviors. This indicates that identification with the parents is helpful for internalizing values but that the equally necessary suppression of antisocial impulses requires authoritative parenting practices.

Finally, there is also evidence for an association between an authoritarian parenting style and open childhood aggressivity ([Patterson, 1982](#)). According to Patterson's data, openly aggressive children receive more punishment for an aggressive act than do normal controls, yet they do not modify their behavior. The particular interactions that determine whether a child of authoritarian parents will be passive or openly aggressive have not been precisely identified, although data point to certain moderating factors within the environment and the child. These are discussed in the next section.

## **FACTORS THAT CAN EXACERBATE OR MODERATE THE EFFECTS OF DISORDERED PARENTING ON CHILDREN'S DEVELOPMENT**

Many life events can have a profound effect on the behavior of parents and, through them, on their children. Such events include parental separation, divorce, or the death of a primary caretaker. These topics are discussed in other chapters ([Chapter 21](#), [Chapter 35](#), [Chapter 36](#), [Chapter 103](#), [Chapter 104](#), [Chapter 108](#), and [Chapter 109](#)).

Another significant factor is the parents' marital relationship. [Emery \(1982\)](#), in an earlier review of this literature, points out that despite methodologic variations among empirical studies, the connection between interparental conflict and behavior problems in children is solidly established. Other investigators find evidence of a compensatory process; that is, parents in less satisfactory marriages may show especially sensitive and involved caretaking ([Brody et al., 1986](#)). Still others find evidence of both facilitating and detrimental effects ([Cowan and Cowan, 1987](#); [Goldberg and Easterbrooks, 1984](#)). [Cox and her colleagues \(1989\)](#) hypothesize that the apparent discrepancy in the data is related to the psychological adjustment of the parents. Thus, disturbed persons tend to marry partners with a complementary psychiatric disorder ([Merikangas, 1982](#)), which may lead poorly adjusted partners to have an outwardly harmonious marriage and family life, whereas in fact their children receive compromised parenting.

Additional support for a connection between marital discord and child behavior comes from behavioral observations obtained from laboratory studies. For example, the number of symptoms displayed by children in the laboratory is correlated with specific marital satisfaction scale scores, as supplied by the mothers ([Emery and O'Leary, 1984](#); [Jouriles et al., 1988](#); [Weiss and Summers, 1983](#)). Correlations between marital status and child behavior in these studies usually range between .20 and .25, which is statistically significant, but nevertheless, it explains only about 5% of the variance and leaves much room for other factors.

Another strategy for looking at the impact of parental relationships on children has been developed by Cummings and his colleagues. In experiments, this group and others exposed pairs of children to an adult couple who, after an initial friendly encounter, engaged in a carefully rehearsed verbal argument, followed by reconciliation. The children were observed both during and after each episode. Results showed that children as young as 2 years old become very upset when they see adults quarrel, and they become more aggressive toward each other after they have witnessed such an argument ([Crockenberg, 1985](#); [Cummings et al., 1985, 1989](#); [El Sheikh et al., 1989](#)). It is of special interest that children from families with reportedly higher marital discord show more preoccupation and feel more responsible for the arguments they see in the laboratory. This finding suggests that children living in troubled families become sensitized to parental arguments and are potentially more strongly affected by each recurrent disagreement.

Work by other investigators provides the important additional information that boys are generally more affected by parental strife than girls, but the behavioral consequences of witnessing behavioral discord may not be apparent for years ([Vaughn et al. 1988](#)). More important is increasing evidence that the negative effect of parental arguments can be significantly modified if the parents can make up after a fight ([Cummings et al. 1993](#)). Conversely, [Vuchinich and colleagues \(1993\)](#) document that parents who invariably unite against their children when problems occur, that is, present a “parental coalition,” prevent their children from learning problem-solving skills, and their children present with more externalizing symptoms, at least in preadolescence. This finding supports the notion that arguing things out can be a useful process, and it may be the lack of closure that compromises the children's later emotional well-being.

Finally, it appears that marital patterns are fairly stable and predictable. For example, [Howes and Markman \(1989\)](#) find a significant correlation between a mother's premarital relationship with her husband and their child's later attachment status. Thus, mothers who, before marriage, confided in their husbands and expressed their feelings freely are more sensitive toward their children, who, in turn, are more securely attached. This finding underlines the remarkable intergenerational continuity of good as well as problematic internalized relationships ([Sroufe and Fleeson, 1988](#)), and it may well be one important mechanism through which we transmit psychological normality or abnormalities to our children. It obviously also supports the attachment theory literature, which suggests that children develop specific types of attachment through actual experiences and create inner working models of the world that are based on these same actual events in their lives ([Main and Goldwyn, 1984](#); [Sroufe and Fleeson, 1988](#)).

As we stated previously, modulations in the quality of parenting can come both through changing support and stress factors within the environment and from the object of parental caretaking, the child. Although many child characteristics have been seen as potential contributors to parenting style, the difficult temperament of a child has been most frequently identified as a potential stress factor for parents. It has been observed that parents who view their children as temperamentally difficult display more negative affect toward them, are more critical, and punish them more severely ([Bates, 1980](#); [Campbell, 1979](#); [Dunn, 1980](#)). These children, in turn, appear to be less able to cope with negative parental behavior. For example, [Dunn and Kendrick \(1981\)](#) report that children with a high intensity of emotional expression and a negative mood show more difficulties coping with a new baby than do children with easy temperaments. Conversely, [Washington et al. \(1986\)](#) show that sensitive and committed mothers of small premature infants report an improvement of temperament in their infants between 3 and 12 months of age, whereas mothers who behave less contingently in the nursery do not report such temperamental changes. This finding underlines the multifactorial nature of even such allegedly biological constructs as temperament.

Other characteristics of children contribute to the caretaking they receive. [Patterson \(1982\)](#), in his study of aggressive youngsters, points out that some children react in an unusual way to punishment. When a psychologically normal child is punished by a parent, the probability that the child will continue to be aggressive is reduced. With certain aggressive children, however, the probability is increased. This finding suggests that these children, at least by school age, are less responsive than nonaggressive children to social reinforcement. In fact, there is evidence that aggressive children respond less to all types of social stimuli and may therefore indeed be more difficult to raise ([Maccoby and Martin, 1983](#)). [Block et al. \(1988\)](#), in a study of 105 adolescents who were followed between the ages of 3 and 14 years, were able to make significant predictions about these youngsters' adolescent use of marijuana and hard drugs by examining their early behavior patterns. Thus, children who used marijuana in adolescence had been seen as rebellious, unconventional in their thinking, unable to delay gratification, and without ambition during their preschool years. Those who later used hard drugs were also described as emotionally bland, keeping people at a distance, and lacking in personal charm. Whether such behavior patterns are the result of genetics or are the result of a parenting style that leads to a general hyporesponsivity or rebelliousness of the child is not

known. However, there is currently no solid evidence that juvenile delinquency and conduct disturbances are genetically determined ( [Rutter et al., 1990](#)).

Finally, data suggest that prenatal and perinatal factors may be important contributors to later parental styles. Work by one group ( [Minde et al., 1983, 1988](#)) shows that the severity of illness a premature infant suffers in the neonatal intensive care unit significantly determines the type of parenting he or she receives. Parents of sicker babies initially behave in a more intrusive way, but they seem to give up after about 6 months; that is, they decrease their overall stimulation and contact significantly ( [Minde et al., 1988](#)). Similar findings are reported by [Wasserman and Allen \(1985\)](#) from an observational study comparing the play of premature, physically handicapped children with no central nervous system damage and control children with their mothers between the ages of 9 and 24 months. These investigators report that by 2 years of age, the mothers of the handicapped children have withdrawn from interaction, and this is associated with an average IQ drop of up to 20 points. This finding suggests that the absence of expected events characterizing normal physical or cognitive development can lead to a disruption of mother-child relations through maternal detachment or other parenting disorders ( [Affleck et al., 1982](#)).

In general, one can say that we think differently today about the families of children with mental handicaps than we did in the past. Whereas before 1980, the birth of a retarded child was viewed from a "pathology-based" model, with an emphasis on parents' "mourning the perfect child" ( [Blacher, 1984](#)), today such a child is seen as a stressor that can have both positive or negative effects on the family ( [Hodapp and Zigler, 1995](#)). In addition, there are special caretaking regimens for children with particular disorders, such as fragile X syndrome. A review article by [Byrne and Cunningham \(1985\)](#) supports this more inclusive notion of mental retardation by stressing that the difficulties parents face in raising mentally handicapped children are multifaceted and complex. Thus, parenting patterns of these children appear to be largely determined by factors such as the age and competencies of the child and the practical needs of each family. There is also evidence that mothers are more flexible when teaching their young mentally handicapped children than their nonhandicapped children, but they may fail to provide them with sufficient positive feedback ( [McConachie and Mitchell, 1985](#)). They may also underestimate their children's actual abilities ( [Banu and Begum, 1991](#)). Finally, in a study comparing how mothers feed 15- to 39-month-old physically normal and severely cerebral palsied children, [Reilly and Skuse \(1992\)](#) document that the handicapped children are fed with minimal verbal interaction and in a rather mechanical way. Furthermore, although the duration of feedings for the two groups is almost identical, the handicapped youngsters, because of severe motor dysfunction and poor overall feeding skills, are offered only 60% and eat only 50% as much food as their nonhandicapped peers. The authors suggest that such feeding practices may be responsible for a significant part of the retarded growth exhibited by many mentally handicapped children. This study also confirms the data by [Wasserman and Allen \(1985\)](#) and [Minde and his group \(1988\)](#), which suggest that parents need to be validated in their parenting activities by their children and that one important aspect of this is the child's "normal" look and behavior.

## ASSESSING PARENTING COMPETENCE

Mental health professionals, especially those working in child welfare agencies, have long wanted to deal with their increasing caseloads more effectively by identifying families or individual caretakers who are likely to neglect, harm, or otherwise seriously compromise a child's development. This has led many regional and state government agencies in 40 U.S. states to implement risk-assessment measures ( [Tatara, 1987](#)) to help agency staff decide on service priorities ( [English and Pecora, 1994](#)). Essentially, these measures consist of a systematic collection of information to help determine the likelihood that a child will be abused or neglected in the future ( [Steinhauer et al., 1993](#)). Once that has been established, other protocols are available to predict the likely severity of the maltreatment ( [Miller et al., 1987](#)).

The three basic types of risk assessment are as follows ( [Pecora, 1991](#)):

1. The matrix approach: Clinicians ask parents questions that are bundled in tables of 16 to 35 factors. Each factor measures behaviors that, in theory, are associated with child abuse (e.g., substance abuse; age of children in the house).
2. Empirical scales: These focus on a few risk factors that are most predictive of child maltreatment (e.g., caregiver abuse history as a child, mother's expectations of the child).
3. Family assessment scales: These assess such factors as family cohesion and adaptability ( [Olson et al., 1979](#)), child well-being ( [Magura and Moses, 1986](#)), and family risk ( [Magura et al., 1987](#)).
4. Child at risk field: This method uses an ecologic approach with 14 open-ended questions dealing with family, child, parent, maltreatment, and intervention issues.

All these measures have some face validity and some content validity, and child welfare workers usually agree on low-risk cases ( [English and Aubin, 1991](#)). However, the number of false-positive results is high, and there is no empirical evidence that any of the many available risk scales reliably predicts serious parenting problem behaviors ( [Wald and Woolverton, 1990](#)). Thus, most parents who drink, have a history of abuse, and have two or more preschool children will never hurt their children. Furthermore, a risk factor may be offset by one that can function as a buffer (e.g., a positive abuse history associated with high educational achievements). Some risks may also be more transitory (e.g., number of preschool children at home), and there are important developmental and other unpredictable components in all behaviors. Finally, cultural factors can significantly modify at least some risk factors for psychopathology in children from other cultures ( [Minde and Nikipota, 1993](#)). For example, family boundaries and kinship relationships even in a more collective subsociety within the United States may convey protection against maternal rejection. For example poverty, a high-risk factor for abuse in white neighborhoods, carries a much lower risk in black neighborhoods because poor African Americans generally have more social cohesiveness than equally poor white Americans ( [Korbin et al., 1998](#)). The previously mentioned work on the developmental appropriateness of an authoritarian parenting style among African Americans ( [Darling and Steinberg, 1993](#)) is also relevant here.

In summary, there is general agreement about the need to evaluate parenting competence and associated risks in many cases. However, at present, no instruments can conceptualize and assess parenting practices and styles with sufficient predictive validity to help clinicians in their day-to-day work. Future research in this area must be sensitive to the parameters of developmental psychopathology; that is, it must recognize developmental changes in potential victims, as well as policy, ethical, and cultural issues ( [Hamby and Finkelhor, 2000](#)).

## PARENT EDUCATION

Recognizing the powerful impact of primary caretakers on the behavior and emotional well-being of their children, also as future adults, has long stimulated educators and clinicians to think about how one can educate parents for the task of raising children and how to make them more sensitive to their needs ( [Sunley, 1955](#)). Although many different parenting programs have been offered to the public during the past 50 years, there have been until recently no specific guidelines for empirically validating parent education programs ( [Fine and Henry, 1989](#)).

1. Information sharing: This consists of providing information about developmental expectations, legal rights of parents and children, and other factual information. Lectures, printed materials, or group discussions are used to reach parents.
2. Improving self-awareness: Parents are encouraged to reflect on their own behaviors, to help them understand how their actions may influence their children. Group discussions, specific individual activities, and the use of diaries or logbooks are the most common methods of instruction.
3. Skills acquisition: Parents learn ways to manage children's behavior appropriately. They are trained through group discussions, practice assignments, and analysis of videotapes.
4. Problem solving: Parents are taught the use of more constructive strategies to deal with situations that may previously have led to conflict and arguments. These skills are taught by using feedback from reported actual events at home, direct observations during group sessions, and videotapes or audiotapes.
5. Psychoeducational preventive intervention: These programs aim to identify etiologic factors that may compromise parenting skills (e.g., a parent's mental illness or an infant's high-risk condition, such as prematurity or hyperactivity) and to enhance the strengths of parents and children. Intervention plans are individually tailored and designed to establish a therapeutic alliance within which information about a psychiatric illness or medical condition and the need for adjusting parenting practices become clinically meaningful ( [Beardslee and Poderefsky, 1988](#); [Beardslee et al., 1993b](#); [Brent et al., 1993](#); [Minde et al., 1980](#)).

Parent education programs are generally based on one of three major conceptual models—rogerian, skinnerian, or adlerian, each focusing on different aspects of development and addressing different areas of caregiver and child behavior.

1. Rogerian programs or reflective counseling: These programs are based on Carl Rogers' teaching and emphasize the understanding and acceptance of the child's feelings. Parent Effectiveness Training or PET ( [Gordon, 1975](#)) is a good example of this approach. Reflective counseling also helps parents to become more authoritative in their interactions with their children.
2. Skinnerian programs or behavioral management courses: Managing the actual behavior of children through behavioral analysis is the dominant feature of these parent education courses, such as the Responsive Parenting Program ( [Clark-Hall, 1978](#)). These programs emphasize information sharing and skills training and devote less attention to improving parental self-awareness.
3. Adlerian counseling: Education programs based on Adler's teaching emphasize that parents must understand the goals and meanings of their children's

behavior and use logical consequences to control it. The best known proponents of this approach are [Dreikurs and Soltz \(1964\)](#).

The effectiveness of these programs has not been well established, mainly because of problems with methods, objective measurements, matched samples of control populations, and adequate follow-up evaluations ([Medway, 1989](#)). Another problem is that different programs demand varying degrees of training and sophistication from their respective group leaders and therapists.

Despite such difficulties, there have been attempts to assess the effectiveness of parent education ([Beardslee et al., 1993b](#); [Minde et al., 1980](#); [Patterson et al., 1983](#)). In addition, in a metaanalysis of the 24 scientifically most acceptable programs, including studies of 12 behavioral training programs, 5 PET programs, and 7 adlerian programs, [Medway \(1989\)](#) reports that all of them are effective in that children and parents show an average of 62% improvement over their respective control populations. Those investigators who followed-up their samples for up to 6 months indicate that gains are enduring. Despite similar final overall outcome, data suggest that the behavior-management approach improves child behavior more rapidly than does reflective or adlerian counseling.

Programs using preventive psychoeducational interventions in clinical settings have typically been carefully evaluated ([Beardslee et al., 1993b](#); [Minde et al., 1980](#)). However, because group leaders usually require lengthy training and detailed knowledge of specific medical or psychiatric conditions, it is difficult for others to replicate the reported treatment effects.

In summary, there is some evidence that parent training can be helpful to interested adults who are committed to improving their parenting skills. Although parent education programs may be based on various educational models, there appear to be few if any differences in their effectiveness. This finding suggests that behavioral changes in children can be brought about by parental insight, by various interactional strategies, and through direct behavioral intervention by the parent. However, the long-term effects of such changes and their relation to more global behavioral variables, such as problem solving or social skills in children, have so far not been established.

## CONCLUSIONS AND UNRESOLVED ISSUES

The research discussed in this chapter shows the complexity of the factors that constitute the task of parenting. We have tried to outline some possible processes of psychological development that underlie the various research findings. We have also attempted to show how disorders of parenting are not static single variables but are best understood within the context of developmental psychopathology; that is, they reflect interactions between internal representations within parents and outside stresses and supports, as well as a range of child-related variables.

Although some of our data are strong enough to provide a basis for teaching those who come to us for advice, many of our hypotheses need further elaboration and confirmation. For example, we are still learning about the degree to which genetic factors determine parenting competence and about the compensating influence of nonparental caretakers on the later behavior of a child.

We also still poorly understand the effects of some child-centered mediating variables. For example, does the possibly genetic contribution children make to the parenting they receive operate through temperamental features or overall vulnerability to stress or through ways in which aspects of the environment are selectively perceived by the child, thus leading to greater or lesser levels of experienced adversity? The difference made by sex or the presence of older and younger siblings in the children's vulnerability to abnormal parenting also needs to be further explored. However, it is well recognized in child psychiatry today that developmental pathways show both continuities and discontinuities, and few experiences cannot be made up later in life; therefore, the study of parenting competence is central to the development of preventive and therapeutic interventions.

Finally, we need to be aware of the potential impact of a volatile political climate on the "status" of children and their caregivers. There are now rapidly growing organizations, such as No Kidding (from two to 47 chapters in 5 years) and online sites such as THINKERS (Two Healthy Incomes, No Kids, Early Retirement) versus SITCOMS (Single Income, Two Children, Oppressive Mortgage), whose protagonists aim to influence government support for parents in the United States ([Belkin, 2000](#)). Adequate parenting, although clearly centered within the personal experiences and philosophy of the individual, needs the continuous nurturing by society to ensure not only the best possible development of our children, but also the future health and welfare of this very society.

[Effects of Acculturation on Personality](#)  
[Culture and Biological Aspects of Personality](#)  
[Culture and Sexual Identity](#)  
[Conclusion](#)  
[Chapter References](#)

*Culture* consists of the variable values, attitudes, beliefs, and behaviors shared by a people and transmitted between generations. They constitute “a way of life” that helps to shape the developing personality from infancy through adulthood. It is generally accepted that cultural forces imprint the human personality, the part of us that deals with the outside world. But how? Culture is not simply a layer on top of a biological core. Rather, cultural influences are woven into personality like a tapestry. The development of this tapestry can actually be seen by watching the direct influence of child-rearing practices on the evolving personality of the child. In every country across the globe, the world of the infant is seen through the lens of a parenting person or persons. In many cultures, the main parenting person is the mother, with the father an important but secondary influence. In Asian societies, however, grandparents also have an important child-rearing function, so the refraction of the lens becomes more complex. Conversely, in African societies, infants and preschool children are managed by older siblings, who offer them a very different view of the world (Earls, 1982). However, whoever the primary caretaker may be, the infant's world soon grows to include others—first relatives, and then neighbors, who add new perspective. Later, the child's world expands to include community influence—other adults such as schoolteachers and peers. As the number of interaction partners expands and changes, the mix of new perspectives forms a more and more complex pattern in the evolving personality tapestry.

The view that an infant needs a primary relationship with one individual has been the traditional dominant view of social development, sometimes called the *continuous care and contact model* (Tronick et al., 1992). It was derived from the studies of Spitz (1965), Bowlby (1969), and Provence and Lipton (1962) on institutionalized children in the Western world. However, more recent work with more representative community population samples in other parts of the world suggests that early social experiences may be powerfully shaped by others than the primary parenting person, including fathers, siblings, and other children (Morelli and Tronick, 1992; Whiting and Edwards, 1988; Zukow, 1989). A newer *strategic mode* has emerged, that infant social engagement occurs in an interactive context heavily influenced by group composition, values, and customs. It is based on studies (Tronick et al., 1992) that show that patterns of simultaneous multiple relationships, rather than a single “mothering” person, may be determined by physical and social ecologic factors. An intriguing notion has been put forth by these developmentalists that such cultural practices may develop in the child a basic sense of self that incorporates other people and, thus, buffers against feelings of insecurity. It can even be hypothesized that the enhancement of self-confidence through multiple secure bases in the surrounding world allows children in some societies to explore their social and physical environment more readily.

### CULTURAL VARIATIONS IN CHILD REARING

How has the influence of culture on personality been studied? What is the evidence that differing child-rearing practices produce differences in personality traits? An anthropologist, William Caudill, was the first to scrutinize the interaction between children and the culture in which they grow. He found consistent cross-cultural differences in behavior that persisted from infancy through early childhood (Caudill and Schooler, 1973; Caudill and Weinstein, 1969; Tulkin and Leiderman, 1973). Caudill and Weinstein concluded (Caudill and Weinstein, 1969) that in Japan, the infant is perceived as a separate biological organism who needs from the beginning to be drawn into increasingly interdependent relationships with others, whereas in the United States, the infant is seen more as a dependent biological organism who needs to be made increasingly independent of others.

More recent, systematic studies of larger populations (Joshi and MacLean, 1997) point out that these early researchers focused too narrowly on the single trait, that is, autonomy, one that is valued and encouraged in the Western world, but that no culture, Western nor non-Western, really expects a child to become completely behaviorally autonomous. Indeed, it has been shown (Roland, 1998) that previous anthropologic writers failed to recognize that there can be other kinds of emotional and cognitive variations with their own developmental stages and schedules, which are highly adaptive to different social and cultural contexts.

Later studies further defined some of these differences (Stevenson and Lee, 1990). For example, a systematic investigation of Western and Eastern children's academic performance finds that U.S. mothers view their children as born with or without academic abilities, whereas Asian mothers are more likely to believe any child can succeed at reading or mathematics if he or she works hard enough. In other words, the emphasis given to effort, relative to ability, is much higher among Asian mothers than among U.S. mothers. These cultural beliefs are reflected in the children themselves; Asian children believe in the importance of effort, whereas U.S. children believe in the role of ability. The practical implications, of course, are that Asian children may work harder if they believe achievement depends on effort, or they may believe that effort is important because they have been successful. Similarly, U.S. children may do better because they believe in their ability, or they may perceive themselves as able because of how well they have done. The conclusion is that the belief that increased effort pays off in improved performance may be an important factor and may account for the time and effort Asian children, teachers, and parents spend on children's academic performance.

The effect of this different value system can be seen beyond the individual and small group. It is reflected, for example, at a national (and international) level in the so-called national character that is partly responsible for the economic success of Asian countries. National commitment to the success of the group over that of the individual and the relative absence of adversarial relationships in the workforce have shifted competition from within the group to another level—with other countries. Cultural values, built in from birth, rather than simply population numbers may be important in Asia's economic productivity.

Observations of children's play also reflects the influence of cultural norms about social behavior and self-expression (Farber and Shin, 1997). Children whose culture emphasizes a relational mode characterized by group interdependence, sensitivity to others, and a collectivist orientation reflect these cultural values in play. Conversely, children whose culture emphasizes independence and self-expression show play that is more conflictual. Whereas the former children enact more familial everyday activities and family role themes, the latter children enact more dangerous and fantastic themes.

Reports of child-rearing practices in other cultures featuring group settings with multiple caretakers have also highlighted the factors shaping personality. In the kibbutz (Beit-Hallahmi, 1977), the number of significant others interacting with the child is higher than in the traditional family unit, but the relationships among these figures is nonexclusive and is often discontinuous; that is, the caretaker is likely to be changed several times during childhood, so the youngster is exposed to a uniform, but less personal, treatment than in the traditional family. Theoretically, this weakens the dependence on a single significant figure, such as a parent, and reduces the intensity of feelings toward specific individual, by spreading it among others (Rabin, 1965). Indeed, a “kibbutz personality” has been described, one that shows positive but only moderate attachment to others, with a reduction in both intimacy and rivalry with peers. However, few differences are found between kibbutz and nonkibbutz children within the same culture because the Israeli culture as a whole is more collectivistic than Western societies.

In any case, we can conclude that human development is not bound to a single cultural model. Some cultures are individual centered, placing emphasis on independence and self-reliance, whereas others emphasize the interdependence of individuals within larger groups such as the family (Chiu, 1987). In these cultures, when individuals are successful, that success is attributed to the group rather than to the individual.

The ethnocentricity or culture blindness of Western theorists is illustrated in our most widely held paradigms of emotional and cognitive development. For example, the concept most central to psychoanalytic theory, the Oedipus complex, was shaped by the middle-class family roles of Little Hans and his parents in 19th-century Vienna. Piaget's own grandchildren in turn-of-the-century Geneva served as his research subjects, and generalizations were made from their cognitive development to that of others throughout the world. Kohlberg's six-stage hierarchy of morality clearly reflects a narrow cultural ideal and one that is male oriented. These observations about the cognitive and emotional development of a few middle-class European children led to narrow conclusions and far-reaching generalizations to other cultures.

Investigators who have studied parenting and child development across cultures (Bornstein et al., 1998; Shweder, 1991) argue that culture constitutes a lens through

which reality not only is seen, but also is interpreted and even constructed. Values deemed to be normative in one culture can be deviant in another; those deemed to have one sort of outcome in one society may well have other outcomes in other societies. Studies of children in cultures whose child-rearing patterns differ from one another teach us not only different models of child development but also what those different models have in common. The Whittings were an anthropologic team who conducted the first large-scale international research project to observe children systematically. They studied adult expectations of child behavior in seven different cultures ([Whiting and Edwards, 1988](#); [Whiting and Whiting, 1975](#)). Their findings led to two major conclusions. First, they found that the traditional stereotype of maternal behavior characterized by nurturance must be revised. Across all the cultures studied, parental efforts to control their children's aggression loomed much larger than nurturance in the profile of mothers' behaviors. Second, the influence of siblings and peers appeared to occur earlier and to be more powerful than previously thought. The influence of children on children, whether siblings, friends, or day care companions, must be better understood to outline a model of personality development.

## EFFECTS OF MINORITY STATUS ON PERSONALITY

Let us move from the usual way in which cultural forces are considered—that is, the effects of child-rearing practices on personality formation—to a consideration of the effects of negative subcultural forces on development. Some of the most important findings about personal identity and self-esteem have emerged from studies of minority children in the United States. Much of this work relates to locus of control. Individuals differ in the extent to which they believe that their own efforts can control the environment. This sense of internal control was traditionally found to be stronger in white children than in black children living side by side but having very different sociocultural experiences ([Karon, 1958](#)). In other words, caste or discrimination may result in lowered self-esteem in the minority group children. As one may expect, however, the context is an important variable. Other studies indicate that ethnic minority status itself is not related to lower self-concept ([Long and Hamlin, 1988](#)), if readily identifiable models for the self can be found among the minority group ([Powell, 1985](#)).

Studies of Native American culture carry these findings further. Cultural beliefs about the nature of the world affect locus of control and shape personality development. American Plains Indians emphasize a unity with nature. Thus, acceptance of natural events such as life and death, geography and climate, is the norm, rather than action to control or alter them. These values appear to produce accepting attitudes and behaviors in the children, in contrast to the competitive achievement orientation of Caucasian children in the same culture ([Long and Hamlin, 1988](#)).

Sharing is an important value taught to Native American children ([Yates, 1987](#)). Allegiance to the family and community is valued more highly than allegiance to the self. Competitive striving is not highly valued. Thus, a particular form of individualism emerges, one that is adaptive in Native American culture, but not in the larger outside world ([Wax and Thomas, 1972](#)). Life is considered to be an unhurried natural progression, with disease, death, and disability accepted as part of life's progress. Children progress at their own pace and are responsible for making their own choices. The result is adaptive within the culture but not across cultures. The basic cognitive development of Native American children approximates that of Caucasian children, but progress on culture-bound standardized tests declines as the verbal content of the scales becomes more prominent with increase in age ([Cazden and John, 1971](#)).

## EFFECTS OF ACCULTURATION ON PERSONALITY

*Acculturation* ([Berry, 1979](#)) is defined as a shift between cultures that forces personality change on the individual. The amount of stress on the developing personality is directly proportional to the distance between the two cultural groups and to the degree of insistence on change. The highest stress is seen in those groups that have been uprooted and geographically transplanted to another culture and have lost traditional social supports. In these cases, youngsters are confronted with a conflict between traditional values from the old country and contemporary values from the new country ([Lee, 1988](#)). Differences between conflicting values of the two cultures then become highlighted: group versus individual, extended versus nuclear family, interdependence versus independence, conformity versus competition, past versus future orientation, emphasis on age versus youth, harmony with nature versus conquest of nature, fatalism versus mastery of one's own fate, patience and modesty versus aggression and assertion, suppression versus expression of emotion. In successful acculturation, adaptation can be seen to occur by the formation of various combinations of these personality traits. However, conflict in values between the two cultures may delay acculturation ([Messer and Rasmussen, 1986](#); [Tobin and Friedman, 1984](#)). For example, many Southeast Asian adolescents who come to the United States have been primary caregivers or breadwinners for their families. Young girls may have been responsible for the care of the younger children; young men may have been heads of households, primary wage earners, or soldiers. To come from a culture in which one becomes an adult at puberty to a culture with the concept of adolescence as a prolonged transition between childhood and adulthood disrupts the developmental process. When a new set of values that reinstitutes dependence is superimposed on an old set in which independence had been achieved, the process of separation and individuation must begin all over again. Other studies of refugee teenagers ([Nguyen and Williams, 1989](#)) clearly demonstrate how contrasting values such as obedience to parental authority from the old culture versus freedom of choice regarding marriage and career in the new society are a source of stress to families and adolescents. The difficulty in the shift in values appears to be greater for girls, who experience more distress and resulting disruption of personality organization than do boys.

## CULTURE AND BIOLOGICAL ASPECTS OF PERSONALITY

Cross-cultural studies have consistently demonstrated that the pace and timing of the biological developmental process are significantly influenced by child-rearing practices ([deVries and Sameroff, 1984](#); [Levine, 1974](#); [Thomas and Chess, 1980](#); [Whiting and Child, 1953](#)). In one study, in which major influences on temperament are measured, cultural affiliation proves to be the strongest predictor of infant temperament in the first year of life. In other words, temperament is not a pure biological measure but is exquisitely sensitive to environmental influences. Perhaps temperament can best be viewed as a constellation of traits with a threshold for expression that varies from culture to culture. Temperament traits tend to fall into two clusters, which can be seen as culture related: rhythmicity, approach, and adaptability form one cluster, whereas activity, intensity, and distractibility form another. Group differences in neonatal behavior organization have been reported by comparing different cultural groups ([Coll et al., 1981](#)). Chinese Americans, Navajo Indians, and Japanese Americans are found to be temperamentally less excitable than other groups, as evidenced by lower levels of arousal, fewer state changes, and ease of consolability. Mexican Indians score higher on motor maturity, have smoother transitions from one state to another, and maintain quiet, alert states for longer periods, as do African infants from Kenya, who score higher on motor maturity and are better able to control increased motor tone.

[Lester and Brazelton \(1981\)](#) state that this motor precocity of African babies is facilitated by culturally determined child-rearing practices built on the infant's responsiveness to being handled in the neonatal period. Motor excitement of infants may elicit intense social handling from caregivers, and this, in turn, promotes accelerated developmental advance in motor skills. The conclusion is that child-rearing practices may facilitate early motor development through such an interaction.

Studies of babies' facial expressions of emotion yield somewhat different findings. Basic emotions of happiness, anger, fear, sadness, disgust, and surprise are the six emotions generally accepted as universal ([Ekman, 1992](#)). There is some evidence, however, that cultures may differ in their relative ability to recognize particular emotions, and the situations perceived as likely to give rise to these emotions may also differ among cultures ([Matsumoto, 1992](#); [Mesquita and Fujida, 1992](#)). Studies of the developmental differences in the recognition of emotion ([Markham and Wang, 1995](#)) find facial expressions of the six basic emotions universally recognized, but cultural differences in recognition of *specific* emotions suggest the extent to which learning may operate in moderating a hereditary trait. For example, the finding that children recognize happiness better than the other emotions across cultures suggests this to be the most commonly recognized facial expression. However, differences among cultures on recognition of sadness and anger suggest differences between collectivist and individualistic cultures.

To understand this interface between culture and child development better, Super and Harkness ([Super and Harkness, 1986](#)) conceptualize a construct called the *developmental niche*. (Niche is a term borrowed from biological ecology, meaning place in a biosystem.) It consists of three complementary components: (a) the physical and social setting, (b) the customs of child care and child rearing, and (c) the psychology of the caregivers. These are coordinated systems that relate to the larger culture and environment. Homeostatic mechanisms keep the three subsystems in harmony with each other and appropriate to the developmental level of the child. Although they are synchronous in developmental thrust, they constitute somewhat independent routes for disequilibrium and change.

Here lies the laboratory for studying the interaction of culture and biology. For example, Jerome Kagan's work shows that shyness, reflected in behavioral inhibition, is one of the fundamental dimensions of human social functioning, a universal biological rooted phenomenon ([Asendorp, 1990](#); [Kagan, 1989](#)). However, it is influenced by human inhibitory behavioral systems within social and cultural contexts. Culture not only imparts *meanings* to the behavior but also determines how other persons perceive and react to the behavior, eventually regulating and directing the developmental process of the behavior. For example, a study of behaviorally inhibited toddlers from different cultures, China and North America, finds that mothers differed in parenting practices based on their socialization values; that is, "inhibited" children are more readily accepted by mothers in the Chinese culture as opposed to the North American. Unlike their Western counterparts, shy-anxious children in China are regarded as socially important and are accepted by peers, and thus they adjust well to their social environment ([Chen et al., 1995](#)). In the West, conversely, children are expected to acquire assertive social skills, rather than be reserved and inhibited, so shyness and social withdrawal are observed to be associated with peer rejection and isolation. There appears to be a fundamental difference in cultural acceptance of biologically determined behavior. In Western cultures, as

opposed to Eastern, social inhibition reflects anxiety, inability to express one's self, and lack of confidence, qualities that are generally regarded as socially immature and psychologically maladaptive (Chen et al., 1998). This view and the finding that shyness and inhibition are correlated with peer and teacher acceptance in Asia, indeed, as markers of psychological adjustments indicate the extent to which behavioral inhibition is not simply a biological trait. It is a culturally bound construct that may have different adaptive "meanings" across cultures (Chen et al., 1995). Perhaps we can view this research on inhibition as an illustration of the Chess and Thomas goodness-of-fit model at a cultural, not just an individual, level.

## CULTURE AND SEXUAL IDENTITY

It is generally accepted that sex is biologically determined. However, *gender* is a broader term that includes cultural forces that shape that biological substrate. Indeed, there is evidence that gender orientation is determined as much by postnatal socialization influences as by the prenatal influence of sex hormones on brain development (Money, 1987). This concept is dramatically illustrated in cultures in which bisexuality is sanctioned. Among the peoples of the eastern highlands of New Guinea (Herdt, 1981), a developmental period of homosexuality preceding heterosexual adjustment is institutionalized. Prepubertal boys must leave the society of their mother and sisters and must enter the society of men to achieve the fierce headhunter's role of manhood. In infancy, the boy is fed women's milk to grow. Now, in the secret society of men, he must be fed men's milk—that is, the semen of mature but unmarried young men—to become pubertal and mature himself. Such an exchange is not allowed between adult men but is reserved for the adult-youth relationship. When the prepubertal boy reaches marrying age, a marriage is arranged for him, thus marking the shift to a heterosexual career. He cannot become a complete man on the basis of heterosexual experience alone. Full manhood requires a prior phase that is exclusively homosexual. Thus, homosexual behavior becomes a defining characteristic of masculinity in that culture.

Studies in which traditionally feminine tasks are assigned to boys or in which male-female roles are not differentiated (Whiting and Edwards, 1973) suggest that the nature of the task assigned, rather than the biological sex of the individual, is the best predictor of masculine or feminine behavior. In societies where boys cook, take care of infants, and perform other domestic functions, there are fewer differences between boys and girls. Boys score proportionately lower in aggression, are less dominant, and score higher in responsibility (Harkness and Super, 1985).

Conversely, other studies find that during certain phases of life such as adolescence, maturational forces weaken the influence of culture on the individual (Hsu et al., 1985; McDermott et al., 1983a; McDermott et al., 1983b). In a study of boys and girls from different ethnic groups in the United States, gender differences prove more powerful than cultural affiliation during adolescence. Although family loyalty and emotional constraint characterize Japanese-American families, compared with affective expression and individual orientation in Caucasian families, the adolescent sons and daughters of both sets of families group themselves by gender rather than by cultural affiliation. Girls, whether Japanese or white, value close family relationships and emotional expression significantly more than do boys. In following these Caucasian and Japanese teenagers from early to late adolescence, the researchers (McDermott et al., 1987) also find changes in male-female role perception that are gender related rather than culture related. Traditional roles (male-power and female-support) are perceived as merging by girls, whereas sons hold to an earlier male-female dichotomy. In other words, young men remain relatively fixed in their male-female role orientation regardless of ethnicity, whereas young women shift their role definitions, which earlier have been determined by family and cultural values.

Thus, the powerful influence of culture on personality formation appears to loosen in adolescence. As we have found, culturally determined parental values indelibly imprint the younger child, but broader social forces lessen the intensity of family forces as adulthood approaches.

## CONCLUSION

Culture provides one of the basic organizing principles of human behavior, a set of hidden rules by which individuals develop. Although early work on the interface between culture and development comes from anthropologic studies, more recent research uses large multiethnic population samples and tests of statistical significance to separate universal tendencies in different settings from the unique influence that cultural variation imposes. In any case, the link between cultural forces and personality is clear. Culture is a powerful shaper of behavior in both parents and their children, and it influences the age at which serious learning and work begin, as well as the very existence or nonexistence of adolescence as a transition from childhood to adulthood. However, beyond the direct effects of culture and ethnicity on personality development, current research suggests an illustration of the interaction of the environment with innate biological forces. The clinician may best approach each child or adolescent as a member of a specific culture with its own developmental pathways (and pitfalls), culturally determined symptomatic expressions of dysfunction, and culture-specific pathways of influence.

## PRINCIPLES OF CLASSIFICATION

The ability and the urge to classify are unique aspects of human experience. They provide us with the capacity to observe, to order our observations, and to formulate general principles and hypotheses. Classification enables us to make use of information for purposes of communication, prediction, and explanation. At the present time in child and adolescent psychiatry, classification systems have their greatest role in facilitating communication for both clinical and research purposes; their role in prediction is somewhat more limited, and their explanatory value is often quite limited. The process of assigning a label may itself be associated with some sense of relief on the part of the patient or the patient's parents ([Werry, 1985](#)). Sometimes this reflects the misconception that having a label implies having an explanation ([Jaspers, 1962](#)). Like all human constructions, classification schemes can be abused or ill used ([Hobbs, 1975](#)). This chapter provides an overview of classification in child and adolescent psychiatry and an overview of the current official systems, that is, the 10th edition of the *International Classification of Diseases (ICD-10)* ([World Health Organization, 1992](#)) and the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* ([American Psychiatric Association, 1994](#)). (Specific criteria for each disorder are discussed in detail in subsequent chapters.)

Various authors ([Blashfield and Draguns, 1976](#); [Hempel, 1961](#); [Jaspers, 1962](#); [Quay, 1986](#); [Rutter, 1965](#); [Rutter et al., 1975](#); [Spitzer and Cantwell, 1980](#)) discuss criteria for psychiatric classification systems. There is no single "right" way to classify disorders in childhood. Classification systems vary, depending on the purpose of classification and what is being classified. As described later, "official" diagnostic systems have tended to adopt, on the whole, a categorical approach, but a dimensional approach would be equally as applicable, if perhaps less useful for clinical purposes.

The goals of classification include facilitating communication among professionals, providing information about given disorders that is relevant to treatment or to prevention, and providing information useful for research aimed at understanding the pathogenesis of disorders. To achieve these goals, classification schemes must be readily and reliably used by clinicians and researchers, hence the need for systems that are readily comprehensible. The disorders should be described, so they can be differentiated from one another. Disorders should differ in important ways, such as associated features and course. The classification system must be applicable over the range of development and must be comprehensive and logically consistent ([Rutter and Gould, 1985](#)). A classification of disorders implies that some clinically significant patterns of symptoms, behaviors, and signs are observed and comprise a source of significant distress or impairment ([American Psychiatric Association, 1994](#)). Deviant behavior itself does not necessarily constitute a disorder unless it is a manifestation of dysfunction within the individual person (e.g., conflicts over political beliefs do not constitute a mental disorder). Although it is often assumed that mental disorders must have a biological basis, this need not be the case; for example, maladaptive, enduring personality patterns can readily be classified as disorders ([Morey, 1988](#)).

Development of a general classification system for psychiatric disorders inevitably involves various tradeoffs. General classification systems must cover the entire range of disorders in a logically consistent fashion; classification systems developed for a highly specific purpose do not share this concern. The need for reasonable parsimony must be balanced with the need for adequate coverage ([Rutter, 1965](#); [Werry, 1985](#)). The needs for a clinically relevant system differ somewhat from those for a research system; for example, highly detailed criteria may be useful for research purposes but are cumbersome in clinical practice. Different diagnostic systems address these issues in different ways. Thus, the DSM-IV ([American Psychiatric Association, 1994](#)) is intended to be useful for *both* clinical work and research, whereas the ICD-10 ([World Health Organization, 1992](#)) system provides *separate* clinical and research descriptions.

## ISSUES IN CLASSIFICATION

### Developmental Aspects

Developmental considerations assume major importance in the provision of a classification scheme for children and adolescents, and, indeed, for adults as well ([Zigler and Glick, 1986](#)). Some disorders such as autism have their origin in a specific developmental period, whereas others are frequently associated with developmental problems (e.g., Tourette syndrome may be associated with attentional difficulties). At other times, the child's overall level of development may have a major impact on the ways in which various disorders can be expressed (e.g., the child with mental retardation who also exhibits conduct problems). Classification systems must be able to encompass such issues without simultaneously making the disorder so developmentally specific that the utility of the category is compromised.

The developmental approach to classification is used whenever disorders are viewed in the context of the unfolding of basic developmental processes. The use of standard, developmentally based assessment instruments such as tests of intelligence or communication skills exemplifies this approach. In contrast, many categorical and dimensional classification systems rely on assessment of deviant behavior. The use of such an approach is often complicated because issues of how deviant behavior is to be evaluated and how instruments are to be "normed" become quite important, and reliability among examiners can be low. Both the ICD-10 and the DSM-IV systems include some categories in which the definition is fundamentally developmental (e.g., mental retardation, articulation disorders), whereas in others the deviant nature of the disorder predominates (e.g., autism, schizophrenia of childhood onset).

### Role of Theory

Theoretical models of psychological disturbance have developed from rather diverse historical traditions; they have considerable value for the individual clinician in understanding and treating children with emotional and behavioral problems. For example, Anna Freud proposes a developmental profile based on and applicable to psychoanalytic assessment of children ([Freud, 1965](#)). More phenomenologically based classification systems can be traced to Kraepelin's delineation of schizophrenia and bipolar disorder ([Mattison and Hooper, 1992](#)). In the early "official" classifications, theoretical concerns were reflected in terms such as "schizophrenic reaction of childhood" or "obsessional neurosis." Classification schemes that are driven by theory are limited because, by their nature, they are based on a set of assumptions and hypotheses not usually generally shared and may give rise to different terms used to describe the same clinical phenomena; for example, a learning theorist may invoke principles of conditioning to explain a child's phobia, whereas a psychoanalytically oriented theorist may be more concerned with the child's level of psychosexual organization. Particularly following the work on development of research diagnostic criteria ([Feighner et al., 1972](#)), the phenomenologic approach to classification has predominated in the various "official" diagnostic systems. The more robust diagnostic concepts have typically emerged from clinical experience

rather than from theory ([Weber and Scharfetter, 1984](#)). In some instances, a theory has been invoked to account for a given set of phenomena, but it is the set of phenomena rather than the theory that has endured. For example, Langdon Down provided a complex theoretical explanation for children with the condition now known as Down's syndrome. His theory, based on obsolete racial stereotypes (mongolism), was incorrect, but his observation of some element of commonality among a large group of children with mental retardation has proved enduring.

For clinicians with pronounced theoretical views, the more phenomenon-based approach can be a source of frustration. It is sometimes incorrectly assumed that in such an approach such matters as history, course, and outcome, and, for that matter, etiology and theory are irrelevant to classification. Information on course and outcome may provide important data relative to external validation of diagnostic categories, and information on the development of the disorder may be highly relevant to differential diagnosis regardless of how similar, at one point, two different disorders appear to be. For example, the syndrome of childhood disintegrative disorder clearly appears to resemble autistic disorder once it is established; however, patterns of early development and outcome differ in these conditions ([Volkmar and Cohen, 1989](#)). Theoretical views of conditions and mechanisms remain highly relevant for both clinical work and research because they are more likely to generate truly testable hypotheses.

## Etiology and Classification

It is often assumed that classification systems are developed to approximate some ideal diagnostic system in which the cause could be directly related to clinical condition. This is not, in fact, the case, in that no single ideal system is waiting to be discovered and that cause need not be included in classification systems ([Rutter and Gould, 1985](#)). Similarly, classification need not reflect a "disease" model ([Rutter and Gould, 1985](#)). Different etiologic factors may result in rather similar conditions, and the same etiologic factor may be associated with a range of clinical conditions. Aspects of intervention may be more directly related to the clinical condition than to the cause. Remedial services for children with mental retardation are, for example, much more likely to be oriented around aspects of developmental level than around the precise origin of the specific mental retardation syndrome. With a few exceptions (e.g., reactive attachment disorder in the DSM-IV), etiologic factors are not generally included in official diagnostic systems.

## Contextual Factors

In certain situations and populations, contextual variables such as family, school, or cultural setting pose major complications to diagnosis. The attentional problems of a child whose difficulties arise only as a result of an inappropriate school placement would not, for example, merit a diagnosis of attention deficit disorder. Contextual variables are particularly problematic in disorders of infancy and early childhood in which the infant exerts effects on the parents, who, in turn, exert effects on the child; attributions of causality may be particularly difficult to make ([Bell and Harper, 1977](#)). A few of the traditional categorical disorders can be readily observed in infants and young children (e.g., autism), but generally clinical complaints in this age group are usually centered around problems that encompass the infant in the context of his or her family or life situation. Although research on disorders of infancy is limited ([Zeanah, 1993](#)), it is clear that infants exhibit a tremendous ability to react, even over relatively short periods, to their environment, and change, rather than stability, is often the rule ([Kagan, 1971](#)). Clinical problems often relate more to issues of *goodness of fit* between parents and the infant than to a disorder in the infant ([Chess and Thomas, 1986](#)). As children become slightly older, traditional diagnostic groupings become more readily applicable ([Earls, 1982](#)). Issues of developmental level also become important in specifying inclusion and exclusion criteria for diagnostic categories; for example, a diagnosis of pica may be appropriate for a 12-year-old child with profound retardation but is less appropriate for a normally developing 10-month-old infant.

Cultural differences may also affect diagnostic concepts and practice ([Mezzich and von Cranach, 1988](#)). Clearly, certain sociocultural factors are associated with certain types of problems (e.g., economic disadvantage is associated with conduct and attentional problems), but the meanings of such relationships often remain unclear ([Farrington, 1986](#)).

## What Is Classified?

It is particularly important that clinicians and researchers alike bear in mind that disorders, rather than children, are classified. This is a source of considerable confusion. Concerns have been raised about the possible effects of labeling children ([Hobbs, 1975](#)), and to some extent these concerns are valid. It is, of course, also the case that having an adequate label for a child's disorder may be helpful, for example, in securing needed services for the child. Thus, a diagnosis of mental retardation or learning disability may be associated with social stigma or other untoward effects, or it may be associated with more realistic expectations on the part of parents and teachers and provision of potentially more appropriate services. These tensions are also exemplified in the debate between those who advocate broad and encompassing definitions (e.g., to maximize service provision) and those who advocate narrow definitions (e.g., by defining more homogenous groups of research subjects).

Similar debates arise about aspects of social stigma related to mental illness and behavioral and developmental problems. In this regard, it is always important to refer to the child's disorder, *not to the child as the disorder*. The term *diagnosis* refers both to the notion of assigning a label to a given problem and to the act of evaluation. In important respects, it is the diagnostic process ([Cohen et al., 1988](#)) that is the most important of the two. Although diagnostic labels have considerable value, they do not provide information specifically about the individual person, who is unique and uniquely related to intervention. Diagnostic categories will, and should, change, and children may exhibit a disorder for variable periods.

## VALIDATION AND STATISTICAL ISSUES

As official classification systems have become more complex and sophisticated, issues of reliability and validity have assumed increasing importance. For example, both the DSM-IV and the ICD-10 use results of large national or international field trials in providing definitions of disorders. Categorical and dimensional approaches to classification share certain statistical concerns ([Blashfield and Draguns, 1976](#)).

### Validity

*Validity* is the extent to which a classification system does what it purports to do in terms of facilitating communication, intervention, and research. Various types of validity have been identified, for example, *face validity* (a judgment about whether the description of a category appears to represent the diagnostic construct reasonably), *predictive validity* (whether some aspect of subsequent course or response to treatment is predicted), and *construct validity* (whether the category has meaning in terms of what it purports to assess). Generally, such concepts are most useful in measuring the validity of psychometric assessment instruments; their applicability to classification systems is somewhat different. In general, childhood psychiatric disorders have face validity but not necessarily predictive or construct validity ([Spitzer and Cantwell, 1980](#)). The validity of a given diagnostic category can be established on the basis of its association with various features other than those incorporated in the definition (e.g., response to treatment, natural history in the absence of treatment, family pattern, biological correlates, and developmental correlates such as age at onset and intelligence quotient). The validity of some categories included in the revised third edition of the DSM (DSM-III-R) appears to be questionable (e.g., identity disorder), whereas for other categories (e.g., autism) ([Rutter, 1978](#)), the disorder appears to have considerable validity, but the statistical data on reliability and validity of the various rating scales used to assess it are more questionable.

The sensitivity and specificity of a given categorical diagnostic instrument can be assessed relative to the true presence or absence of a specific disorder. However, a general problem for both categorical and dimensional classification systems is the nature of the standard against which a given category or criteria set is to be judged. Given the usual absence of an unequivocal diagnostic marker for the various conditions, clinical judgment is often used as the standard against which new instruments or definitions are assessed. The issues of "caseness" and diagnostic thresholds are particularly important in the derivation and validation of diagnostic systems ([Swets, 1988](#); [Valliant and Schnurr, 1988](#)).

### Reliability

In addition to validity, classification systems should exhibit *reliability*; that is, users in different locations seeing rather similar disorders should be able to agree on the applicability of a specific category or criterion ([Grove et al., 1981](#)). Various kinds of reliability have been identified: interrater, test-retest, and internal consistency. If a given category is not used reliably, it has little value for purposes of communication. Some disorders, almost by definition, have limited test-retest reliability over a relatively short period, whereas others are presumed to be highly stable (e.g., adjustment disorders versus profound mental retardation). Sources of unreliability in psychiatric diagnosis include differences in the kinds of information clinicians collect, theoretical biases in the clinician, and differences in diagnostic thresholds, as well as, of course, the true differences that persons with disorders will exhibit at various points.

High reliability does not guarantee validity; it is possible that a disorder could be reliably defined but have little or no validity. Conversely, a disorder may have validity, but criteria and diagnostic instruments designed to detect its presence may have little or no reliability. In providing diagnostic criteria and descriptions, there is often a trade off between the level of detail of a definition and its reliability. More detailed definitions, designed for research studies, may, for example, be used reliably in such contexts but may not prove reliable when they are applied by clinicians less experienced with the disorder. What appear to be relatively minor changes in the wording of a criterion can produce major changes in the way in which a diagnosis or diagnostic criterion is applied.

## Statistical Analyses

Various *statistical techniques* have been applied to data derived from assessment methods ([Achenbach, 1988](#); [Achenbach and Edelbrock, 1978](#); [Quay, 1986](#)). These techniques are theoretically of great interest in that they can provide more rational and empirical approaches in the derivation of diagnostic schemes. The fundamental assumption of such techniques is that the variables of interest lie along some dimension of function and dysfunction that all persons exhibit to some degree. For many types of problems, this assumption is probably justified, such as relative to anxiety or depression. However, the usefulness of such techniques is limited in important ways ([Rutter and Gould, 1985](#)). In the first place, these methods are highly dependent on both the sample and the type of data entered in the analysis. For example, *factor analysis* of an instrument designed to detect conduct problems would not likely produce a factor related to eating disturbance. Similarly, cluster analysis of even a very large normative sample would not likely produce a cluster that corresponded to autism, given the low base rate of this disorder in the population. For rare disorders, other statistical approaches may be useful. Other relevant statistical procedures include *signal detection analysis* ([Kraemer, 1988](#)), which can be used to establish which symptoms and symptom combinations are most strongly related to a particular diagnosis. Similarly, *latent trait analysis* and *latent class analysis* ([Szatmari et al., 1995](#); Zoccolilio et al., 1992) provide other approaches.

## MODELS OF CLASSIFICATION

Werry delineated three general approaches to classification of disorders: categorical, dimensional, and ideographic (1985). The *categorical approach*, sometimes referred to as the medical model of classification, views disorders as either present or absent (e.g., the patient does or does not have appendicitis). This approach assumes that patients exhibiting a given disorder display certain similarities, that these similarities outweigh differences, and that this knowledge has certain implications for understanding pathophysiology, course, treatment, and so on. Unlike the categorical approach, which views disorders as dichotomous, the *dimensional approach* to classification relies on assessment of dimensions of function or dysfunction by reducing phenomena to various dimensions along which a child can be placed. Various sources of data can be used for this approach, such as behavioral ratings, parental reports, yes-no criteria, developmentally based test scores, and the like. Although the dimensional approach is more commonly used in nonmedical settings, many medical phenomena also exhibit continuous (i.e., dimensional) characteristics (e.g., stature, blood pressure). For some purposes, categorical diagnoses (e.g., levels of mental retardation) are derived from what is essentially a continuous variable, whereas some dimensional assessment instruments can similarly be used to generate categorical diagnoses. *Ideographic classifications* reject simple labels and focus on the total context of the individual person; this approach may be theory driven (e.g., by psychoanalytic or behavioral theories) or may be used eclectically. Ideographic approaches are commonly used in clinical work; that is, the child or adolescent is viewed in the totality of his or her life circumstance, and various disorders, problems, and psychosocial situations may be viewed as worthy of notation and treatment.

## Categorical Approaches

The most widely used “official” systems are those developed by the World Health Organization (ICD-10) and the American Psychiatric Association (DSM-IV). Both systems have their historical origins in medicine in the 19th and 20th centuries as advances in diagnosis and public health concerns necessitated more systematic approaches to record keeping ([Table 39.1](#)). During the 19th century, many advances in the taxonomy of adult psychiatric disorders were made, and this led Kraepelin to attempt a comprehensive classification system ([Kraepelin, 1883](#)). By the mid-20th century, certain psychiatric disorders were generally recognized. The second edition of the DSM (DSM-II) ([American Psychiatric Association, 1968](#)) includes only a handful of diagnostic categories specific to children: mental retardation, childhood schizophrenia, adjustment, and other “reactions” (hyperkinetic, withdrawing, overanxious, runaway, unsocialized aggressive, group delinquent, and “other”). By the time the DSM-III appeared ([American Psychiatric Association, 1980](#)), the number of disorders first evidenced in infancy, childhood, or adolescence had increased more than fourfold to include the following major classes of disorder, each of which included some specific diagnostic categories: mental retardation, specific developmental disorders, attention deficit disorder, conduct disturbance, eating disorders, stereotyped movement disorders, pervasive developmental disorders, other disorders with physical manifestations, and other disorders of infancy, childhood, or adolescence (see [Mattison and Hooper, 1992](#), for a review). Similar, although not precisely corresponding, changes occurred in the revision of the ICD ([Rutter et al., 1975](#)). In the DSM-III, for example, disorders generally specific to childhood were grouped together, and there were many more DSM-III subcategories ([American Psychiatric Association, 1980](#)). The DSM-III and its successor, the DSM-III-R ([American Psychiatric Association, 1987](#)), differ from the ICD-9 in terms of their greater diagnostic reliance on explicit (if not always truly operationalized) diagnostic criteria ([Puig-Antich, 1982](#); [Spitzer and Endicott, 1978](#)). Both the DSM-III and the ICD-9 incorporate a multiaxial framework, although the specific systems adopted differ from each other in some respects. Both systems are hierarchically organized, although the DSM-III and the DSM-III-R encourage multiple diagnoses.

Kraepelin (1883): Proposal for a comprehensive classification system
ICD-6 (1948): Psychiatric disorders included
DSM-I (1952): First US official classification system
Group for the Advancement of Psychiatry (1966): Diagnostic system for children
DSM-II (1968): Some child disorders, emphasis on theory and Meyer's concept of reaction types
DSM-III (1980): Fourfold increase in child psychiatric disorders, greater diagnostic precision, multiaxial
DSM-III-R (1987): Refinements in criteria, categories
ICD-10 (1992): Separation of research diagnostic criteria from clinical descriptions
DSM-IV (1994): More emphasis on data based modifications in categories and criteria
DSM-IV-TR (2000): Generally minor revisions in text (not criteria)

DSM, Diagnostic and Statistical Manual of Mental Disorders; ICD, International Classification of Diseases

## Table 39.1. Landmarks in the Development of Psychiatric Taxonomies

Changes in the DSM-III-R and DSM-IV are generally less dramatic than in the DSM-III ([Schwab-Stone et al., 1991](#)). Work on the DSM-IV began in 1988 ([Frances et al., 1989](#)), stimulated, in part, by a treaty obligation that mandated terminology compatible with the ICD, which was also undergoing revision at that time. As part of the process of producing the DSM-IV, steps were undertaken to ensure that changes made were based on solid data and thorough documentation ([Frances et al., 1989](#)). This task was somewhat facilitated because it was clear that the DSM-III and III-R had stimulated considerable research of relevance to the DSM-IV ([Widiger et al., 1991](#)). Other issues for the DSM-IV relate to clinical utility and compatibility with ICD-10. As part of the revision process, extensive literature reviews were conducted, data sets were aggregated and analyzed or reanalyzed, and working groups of experts convened to evaluate the available data and, in some cases, to generate new data. For the child disorders section, field trials were conducted for disruptive behavior disorders ([Lahey, et al., 1994](#)) and for autism and related conditions ([Volkmar et al., 1994](#)).

The *International Classification of Causes of Death* was adopted by the International Statistical Institute in 1893 ([Kramer, 1968](#)). By the 1960s, the ICD had been revised six times, and the deficiencies of the ICD-7 for psychiatric disorders ([Rutter et al., 1975](#)) were particularly clear. Many changes were made in eighth edition of the ICD in 1968. Even when this edition was adopted, however, it was clear that further revision would be needed, and a process was instituted for further revision. An important part of this work was the development of a multiaxial classification system for child disorders ([Rutter et al., 1975](#)).

The ICD-9 was published in 1977, and work on its revision began shortly thereafter ([Brämer, 1988](#); [Sartorius, 1988](#); [World Health Organization, 1977](#)). As part of the extensive revision process, the number of categories increased substantially ([Cooper, 1988](#)), and a decision was made to have various versions of the system—one for primary health care providers, another for specialty-based researchers, and one for psychiatric practitioners. The ICD revision process did not, in contrast to the DSM-IV, employ extensive field trials. The ICD-10 draft generally had good clinical utility and good, although variable, reliability (the latter being less optimal for disorders with more subtle symptoms such as personality disorders) ([Sartorius, 1988](#)).

## COMPARISON OF THE ICD-10 AND THE DSM-IV

Although, on balance, the two categorical systems are more alike than different, there are some differences, some more and others less explicit, between the two systems. The ICD system has rather more constraints than the DSM, given its international nature and the fact that the psychiatric section is but one part of a large body of diagnostic coding. The systems also differ in the degree to which diagnoses are operationalized. The ICD-10 provides a comprehensive description of the clinical construct, followed by a discussion of differential diagnosis and major symptoms that should be present. In contrast, the DSM-IV is much more truly operationalized but is also accordingly somewhat less flexible for clinicians. Although both systems allow for multiple diagnostic codes, the ICD-10 also gives the option of applying some combination categories (e.g., depressive conduct disorder). Rutter discusses the pros and cons of this approach ( [Rutter, 1989](#); [Rutter and Tuma, 1988](#); [Volkmar and Woolston, 1997](#)). Although there are some issues relative to certain disorders (e.g., the anxiety disorders), in general the trend has been toward convergence of the DSM and ICD classification systems. The remaining differences largely stem from the emphasis of clinical-diagnostic guidelines in the ICD and the greater specificity for research of the DSM. The more recent text revision of the DSM-IV (DSM-IV-TR) ( [American Psychiatric Association, 2000](#)) includes generally minor modifications in accompanying text but not in criteria. With regard to children, probably the most extensive revision is that for Asperger's disorder; it is also the case that an error in the description of the "subthreshold" category "Pervasive Developmental Disorder Not Otherwise Specified" was corrected ( [Chapter 46](#)).

Detailed critiques of the various diagnostic approaches have appeared ( [Achenbach, 1980](#); [Garnezy, 1978](#); [Quay, 1986](#); [Rutter and Shaffer, 1980](#)). Criticisms have been made of both the overarching framework and its specifics. In the DSM-III in particular, certain categories were introduced on the basis of rather limited data. The reliability and validity of at least some of the various categories proposed (e.g., childhood-onset pervasive developmental disorder) were questionable. Reliability is generally best for the more common and more broadly defined disorders. Information on the stability of the various childhood diagnoses has been limited.

### Dimensional Approaches

In contrast to the more clinically oriented (categorical) approach, multivariate (dimensional) approaches to diagnosis offer several potential advantages in that various behaviors and dimensions of behavior are assessed, rather than single, presumably pathognomonic, features ( [Achenbach, 1988](#); [Achenbach and Edelbrock, 1978](#); [Quay, 1986](#)). Similarly, the dimensional approach can encompass symptom coding in other than a dichotomous fashion; for example, "never," "sometimes," and "always" could be coded, rather than simply presence or absence, to rate-specific diagnostic features. Various rating scales, checklists, and so forth can be used for multivariate classification schemes based on self, parent, or teacher report or on direct observation; many such instruments are described in subsequent chapters. As noted previously, various statistical techniques such as factor and cluster analysis may be used to derive relevant clinician patterns or profiles. These patterns may, in turn, be used to derive categorical diagnoses. Given the inherent problems in sample selection and instrument development, issues of replication are particularly important ( [Rutter and Gould, 1985](#)).

[Jenkins and Glickman \(1946\)](#) and [Hewitt and Jenkins \(1946\)](#) were among the first to examine patterns of relationships (correlations) between variables to derive syndrome groupings. A large series of case records was studied, and the presence or absence of specific behaviors was noted in each case. Clusters of deviant behavior were noted, and broad patterns of disturbance (socialized delinquent, overinhibited, unsocialized aggressive) were identified. Subsequently, more sophisticated methods have been applied to a range of children using a variety of assessment instruments ( [Achenbach, 1988](#)). Studies done using this approach generally identify several factors with relative consistency; factors identified have included conduct disturbance, overactivity, and emotional disturbance ( [Achenbach et al., 1989](#); [Rutter and Gould, 1985](#)). Not surprisingly, the stability of more narrowly defined factors is less robust. Similarly, as would be expected, such techniques have limited usefulness in detecting children with disorders of very low prevalence.

Reliability of dimensions derived from multivariate studies has been assessed and is generally satisfactory ( [Quay, 1986](#)). Stability of dimensions or profiles is somewhat more complex to assess, in that some change is, of course, expected, but short-term stability appears to be within acceptable limits ( [Quay, 1986](#)). The use of dimensional assessment instruments clearly avoids certain of the pitfalls inherent in the categorical approach, for example, in terms of the loss of information inherent in application of dichotomous categories, in increasing reliability, and in issues of "caseness." These issues are relevant to medicine in general and not just to psychiatry.

For some purposes, dimensional assessment instruments are particularly valuable. For such assessments to be clinically useful, their validity must be demonstrated, for example, in terms of some associated features, such as familial pattern or course. The assumption that characteristics have the same meaning throughout their distribution is often questionable (e.g., severe mental retardation differs in a host of ways from normal intelligence) ( [Rutter and Tuma, 1988](#)). Certain disorders clearly do *not* shade off into normality.

### Relationship of Categorical and Dimensional Approaches

There are major areas of agreement between both the categorical and dimensional approaches; this is particularly true for the more common disorders. Analysis of data from dimensional assessment instruments has proved useful in the development of categorical systems, for example, in supporting division of conduct disorder into various types. Probably the greatest drawback to the use of such assessments in clinical practice arises from the difficulty in using such instruments in a simple way for purposes of communication; for clinical purposes, it is more helpful to know that a child has attention deficit hyperactivity disorder and learning problems than to know his or her factor or profile scores on a dimensional assessment instrument. Dimensional and categorical approaches need not be used in mutually exclusive ways; the multiaxial classification used in the DSM-III-R, for example, employs both approaches in that although disorders are categorically defined, assessments of severity of psychosocial stressors and global assessment of functioning are dimensional.

### Ideographic Approaches

Ideographic approaches to diagnosis are common in clinical practice. In the broader sense of diagnosis (i.e., as diagnostic process) ( [Cohen et al., 1988](#)), most clinicians target certain problems or issues for intervention that relate only in part to categorical or even dimensional diagnosis. In some ways, such approaches are more practical in certain situations (e.g., family therapy), although again they can be used in conjunction with categorical approaches. They are less useful for certain purposes (e.g., in considering pharmacological intervention) ( [Werry, 1985](#)). Past the level of the individual cases, the utility of ideographic approaches is limited. Such approaches make it very difficult to communicate information for clinical and research purposes in a concise and readily understood fashion.

## MULTIAXIAL CLASSIFICATION IN CHILD AND ADOLESCENT PSYCHIATRY

*Multiaxial classification* offers considerable potential advantages for child and adolescent psychiatric disorder ( [Cohen et al., 1988](#); [Rutter and Gould, 1985](#); [Rutter et al., 1975](#)). In important ways, it parallels the diagnostic process in that different kinds of information are collected and coded independently. Given that the diagnostic picture is often complex and that different conditions and kinds of conditions are associated with one another, the use of a multiaxial system, at least theoretically, should help clinicians by directing their attention to the major relevant areas of diagnosis. In actual practice, clinicians vary considerably in their use of multiple axes, although the use of such a system would be expected, generally, to increase reliability. Putting developmental disorders on a separate axis would, for example, emphasize their developmental, as opposed to "psychiatric," nature and would remind clinicians to look for such disorders in the course of their regular clinical work. Conversely, the placement of certain disorders within a multiaxial framework is problematic; enuresis, for example, clearly has developmental correlates but is generally included as a psychiatric, as opposed to developmental, disorder.

In the absence of a multiaxial system, certain conditions are particularly likely to be overlooked, such as the developmental learning disorders of a child with conduct disorder. Similarly, coding of medical syndromes is helpful in alerting the clinician to potential problems that contribute to the mental or developmental disorder, are associated with it, or should be considered in the provision of a remedial plan. Theoretically, many different kinds of information could be incorporated within a multiaxial framework (e.g., intellectual level, adequacy of school placement, associated psychosocial problems). One of the dilemmas, particularly for disorders in adolescence, relates to the problem of comorbidity; that is, often children have more than one diagnosis. This comorbidity may be more apparent than real or may represent a more substantive problem in which, for example, having one disorder predisposes to the second or in which the risk factors for one disorder are also risk factors for the second. Artfactual comorbidity adds little to the classification system; for example, for a child with autism to also receive a diagnosis of stereotypy-habit disorder seems pointless because stereotypies are commonly observed in autism and are included as one of the potential defining features of this condition. In other instances, such as conduct disorder with depression, the particular comorbid pattern does appear to have some important distinguishing features ( [Angold and Rutter, 1992](#)). In ICD-10, the general approach is to provide a special code for such conditions, whereas in DSM-IV, the usual diagnoses would be made with no special notation of the concomitant occurrence of the condition. Despite this difference, the general difference in approach to clinical and research diagnosis, and some

differences around a few categories, these two systems have tended toward convergence.

## SUMMARY

Classification in child and adolescent psychiatry has multiple meanings and functions. Complications for classification of child and adolescent disorders are myriad: The child is often not the person complaining; different kinds of data may be used in making a diagnosis; developmental factors may have a major impact on the expression of disorders; and certain features (e.g., beliefs in fantasy figures) are normative at certain ages but not at others. Additional complications are posed by the unintended, but no less real, uses to which diagnostic concepts are put, such as their inclusion in legislation and their use as mandates for services in educational programs or for purposes of insurance reimbursement for services. Different kinds and levels of classification are needed for different purposes.

The 1980s and 1990s witnessed tremendous advances in the area of diagnosis and classification of child and adolescent psychopathology ( [Rutter and Tuma, 1988](#)). These advances are particularly welcome because work in this area has lagged behind that in the adult psychiatric disorders. Various approaches to classification have been employed; each has its advantages and limitations. Issues of reliability and validity remain to be addressed for many categories and classification systems; the attempt to address these issues through examining empirical data rather than theorizing is perhaps the greatest accomplishment of the 1990s.

Tensions between clinical and research utility will continue to exist. As classification systems become more complex, they are less readily used; conversely, simplistic systems fail to capture important aspects of clinical experience. The likely ability, over the next decade, to identify more clearly the role of genetic factors for at least a few conditions and the growing sophistication of statistical approaches to aspects of classification and diagnosis represent important areas for future work.

A classification scheme is best used by persons with considerable training who take the task of diagnosis (in its broadest sense) seriously. Although categorical systems increasingly use diagnostic criteria, these are often not truly operationalized, although they are often abstracted and reified for specific purposes (e.g., development of interview schedules administered by lay interviewers or the use of simple frequency counts or symptom duration that obscures the more central aspects of the underlying clinical construct). Although the various "official" systems present areas of disagreement, the areas of agreement are even more noteworthy. Certain issues, such as classification of comorbid condition versus use of multiple diagnoses, remain to be resolved. Specific issues arise with respect to inclusionary and exclusionary rules and aspects of comorbidity. Although much has been accomplished, considerable work remains to be done.

The developmental assessment of infants involves more than the simple administration of a set of developmental test protocols. Assessments performed in the first 3 years of life require the clinician to function simultaneously as a generalist and as a specialist, to blend quiet observation with active probing, to synthesize information from caregivers with that gathered through direct observation of the child, and to be involved in a curious blend of searching for specifically defined responses from a child with inferences based on behavior. This set of skills is indeed important for adequate clinical assessment of children of all ages. However, the need is even greatest for those providing clinical services to these youngest of patients, because development during the early years is the most rapid, context dependent, and intersystemic. Clinical assessment of infants and toddlers is indeed a subspecialty area of practice. Not all psychiatrists, psychologists, pediatricians, and other professionals possess the training and degree of closely supervised practice necessary to conduct such evaluations competently and independently. Those professionals who do possess these specialized skills typically have acquired them through formal subspecialization near the end of their professional training.

Most scientists and clinicians define the periods of infancy and toddlerhood as being the first 3 years of postpartum life. More specifically, *infancy* refers to the time before the explosion of expressive verbal communication that occurs at about 18 months. The developmental shift that occurs at this time has a massive transformational impact on the child's ability to reason cognitively, to deepen elaborate social relationships, to develop moral reasoning capacities, and to mediate emotional experiences linguistically. *Toddlerhood* is a period of increasing autonomy in which the child uses his or her new skills to explore their world, physically, cognitively, and socially. Regardless of the exact chronologic time frame, infancy and toddlerhood encompass the most rapid and contextually transactional period of neurodevelopmental change throughout the postpartum life span. Therefore, all clinical assessments of infants and toddlers are framed by the context of rapidly changing, growing systems that may be in or out of synchrony with one another.

In this chapter on infant assessment (for ease of communication, the term *infant* is used to identify both infants and toddlers, except when a clear distinction is made in the text), four areas of inquiry implicit in these introductory statements are addressed:

1. What is the history of the field of infant assessment, and what concepts underlie the process of infant assessments?
2. Why perform developmental assessments of infants? When are such assessments indicated, what can we learn from the process, and what, if anything, can we predict about the infant's future development?
3. What kinds of information define an assessment of an infant's development? Does such an assessment entail only a simple quantitative charting of emerging skills and capacities, or does it require a more complex qualitative evaluation of the infant's developing social, affective, and cognitive adaptation within the environmental matrix? What are the sources of data for this more complex assessment profile, and does the process itself have a therapeutic effect?
4. What are the available formal assessment tools? What are their strengths and limitations?

## BRIEF HISTORY OF INFANT DEVELOPMENTAL ASSESSMENT

A brief discussion of the history of infant assessment may provide an illustration of the evolving aims and technologic advances in this field. (For a more complete history of infant assessment, see Brooks and [Weinraub, 1983](#), and [Wyly, 1997](#).) In the late 19th century, the European scientific community was consumed with a fervor and creativity best characterized by the studies of evolution, theories about the unconscious mind, and a growing concern for the mentally deficient and insane. The concept of measuring infant capacities grew out of the concern of scientists of the time to find a metric for human intelligence that would identify the mentally deficient. The French had been the first to distinguish mental deficiency from insanity ( [Esquirol, 1938](#)), and in so doing, they had started a controversy about the educability of the former. Schools for the mentally retarded were being opened throughout Europe. The interest in measuring intelligence reflected a practical need to find criteria for mental deficiency, to develop standards for admission to such schools.

### Early 1900s: The Birth of Intelligence Testing

In 1904, the minister of public education in Paris appointed Binet and Simon to be members of a commission studying the question of special education. Binet, an experimental psychologist, had been interested in mental functioning in normal children, and Simon had worked with him on earlier versions of tests to rank intellectual functioning. In response to their charge from the minister, Binet and Simon developed the concept of *mental age*, which describes how an individual child's performance on tasks involving memory and reasoning compares with the chronologic age of a large group of children who succeed with the tasks. This test, published in 1905, revolutionized the testing movement, and the concepts quickly spread to other scientific and educational communities (Brooks and Weinraub, 1976). In the United States, Terman created an adaptation of the Binet-Simon test and revised their mental age concept by creating the intelligence quotient (IQ), a ratio between mental age and chronologic age multiplied by 100 ( [Terman, 1916](#)). It is not an exaggeration to say that the concept of IQ singularly preoccupied many psychologists for several decades. American psychologists of the early 20th century in particular believed that IQ was fixed, and they found it an exciting possibility that one well-administered test would provide stable, predictive information about a child's underlying potential.

In the decades that followed the development of Terman's IQ test, many psychologists turned their attention toward the subject of intelligence and development in infants. Two basic approaches were used in exploring intellectual development in infants. One approach, the *infant IQ model*, sought to extend the IQ assessment model downward to children younger than school age, eventually including infants. A second approach, the *Gesellian model*, sought to create a new model of assessment that began with the newborn and extended upward. Both these models represented a radical departure from the *case study method* of inquiry employed in the previous century. In contrast to these "baby biographers" of the previous century, the scientists of the 1920s and 1930s brought to the study of infant development a level of empiricism, championed by the behaviorist movement of the time, by relying on direct observations of child behavior across several children

under highly structured conditions.

### 1920s and 1930s: The Infant IQ Movement Versus the Child Study Movement

In the 1920s and 1930s, a few “infant IQ tests” were first introduced. The best example of such an infant IQ or infant cognition test is the *Cattell Infant Intelligence Scale* (Cattell, 1940). Cattell's test was conceptualized as a downward extension of the 1937 Stanford-Binet Intelligence Scale, the much-revised American version of the Binet-Simon test. Although some initial studies were encouraging, the ability of the Cattell and other infant IQ tests to predict an infant's later IQ was weak (Thomas, 1970). Overall, infant IQ tests were found to be inadequate for meaningfully extending the IQ assessment model into infancy and are now all but extinct in use.

#### ARNOLD GESELL AND THE CHILD STUDY MOVEMENT

At about the same time that the first infant IQ tests were being developed, Yale University psychologist and physician Dr. Arnold Gesell began his groundbreaking work on systematically documenting development in infants and toddlers. Several aspects of Gesell's work distinguish it from those of his predecessors and contemporaries. First, whereas the infant IQ tradition grew from an interest in identifying deviant patterns of development, Gesell's interest was mostly in documenting normal developmental trends, as espoused by G. Stanley Hall's Child Study Movement. Of course, this implied a model of developmental maturation, rather than the downward extension of the IQ model endorsed by many of Gesell's contemporaries. Second, Gesell's model supported the conceptualization of development occurring simultaneously in many distinct but interrelated domains (Gesell, 1940), whereas the infant IQ model was predicated on the proposed existence of a singular factor of intellectual ability. This conceptualization of multiple interrelated domains of development revolutionized the fields of developmental assessment and early intervention in a way that endures to this day. Third, the infant IQ model was a product of the prevailing conception of intelligence as an innate genetic endowment with infant assessment viewed as a way of quantifying that endowment. In contrast, Gesell's model of developmental maturation supported an understanding of the effects of the child's environment in altering the course of development and opened the way for the more transactional and dynamic understanding of developmental processes that would later prevail.

For Gesell, diagnosis was the primary objective of measuring infant development. He modeled his approach after the work of Wilhelm His, one of the first investigators of human embryology (Yang, 1979). In 1925, when his observational techniques were well established, Gesell wrote: “Just as the embryologist gets his basic conceptions of morphogenesis by building up indefatigably, step by step, detailed sectional views of growing organisms, . . . so may genetic psychology build up a continuing series of sections corresponding to the stages and moments of development” (Gesell, 1925). Gesell began his descriptions of infants at 3 months of age and initially included five other assessment points in the first 2 years (6, 9, 12, 18, and 24 months). For Gesell, the scales were descriptive, and specific items were included for normative purposes rather than for measuring intelligence. He did argue, however, that the scales were a measure of a child's capacity and personality characteristics (Honzik, 1983).

As early as 1916, Gesell and his colleagues began a series of meticulous observations of infants' and preschool children's behavior at home and in the well-child clinic, to define norms for behavior (Yang, 1979). In fact, Gesell was actually the first to develop the procedure of systematically observing the infant's natural responses in a natural setting (Buhler and Hetzer, 1935). The result of his work was a series of age-specific markers of normative development, known as the *Gesell Developmental Schedules*. His work was far reaching, and the developmental tasks and techniques pioneered by Gesell and his colleagues were borrowed extensively by subsequent researchers (Honzik, 1983). Indeed, many of the modern assessment instruments described later in this chapter bear a striking resemblance to Gesell's earliest schedules.

The Gesell Developmental Schedules addressed several areas of infant and toddler development, including motor development (posture, prehension); language development (comprehension, imitation); adaptive behavior (eye-hand coordination, recovery, and manipulation of objects, alertness); and personal-social behaviors (reactions to people, play behavior, independence). The first completed scale, published initially in 1925, consisted of 144 items divided among these four general fields. Some items appeared in more than one subdomain, and motor items predominated at the early ages, whereas language and personal-social items predominated later. Age placements were determined by the percentage of subjects who passed each item. The first version of the Gesell Developmental Schedules was based on a small, normative sample (107 infants from white middle-class families living near New Haven, CT). Subsequent revisions of the 1925 Gesell Developmental Schedules were directed toward determining ever-finer age gradations of infant and toddler responses (e.g., defining by weeks and days, rather than by months, the appearance of the response to the sound of a bell). Table 40.1 gives examples of items during the first 3 months of development.

Area of Development	Coverage (months)		
	1st	2nd	3rd
Gross motor	Does not hold head up	Holds head occasionally erect, mostly steady	Supports self on hands in prone position
Fine motor	No release grip	Has nonreflexive grasping and prehending	Actively holds objects
Problem solving	Reaches toward	Steady reach beyond the midline	Steady reach beyond 180 degrees
Communication and language	Wakes and reacts to sounds	Reacts to single words	Cries
Social	Attends to faces and voices	Has directed regard of faces, clear social smiles	Initiates being held
Motoric	Quiet when held	Clearly attends to voices	Shows anticipatory excitement

Table 40.1. Sample of Items from Gesell's Developmental Schedules During the First 3 Months

#### NANCY BAYLEY'S LONGITUDINAL STUDY

Meanwhile, on the West Coast of the United States, Dr. Nancy Bayley of the then-named Berkley Institute of Child Welfare, who borrowed many of Gesell's assessment techniques along with concepts more familiar to the infant IQ model, worked on the creation of two scales of infant development that would later revolutionize the field. The *California First-Year Mental Scale* (Bayley, 1933a, 1933b) and the *California Infant Scale of Motor Development* (Bayley, 1935, 1936) were developed by Bayley for use in her own longitudinal study of development in 61 typical infants, with follow-up measures extending into their adulthood.

### 1940s and 1950s: Reconceptualizing Infant Development

In the 1940s and 1950s, the science of infant developmental assessment gained greater international attention, through the publishing of the *Griffiths Mental Development Scale* in London (Griffiths, 1954). At that time, infant assessment techniques were used primarily for diagnosis and categorization purposes, such as for preadoptive screening, testing for admission to special schools, or evaluating physical handicaps (Stott and Ball, 1965). Few scientists, however, used the techniques for longitudinal studies or empirical research. The assessments for diagnosis and categorization were predicated on clinicians' continuing adherence to the belief that intelligence is fixed from infancy. This belief in a fixed IQ still was so well rooted that evidence to the contrary, such as findings documenting an increase in IQ in high-risk infants after nursery school attendance, was dismissed and was attributed to poor standardization of the scales (Brooks and Weinraub, 1976). Indeed, it was largely on the basis of Bayley's longitudinal study (Bayley, 1949) that the concept of an immutable IQ that was fixed at birth was discredited.

The inability of infant developmental scores to predict school-age IQ adequately sparked considerable debate that shaped significantly our understanding of human intelligence and models of assessment. Some scientists claimed that the poor predictive ability of infant developmental tests reflected a fundamental discontinuity between infant and later abilities; that is, intelligence in infants is qualitatively different from intelligence in older children and adults. Others claimed that cognitive development is not fundamentally different for infants, but infant development tests tend to assess different aspects of intelligence than do school-age IQ tests. In the context of this debate, American developmentalists first began to consider seriously the stage theory of Jean Piaget, which clearly favored the view of qualitative, rather than simply quantitative, differences in the abilities of children of various ages.

### 1960s and 1970s: Breakthroughs in Infant Test Development

The 1960s and 1970s brought a new wave of infant development tests, more rigorously standardized on larger numbers of infants, with careful testing of interobserver agreement and test-retest reliability. Developments in the work of Bayley best typify this previously unseen level of commitment to psychometric rigor in infant tests. The *Bayley Scales of Infant Development* (BSID) consolidated Bayley's original two scales into one assessment instrument with norms based on a nationally representative sample of infants ([Bayley, 1969](#)). The BSID set a new and enduring standard of sophistication for the development and standardization of infant developmental assessment tools. Thoughtful research led to far more caution about the predictive validity of early assessment and to important conceptual revisions, such as a growing recognition that IQ is not a unitary construct. In addition, investigators added more global appraisals to their scales ([Escalona and Moriarity, 1961](#)) and began to understand that some items, particularly verbal items, had higher predictive validity than the overall scales ([Cameron et al., 1967](#)). These and other conceptual shifts led to yet another group of infant tests designed to measure specific types of behavior, such as social competency or language development. Moreover, infant developmental tests reflecting Piaget's stage theory began to emerge. Concomitant interest in newborn capacities and the rapidly emerging field of newborn sensory perception also led to the development of certain scales to measure competency in newborns.

### 1980s and 1990s: New Directions in Infant Developmental Assessment

The 1980s and 1990s were dominated by increasing psychometric improvements, by a renewed interest in diagnostic functionality, again primarily driven by the needs of public education, and by the application of information-processing theory to the study of infant development. In 1986, special education laws were revised to mandate special education services for children 3 to 5 years old (P.L. 99-457, Part B) and to allow states to offer early intervention services to children from birth to 3 years old (P.L. 99-457, Part H). Infants and toddlers can qualify for these intervention services based on their having documented developmental delays in motor (gross or fine motor), communication (receptive or expressive), cognition, social, or self-help skills, or by having an environmental or biological condition that is likely to lead to a significant developmental delay in one or more of the foregoing areas. Assessments must draw from information from multiple sources (e.g., both direct assessment and caregiver report), and an individualized intervention plan, based on the unique needs and strengths of the child and family, must be developed. Furthermore, states must create a system for identifying eligible children using various methods of recruitment and developmental screening. These mandates created the need for an arsenal of assessment tools that encompass all the qualifying areas of delay and use information from a variety of sources. Additionally, instruments were developed that were designed to facilitate better treatment planning by focusing on skills that can be targeted easily for intervention (criterion-referenced tests). Moreover, a plethora of brief developmental screening instruments was developed for use by professionals with relatively little training in formal assessment or statistics. In addition to tests for entry into early intervention programs, test developers and state agencies have recently begun to turn attention to the creation of developmental tests specifically for the purposes of measuring developmental progress and holding early intervention programs accountable for improvements in child outcomes ([Ripple and Gilliam, 2000](#)).

The advent of information-processing theories of human intelligence led to more elaborate models of infant cognition. Further, the focus of infant developmental tests on gross and fine motor skills and emerging perceptual motor coordination may contribute to their weak predictive validity for later IQ, because these skills may have relatively little to do with information-processing capacities ([Bornstein, 1989](#)). Several studies have shown measures of infant information processing (e.g., attention, recognition, stimulus habituation, and memory) to be significantly related to later IQ scores ([Bornstein and Sigman, 1986](#); [McCall and Carriger, 1993](#)). However, these measures can be difficult to administer under usual clinical assessment conditions, and the model has not been translated to clinical assessment tools. Regardless, measures of information processing may play an important role in the next generations of developmental assessment instruments.

## OBJECTIVES OF INFANT ASSESSMENTS

Why perform infant assessments? It is perhaps easier to state definitively what infant assessments cannot provide. They do not provide a measure of fixed or immutable intelligence, a trajectory for future development, or a window on future adjustment, nor can they typically parcel out the various potential causal factors. Results are descriptive, with only limited application for etiologic understanding or detailed prognosticating. Questions such as "How much of this infant's delay comes from environment, versus how much from prematurity?" or "What will be the eventual extent of this child's developmental disability?" are not definitively answerable by a developmental assessment. Developmental assessments, however complete and skillfully done, cannot provide sure predictions of long-term outcome or parcel out the complex contributions of endowment, experience, and maturational forces.

Despite the foregoing caveats, assessment of infant development can be highly useful and in many cases essential to proper clinical treatment. Skillfully done, these assessments can help to create a picture of the child's current developmental level and environmental context that can be invaluable to sound clinical decision making and treatment planning. Essentially, developmental assessment results help to provide a lens through which we may be better able to perceive the world from the child's perspective. Indeed, Bagnato and Neisworth point out that the word *assidere* (the Greek origin of *assessment*) literally means "to sit beside" and, hence, to get to know someone ([Bagnato and Neisworth, 1999](#)).

From a problem-oriented stance, there are several general problem areas and more specific concomitant disorders and conditions for which infant assessments may be indicated. These are summarized in [Table 40.2](#) and include the following:

Regulatory disturbances
Sleep disturbances (e.g., frequent waking)
Excessive crying or irritability
Eating difficulties (e.g., slowly eating or food refusal)
Low frustration tolerance
Self-stimulatory movements (e.g., rocking, head banging, excessive finger sucking)
Social and environmental disturbances
Failure to discriminate caregivers
Atypical or no expressions of affect or interest in social interaction
Excessive negativism
Atypical, hostile, or multiple attachments or caregivers
Separation or prolonged separations from caregivers
Psychophysiological disturbances
Recurrent vomiting or chronic diarrhea
Recurrent wheezing
Recurrent skin rashes
Developmental delays
Specific delays (e.g., gross motor, language)
Language delays or delayed development
Genetic and metabolic disorders with known neurodevelopmental sequelae
Down's syndrome
Fragile X syndrome
Prader-Willi syndrome
Exposure to toxins
Fetal alcohol syndrome
Lead poisoning
Central nervous system damage
Traumatic brain injuries
Intracranial hemorrhages
Prematurity and serious stresses early in life

**Table 40.2. Some Clinical and Diagnostic Indications for an Infant Developmental Assessment**

1. Regulatory disturbances: disturbances in self-regulatory capacities, such as sleep or eating disturbances, including food refusal, night terrors, repeated waking, or problems in impulse control such as excessively aggressive behavior. Low frustration tolerance is another mark of regulatory difficulties. Self-stimulatory behaviors, such as rocking or head banging, may indicate a variety of social or regulatory difficulties, may be a manifestation of environmental stress, or may signify more profound difficulties in relatedness, as in pervasive developmental disorder.
2. Social and environmental disturbances: disturbances in social development or the caregiving environment, including serious and profound problems in differentiating mother or caregiver, such as may be seen in pervasive developmental disorder or infantile autism, and disturbances in predominant mood. Infants who are predominantly withdrawn and apathetic are at great risk of developmental difficulties. In this category are also included environmental conditions such as repeated or prolonged separations or neglect, abuse, and exposure to violence, all of which place infants at risk of social and affective disturbances ([Kaufman and Henrich, 2000](#)).
3. Psychophysiological disturbances. These include, among others, failure to thrive, recurrent vomiting, wheezing, or chronic skin rashes. The younger the child, the more likely the response to an environmental stress will be global, involving several organ systems (e.g., failure to grow). Clearly, any one of these problems may have physical causes, but clinicians should be alert to the close connection between physiologic and psychological adjustment in young children.
4. Developmental delays: delays in specific areas of development, including motor development and activity, language and communication, awareness of others and degree of relatedness to others (often seen together with language delay), or delays in more than one of these areas. Such delays may be more common among infants with complicated perinatal courses such as those born severely premature or after parental substance abuse and prenatal exposure to alcohol, cocaine, or other drugs. Thus, infants with such histories are more often referred for assessments early, to plan for appropriate interventions.
5. Genetic and metabolic disorders with known neurodevelopmental sequelae. Various genetic and metabolic disorders have known neurodevelopmental sequelae. These include, but are not limited to, Down's syndrome, fragile X syndrome, Prader-Willi syndrome, certain sex chromosome anomalies (e.g., Klinefelter's syndrome), and poorly managed phenylketonuria ([Madrid and Marachi, 1999](#)). Although certain developmental and behavioral sequelae are associated with these conditions, the extent can often vary considerably, and developmental assessment can be useful to document its course and to target psychosocial interventions better.

6. Exposure to toxins. Exposure to environmental toxins, such as the case with fetal alcohol syndrome and lead poisoning, has been associated with both developmental delays and behavioral dysregulation. Although useful in treatment planning, assessments are not able to determine the proportion of the developmental presentation attributable to these potential causal factors.
7. Central nervous system damage. Central nervous system damage (e.g., traumatic brain injuries and intraventricular hemorrhages) can, of course, lead to developmental sequelae, and follow-up with a developmentalist can be invaluable in understanding the level of functional impairment and in tracking recovery.
8. Prematurity and early illnesses. Prematurity and other serious medical conditions that may result in hospitalization or other restriction of appropriate stimulation early in a child's life may lead to altered parent-child interaction and may adversely affect development ( [Minde, 2000](#)).

Extant research suggests that the specific disturbances and conditions included in the foregoing list are highly interrelated and are mediated by the social context of the child ( [Zeanah et al., 1997b](#)). For example, failure to thrive may also indicate social (e.g., the family and caregiver-child dyadic relationships) or environmental disturbances, or general developmental delay may occur in children with repeated separations or in a withdrawn, apathetic child. A particular developmental profile, such as delayed language skills but age-appropriate motor and problem-solving skills, may occur with different presenting difficulties, and thus, it is not possible to specify a characteristic diagnostic developmental pattern for failure to thrive, sleep disturbances, or the other problems listed here.

In addition to the foregoing caveats, three general points are important to remember. First, language and communication skills are particularly vulnerable to biological and environmental stresses. Moreover, problems in communication also affect personal-social development. For most of the problems listed under social and environmental disturbances, the infant will likely show minimally delayed language and personal-social development. In addition, any adaptive or motor items that require interaction with the examiner are affected by disturbances in relatedness, and the child's skills in these areas appear scattered not necessarily because of motor impairment but rather because of the necessity for social interaction for administering the item. Second, it is possible for an infant presenting with some of the difficulties outlined in [Table 40.2](#) to have an age-appropriate developmental profile in terms of what things the child can and cannot do. In this case, the qualitative observations of how the infant approaches the setting are crucial. The qualitative aspects of the child's interactions with the caregiver and the evaluator, motivations, problem-solving processes, and mood state are infinitely more important than a simple inventory of the infant's skills. Third, an infant's level of developmental functioning may vary considerably between domains. Infants with psychophysiological disturbances often show such a scattered developmental profile. Qualitative observations are again important with this kind of profile, as well as repeated assessments over time, to gain a better sense of the child's developmental trajectory.

Generally, the developmental assessment provides a description of the child's functional capacities, the relationships among the various domains such as language and socialization, the child's ability to adapt, and the range of coping strategies. For the very young infant, developmental assessments describe neurodevelopmental functioning and individual regulatory capacities. For caregivers, the evaluation provides information about both the child and the potential therapeutic value of the alliance established with the clinician. For the referring clinician, the assessment may provide a more integrated view of the infant's psychological as well as physical status. Finally, infant assessments often serve the purpose of facilitating referrals to appropriate educational or rehabilitative services. In such cases, the useful question is not whether the infant is delayed or has problems, but rather what are the most appropriate services to ameliorate these problems or to compensate for these conditions. In cases such as these, the evaluating clinicians will need to be collaborators themselves with persons directing intervention and educational services for infants. (For reviews of the development and effectiveness of early intervention services for infants, see [Clarke-Stewart and Fein, 1983](#); [Guralnick, 1997](#); and [Shonkoff and Meisels, 1990](#).)

## DEVELOPMENTAL FORCES

Several important forces drive or moderate developmental processes. Indeed, clinical assessment of infants and their families represents a process of gaining a better understanding of these interacting forces. Four specific areas are discussed: (a) the interaction of innate and experiential factors, (b) maturational processes, (c) the essential role of relationships with others for healthy development, and (d) developmental stages and critical or sensitive periods. Although these areas are inextricably interrelated, some points are unique to each.

### Interaction of Innate and Experiential Factors

The interactive balance between innate and experiential factors is a well-worn, time-honored controversy in developmental science, and even now it is possible to find proponents emphasizing the singular importance of one over the other. Rarely are these issues clearly distinguishable in a clinical evaluation. At the least, infants bring sets of innate capacities that influence how they respond to the environment and how it responds to them. The clinician is always faced with considering how intrinsic and extrinsic factors have interacted to contribute to an infant's developmental difficulties or strengths. Infants are more vulnerable to developmental dysfunction, even with a supportive environment, if they have biological dysfunction, as in genetic disorders or severe prematurity. Conversely, even "well-endowed" infants are at risk of developmental dysfunction if their environment provides inadequate or inconsistent nurturing. A combination of an impoverished or dangerous environment and biological or genetic risks is a significant predictor of developmental dysfunction, and as the number of risk factors increase so increases the likelihood of poor outcomes ( [Peck et al., 1999](#); [Sameroff and Chandler, 1975](#)). Indeed, an extensive review of genetic research conducted by a special task force of the American Psychological Association concludes that genes, the environment, and the interaction of these two forces all play a large role in cognitive development ( [Neisser et al., 1996](#)). This transactional model of child development, which stresses the dynamic interplay between individual-level and contextual-level factors, is the prevailing paradigm ( [Sameroff and Fiese, 2000](#)).

### Maturational Processes

Depending on the clinician's frame of mind, *maturation*, or the progressive unfolding and differentiation of intrinsic capacities, presents either a complication or a challenge in the process of developmental assessment. Infants change rapidly, and the appearance of behaviors and responses can be highly variable despite certain expected sequences. Moreover, although very young infants begin life in a relatively undifferentiated state, within the first months, perceptual and motor systems differentiate rapidly. Implicitly, we accept Gesell's model of infant development by acknowledging that sequences of development *generally* are based on orderly maturational steps that have been well described and defined. This sequence and the knowledge of when children typically achieve certain skills can be used to establish norms, against which an individual infant's developmental skills can be contrasted. As Provence states: "Maturation . . . is a necessary construct, an invisible process represented by observable behaviors" ( [Provence, 1972](#)).

As described earlier, environment, genetic predisposition, and the interaction of both can alter maturational forces significantly. For example, we expect grasping patterns to follow an expectable, regular sequence of neurologic maturation but know that the timetable for infants' use of a particular grasp to hold a toy or to explore a box is individually variable and can be highly related to the infant's exposure. Or, although the infant may have the neurologic capacity for a responsive smile and the perceptual-motor integration to extend his or her arms toward an adult, experience in interaction with the environment is a necessary factor for such observable behaviors to emerge. In addition, it is true some variants of typical maturational processes are not necessarily associated with later problems. For example, it is typical for infants to learn to crawl on hands and knees at 8- to 9-months old and then to walk at 12-months. However, various alternative pathways of infant locomotion are fairly common and are not necessarily related to underlying problems, and researchers have long known that age of walking alone is not a good predictor of developmental outcomes ( [McGraw, 1932](#)).

It is important to draw a distinction between developmental processes that are primarily delayed and those that represent a qualitative deviation from the typical progression of skills. For example, some infants and young children present a pattern of development that approximates the typical orderly progression of developmental skills, but they are nonetheless developing along that track at a pace significantly behind their same-age peers. Other infants, however, may evidence patterns of development that are substantially different from the normal progression or may show signs of qualitative differences in neuromuscular development (e.g., localized or diffuse hypotonia, abnormal reflex patterns). Significantly deviant patterns of development appear to be more common in children whose overall development is very delayed relative to chronologic age expectations.

### Relationships

It is impossible to overstate the role of human relationships in development. The essential role of stable and nurturing human relationships is well established and is universally acknowledged among researchers ( [Shonkoff and Phillips, 2000](#)). However, most formal infant assessment techniques were developed to focus exclusively on the measurement of maturational forces, as if assuming that development proceeds relatively independent of environmental input. Thus, it is important to emphasize that every infant assessment must consider the other persons in that infant's life. Understanding normal, delayed, or deviant development requires some understanding of the infant's experiences with adults. The younger the child, the more central are such persons to the child's safety and total well-being. Such serious events as traumatic separation, physical abuse, witnessing of violence, deprivation, loss, and neglect often have devastating effects on a child's development

(Rogeness et al., 1986).

Adequate care and nurturing for an infant involve a balance between gratification, comfort, and support and the frustration inevitable in all developmental phases. Adequacy in caregiving, difficult as it is to define, generally includes attempts to mediate painful, tension-producing situations and to adjust the balance between comfort and frustration. The appropriate balance varies depending on the child's age. For example, the infant's frustration at not being fed immediately is different from the toddler's frustration at being unable to reach a favorite toy, and each requires a different response from the parents. In one instance, frustration may produce a painful, tense state; in another, it may lead to an adaptive solution that enhances further learning and appropriate individuation and independence.

Often clinicians are not always dealing with gross parenting deficits or failures, such as in serious abuse and neglect ( Kaufman and Henrick, 2000). For many infants and young children, crucial experiences may have adverse effects that are much harder to identify. For example, we are only beginning to understand the critical effect of maternal depression in the first month to 1 year, when the mother is psychologically and sometimes physically unavailable to her infant ( Garrison and Earls, 1986; Murray and Cooper, 1997). A growing body of research on the issue of caregiver mental illness, however, suggests that serious psychopathology in caregivers can significantly alter dyadic and familial interaction patterns, which, in turn, lead to altered developmental courses for infants. Caregivers, however articulate and enlightened, may be unaware of their own difficulties in responding to their infants or of how their mood states, worries, and frustrations affect their parental responsiveness. It is at this level that the importance of establishing a working relationship between parents and evaluator is clearest.

### Developmental Stages and Critical Periods

Historically, theories of development have conceptualized the phenomenon primarily either quantitatively or qualitatively. A quantitative conceptualization portrays development primarily as a continuous orderly accumulation of skills, dependent on the mastering of prerequisite skills. Qualitative conceptualizations, in contrast, stress the importance of various developmental stages that are qualitatively different and represent a marked shift in the manner in which the person perceives, understands, and interacts with the environment. In short, the quantitative conception represent development as a continuous process, whereas qualitative theories propose that development is a process marked by periodic discontinuities or reorganizations. The concept of developmental stages involves such theories as Freud's theory of psychosexual stages, Erikson's theory of psychosocial stages, and Piaget's theories of cognitive stages. Clinically, the concept is valuable in that it provides schemata for understanding development. Extant research provides some support for both conceptualizations, and the developmental continuity versus discontinuity debate continues.

Research suggesting the existence of certain *critical periods* in human development provides some support for conceptualizing development as occurring in qualitative different stages. The concept of critical periods for the optimal development of different functions suggests that certain capabilities are optimally mastered at certain times, and difficulties arise when this optimal period is disrupted. Although the concept of critical periods was first clearly established in animal models, it has been demonstrated in humans, especially in the areas of social competence and language acquisition. Indeed, it appears clinically true that when the critical period passes without optimal organization of a given function, mastery is fully achieved with far more difficulty, if ever. It is also a clinical truism that when a function is newly emerging, it is most vulnerable to environmental stresses. This statement is supported by the common observation that an infant may stop talking if hospitalized just as the first words appear. Similarly, for an infant, chronic environmental stressors may result in a delay of appearance of age-appropriate skills. For example, a parent's anxiety over a toddler's growing motor independence may slow the development of motor skills and the elaboration of exploration. An infant's particular stage of development may influence which issues are most salient and most vulnerable to stress. During an evaluation session, stage-specific developmental characteristics also may influence not only the child's ability to demonstrate mastery of certain developmental skills, but also how the infant approaches challenges, including challenges elicited during a developmental assessment. For example, toddlers struggling with emerging independence may react differently to an evaluator's assessment tasks than would the younger infant who is focused more establishing social reciprocity and engaging his or her surrounding environment.

Reviewing research conducted in the 1980s and 1990s, Zeanah et al. (1997b) concluded that there are four distinct stages of qualitative reorganization during the first 3 years of life (see also Greenspan, 1981). Although their perspective is primarily focused on social-emotional aspects of development and draws from research and theory, the stages correspond rather closely to those of earlier developmentalists, especially Piaget ( Piaget and Inhelder, 1966). Indeed, many of the qualitative changes in cognitive development first proposed by Piaget seem to provide the prerequisites for qualitative changes in social and emotional functioning now being proposed. The following description of different stages during infancy and toddlerhood illustrates these qualitative changes, as well as the dynamic interaction between maturational processes and social relationships and the interactive nature of development across cognitive, sensorial, social, linguistic, and motor domains.

### Four Qualitative Stages of Infancy

#### STAGE 1 INFANT (0 TO 2 MONTHS)

During the first couple of months postpartum, infants primarily work toward achieving homeostasis, or the capacity for maintaining physiologic equilibrium, in the presence of internal and external stimulation. However, they are also surprisingly active and sophisticated learners, capable of cross-modally exploring and perceiving their environment, visually tracking objects as they move through space, habituating to invariant stimuli, discriminating novelty, and even anticipating caregiver actions.

#### STAGE 2 INFANT (2 TO 7 MONTHS)

The second stage (2 to 7 months) is marked primarily by increased social reciprocity between the infant and caregivers. This qualitative change follows increased awareness of the external world (made possibly by greatly enhanced visual abilities) and improved coordination of sensory input and nonreflexive (voluntary) motor output occurring at about 1 month of age. During the second stage, the infant's responsive cooing, repertoire of increasingly differentiated emotional responses, and a proclivity toward direct imitation of others' behaviors starting at about 4 months serve to facilitate reciprocal or contingent social interactions. During the latter half of the second stage (beginning as early as about 4½ months), infants start to show an understanding of *object permanence* (i.e., the understanding that objects and people continue to exist even when they are no longer within sight or sound) and a rudimentary understanding of the principles of *cause and effect*. These two epiphanies transform the infant's perception of the world and provide the requisite abilities for all future social-cognitive development. The concept of object permanence allows the infant to create mental representations of objects and others. It is therefore a prerequisite skill for imagining and for visual differentiation between caregivers and strangers. Cause-and-effect reasoning leads to increased intentionality of actions. Both these newfound cognitive abilities make possible simple interactive games between infants and caregivers, such as peek-a-boo.

#### STAGE 3 INFANT (7 TO 18 MONTHS)

At about 7 to 9 months, another qualitative shift occurs with profound impacts on reciprocal communication and social preference or familial belonging. At this time, infants develop a sense of *intersubjectivity*, the understanding that their thoughts, feelings, gestures, and sounds can be understood by others. Also at about this age, most infants begin to demonstrate means-end reasoning leading to goal-directed behavior. They can string together several behaviors to achieve a final outcome, often the attainment of some desired object. Through intersubjectivity and means-ends reasoning, the infant is able to consider caregivers as objects that can be used to meet their needs and wants (and the stage 3 infant's now solid grasp of object permanence gives him or her a large inventory of these wants and needs!). Together, intersubjectivity and means-end reasoning lead to the beginning of *communicative gesturing* (e.g., the moment when stretching for an object just out of reach becomes pointing to that object while looking at the caregiver, to request assistance). In the context of all these qualitative changes in the way in which the infant interacts with others, social preferences are established and become increasingly salient. At about 6 to 8 months of age, *separation anxiety* is first observable with most infants, peaking at about 14 to 18 months and declining thereafter ( Kagan, 1976). Relatedly, *stranger anxiety* appears to begin at about 8 months, peaks at about 24 months, and steadily declines thereafter.

By the second half of stage 3 (starting at about 12 months), several new skills in the cognitive, language, and motor domains create profound changes. At about 12 months, infants typically first learn to walk, and this new form of independent locomotion, more so than crawling, heralds increased independence and a broadening world. Cognitively, the infant's reasoning becomes strikingly less rigid and more open to alternative solutions. For example, before about 12 months, infants who learn that an object is hidden in a particular place will persist in looking for that object at that same location even after watching someone relocate that object to a different location. This is commonly referred to as the *AB error*. However, after about 12 months, the infant's ability to hold increasingly larger amounts of information and to discard outdated information allows for a fluidity of reasoning such that the AB error diminishes or disappears. Given this increased cognitive capacity and fluidity of reasoning, *trial-and-error problem solving* begins to replace conditioned response learning. Moreover, from about 12 to 18 months, infants develop rudimentary communicative speech. By 12 months, most infants understand the meaning of several words and may have an expressive vocabulary of about 5 to 6 words. By the time they reach 18 months of age, infants typically understand the meaning of an amazing number of words, can communicate in one-word sentences, and have

doubled their expressive vocabulary to about 10 words. Their melodic, jargoned speech patterns now closely resemble the inflections and turn-taking pauses observed in conversation.

#### STAGE 4 INFANT (18 TO 36 MONTHS)

At about 18 months, an increased ability to use *symbolic representation* transforms the infant's cognitive and social world. About 12 months earlier, object permanence marked the beginning of the infant's ability to hold in the mind mental representations of objects. The stage 4 infant is now well able to allow symbols to stand for objects, and this advance heralds greatly increased language proficiency. The use of words marks a qualitative change in the way infants think about the world and interact with others, and, likely, the reverse is true as well ( [Hollich et al., 2000](#) ). The beginning of this transformation appears to be marked by a move from direct imitation of others to *deferred imitation*, in which the behaviors of others are remembered and then are practiced later. *Symbolic play* appears as the infant uses a doll to symbolize a baby, and the infant begins to combine words and gestures to label objects in his or her world or make needs and wants known to caregivers. By 18 months, these skills are becoming solidified, and the infant's interactions with others change dramatically. Additionally, at about 18 to 24 months, *internal problem solving* begins to replace trial-and-error problem solving, as the infant's mental ability to hold and manipulate internal representations increases. From 18 to 24 months, infants' expressive vocabularies typically increase from about 10 words to about 50 to 75 words. By 30 months, the infant's expressive vocabulary has increased to nearly 300 words, and by 36 months, many infants have an expressive vocabulary of 500 to 1,000 words and typically speak in three- to four-word sentences ( [Ulrey, 1982](#) ) ( [Fig. 40.1](#) and [Fig. 40.2](#) ).

**Figure 40.1.** Typical rate of increase in expressive vocabulary of infants.

**Figure 40.2.** Typical rate of increase in average number of words per sentence in infants.

### SOURCES OF INFORMATION IN AN INFANT ASSESSMENT

We next discuss general sources of information and three techniques that are central for the clinician doing infant assessments: interviewing skills, observation of children and of caregiver-child interactions (apart from formal structured testing), and synthesis of the information gathered during the evaluation. [Figure 40.3](#) provides a summary of some of the information obtained during an infant assessment. Although interviewing, observation, and synthesis are skills of medical diagnosis in general, there are unique aspects to each in the process of assessing infants.

Caregiver Interview	Observation or Formal Evaluation of Child
<ul style="list-style-type: none"> <li>Family history</li> <li>Genetic influences</li> <li>History of pregnancy, delivery, perinatal period</li> <li>Developmental history</li> <li>Developmental milestones, previous assessments</li> <li>Medical history</li> <li>Children &amp; extended family arrangements</li> <li>Child's psychological role in family</li> <li>Caregiver perceptions &amp; expectations of child</li> <li>Stability of home/family environment</li> <li>Family social support systems</li> <li>Family functioning, stress &amp; coping (abused &amp; drug abuse, domestic violence, etc.)</li> </ul>	<ul style="list-style-type: none"> <li>Physical health, appearance &amp; growth parameters</li> <li>Sensory development (vision, hearing, touch, etc.)</li> <li>Gross motor development</li> <li>Fine motor development</li> <li>Communication development <ul style="list-style-type: none"> <li>Receptive communication</li> <li>Expressive communication</li> <li>Speech clarity &amp; fluency</li> </ul> </li> <li>Cognitive problem-solving</li> <li>Developing sense of self</li> <li>Social relationships &amp; interest in environment</li> <li>Capacity for affect regulation &amp; coping skills</li> <li>Emerging sensory motivation</li> <li>Capacity for symbolic representation &amp; play</li> </ul>

### Interviewing

It is axiomatic that skillful interviewing is central to a complete developmental assessment because many of the data about infants' daily functioning and their relationships with others come from interviews with the caregivers. Skillful interviewing techniques include the following: letting caregivers begin their story wherever they choose; using directed, information-gathering questions in such a way as to clarify but not disrupt the parents' account; and listening for affect as much as for content. Nearly every step of the assessment process requires an alliance between clinician and caregiver, because infants usually perform better when they are in the company of familiar adults, and the initial interview between clinician and family is crucial in setting the tone for such an alliance. Moreover, establishing an alliance is central to evaluating infants' interactions with the adults in their world. Indeed, infant assessments are quite compromised when there are no familiar adults available to meet with the clinician and to be with the infant. Parenthetically, it is often in cases involving the most severe environmental disturbance that clinicians do not have access to caregivers who are able to describe the infant's history.

### ADDRESSING CAREGIVER FEARS REGARDING THE ASSESSMENT

When parents, foster parents, or other caregivers are available, skillful interviewing is also critical in helping parents to follow through with the assessment process. Coming for a developmental evaluation or participating in one while their infant is hospitalized is enormously stressful and is often frightening for caregivers. Clinicians working with infants and their families need to understand that, regardless of what caregivers have been told about the assessment, caregivers' fears and fantasies about the process are as potent as the facts of the presenting problem. Not uncommonly, caregivers have begun to see the infant as damaged or defective

in some way and are afraid and guilty about the effect of their own behavior on the infant. Their fears of what the infant's problems signify may be expressed in many ways. They may anticipate that their infant has a serious developmental disability, such as autism or mental retardation, or that the infant will have serious emotional difficulties in school, or that they themselves will be, or already are, inadequate caregivers. It is always a vulnerable time for caregivers, and clinicians should keep in mind that what seem inconsequential moments and statements to them may be memorable and powerful for many caregivers. Furthermore, the stress of coming for an assessment affects the caregivers' abilities to report about the infant's development. Often, the "facts" start to change as the alliance between caregivers and clinician develops.

### ACTIVE LISTENING

When first interviewed, caregivers may be reluctant to be candid or may not themselves be fully aware of their own perceptions and beliefs about the infant. Open-ended questions, allowing caregivers to begin their story wherever they feel most comfortable, and conveying a nonjudgmental attitude are crucial beginning points in establishing the working alliance. In addition, at the risk of stating the obvious, such "interviews" involve considerably more listening than active questioning. Indeed, the type of *active listening* involved in this type of interview requires the clinician to do much more than just passively collect and record requested information. Rather, it involves forming numerous connections among "factual" information, observational information (the reactions of the caregivers and their affective responses), and an appreciation the context of the relationship between the caregiver and the clinician.

### CONTENT OF THE INTERVIEW

Practically, the purpose of interviews with parents, foster parents, or other caregivers is to gather information about the infant. Highlighted earlier is the affective atmosphere in which such data gathering best occurs. The important areas to cover in terms of the infant's development are as follows: the infant's medical history and major developmental milestones; the history of the mother's pregnancy, delivery, and immediate perinatal period; the number, ages, and health of family members; and how the infant fits in the family's daily life (Cox, 1999). The meaning of the individual child for all caregivers is an important window on the infant's place in the family. Many infants and toddlers attend child care or early intervention programs, and the perceptions of those teachers, as well as their relationship with the infant's primary caregivers at home, are also important.

More specifically, the interviewer should try to obtain a picture of the caregivers' perceptions of the infant's level of functioning in several areas. These include motor development and activity level, speech and communication, problem solving and play, self-regulation (ease of comforting, need for routines), relationships with others, and level of social responsiveness. Questions about whether the pregnancy was planned or came at a good time for the family and what expectations the parents had for the infant provide important information about perceptions, disappointments, and stresses. Similarly, asking the caregivers of whom the infant reminds them or what traits in their infant they like best and least may be useful avenues for learning about how the parents view both the infant's problem and his or her place within their family.

### TECHNIQUES OF ORGANIZING INFORMATION

Provence suggests that a productive method of gathering developmental and family data is to ask the caregivers to describe a day in the life of their child (Provence, 1977). Provence outlines how this question can be the framework for learning about daily activities, how the infant and caregivers interact throughout the day, and about interactions around mealtime, bedtime, or times of distress. When all major caregivers are present for the interview, this question provides a time for each of them to present descriptions of his or her time with, and perceptions of, the child. Additionally, clinicians may use structured interviews, such as the *Vineland Adaptive Behavior Scales* (Sparrow et al., 1984), currently under revision, to collect both quantitative developmental data and to provide an opportunity to open new areas of clinical discussion. Moreover, the *Infant-Toddler Developmental Assessment* (Provence et al., 1995), appropriate for infants from birth to 36 months, is particularly useful in providing a schema for organizing important information from caregiver interviews, medical and developmental records, and behavioral observations.

Implicit in this overview of interviewing caregivers as a part of the clinical assessment is the assumption that such assessments require several sessions. Minimally, one meeting with caregivers, two or more with the child and caregivers together, and another to present the results to the caregivers are necessary. The sessions with the infant also provide an opportunity to gather more interview information, because other questions will occur in the context of the child's behavior and performance. For example, asking whether the child's response to a particular situation within the evaluation context is usual for him or her may open up another area of information from the caregivers. As is likely clear from these suggestions, in our view, infant assessment is a process of constantly gathering information, revising impressions, and testing hypotheses, and that requires time.

Conversely, clinicians asked to evaluate infants and young children do not always have the ideal situation outlined earlier. At times, consultants, caregivers, or both may insist that the evaluation be done in one session, or the clinician may have limited access to the child, as with many evaluations done in a hospital setting. It is important at these times for the clinician to be clear about the limitations of the evaluation findings. Another situation that occurs increasingly commonly and does not fit the ideal model just outlined is when no parents, family members, or other caregivers are available. Situations of severe abuse, abandonment, multiple placements, or seriously ill parents are examples of times when the clinician will not have available certain critical sources of information. In these instances, certain hypotheses suggested by the child's presentation and status may be left unconfirmed. As in situations when the time for the evaluation is brief, it is most important for clinicians to acknowledge which aspects of their diagnostic formulation are relatively certain, which are not, and what information would likely be clarifying, were it available.

### Observing

*Observation* is the fundamental skill needed for measuring infants' development. After all, most diagnostic evaluations are based on observation of physical signs or behavioral responses. However, what distinguishes the observational skill necessary for developmental assessment is that it occurs on many levels simultaneously and is perhaps the area in which the developmentalist's dual role as both generalist and specialist is most evident. Moreover, the observational skills inherent in assessments of infants require a blend of free-floating attention bounded by a structure. In other words, although the clinician must be comfortable enough in the setting to attend to whatever occurs, he or she must also have a mental framework by which to organize the observations collected during the session. Such a framework entails at least four broad areas: (a) predominant affective tone of the participants; (b) involvement in the situation (curiosity and interest); (c) use of others (child's use of the caregivers or examiner); and (d) reactions to transitions (initial meetings, end of sessions, changes in amount of structure).

### WHAT TO OBSERVE

There are several opportunities for careful observation during the course of a clinical assessment. Clinical observation begins from the very first contact with the caregivers and infant, including the caregiver interview addressed earlier. Many important observations of the infant and infant-caregiver and familial interactions can be obtained during the course of formal developmental assessment. Benham provides an elaborated framework for structuring observations of infants and toddlers that may be useful during clinical assessment (Benham, 2000). In many cases, however, the formal developmental evaluation alone may not provide sufficient opportunity to observe all the important behaviors of the infant and caregiver. Infants may behave differently with different caregivers and in varying contexts. For this reason, both naturalistic and structured analog procedures can often be used to gather additional observational data that can be useful for both clinical and research purposes (Zeanah et al., 1997a). Play-based assessment allows the clinician the opportunity to observe the infant and caregivers in a less structured format than provided by the formal developmental assessment. Moreover, play observations can be very useful in gaining additional information about the infant's cognitive, symbolic and linguistic, social, and motor development, as well as in assessing internal emotional states and conflicts and the infant's internal dynamic representations of the world (Close, 1999).

### LEVELS OF OBSERVATION DURING ASSESSMENT

Within the four broad areas of observation described earlier, the clinician makes observations continuously on at least three levels. Perhaps the most obvious level is the observation of how the child responds to the structured assessment items administered during formal testing. As already stated, observations during formal testing should not be confined solely to whether the child passes or fails a given item, but to how the child approaches the task. The second level of observation during an infant assessment is how the child reacts to the situation apart from the formal testing structure. Does the child approach toys, initiate interactions, refer to the examiner or his caregivers? How does the child react in the beginning of the evaluation versus later when the situation and the examiner are more familiar?

The third observational level is a specific focus on the interactions between caregivers and infant. The clinician makes these observations throughout the evaluation process and revises his or her hypotheses as both caregivers and infant become familiar with the process. How to interpret the behaviors one observes between caregivers and child in terms of their ongoing relationship is learned partially by experience and requires time to gather many observational points. However, several

general areas may provide important descriptive clues. Does the child refer to the caregivers for both help and reassurance? Similarly, does the child show his successes to the caregivers, and do the caregivers respond? Another important observation for toddlers is whether the child leaves his caregivers' immediate company to work with items or explore. For infants, how caregivers hold, feed, and comfort their baby may be windows in the emerging dyadic and familial relationships. A caregiver participates with his or her child during such sessions in varying ways, and the clinician continuously is assessing qualitative aspects of that participation—how intrusively involved, withdrawn, or comfortably facilitative the caregivers are. One of the most important lessons when learning how to observe interactions between infants and caregivers is that clinical observations, even when based in a naturalistic setting, may or may not be an adequate reflection of what is typical for that particular family. Adults may appear very different as individuals in their own right, compared with when they are interacting with their children. Moreover, the assessment context in which one's child (and by implication, one's self as a person and as a caregiver) is observed by another is anxiety provoking in varying degrees for all parents, and it may profoundly alter their parenting style.

Formal quantitative developmental evaluation is only part of the overall clinical assessment of infants. Indeed, in some ways, formal testing is the least critical of the clinical assessment tasks and serves more as a frame for clinicians to guide their observations ( Gilliam, 1999). It is not sufficient in assessing infants simply to say that the infant is either developmentally delayed or age adequate. For very young children, assessing development involves elaborating a more complex view of the child and his or her environment, and at this age, every developmental evaluation must include descriptions of behavior and the qualitative aspects of the child's behavior in the structured setting. For example, *when* the infant first turned to a voice or successfully retrieved a toy in a manner appropriate for age may be less important than *how* he or she responded to these tasks (e.g., with excitement, positive affect, and energy versus slowly, deliberately, and with little affective response). Such qualitative observations are often the best descriptors of those capacities for which we have few standardized assessment techniques but that are absolutely fundamental for fueling the development of motor, language, and problem-solving skills. Through observing how infants do what they do, the clinician gains information about how infants cope with frustration and how they engage the adult world, as well as about their emotional expressiveness, their capacity for persistence and sustained attention, and the level of investment and psychological energy given to their activities.

## Synthesis

The process of synthesizing all the data gathered from the different sources during an assessment is a technique and skill unto itself. Moreover, how this synthesis, with its attendant recommendations, is conveyed to caregivers and other professionals is another essential step in the assessment process, and the assessment is not complete until the therapeutic alliance among all stakeholders is brought to fruition in a collaborative formulation. Infant assessments often involve referring pediatricians and other clinicians, all of whom need to be included individually in the clinician's data-gathering interviews and in the final synthesis.

The synthesis of information from an infant assessment differs from the synthesis involved in other medical diagnostic processes in that very few specific diagnostic categories encapsulate all the findings of an infant assessment. The synthesis involved in an infant assessment requires bringing together all the data gathered from interviews, observations, and testing into a qualitative description of that infant's capacities in different functional areas (motor, problem-solving, language and communication, and social) and of the infant's current strengths and weaknesses. It also involves integrating the assessment information in the context of the infant's individual environment. For example, an infant who has experienced multiple foster placements may be socially delayed, but such a finding may assume a different significance for an infant who has had a stable home environment.

Synthesizing the large amount of data obtained from a comprehensive clinical infant assessment can be quite daunting. As stated in the introduction, in performing the infant assessment the clinician must be both generalist and specialist. The clinician must draw on and synthesize knowledge from child psychiatry, pediatrics, neurology, developmental psychology, speech and language therapy, physical and occupational therapy, and often genetics and endocrinology ( Mayes and Gilliam, 1999). Increasingly, clinicians evaluating young children also need know about early childhood education programs and early intervention, as well as laws regarding child abuse, neglect, and domestic violence. Knowledge from these diverse fields allows a clinician to place the results of a developmental assessment in a meaningful context for the individual child and leads to a better conceptualization of treatment options. For example, understanding the physiologic effects of prolonged malnutrition and episodic starvation in infancy ( Dickerson, 1981; Shonkoff and Marshall, 1990) helps the clinician to evaluate the relatively greater gross motor delays of a child with failure to thrive who has no other neurologic signs. Similarly, understanding the effects of a parent's affective disorder on a child's responsiveness to the external world ( Seifer and Dickstein, 2000) adds another dimension to understanding the infant's muted or absent social interactiveness, babbling, and smiling.

Finally, it is often during the synthesis process that the therapeutic effect for caregivers participating in the assessment is most evident. At the very least, caregivers often change their perceptions of their infant's capacities. They may see strengths in their infant they had not previously recognized, or they become deeply and painfully aware of weaknesses and vulnerabilities that they may or may not have feared before the assessment. Any of these changes in perceptions may affect the caregivers' view of themselves and of their role as caregivers. Moreover, infants often change during the assessment process, as their caregivers become more involved in the alliance with the clinician, and they experience, at least temporarily, another adult's concern and interest in their family. Emphasizing the potentially therapeutic value of an assessment underscores that the synthesis process is not simply wrapping up the assessment and conveying information, but it is also a time to explore with the caregivers the meaning of the process for them and their infant.

## FORMAL DEVELOPMENTAL ASSESSMENT TOOLS

Many different formal developmental assessment tools for infants and toddlers exist. In this section, we discuss the types of quantitative data obtained from these tests and offer basic considerations for choosing an appropriate evaluation tool. Later, we describe some of the most commonly used developmental instruments.

### Types of Quantitative Data

Besides the vast amount of qualitative data obtained by careful observation during testing, most developmental assessment procedures provide several methods of quantifying results. As described later in this chapter, most developmental tests have been standardized and normed on a sample of children selected to represent the performance of typically developing children. It is by comparing an individual infant's performance against this set of norms that most test scores are derived. These scores are then used to convey something about the infant's level of developmental skills acquisition, relative to other presumably typical infants.

Of the several different types of scores available, standard scores and age equivalents are the most commonly used. *Standard scores* are the most robust scores obtainable and represent the infant's performance in relation to other infants of about the same chronologic age. Common forms of standard scores include *Z*-scores, deviation scores, and *T*-scores, the later two being linear transformations of the former. Most tests provide some guidance on how to describe an infant's standard score by placing the scores in descriptive bands (e.g., average, below average, mildly delayed). Often, to increase the interpretability of these scores, they are converted to percentile ranks. Table 40.3 presents one common method for descriptively banding standard scores, although many other methods also are used.

Range	ZScore	Deviation Quotient	TScore	Percentile Rank
Significantly delayed	<-2	<70	<30	≤2
Mildly delayed	-2~-1	70-84	30-39	2-15
Average	-1~+1	85-114	40-59	16-83
Above average	>+1	≥115	≥60	≥84

**Table 40.3. Descriptive Ranges for Standard Scores and Their Corresponding Percentile Ranks**

*Age-equivalent scores* represent an estimate of the chronologic age (typically expressed in months) at which the typically developing infant would demonstrate the skills observed in the infant being assessed. This type of score is often appealing to many caregivers and others with little or no training in psychometric tests

because the interpretation is seemingly straightforward. However, age-equivalent scores are notoriously easy to misinterpret and may lead to erroneous conclusions. First, age-equivalent scores on infant developmental tests tend to be highly unstable, with the infant's performance on only one or two items largely affecting the age equivalent. Second, age-equivalent scores may imply too much about an infant's development, especially when skills are highly scattered. Because of the way in which age-equivalent scores are computed, the score may greatly overestimate or underestimate an infant's developmental level. As a result of the way in which tests are scored, infants who are very consistent in their ability to do tasks typical for their age often receive an age-equivalent score much higher than their chronologic age, even though they are not yet developmentally ready to do the things associated with that age equivalent. Conversely, infants who, for whatever reason, struggle with some less developmentally mature tasks likely will receive an age-equivalent score much below their chronologic age, even if they are able to do many things typical of their chronologic age or older. In cases such as these, age equivalents are best expressed as a range, if expressed at all. Third, developmental delay expressed in age equivalents does not adequately address the frequency or severity of the delays. Clearly, a 6-month delay in development is different for a 12-month-old infant versus a 30-month-old child. Standard scores, with associated percentile ranks, better expresses this delay in terms that are less dependent on the chronologic age of the infant. Finally, the type of data used to compute age equivalents is too weak statistically to support the calculation of confidence intervals that are useful in placing the score within the context of appropriate bands of error. This lack of confidence intervals further exacerbates the preceding limitations. Of course, there are times when age equivalents may be the best or only option available for expressing an infant's performance (e.g., when the extent of developmental delay is so great that standard scores cannot be easily calculated and percentile ranks below the first percentile are obtained).

### Considerations for Selecting a Formal Developmental Assessment Tool

The following discussion includes some basic guidelines for choosing an infant developmental test that best meets the clinician's specific needs. These guidelines also help to provide a framework for evaluating the usefulness of some of the various tests currently in use. Four areas of consideration are presented: purpose, sources of data, standardization, and psychometric properties.

#### Purpose

A developmental test may be useful for one or more of several different purposes: diagnosis, screening, and early intervention planning. Tests designed for these three purposes are quite different, and selecting the correct tests to match the stated purpose is essential. First, *diagnostic tests* are used to provide information necessary for either clinically or eligibility-oriented diagnoses. Clinically oriented diagnoses are used by clinicians to capture succinctly the infant's overall presentation and to provide a common nomenclature for communicating that information to other clinicians. Eligibility-oriented diagnoses, however, are used to identify which infants have levels of developmental delay significant enough to establish eligibility for publicly funded early intervention programs. Often, the infant must demonstrate a particular degree of developmental delay (e.g., performance that is two standard deviations below the mean) to "qualify" for these services. Second, *screening tests* are used when it is desirable to use a relatively brief instrument to identify infants who may be at risk of delayed development and who would benefit from further diagnostic testing. Usually, screening tests are used when many children need to be assessed, and a full diagnostic assessment for all children would be too costly or cumbersome. Third, *intervention-planning tests* are used to plan an individualized early intervention program once children have been diagnosed. These instruments help to identify important program goals and objectives or to track an infant's achievement of these goals over time to document the effects of the intervention.

#### SOURCES OF DATA

Developmental assessment instruments, like all psychometric tests, are methods of collecting and organizing data. Developmental tests for infants use one or more of at least three different types of data: direct assessment, incidental observation, and caregiver report. It is important to acknowledge the strengths and limitations of each data source. Direct assessment has the strength of being potentially very standard in its presentation, so an infant's performance may be directly compared with that of other infants, with the assumption that the material was presented in a similar standard method. The limitation of direct assessment, however, is that it represents only a small sample of the infant's developmental repertoire that will be influenced greatly by current issues regarding the infant's motivation, mood, comfort, and responsiveness to the examiner and the evaluative process. Caregiver report surveys are a useful addition to formal assessment, in particular to document behaviors that occur too infrequently to be observed in a clinical evaluation or to assess the caregivers' individual perspectives of their infant. However, caregiver reports should not be the sole measure of the infant's development, because they are highly subject to rater bias ([Meisels and Wasik, 1990](#)). Given the strengths and limitations of each of these sources of data, a comprehensive assessment should use multiple sources of data across multiple contexts.

#### STANDARDIZATION

Test standardization involves the process of developing a consistent method of administration and collecting normative data regarding children's typical performance on the test. It is by this normative data that evaluators determine a specific infant's standing relative to the normative group. This relative standing can then be expressed in terms of either standard scores or age equivalents, as described earlier. It is the responsibility of the test user, however, to decide whether a given test's standardization sample is representative of the type of infants the test user plans to assess. For instance, it clearly would be inappropriate to compare the developmental performance of an infant raised in a large city in a highly developed nation to a normative sample of infants living in a small village in a less-developed nation, unless one knew beforehand that infants from both these settings scored very similarly on the test. Most decisions regarding the representativeness of a test's standardization are not this apparent, however. Moreover, standard scores and age equivalents are norm sample dependent. In other words, scores derived from a nationally standardized test indicate an infant's standing relative to other infants throughout that nation and not necessarily to other infants of the same specific locality, gender, ethnicity, or economic status. Of course, the inverse is true as well. Some tests are normed on very specific populations of children, such as children from a specific city or state or of a particular economic status. The use of standard scores derived from these tests with infants from other localities or economic backgrounds, without specific empirical evidence to justify their generalization, is generally not recommended. Furthermore, to yield reliable results, normative data should be no more than about a decade old, to keep pace with intergenerational escalation in test performance ([Flynn, 1984](#)). Grossly outdated norms often yield inflated scores that may lead to erroneously disqualifying infants for needed services.

#### PSYCHOMETRIC PROPERTIES

The soundness of a psychometric test is judged based on its *reliability* (the ability to produce similar results under differing conditions) and *validity* (the collection of evidence that suggests that the test measures what it is supposed to measure). Several forms of reliability exist. *Test-retest reliability* is a measure of a test's stability over time. Test-retest coefficients are often lower for infant tests as compared with tests designed for older children, partly because of the rapidity of early development. *Interrater reliability* refers to the degree to which test scores are not dependent on individual differences among test examiners, but rather reflect the infant's abilities regardless of who is administering the test. Finally, *internal consistency* refers to the correlation between various test items and provides evidence of the degree to which a test measures a single unitary construct, as opposed to representing an unrelated collection of test items. As a guideline, reliability coefficients of at least 0.90 for diagnostic tests and 0.80 for screening tests are recommended in each of these three areas of reliability ([Salvia and Ysseldyke, 1991](#)). Besides their use in evaluating the psychometric soundness of a test, reliability coefficients also serve a clinically relevant purpose. Because no test can be completely reliable, scores are often presented within a given *confidence interval*, which bands the infant's obtained score within a certain range of error (e.g.,  $100 \pm 8$ ). This presentation acknowledges the error inherent in all tests, as opposed to presenting a single score, as if it were an exact measurement. *Validity*, in comparison to reliability, is even more multifaceted. There is no single or preferred way to establish a test's validity. Rather, validity represents an accumulation of evidence that together builds a case for the accuracy of that test. Specifically, infant developmental tests are expected to correlate significantly with other similar tests, to reflect developmental changes that result from expected maturation, and to be sensitive to the presence of diagnosable disorders with clear developmental manifestations.

Psychometric reliability and validity are based on a test's properties as demonstrated with groups of test takers. However, psychometric properties that are more individually relevant are also important. For example, developmental tests should have adequate floors and ceilings. In other words, there should be enough lower-level items that significant developmental delays can be detected in even the youngest infants for which the test is to be used (floor). Likewise, there should be enough upper-level items that significant developmental precocity can be detected in the oldest children for whom the test is to be used. Because standard scores are obtained by comparing an infant's performance with that of peers of similar age, the degree to which the normative data approximates the infant's age also is important. The current standard in infant developmental tests is normative bands of 1 month for infants up to 12 or 18 months old and 1 to 2 month bands for infants up to 36 months old. In other words, infant tests typically compare an infant's performance with that of other infants no more than 1 month older or younger, whereas a toddler's performance may be compared with that of other toddlers 1 to 2 months older or younger. Of course, normative bands that are narrow are preferable to those that are wider.

### REVIEW OF SELECTED DEVELOPMENTAL TESTS

A few of the more widely used developmental tests are presented in [Table 40.4](#), and some of the most common examples are further described here, organized under three basic headings: neonatal assessment tests, infant and toddler development tests, and infant and toddler screening tests.

**Table 40.4. Selected Formal Tests of Infant and Toddler Development**

### Neonatal Assessment Tests

Several specific procedures exist for assessing infants during the neonatal period (birth to 4 weeks). Previous studies showed the well-known *Apgar Screening Test* ([Apgar, 1953](#)) to be an inconsistent predictor of subsequent infant development ([Francis et al., 1987](#)), and neonatal tests were created to focus more expressly on describing the range of neurobehavioral differences in normal newborns and highlighting areas of newborn competency. By the early 1960s, newborns and young infants were seen as more active participants in their environment ([Bullowa, 1979](#)). Not only were they seen as developing intrinsic perceptual-cognitive competencies, but they were also viewed as possessing an individualized repertoire of behaviors, known as temperament, that elicited different responses from others. Although clinicians assessing infants are not often asked to evaluate neonates, the conceptual point inherent in these instruments—combining an assessment of innate capacities with attention to individual variability and responsivity—is relevant to all assessments of infants and young children.

#### BRAZELTON NEONATAL BEHAVIORAL ASSESSMENT SCALE

Although the predecessor scale to the *Graham/Rosenblith Behavioral Test for Neonates* ([Rosenblith, 1979](#)) was the first neonatal development test, the *Brazelton Neonatal Behavioral Assessment Scale* (NBAS), currently in its second edition (NBAS-2) ([Brazelton, 1984](#)), dominates the field today. The NBAS-2 is intended to assess the neonate's current level of neurobehavioral organization, capacity to respond to the stress of labor and delivery, and adjustment to the *ex utero* environment. It is designed for use with neonates of 37 to 44 weeks' gestational age who do not currently need mechanical supports or oxygen. Although it is recommended that neonates be at least 3 days old before testing, the test has been used on neonates during the first day of life. It takes about 20 to 30 minutes to administer, followed by about 15 minutes to record and score the neonate's performance. Although the NBAS was originally designed for use with full-term healthy newborns, it has been used extensively with premature and otherwise medically fragile newborns.

The NBAS-2 is used to describe the range of behavioral responses to social and nonsocial stimuli, as the neonate moves from sleeping to alert states. Items assess the neonate's neurologic intactness, behavioral organization (e.g., state regulation and autonomic reactivity), and interactivity and responsiveness with both animate and inanimate stimuli on the basis of 27 behavioral items and 20 reflexes. Relative to preceding neonatal development tests, the NBAS-2 places a greater emphasis on assessing the neonate's social competencies, as opposed to assessing only perceptual capacities or behaviors that were presumed to be related to cognitive functioning (Brooks and Weinraub, 1976). The NBAS-2 is begun optimally when the neonate is sleeping and is completed as the neonate is brought to an alert, interactive state. Each behavioral observation is scored along a seven- to nine-point continuum.

The NBAS-2 does not yield a single score, although Als and colleagues proposes an *a priori* four-factor solution ([Als et al., 1977](#)). The four-factor scores describe interactivity, motor behavior, state control, and physiologic response to stress. Lester and fellow researchers ([Lester et al., 1982](#)) summarize the behavioral items into six factors (habituation, orientation, motor, range of state, regulation of state, and autonomic regulation) and use the neurologic reflex behaviors to define a seventh factor. Each of the seven factors can be used to yield a numeric score describing the infant's performance in that area. Higher scores on the six behavioral factors indicate more mature newborn performance, whereas higher scores on the reflex factor indicate a more deviant neurologic examination result. However, methods to derive factor scores are somewhat complicated, requiring recoding items to a continuous scale to derive meaningful summative scores.

With training, interrater reliability for the 27 items has been shown to be adequate ([Lancione et al., 1980](#); [Sameroff, 1978](#)), although a considerable degree of judgment is required of the examiner for assigning a rating to the neonate's responses. Although interrater reliability for the NBAS is quite high, studies of the test-retest reliability of the NBAS suggest poor temporal stability for most items ([Sameroff, 1978](#)). The validity of the NBAS is supported by research that has *in utero* drug and alcohol exposure, maternal malnutrition, and gestational diabetes. Additionally, the NBAS has been used in studies examining the effect of maternal general anesthesia, withdrawal from methadone, and interventions aimed at teaching mothers and fathers about their newborns' capacities ([Sostek, 1978](#)). In fact, the NBAS-2 has been shown to be an effective intervention tool for increasing the maternal involvement and responsiveness of mothers of low socioeconomic status and adolescent mothers ([Worobey and Brazelton, 1990](#)). Furthermore, the NBAS has been shown to predict infant–parent attachment and subsequent infant development. Unfortunately, research has not consistently shown the NBAS to be a good predictor of infant development much beyond the first year of life ([Horowitz and Linn, 1982](#); [Vaughn et al., 1980](#)). Of the dimensions assessed by the Brazelton, state control appears the most stable and predictive ([Als et al., 1979](#)), possibly reflecting the fundamental importance of early state-regulatory capacities for other more complex functions, such as attention and social interactivity, that emerge in the first year.

### Infant and Toddler Development Tests

Of the various models of infant developmental tests, the norm-referenced multidomain model is arguably the most enduring. Based on the work of Gesell and Bayley, development is assessed in multiple distinct yet interrelated domains. The most notable current examples of these tests (described later) are the second edition of the *BSID (BSID-II)*, *Mullen Scales of Early Learning*, *Battelle Developmental Inventory*, and *Griffiths Mental Development Scales*. Additionally, criterion-referenced instruments are also popular among professionals who wish to compare an infant's development with expectations based either on a particular model of development (e.g., Piaget's model of infant cognitive development) or expected program outcomes. Although not typically useful for diagnostic or screening purposes, criterion-referenced tests may be quite useful when planning intervention programs. To accomplish this goal, criterion-referenced tests are designed to sample extensively the universe of skills that a child is expected to have mastered at various ages. The infant's performance on these tests can then be translated directly into an individualized intervention plan by targeting those skills that the infant was expected to have mastered but as of yet has not.

One of the most popular criterion-referenced tests for use with young children is the *Brigance Diagnostic Inventory of Early Development-Revised* ([Brigance, 1991](#)), which is useful for children birth to 7 years old and surveys skills in 12 different developmental domains (e.g., social and emotional, communicative, motor, preacademic skills). Other similar tests specifically for infants include the *Hawaii Early Learning Profile* ([Furuno et al., 1987](#)) and the *Early Learning Accomplishment Profile for Infants* ([Sanford, 1981](#)). The *Rossetti Infant-Toddler Language Scale* ([Rossetti, 1990](#)) is a popular scale that is designed specifically to assess an infant's verbal and nonverbal communication and level of caregiver-infant interaction. One of the most commonly used piagetian model instruments is the *Infant Psychological Developmental Scale* (described later), which assess an infant's ability to grasp object permanence, to understand means-ends and cause-effect relationships, to imitate vocalizations and gestures, and to manipulate objects in space ([Uzgiris and Hunt, 1975](#)).

#### BAYLEY SCALES OF INFANT DEVELOPMENT-II

The *BSID*, currently in its second edition (BSID-II) ([Bayley, 1993](#)), is the most widely used measure of the development of infants and toddlers in both clinical and research settings. The BSID's extensive history of test development and validation makes it the most psychometrically sophisticated infant test on the market. As previously mentioned, the BSID-II is predicated on the early tests developed by Bayley in the 1930s. During the 1960s, these tests were substantially revised and

subjected to a level of psychometric standardization and validation previously only attempted with IQ tests, resulting in the original BSID ( [Bayley, 1969](#)). The current BSID-II, a substantial revision and renaming of the original scale, is applicable to children from 1 through 42 months of age. Administration time is about 25 to 35 minutes for infants less than 15 months old and up to 60 minutes for children older than 15 months.

The three main components of the BSID-II are the Mental Development Index (MDI), the Psychomotor Development Index (PDI), and the Behavior Rating Scale (BRS). The MDI provides information about the child's language development and problem-solving skills, whereas the PDI assesses the child's gross and fine motor development. The BRS is a form that evaluators may use to rate the child's behaviors during the assessment. Items on the BRS assess attentional capacities, social engagement, affect and emotion, and the quality of the child's movement and motor control. The BSID-II provides a method for obtaining age equivalence scores for four facets of development: cognitive, language, social, and motor. Unfortunately, little empirical evidence exists to support the reliability and validity of these facet scores. Moreover, determining the correct facet age-equivalent score is often difficult because several months of development are often determined on the basis of passing only one item. Therefore, considerably more research is needed before clinicians and researchers can have confidence in these facet scores.

The BSID-II is administered in item sets, determined based on the age of the infant. This represents a substantial revision from the original BSID, which, like most tests, used a continuous series of items. This change has created some confusion among examiners of infants in terms of which item set to use for infants born prematurely ( [Ross and Lawson, 1997](#)). Indeed, the choice of which item set to use as a starting point can significantly affect the infant's final score ( [Gauthier et al., 1999](#)). For testers who use the corrected age procedure, the test developers recommend using the same item set that corresponds to the normative group used for determining that child's standard score ( [Matula et al., 1997](#)).

The BSID-II is normed on 1,700 infants (an exceedingly large normative sample by infant assessment standards) representative of 1988 U.S. Bureau of the Census data as stratified by gender, ethnicity, regionality, and parental education. Test-retest reliability for 1 to 16 days ranges from 0.83 to 0.91 for the MDI and from 0.77 to 0.79 for the PDI. Stability for the BRS varies greatly depending on the age of the child, ranging from 0.55 to 0.90. Because the BRS samples behaviors as observed during a given testing session, it may be more subject to state variation than items contributing to either the mental or the motor scales. Interrater reliability for the BSID-II is reported to be 0.96 for the MDI, 0.75 for the PDI, and 0.70 for the total BRS. Across BRS domains, interrater reliability varies, with the lowest agreement being for ratings of attention and arousal in younger children (0.57). Agreement among observers for the behavioral ratings improves for children older than 12 months. These stability coefficients approach adequacy for the MDI, but they fall somewhat short of optimal for a diagnostic test on the PDI and BRS ( [Salvia and Ysseldyke, 1991](#)). Concurrent validity of the MDI, as correlated with other measures of general cognitive ability, typically falls in the 0.70 range, whereas the PDI correlates best with the motor score of the McCarthy test at .59. In general, the BSID appears to have some ability to predict which infants will score very poorly on intelligence tests in their preschool years, but it shows limited ability to predict specific IQ scores accurately, especially in average developing infants ( [Gibbs, 1990](#); [Whately, 1987](#)).

Bayley did not intend that the MDI or PDI scores be interpreted as IQs. Correlations between BSID performance and subsequent IQ assessments are variable. In her 1933 sample of 61 infants, Bayley found no relation between the mental scale administered before 24 months and the Stanford-Binet test administered from 5 to 13 years of age ( [Bayley, 1949](#)). For the 24-month mental age scale with another sample of infants, she reported a correlation of 0.53 with the Stanford-Binet test. Others have investigated the relation between performance on the 1969 version of the BSID and subsequent IQ tests and have found modest correlations between MDI and PDI measures collected through 24 months with 30- to 36-month Stanford-Binet scores ( [McCall, 1979](#); [Ramey et al., 1973](#); [Siegel, 1979](#)). In the 1993 version, more robust correlations were found between the MDI and subscales of both the *Wechsler Preschool and Primary Scale of Intelligence* and the *McCarthy Scales of Children's Abilities* (1972), a finding suggesting that items added to the 1993 version may tap constructs more similar to measures of information processing ( [Bayley, 1993](#)). However, for the most part, performance on the BSID does not consistently predict later cognitive measures, particularly when socioeconomic status and level of functioning are controlled ( [Rubin and Balow, 1979](#)).

#### MULLEN SCALES OF EARLY LEARNING

A relatively recent addition is the *Mullen Scales of Early Learning* ( [Mullen, 1995](#)). This revision of the original Mullen scales combines earlier versions of the test designed for infants and preschoolers into one test with continuous norms from birth through 68 months. The Mullen takes about 15 to 60 minutes to administer, depending on the age of the child (15 minutes at 1 year old, 30 minutes at 3 years, and 60 minutes at 5 years). The Mullen scales assess child development in five separate domains: gross motor, visual reception (primarily visual discrimination and memory), fine motor, receptive language, and expressive language. The gross motor scale is only applicable to children birth through 33 months old and does not contribute to the overall early learning composite score.

Normative data for the Mullen scales is based on a sample of 1,849 children from across the United States, somewhat overrepresentative of children from the Northeast. Internal reliability ranges from 0.75 to 0.83 for Mullen subtests and is 0.91 for the overall developmental score. Median 1- to 2-week test-retest reliability coefficients range from 0.78 to 0.96 across subtests, and interrater reliability coefficients range from 0.94 to 0.98. The Mullen receptive and expressive language scales show acceptable correlation with similar scales from the Preschool Language Assessment Scale, 0.85 and 0.80, respectively. The gross motor scale correlates with the Bayley MDI at 0.76, and the fine motor scale correlates with the Peabody Fine Motor Scale at 0.70. These correlations for the motor scales also are acceptable. Overall, these validation studies are quite promising. Additional studies of the Mullen scales' concurrent and predictive validity, particularly with specific subpopulations, are warranted, however.

#### BATTELLE DEVELOPMENTAL INVENTORY

The *Battelle Developmental Inventory* (BDI) ( [Newborg et al., 1984](#)) is exceedingly popular, especially among professionals working in publicly funded early intervention and special education programs. It is intended to measure development in children ages birth through 7 years old. Five domains are measured by the BDI: personal-social, adaptive, motor, communication, and cognitive. Each of the five domains of the BDI is divided into subdomains that finely assess the components of each domain, and all domains contribute to a total developmental score. The assessment time required by the BDI is quite long compared with other similar tests, ranging from about 1 to 2 hours, depending on the age of the child.

The standardization sample for the BDI consists of 800 children, stratified to match the 1980 U.S. Bureau of the Census data based on geographic region, race, and gender. In a review of the technical merits of the BDI, McLinden raises several concerns (McLinden, 1981). First, although the test authors report exceptionally strong test-retest and interrater reliability for the BDI, a general lack of procedural details in the manual makes it difficult to evaluate these data adequately. Furthermore, no information regarding the BDI's internal reliability is provided. Second, the concurrent validity of the various domains is based on findings from exceptionally small studies, ranging from only 10 to 37 subjects. Furthermore, resulting correlations for the BDI's cognitive domain are much less than optimal (  $r = 0.44$ ;  $n = 13$  for the full-scale IQ from the *Wechsler Intelligence Scale for Children-Revised*;  $r = 0.50$ ;  $n = 23$  for the *Stanford-Binet Intelligence Scale*; [Newborg et al., 1984](#)).

Third, a potentially more detrimental limitation of the BDI exists in its normative data ( [Boyd, 1989](#)). For the first 2 years, normative data are presented in 6-month bands and in 12-month bands thereafter. Therefore, an infant's performance is compared with that of other infants that can be as many as 6 to 12 months older or younger. Obviously, standard scores for infants who are old for their normative group are inflated, whereas standard scores for infants who are young for their normative group underestimate their true development. Because of these normative discontinuities, children could theoretically score solidly in the average range just before their birthday, and a day or so later, with the exact same performance, score in the range suggestive of serious developmental delay or mental retardation. For this reason, age-equivalent scores may be more stable on the BDI than standard scores ( [Boyd, Welge, Sexton, and Miller, 1989](#)). This limitation greatly reduces the diagnostic utility of the BDI and may even lead to grossly distorted results when BDI standard scores are used for longitudinal research or for tracking the development of individual infants. For these reasons, diagnostic use of the BDI for infants and toddlers in general is not recommended, and BDI results administered by others should be interpreted very cautiously.

#### GRIFFITHS MENTAL DEVELOPMENT SCALES

Although the *Griffiths Mental Development Scales* are seldom used in the United States, they warrant a brief description because of their continued use in Europe and their early influence on extending infant developmental testing internationally. The Griffiths scales consists of two tests: *The Abilities of Babies* ( [Griffiths, 1954](#)), designed for infants birth to 24 months old, and *The Abilities of Young Children* ( [Griffiths, 1979](#)), for children 24 months to 8 years old. The infant scale consists of five domains, modeled closely after Gesell's early work: locomotor, personal and social, hearing and speech, eye and hand coordination, and performance. The test is normed on 571 infants from London, but it is oddly stratified to match the 1940 U.S. Bureau of the Census figures. Reliability studies for the Griffiths scales have yielded mixed results, and validity studies have indicated relatively weak predictive ability for later IQ test scores ( [Thomas, 1970](#)). Despite its outdated and questionable standardization, the Griffiths scales apparently remain popular in Europe and in Quebec.

## UZGIRIS-HUNT INFANT PSYCHOLOGICAL DEVELOPMENT SCALES

Piaget presented a view of the child that was quite different from Gesell's and that reflected, at the least, their different theoretical backgrounds ( [Yang, 1979](#)). Gesell, the essential pragmatist, presented development as the steady march forward of increasingly complex behaviors and capacities that were relatively unaffected by environmental contingencies. Piaget, the essential epistemologist, described development as a hierarchical series of qualitatively different stages that cut across observable behaviors and that are closely linked to environmental influence. For Gesell, children unfolded on a maturational timetable. For Piaget, children grew to understand the world and themselves, and development was the process of "knowing" in ever more complex ways. Maturation of motor skills and other capacities was the vehicle that would lead to such knowing, and progress depended on previous achievements in all functional areas. It was not until the 1950s that American psychologists became seriously interested in Piaget's work ( [Baldwin, 1967](#)), and this was long after the infant assessment field was well established in the tradition of Gesell and Bayley. Thus, the assessment techniques based on piagetian theories are even now far less widely used or considered, but these techniques are available and present a useful contrast to the norm-referenced multidomain tools described earlier. Of the two most widely known examples, the *Einstein Scales of Sensorimotor Intelligence* ( [Corman and Escalona, 1969](#)) and the *Uzgiris-Hunt Infant Psychological Development Scales* ( [Uzgiris and Hunt, 1975](#)), the latter is used more often.

The Uzgiris-Hunt scales, based on Piaget's theory of the sensorimotor period of development, consist of six subscales. The first subscale, visual pursuit and permanence of objects, consists of the infants' increasing awareness of objects outside their immediate perceptual field. Behaviors involving searching for a hidden object fall within this subdomain. The second subscale, development of means for achieving desired ends, covers such activities as using a tool to obtain an object. Development of imitation, the third subscale, is divided into vocal and gestural imitation and includes not only repetition of words but also different sounds for distress and pleasure. The fourth subscale, development of operational causality, includes anticipatory behaviors, such as attempting to start a mechanical toy or, in younger infants, watching one's own hand movements. Object relations in space, the fifth subscale, describes the infant's capacity to discriminate dimensionality, to track and locate objects, or to localize perceptual cues. Finally, the sixth subdomain involves the development of schemas for relating to objects (e.g., how the infant's use of toys changes) and how exploratory behaviors with objects become increasingly differentiated and complex. The position of an item in the Uzgiris-Hunt scales is determined *a priori* by the theory, not by the chronologic age at which most children complete the item, as in the Gesell-based test described earlier. There is also an ordinal assumption in the piagetian-based scales; that is, success on an item at one level presumes success at all previous levels because of the hierarchical assumptions in the theory.

The Uzgiris-Hunt scales are administered using a series of situations and materials that elicit children's responses in the various subdomains. The procedures for administering the situations are quite flexible. The six scales are not presented in a specified sequence, nor does the examiner need to cover all the scales. Specific directions for types of items, number of presentations, and types of expected responses are given, but judging success is more flexible because of the more conceptual nature of the tasks. The scales were tested and revised in three samples of infants drawn exclusively from middle-class families. Interrater agreement percentages and test-retest reliability are adequate in the three original samples, ranging from 92% to 97% and 0.70 and 0.85, for the six subscales, respectively. The subscales are also highly intercorrelated ( $r^3$  0.80), and each subscale is highly correlated with chronologic age ( $r^3$  0.88). Although Uzgiris and Hunt present mean ages for the achievement of each scale stage, they emphasize that their samples are not selected to provide normative data for different ages. Subsequently, Dunst estimated norms for age-equivalent scores based on performance in the various subdomains ( [Dunst, 1980](#)). However, these age-equivalent scores tend to average about 2 months lower than Bayley MDI age equivalents ( [Dunst et al., 1986](#); [Sexton et al., 1988](#)). In terms of concurrent and predictive validity, there appears to be little correlation with current Bayley scores but moderate correlation with later Stanford-Binet scores ( [King and Seegmiller, 1973](#); [Wachs, 1975](#)). Wachs followed a sample of infants between 12 and 24 months and correlated their performance with the Stanford-Binet test at 31 months. By 24 months, all scales except *means for obtaining an end* were significantly correlated with performance on the Stanford-Binet IQ test.

### Infant and Toddler Screening Tests

Screening tests are brief assessments of a child's current level of functioning that are used to determine which children may be developmentally at risk and may require further diagnostic assessment. To fulfill their goal, screening tests should yield scores that are predictive of scores from more comprehensive diagnostic assessments (e.g., the BSID), but they require substantially less time to administer and to score. Screening tests are intended to be used routinely when a comprehensive assessment for all children would be either too costly or unwarranted. These instruments usually are not as reliable or valid as comprehensive assessment tools, largely because of their brevity.

The goal of all screening tests is to identify correctly those children who would likely score poorly on a more comprehensive assessment and to reduce two possible sources of error: false-positive results and false-negative results. The ability of a screener to reduce false-negative rates is referred to as the test's *sensitivity*, its ability to detect children with delays or disabilities accurately. Conversely, the ability of a screener to reduce false-positive results is referred to as its *specificity*, its ability to avoid mislabeling a child as delayed or disabled, when, in fact, that child is not. Although it is desirable to reduce the percentage of both types of error, sensitivity may be more important than specificity with screening tests, because it is assumed that follow-up assessment will correct any false-positive results. [Meisels \(1989\)](#) recommends that developmental screeners possess both sensitivity and specificity levels of at least 80%. Unfortunately, too many developmental screeners do not provide these data. Several of the more common screening tests are presented in [Table 40.4](#). All screening tests presented use direct assessment or observation of the child, unless otherwise stated. Most also allow for caregiver report of information, to gain additional data about behaviors that may be difficult to elicit in the brief assessment period. Some, however, are based solely on caregiver report (e.g., the *Developmental Profile-II* and the *Developmental Observation Checklist System*). In addition, two specific screening tests are further described here.

### DENVER DEVELOPMENTAL SCREENING TEST-II

The *Denver Developmental Screening Test-II* ( [Frankenburg et al., 1990](#)) is one of the most popular developmental screening tests, especially in medical settings. The reason, at least in part, may be its brevity, because it can be administered in as little as 15 to 20 minutes. It is applicable for children birth to 6 years. Items are scored based on a combination of caregiver report, direct assessment of the child, and observation. The Denver-II test produces one overall score, placing children in one of four descriptive categories: pass, questionable, abnormal, or untestable. Because the Denver-II test was normed exclusively on children living in Colorado, caution should be used when employing this screener in other localities. The original edition of the Denver test ( [Frankenburg et al., 1975](#)) has been criticized for not being sensitive enough, missing as many as 80% of children with delays or disabilities ( [Greer et al., 1989](#)). Although the Denver-II test is a clear improvement over the original Denver test, there is evidence that it now significantly overidentifies as many as 72% of children ( [Glascoe and Byrne, 1993](#)). As a result, early intervention administrators in both Kentucky and Tennessee reportedly have requested that evaluators use a different screening instrument before referring children for developmental services, to reduce costly false-positive results ( [Johnson et al., 1992](#)).

### EARLY SCREENING PROFILES

The *Early Screening Profiles* ( [Harrison, 1990](#)) is applicable for children 2 through 6 years old. It screens for cognitive, language, speech, physical, and social disabilities or delays that may interfere with a child's learning and may warrant further diagnostic assessment. Children complete three different subtests: cognitive/language (assessing children's visual discrimination, logical reasoning, verbal concepts, basic school readiness skills), motor (assessing both fine and gross motor skills), and speech articulation. Total testing time per child is only 15 to 30 minutes, depending on the child's age. Additionally, the person who administers the test completes a 2- to 3-minute Behavior Survey documenting the child's behaviors during the assessment (e.g., activity level, attention span, cooperativeness, independence). Caregivers, or sometimes teachers, complete three different rating forms: the Self-Help/Social Profile (which provides a rating of the child's adaptive behaviors); the Home Survey (regarding the caregiver's perception of the child's home environment and caregiver-child interaction); and the Health History Survey (which provides information regarding immunizations, health problems, and prenatal health and delivery). Each of these rating forms can be completed in about 5 minutes. The Early Screening Profiles provide a wide variety of scores for all domains and subdomains, including age equivalents, standard scores, percentile ranks, and easy-to-use six-point screening categories. Screener cut points can be set at several different levels to manipulate the ratio of false-positive to false-negative results. The primary drawback of the Early Screening Profiles, however, is that it has no Spanish version. Psychometrically, the Early Screening Profiles are quite sound and comprise one of the very best screening tests on the market.

### CONCLUSION

Infant assessments are in part clinical explorations involving a fair amount of uncertainty and inference. Whereas the medical diagnostic process always involves some element of uncertainty, the assessments made in infancy require of the clinician a particular comfort with uncertainty and the unknown. Although the second half of the 20th century brought a veritable explosion of knowledge about infancy and the neonatal period, the more we learn, the more we understand how inextricably

woven are the forces of development. As emphasized throughout this chapter, infant assessment involves far more than the infant and is as much a measure of the infant's environment as it is of his or her functional status. Thus, clinicians assessing infants are always dealing more with what they cannot know than with what they can, ever exploring the limits of predictive capabilities and constantly mindful of those distinctions ( [Chapter 22](#), [Chapter 34](#), [Chapter 35](#), [Chapter 37](#), and [Chapter 41](#)).

### Appendix A/Child Psychiatry Emergency Consultation Mental Status Examination Checklist

The psychiatric assessment of infants, children, and adolescents is both complex and subtle, requiring multiple sources of information, including the child, parents, teachers, pediatricians, hospital records, and previous evaluations, as well as observations of family interactions. The range of assessment methods includes the clinical interview, standardized structured and semistructured interviews, questionnaires, rating scales ( [Chapter 42](#)), standardized tests, including developmental, psychological, neurologic, educational, and linguistic tests ( [Chapter 40](#), [Chapter 43](#), [Chapter 44](#) and [Chapter 45](#), and [Chapter 51](#)), and biological studies cited in syndromes (Section VI).

## REFERRAL AND GOALS

Before proceeding with a formal psychiatric assessment of the child, it is important to consider the goals and context of the *referral*. The *goals* of the psychiatric assessment are as follows: to determine whether psychopathology is present, and, if it is, to establish a differential diagnosis; and to determine whether treatment is needed, and, if so, to develop treatment plans and recommendations ( [King et al., 1995](#)).

The first task for the evaluating clinician is to understand clearly the implicit and explicit reasons for the *referral*. Concern over difficulties that may reflect a psychiatric disorder is just one of many possible reasons for parental referral; other reasons, sometimes covert, may include marital problems, child custody conflicts, problems in school, and pending juvenile court decisions. Indeed, the impetus for the referral may frequently lie outside the family, as when the school or court are the source of the referral. When the referral source is external to the family, it is important to know the parents' attitude toward the referral, as well as obtaining the parent's (or legal custodian's) permission for the evaluation.

The parents' concerns often need to be clarified to be understood: Why are the parents coming at this particular time with these apparent referral questions? What help is truly being sought? Parents may be seeking (or fearing) a diagnosis, treatment recommendations, relief and respite, safety for the child or themselves, or answers to questions for which the presenting complaint is but a "ticket of admission" for some other concern that troubles them, such as a marital problem.

A universal set of questions for the clinician defines the basic goals of every evaluation: What are the nature and extent of the child's behavioral difficulties and what degree of functional impairment and distress do these cause? What are the potential individual, family, or environmental factors that may be causing these difficulties or potentially influence them for good or for ill? Does the child indeed have a psychiatric disorder, and, if so, what are the causes of that disorder and what treatment is needed? Sometimes the child's symptoms reflect more a problem of "fit" between parent and child or between the school and child, rather than a psychiatric disorder. At other times, the presenting problem may represent the child's reaction to an environment that is stressful and adverse for that particular child.

Certain evaluation questions, such as custody disputes, require special arrangements and are discussed elsewhere ( [Chapter 115](#)). At all times, a good diagnostic assessment should also be a therapeutic occasion. The child's and family's experience of the diagnostic interviews will, at the very least, influence how the diagnosis and recommendations are heard, understood, and regarded. More than that, the diagnostic interviews may sometimes provide an opportunity to offer a therapeutic intervention.

In short, the basic aims of the psychiatric assessment of a child are as follows:

To elucidate the sources, reasons, and causes that culminate in the referral

To assess the child's overall developmental status, including neurodevelopmental strengths and weaknesses

To characterize any difficulties in thinking, behavior, and emotions

To identify stresses or pathogenic factors in the child, the family, and the environment that may cause or exacerbate these difficulties

To establish a differential diagnosis (according to the *Diagnostic and Statistical Manual of Mental Disorders* or the *International Classification of Diseases*) and arrive at a multiaxial diagnosis

To develop and present a treatment plan

The methods employed in the psychiatric assessment of the child include the following:

Taking a comprehensive history from the parents (or caretaker), including a review of all past relevant evaluations, treatments, and outcomes

Interviewing the child to obtain the history from the child's perspective

Performing a mental status examination of the child

Recommending and reviewing any further indicated diagnostic tests and screening measures

Urgent, highly focused evaluations may be requested for emergencies, especially those involving possible dangerousness to self or others, that require immediate decisions regarding treatment, including the need for hospitalization or medication. Other specialized evaluations concern specific medication consultations, custody evaluations, or other court-ordered evaluations that pose specific questions. Although these evaluations may need to be abbreviated (e.g., in the emergency room situation) or specifically focused, they are informed by the same general principles regarding the need to collect data from multiple informants regarding the child's functioning in multiple adaptive contexts over time.

## Consent

*Parental consent* is required when the referral comes from another source. In an emergency in which the parents are not available, the consultation should go forward while the parents are being sought. Specific statutes that vary by state permit minor adolescents to seek mental health help without parental consent under specific circumstances. However, parental involvement is always preferable. Ethical issues are involved in transmitting information to others. A useful account of the foregoing outline can be found in the American Academy of Child and Adolescent Psychiatry's "Practice Parameters for the Psychiatric Assessment of Children and Adolescents" ([King et al., 1995](#)).

## HISTORY TAKING

The clinician should consider all the foregoing items and questions before proceeding with the first part of the psychiatric assessment of the child, namely, taking the history. At the same time, many of these questions may only emerge or become more sharply focused in the course of taking the history and performing the whole evaluation.

A prerequisite of an informed *history taking* is a knowledge of normal development and its variations and of common psychological reactions to various developmental stresses. A knowledge of psychiatric disorders is, of course, essential. In short, the history and evaluation should help one to understand in detail how this particular child has arrived at this point in his or her life.

The history is the beginning of an exploration, not only of the child's symptoms, behavior, thought processes, feelings, and environment in its largest sense (e.g., family, school, community, culture), but also of the child's total inner life of fantasies, wishes, fears, hopes, and anxieties, as well as the child's strengths and supports.

## PARENT INTERVIEW AND HISTORY TAKING

Parents are most often interviewed first, especially in the case of young children. Adolescents may be given the choice of being seen first or of being present during the initial interview with the parents. Each parent should also be interviewed individually. Seeing the whole family, or at least the patient and parents, together at some point in the assessment is often a useful diagnostic approach, because it permits observing family interactions first hand.

Historical and factual data, such as age, sex, race, legal status, birth history, developmental milestones, and previous illnesses, generally are best gathered by asking specific questions ([Cox et al., 1981](#)), whereas data about feelings and relationships are best elicited by an open, indirect approach. Parents, in any case, frequently recall historical dates incorrectly, although they may offer comparisons; for example, "Johnny was much slower in learning to talk than Jane." To offset these shortcomings, data should be gathered from as many objective sources as possible, including hospital records; school reports; previous tests; and multiple observers (child, mother, father).

A comprehensive and detailed pediatric psychiatric history should include a careful description of the problem as seen by the parents, including why help is being sought now and what previous attempts at obtaining help have been made. The clinician will want to be attentive to what sort of help is being sought by the parent and what explicit or implicit ideas the parents have about the nature of the child's problems.

Having explored the presenting problems, the clinician will also want to obtain the personal and developmental history of the child, including the following: the history of previous illnesses and accidents; the social history; the family history; the school history; the history of such biological functions as appetite, sleep, bladder and bowel control, and menstruation; a description of the child's relationship within the nuclear and extended family and with peers; a description of significant events, such as separations, losses, illnesses, accidents, abuse, and deaths; and an account of the previous and present medical and psychiatric status of the parents, their marriage, and the nuclear and extended family ([King, 1998](#); [King et al., 1995, 2000](#)). Parenting skills, style, and parental expectations of the child are also noted. Inquiry should also be made about the child's temperament, with attention paid to the apparent *goodness of fit* between the child's and parents' temperaments ([Chapter 14](#) and [Chapter 15](#)).

Each question should have a purpose and should be asked with tact. The clinician listens intently to the reply, not only for its content but also for its tone and affect.

The larger context of the child and family should also be considered in terms of school, community, and culture. Finally, various administrative aspects of the evaluation process may be clarified. Thus, fees, confidentiality, releases for information requests, and an outline or overview of what is entailed in an evaluation should be discussed with the parents. There should also be some discussion of what the parents will tell the child to prepare the child for the forthcoming evaluation.

## CHILD INTERVIEW: HISTORY TAKING AND MENTAL STATUS EXAMINATION

History taking and the mental status examination of the child are best performed in the context of the clinical interviews of the child. A major advantage of clinical interviewing techniques with children is that their flexibility offers the clinician the opportunity to explore clinical clues in detail. Disadvantages of clinical interviews are as follows: (a) they may not be sufficiently comprehensive by themselves to establish some diagnoses (e.g., learning disabilities, specific genetically determined forms of mental retardation, certain forms of seizure disorder); (b) the data may not be systematically acquired and hence not valid for comparisons across cases; and (c) because of differences about what realms are assessed and criteria employed, there may be poor interrater diagnostic agreement among clinicians. In addition, the acquisition of the necessary clinical skills requires considerable training.

### General Considerations and Techniques

The clinical interview of the child provides an opportunity to explore the child's own views of the presenting problem and to assess the child's mental status ([King et al., 1995](#)). The child may be a unique source of information only he or she is aware of, such as suicidal or obsessional thoughts, hallucinations, or secrets concerning abuse or antisocial activities. The history taking with the child covers many of the same elements as the developmental history taken from the parents, only with the emphasis on the child's perspective on this history. Although the child is likely to be a less reliable reporter than the parents regarding chronology, family history, and early development, the child is more likely than parents to report anxious or depressive thoughts or suicidal ideation. Although children are more prone than parents to report on their internalizing symptoms, children are less likely to report their disruptive or externalizing behaviors, such as impulsiveness, oppositionality, or aggression.

Although history taking and the mental status examination are two distinct aims of the child interview, in actual practice they are usually not separate processes, but they unfold simultaneously in the interview. Thus, while the clinician is inquiring into the various areas of the child's past and present life and functioning (e.g., how the child gets along with friends), the clinician is concurrently gathering data for the mental status examination (e.g., how warily or trustingly the child relates to the interviewer, how well the child conceptualizes or describes his or her behavior, how much the child tends to blame himself or herself or others for any difficulties). The interview techniques employed in a given child interview depend on the child's developmental, cognitive, and linguistic level.

### DIRECT QUESTIONING

Direct discussion of the presenting problem and other aspects of the child's life requires tact and attention to the child's cognitive and language level ([Lewis, 1974a](#)). It is important to use terms comprehensible to the child and to avoid overly abstract or overly concrete questions that may either lose the child or yield unproductive responses. Tact is required in probing sad or vulnerable feelings with which children may be uncomfortable or perceived transgressions about which the child may be defensive.

### PLAY, PROJECTIVE, AND INDIRECT TECHNIQUES

Young children in particular may be reluctant or unable to reflect and report in detail about their private concerns and feelings. To surmount these limitations, various play and projective techniques can be useful in eliciting these concerns. Although some researchers eschew these methods as insufficiently reliable or validated, many clinicians find them a valuable avenue of exploration as well as a useful means of facilitating the interview process by helping to place the child at ease and introducing an element of fun ([King et al., 1995](#)). Some of these specific techniques are described later. In general, however, it is useful to inquire about what books,

movies, or television shows the child recalls because this provides useful information about his or her interests, preoccupations, and degree of parental supervision. Inquiring about what the child would like to be when grown up provides data about areas of self-esteem and competency, aspirations, and values.

### GENERAL DEVELOPMENTAL CONSIDERATIONS

The child's age and developmental level have important implications for the technique and conduct of the child interview. Young children in particular may be more labile in their behavior and more prone to regress to more immature modes of behavior and relating when they are tired, anxious, or in unfamiliar surroundings. As a result, more than one interview is often desirable because a single interview may not provide an accurate picture of the child's typical or optimal level of function. It is important for the interviewer to be aware of this vulnerability to regression, in order not to be misled by an initial impression and thereby prematurely narrowing the scope of inquiry or the range of the differential diagnosis to be considered.

### Infants and Preschool Children

Clinical interviews with infants and preschoolers require special techniques in a suitably equipped room ( [Chapter 40](#)). A simple screening technique for preschool children is shown in [Table 41.1](#). The parents of infants and preschoolers should be present during the assessment to place the child at ease and hence render the child most likely to function at his or her best (unimpaired by separation or stranger anxiety). Their presence permits them to share in the observations and to learn, and it also allows the examiner to observe parent-child interactions.

Age	Observation Checklist Items	Areas to Assess
2 yr	<ul style="list-style-type: none"> <li>Walks well</li> <li>Stands up (with down stairs—one step) off of knee</li> <li>Stacks blocks</li> <li>Imitates on cardboard</li> <li>Pushes three wheels together</li> <li>Removes grocery card</li> <li>Draws in circles</li> <li>Labels to children with pictures</li> </ul>	<ul style="list-style-type: none"> <li>Stable footing of the child</li> <li>Creative activity</li> <li>Imaginative play with parent</li> <li>Self-expression</li> </ul>
3 yr	<ul style="list-style-type: none"> <li>Went up stairs</li> <li>Walks up stairs</li> <li>Labels to self "penicillin," "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> </ul>	<ul style="list-style-type: none"> <li>Stable footing of child</li> <li>Copies horizontal and vertical shapes (dot in center)</li> </ul>
4 yr	<ul style="list-style-type: none"> <li>Labels to self "penicillin," "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> </ul>	<ul style="list-style-type: none"> <li>Stable footing of child</li> <li>Imagines construction of bridge with three cubes</li> </ul>
5 yr	<ul style="list-style-type: none"> <li>Labels to self "penicillin," "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> <li>Labels and "penicillin" "1"</li> </ul>	<ul style="list-style-type: none"> <li>Stable footing of child</li> <li>Imagines construction of bridge with three cubes</li> <li>Imagines construction of bridge with three cubes</li> <li>Imagines construction of bridge with three cubes</li> <li>Imagines construction of bridge with three cubes</li> <li>Imagines construction of bridge with three cubes</li> <li>Imagines construction of bridge with three cubes</li> </ul>

**Table 41.1. Checklist for Assessment by Observation of Developmental Level of Preschool-Age Child**

An evaluation of the parents' child-rearing skills is particularly important in the psychiatric assessment of the infant. General characteristics to be assessed include the parents' self-esteem, competence, flexibility, and ability to provide a safe, nurturing, and appropriately stimulating environment. Specific characteristics to be assessed include the following: the sensitivity and accuracy of the parents' perceptions of the infant's needs; the goodness of fit between parent and child; the parents' ability to respond rapidly and appropriately on a contingent basis to the infant's expressed needs; the quality of play between parent and infant; and the amount of affection, support, encouragement, and assistance (scaffolding) the parent can provide for the child. The parents should also be able to buffer and titrate the level of stimulation appropriately to foster development on one hand, while preventing the child from being overwhelmed on the other.

Infants less than 18 months old should also subsequently be observed in spontaneous, free play, using such games as peek-a-boo and patty cake. Children between the ages of 18 months and 3 years can participate more fully in regular unstructured play interviews. The play items should look reasonably realistic because children at this age have a limited capacity for abstraction and symbolic play.

A more systematic and detailed assessment requires the use of such scales as the Gesell Infant Scale, the Bayley Infant Scales of Development, the Uzgiris-Hunt Scales, and the Denver Developmental Screening Test ( [Table 41.2](#)) ( [Chapter 40](#)).

**Table 41.2. Selected Developmental and Psychological Tests**

### School—Age Children

Clinical interviews with school-age children similarly require sufficient time (a minimum of 45 to 60 minutes for each interview) and suitable space and the availability of such play items as a ball, crayons and paper, a dollhouse, rubber dolls, puppets, toy guns, a toy doctor's bag, and toy telephones. Elaborate, highly structured games, such as chess or Monopoly, are too likely to interfere with the evaluation by preoccupying the child's attention and cognitive efforts and too readily lend themselves to defensive purposes.

Play and play materials serve several functions. They help to place the child at ease. They provide a context in which to observe many facets of the child mental status, ranging from attitude to the examiner, motor control, thought content, and affective regulation (see the later discussion of mental status). Most important, these unstructured play sessions allow the clinician to make inferences about the child's psychic life, including the child's wishes and preoccupations, fears, impulses, conflicts, defenses, affects, and relationships.

Having previously discussed with the parents how to prepare the child for the interview, the interviewer greets the child from a reasonable physical distance in the waiting room and takes care not to loom too intrusively or intimidatingly. The interviewer should introduce himself or herself to the child and should invite the child to come into the office while reassuring the child that his or her parent or parents will be in the waiting room on return. Once inside the office, the interviewer should ask for the child's preferred name and should make sure the child knows the interviewer's name. The interviewer should not sit behind a desk. He or she should clarify what is the child's understanding of why the child has come, and then the interviewer should give his or her own understanding. Next, the interviewer should tell the child what will take place: "This is a time set aside to see whether I can help you understand what may be bothering you. We will have 45 minutes together, at the end of which you will return to your parents." The interviewer should also clarify the extent of the confidentiality: "I will be meeting with your parents, but I will first discuss with you what I will or will not say to your parents." In some circumstances, such as a court-ordered evaluation, there is no confidentiality, and a report must be rendered to the court. The interviewer should inform the child of this fact.

It is probably best not to take notes during the interview. Note taking may inhibit the child, and it inhibits the interviewer's ability to observe. The interviewer should avoid leading questions or any kind of demanding interrogation because that, too, is unproductive and may inhibit the play and communication. Open-ended

questions (e.g., "What happened then?") are better than leading questions and questions that require only a single-word answer.

In addition to inquiring about the areas of difficulty or worry that have brought the child to clinical attention, it is also helpful to inquire about what the child does for fun and about activities he or she is good at doing. In addition to the clinician's genuine interest in these areas of strength and potential sources of self-esteem, this topic helps to place the child at ease and conveys the sense that the assessment will not be an interrogation focused on what the child may find most embarrassing, anxiety provoking, or humiliating.

In interviewing a child, the clinician can also sometimes offer an interpretation of an obvious preconscious feeling or fantasy. It is often eye-opening, clarifying, and interesting for the child or adolescent, and it sets a model for any subsequent psychotherapy that may be recommended. For example, the child's attention can be directed to the content of his or her actions or verbalizations. Sometimes attention can be drawn to a coincidence that the child has perceived but has not, or professes not to have, registered; more frequently, one can draw attention to certain paradoxes. Thus, in the course of the child's play, the therapist may provide a verbal counterpart to the action being portrayed, an affect that may be present, or the conspicuous absence of certain persons, actions, or affects. (For an example of such an "attention" interpretation, see [Chapter 79](#).)

This kind of interpretation during a diagnostic interview is different from the direct translation of a possible unconscious symbolic representation in the play that may occur in the course of psychodynamic psychotherapy. The play characteristic to which attention is drawn here is in bold relief, capable of being fully recognized and understood by the child.

## Adolescents

Clinical interviews with adolescents require a direct and explicit approach. The clinician can explain to the adolescent that his or her parents came to see the clinician and spoke of their concerns but that the clinician would like to learn directly from the adolescent his or her views on what the parents have said or on what bothers him or her. The clinician should show a genuine interest in the adolescent's view of the matters that have led to the evaluation and should not try to be deceptive, overly ingratiating, or phony. The clinician should not try too hard to appear "with it" or "cool." It is often more productive to employ what Hilde Bruch termed "the constructive use of ignorance" ([King and Schowalter, 1997](#)). If an adolescent enthuses about (or denounces) some activity, group, program, or style with which the clinician is unfamiliar, rather than feigning knowledge of it, one can ask "I don't know much about that; who (or what) is that and what it is that you like so much (or can't stand) about them (or it)." This approach serves several functions. It permits the adolescent to be the expert, educating the grown up, and it also conveys the notion that antipathies or enthusiasms can be thought about and discussed, rather than simply being givens to be taken for granted. In general, it is important for the clinician to be aware of and in control of his or her own predilections to identify with parental authority or adolescent oppositionality.

If the adolescent talks in terms of a third person ("I have a friend who . . ." or "Can a person catch herpes from kissing . . ." or "I read that . . ."), the clinician should answer matter of factly, in the same third-person way. The adolescent is not fooling the clinician, and the clinician is not fooling the adolescent; the adolescent is being allowed room to move and then will not feel so much on the spot.

Rejection, even outright hostility, toward the clinician on the first few visits with an adolescent is not uncommon. The clinician should be patient and should not jump to conclusions. This attitude may turn out to be a test of how much the clinician can be trusted, a defense against anxiety, or a transference phenomenon. The clinician should recognize the adolescent's anger by saying something such as, "I can see you're pretty angry at being here, but you know, I don't know much about how you see things. What are you particularly angry about? Perhaps there is some way I can be of help to you."

Silences should not be allowed to continue for too long, because this risks a useless power game to see who can hold out longer. Similarly, it is important not to be rigid about the length of the interview. The 50-minute session is not a sacred rule; the clinician should feel free to vary the time according to the situation at hand. In some instances, an adolescent may feel more comfortable initially if he or she is invited to go for a walk with the clinician rather than asked to sit face to face in a confined space.

The clinician must be particularly clear with the adolescent about the extent of confidentiality. When appropriate, the adolescent should be informed that a report will be made to a third party, such as a judge. A sense of trust is infinitely preferable to a feeling of betrayal, even at the expense of some tidbit of knowledge.

In general, it is better not to give advice; however, the clinician should not rigidly deny any opinion or advice. An occasional well-judged opinion (if asked) on, for example, the color of a lipstick, or some well-chosen advice may help an adolescent to feel understood and supported.

Eventually, the clinician must inquire about such sensitive areas as suicidal thoughts, hallucinations, drug use, and sexual relationships. This should be done in a matter-of-fact, straightforward manner (see later).

## Countertransference and Other Issues for the Interviewer

During clinical interviews with children and adolescents, the clinician must be aware of important countertransference, as well as transference, phenomena that may occur. For example, children who are aggressive often tend to mobilize strong defenses, such as critical, punitive, or retaliative feelings in the clinician, mentally retarded children are often overlooked or inadequately served, and deformed children may initially repel some clinicians. Other signs of countertransference include the following:

1. The clinician may fail to recognize the developmental level of the child or adolescent. Expectations will then not be commensurate with the child's or adolescent's maturational and developmental capacities.
2. The regressive pull experienced by the clinician interviewing the child or adolescent may give rise to the temptation to identify or act out with the child or adolescent.
3. In too readily regarding the patient's reactions toward the clinician as realistically determined, the clinician may misread transference reactions stemming from the child's or adolescent's feelings toward aspects of the relationship with his or her parents, past or present. Clinicians are usually well aware of a child's or adolescent's aggressive feelings but may be less consciously aware of a youngster's seductiveness toward an adult (parent).
4. Certain specific behaviors in the child or adolescent may stir up old conflicts within the clinician, together with attendant anxieties and defenses. For example, delinquent behavior or disguised masturbation may be upsetting to the clinician resulting in feelings of anxiety, irritation, disapproval, or punitiveness.
5. Sometimes clinicians transfer early feelings from their own childhood onto the parents of the child or adolescent. As a result, clinicians may then overidentify with either the child or the parents in the course of their conflicts. Similarly, residual feelings from the clinician's own childhood relations with brothers and sisters may be an important source of ambivalence toward the child or adolescent.
6. Sometimes the clinician simply cannot understand the meaning of certain behaviors in a child or adolescent. Anyone can occasionally find some item of behavior inexplicable. However, the persistent drawing of a blank in understanding a repeated item of behavior should lead to the suspicion of an interference by one's own conflicts—an emotional blind spot, so to speak.
7. A clinician may feel depressed or uneasy when working with a certain child or adolescent. Assuming that the clinician is not suffering from true depression, the possibility exists that emotions from old conflicts have been aroused and are interfering with the clinician's functioning. A clinician may occasionally become aroused and experience great affection or rescue fantasies toward a child or adolescent, and this also may interfere with the assessment or treatment.
8. A clinician may be unwittingly tempted to encourage acting out in children or adolescents. For example, a clinician may suggest to them that they must stand up for themselves and hit back. This inclination and the suggestion should be carefully examined.
9. A clinician may feel the need for approval from the child or adolescent. Such a desire often represents a need of the clinician and may not be in the best interests of the child or adolescent.
10. Conversely, repeated arguing with a child or adolescent may suggest that the clinician has not only become involved but has become embroiled with the child or adolescent in such a way as to replicate aspects of the child's conflicts at home or at school, with the clinician drawn into a critical or adversarial stance.
11. Recurring countertransference problems commonly arise in relation to specific characteristics of a child or adolescent. For example, a retarded child or adolescent may evoke guilt and defenses against such guilt in the clinician, or the clinician may act out omnipotent rescue fantasies. Passive, hostile children or adolescents may arouse anger or punitiveness in a clinician. Aggressive children and adolescents of either sex may threaten the clinician and may lead either to vicarious and excessive exploitation of sexual issues or to denial and avoidance.

## Mental Status Examination

How and what the child plays, says, and does constitute the raw data for the mental status examination. To bring some order to the understanding of what may seem like random play, it is useful to have an outline of points one particularly wants to observe and why. When completed, such an outline constitutes the report of the child's mental status.

Another useful organizing principle is to keep in mind the major categories of psychopathology one wants to be sure to cover. A list of such categories is shown in [Table 41.3](#).

---

Developmental delay
Organic brain dysfunction
Thought disorder
Anxiety
Mood disorder
Temperament and personality (character) problems
Somatiform disorders
Effects of general medical conditions
Mental retardation
Reaction to unfavorable environment

---

Adapted from Lewis M: Psychiatric examination of the infant, child, and adolescent. In: Kaplan HI, Sadock BJ (eds). Comprehensive Textbook of Psychiatry. Baltimore, Williams & Wilkins, 1989, with permission.

**Table 41.3. Categories of Psychopathology**

Some of the data emerge spontaneously, some only after questioning. The categories in the mental status examination outline that follows are for convenience only; the behaviors described here usually do not occur in any special sequence and are not isolated items. The child or adolescent acts as a whole and in the context of a given environment, and his or her present behavior is always continuous with past behavior. It is not necessary to elicit the information required in the precise order presented here, and all these categories need not be covered in equal detail or in one sitting. The presenting symptom and history may indicate important areas for close attention. The clinician uses his or her clinical judgment to determine what to look for and how fast and in what detail to proceed. The clinician should also consider the age and developmental level of the infant, child, or adolescent when assessing a given response. An outline of the mental status examination is shown in [Table 41.4](#). A useful questionnaire that can be used as a checklist in the emergency room is shown in Appendix A.

---

1. Physical appearance

**Table 41.4. Mental Status Examination Outline**

#### PHYSICAL APPEARANCE

1. Small stature is often associated with a more immature self-image; the self-esteem of the child who is short may suffer because of his or her size. The cause of shortness is important to determine, and referral for a pediatric endocrine evaluation may be appropriate. Precocious or delayed pubertal development may also have important psychological consequences ([Chapter 24](#)) and should be noted.
2. Head size may indicate microcephaly and mental retardation or hydrocephaly.
3. Physical stigmata, such as unusual facies or other minor physical anomalies, may indicate the presence of a chromosomal disorder (e.g., Down's syndrome, Turner's syndrome, fragile X syndrome, velocardiofacial syndrome) or prenatal toxicity (e.g., fetal alcohol syndrome).
4. Bruising may indicate child abuse.
5. Nutritional state may indicate an eating disorder, ranging from anorexia nervosa to obesity.
6. A level of anxiety may be manifested in the interview by restlessness, hyperalertness, tics, nail biting, or hair pulling. The child's activity may have a driven quality, with an inability to sit still, restless moving from one thing to another, easy distractibility, short attention span, low frustration tolerance, and labile emotions. Differentiating among a primary attention deficit hyperactivity disorder (ADHD), hypomania, and anxiety disorder may prove a challenge to the clinician.
7. Momentary lapses of attention (staring, head nodding, eye blinking) may indicate epilepsy or hallucinatory phenomena. The clinician subsequently inquires about such seizure-associated phenomena as auras (nausea, vomiting, epigastric sensations), micropsia or macropsia ("Do things seem to get smaller or bigger as you look at them?"), and hallucinations.
8. Dress gives some idea of the care the child receives and how much the child cares for himself or herself. In adolescence especially, choice of clothing is an important indicator of ideology and ethnic and group affiliations and identifications (e.g., prep versus grunge or goth). Sexual orientation and conflicts may also be expressed in attitudes, behavior, and dress.
9. Motor mannerisms or stereotypies may provide a clue to a disorder. For example, repetitive flapping or twirling may accompany various forms of pervasive developmental disorder or social relatedness ([Rapin, 2000](#)). Motor or vocal tics may be a transient sign of anxiety or a feature of a chronic tic disorder, such as Tourette's syndrome. Rocking, thumb sucking, or repetitive play may be signs of regressive attempts at self-soothing.

#### EASE OF SEPARATION

Some caution on the part of the child in separating from the parents to go with the clinician is usually appropriate. Too much ease in separating from the parents may indicate superficial relationships associated with frequent separations and maternal deprivation. Difficulty in separating may indicate separation anxiety or an ambivalent parent-child relationship.

#### MANNER OF RELATING

Once in the examining room, the child usually relates to the clinician cautiously at first. However, some children (e.g., deprived or abused children) are indiscriminately friendly and shallow. Children with autism may appear aloof or to look through people.

#### ORIENTATION TO TIME, PLACE, AND PERSON

Orientation may be impaired by organic brain factors, low intelligence, anxiety, or a thought disorder.

#### CENTRAL NERVOUS SYSTEM FUNCTIONING

During the interview of the child, it is often possible to include in a playful fashion many elements of a developmentally oriented neurologic examination to assess a child's neuromaturation status. Such an examination tests functions such as laterality, rapid alternative movements (diadochokinesis), rapid finger tapping, cerebellar functioning (e.g., finger-to-nose test), gait (e.g., heel-to-toe walking), and balance (e.g., Romberg test, hopping on one foot) and looks for the presence of findings such as motor overflow phenomena, motor drift, or choreiform movements. Various standardized formats exist for administering and scoring this examination (Denckla, 1985; Rutter et al., 1970). Abnormalities may include either mild focal or localizing signs (e.g., asymmetry) or signs of developmental immaturity. However, the diagnostic implications of such "soft signs" are unclear (Chapter 44). In some studies they appear to be nonspecific, perhaps correlating with intelligence quotient (IQ) or even with vulnerability to later anxiety disorder, whereas other studies suggest that, when these signs present, they may reflect vulnerabilities in cerebral organization that may predispose the child to learning difficulties.

#### Gross Motor Coordination and Abnormal Movements

The clinician should note the presence of any awkwardness, clumsiness, tremors, motor overflow with extraneous movements, motor tics, and any abnormalities of posture, gait, and balance. These can be observed informally in the course of unstructured activities (e.g., pencil grip in writing, skill in climbing stairs, ball throwing, and catching) or explicitly examined. For example, the presence of any choreiform movements can be elicited by asking the child to stand with his or her arms extended and hands outstretched with the fingers spread.

#### Fine Motor Coordination (Perceptuomotor Capacities)

The child is asked to copy the designs seen in Fig. 41.1 or the more demanding figures of the Bender-Gestalt Test (Bender, 1938) (Fig. 41.2). Formal testing is indicated if the child has difficulty copying the designs at an age appropriate level (Fig. 41.3). The difficulties may include trouble with angulation and juxtaposition, a tendency to verticalize a diagonal, and substitution of loops for dots. Further discussion and illustration of the Bender-Gestalt Test are given in Chapter 43.

Figure 41.1. Simple designs by age.

2 yrs										

Figure 41.3. Norms for the Visual Motor Gestalt Test. (From Bender L: *A Visual Motor Gestalt Test and Its Clinical Use*. New York, American Orthopsychiatric Association, 1938.)

#### Laterality

Laterality, preference, and dominance are not identical. *Laterality* is a measurable, specialized, central function of a paired faculty, such as eyes, ears, hands, and feet. *Preference* is the subjective, self-reported experience of an individual, as opposed to laterality, which may be objectively measured. *Dominance* is the term used for the concept of cerebral hemisphere specialization, such as in language and speech. Clinically, one may merely be testing preference, which, in turn, may depend more on the peripheral organ than on any central mechanism.

Handedness is usually consolidated by age 5 years, footedness by about age 7 years, eye lateralization by about age 7 or 8, and ear lateralization by about age 9 (Towne, 1980). Clinically, these may be tested by observing which hand the child writes with, what foot he or she kicks a ball with, and which eye is preferred when the child is asked to look through a rolled-up piece of paper (as through a telescope) or to look at the examiner through a small hole in a sheet of paper.

#### Right-Left Discrimination

The child should be asked to put the right hand to the left ear, the left hand to the right knee, and so forth. At the age of 5 years, children can identify right and left hands (i.e., if they have been taught). At age 6, the child has ipsilateral double orientation (i.e., left hand on left ear), and at age 7, contralateral orientation is achieved (i.e., left hand on right ear) (Silver and Hagan, 1982).

### Short Attention Span

Easy distractability and short attention span during the interview may have a variety of causes in addition to or instead of attention deficit disorder. These include fatigue, anxiety, language problems, or a level of discourse between the parents and clinician that is too abstract for the child to follow. Frequent petit mal or other seizure disorder or sedation from medication may also interfere with a child's attentional focus. In addition, some children with pervasive developmental disorders or disorders of social communication may not be sufficiently entrained by social discourse and, hence, may be inattentive to the clinician's attempts at communication.

### Hyperactivity

Although the possibility of ADHD is a common impetus for referral, hyperactivity may not always be observed in the clinician's office, especially in the one-to-one setting of the child interview. Even children with ADHD may be able to remain focused in a structured one-to-one setting. Hence, reports from multiple settings, including parents and as many different classroom settings as possible, are needed to confirm or rule out this diagnosis. As noted earlier, various other conditions can also cause hyperactivity and disorganized activity in the interview, including anxiety, intense oppositionality, psychosis, and hypomania.

### Sensory Difficulties

**Visual and Oculomotor Difficulties.** These include strabismus, nystagmus, convergence difficulties, and problems in visual acuity.

**Hearing Difficulties.** Hearing should be assessed clinically in the interview, especially if there are difficulties with speech or aural comprehension or a history of recurrent otitis media. In such cases, formal audiometric testing should also be obtained if not already done.

### Reading, Writing, Language, and Speech Difficulties

A prerequisite for assessing the possible causes of a child's academic difficulties is a careful educational history, including the child's previous educational placements and any special educational resources or curricular modifications attempted. For children from bilingual backgrounds, it is also important to know the principal language in which instruction has taken place and the child's and parents' level of fluency in that language.

Formal assessments of reading, writing, and language skills are usually indicated if academic difficulty is one of the chief complaints ( [Chapter 50](#)). Although ADHD or disruptive behavior can interfere with the academic progress and classroom comportment of children with otherwise intact cognitive skills, it is also the case that undiagnosed learning disabilities can be the cause of restless and maladaptive classroom behavior.

Although no substitute for formal psychoeducational assessment, it is often useful to ask the child to read a passage or to write a few sentences during the evaluation. It is also useful to inquire what sort of reading the child does for fun. In addition to providing some insight into the child's reading and concentration abilities, the choice of books also provides information about the child's interests and fantasy life.

Asked to read or produce some sample writing, the child may struggle to read or write and may exhibit poor spelling or handwriting. Typical reading difficulties include reversals and inversions (e.g., d-b, q-p; was-saw, felt-left), confusions (e.g., f-l, m-n; of-off, me-we), omissions (e.g., afraid for afraid, place for palace), and substitutions (e.g., a for the, house for home). At the same time, many normal first-grade (6-year-old) children show reversals. These reversals usually disappear as reading skill matures. The brief screening test shown in [Table 41.5](#) can be used to approximate the child's reading ability ( [Kanner and Eisenberg, 1957](#)).

First grade	40 seconds; 4 errors A little boy had a cat; she ran away; she said, "I want some milk."
Second grade	25 seconds; 2 errors A man took me to see his large barn. There was a horse in the yard; its tail was black.
Third grade	30 seconds; 2 errors One of our favorite birds is the robin. He is a very useful bird. He eats many insects and worms. The robin is less afraid of people than most birds.

Reproduced by permission of Kanner L, Eisenberg L. Childhood problems in relation to the family. *Pediatrics* 20: 155, 1957, with permission.

**Table 41.5. Screening Tests of Reading Ability**

Children with reading difficulties often come from large families and neighborhoods with poor schools and may have symptoms of ADHD or of conduct disorder. Because reading level in general correlates highly with IQ, the most common cause of general reading backwardness, that is, below-average reading level despite adequate educational opportunities, is below-average IQ. Children with *specific* reading retardation (sometimes called dyslexia or developmental reading disorder and often part of a multifaceted, complex learning disability) have reading levels lower than expected from their overall IQ. The causes of dyslexia are still poorly understood, but in at least some children they include a genetic component and are accompanied by more general language processing difficulties, such as difficulties in rapid naming and phonemic segmentation ( [Chapter 32](#)). If the child shows positive findings in any of these clinical screening tests for reading, writing, and spelling, more systematic evaluation is required using standard tests ( [Chapter 50](#)).

### SPEECH AND LANGUAGE

Children who do not use words by age 18 months or phrases by age 2½ to 3 years, but who have a history of normal babbling, who understand commands, and who can use, as well as respond to, nonverbal cues and gestures are probably developing normally. However, delays beyond these ages or disturbances in these and other forms of communication are indicators for further evaluation. The general clinical signs of a language dysfunction include the following:

1. Reduced vocabulary, especially for abstract concepts such as feelings and for question words such as "when" and "where."
2. Overuse of concrete nouns and verbs.
3. Underuse or omission of abstract word classes (e.g., adjectives, adverbs, prepositions, articles, and conjunctions) often giving rise to telegraphic or unintelligible speech. (Some children may then avoid speaking or may have interpreters speak for them.)
4. A tendency to repeat their utterance, or simply nod their head, rather than to clarify what they were trying to say.

Specific language difficulties may result from receptive or expressive problems: Clinically, both commonly occur together.

*Receptive language problems* include sensory impairment (e.g., hearing impairment, also giving rise to delayed and unclear speech) and neurologic damage (e.g., mental retardation, primary disorders of speech) ( [Table 41.6](#)). Children with pervasive developmental disorders may have difficulty in understanding communicative nuances such as metaphor, irony, or humor; these deficits stem in part from relative difficulties in reading paraverbal cues such as facial expression, gesture, and intonation.

	Deafness	Mental Retardation	Infantile Autism	Ectopic W/len
Sound discrimination	↓	Normal	Normal	Normal
Attentiveness	↓ Watches face	↓	↓↓	Normal

**Table 41.6. Receptive Abilities**

*Expressive language problems* involve delays or abnormalities in the development of syntax and semantics and problems of speech production. *Syntax*, the term used to categorize the rules for combining words to form sentences, may be delayed. The normal child can make one-word utterances at age 18 months, two- to three-word phrases at age 30 months, and four-word sentences at age 40 months. *Semantics*, the term used to categorize the meaning of language, may similarly be delayed. Delays in syntax and semantic development may first be encountered in a history of limited or poor babbling. The child may subsequently use gestures instead of verbal language to communicate.

Abnormalities of expressive language include echolalia and delayed echolalia, the persistent use of neologisms, and misuse of pronouns and gender. Such abnormalities are commonly seen in childhood autism and may be associated with a lack of nonverbal communication behavior, including lack of direct eye gaze and communicative use of facial expression. Despite sometimes good vocabularies, children with pervasive developmental disorders have difficulty using language as a means of social interchange, with deficits in taking turns when speaking and an inability to infer the interlocutor's interests or perspective. Some useful language tests are shown in [Table 41.7](#).

**Table 41.7. Language and Speech Tests**

Common speech difficulties consist of delays, omissions, or distortions in the normal acquisition of particular sounds (e.g., wabbit instead of rabbit). Most uncomplicated, common speech acquisition difficulties of this kind resolve by the age of 7 or 8 years. Stuttering (consisting of repetitions, hesitations, or blocks in the production of a speech sound) often begins about the age of 3 years, follows a fluctuating course, and usually ends at adolescence. In some cases (less than 20%), it may persist into adulthood. There is often a family history of stuttering, a finding suggesting a genetic component.

Other dysfunctional speech patterns may reflect the level of integration at which the central nervous system is affected. Thus, aphonia may occur when the neuromuscular level is involved, including such apparatuses as the lips, tongue, palate, nasopharynx, larynx, and medulla oblongata; dysarthria may occur when the corticobulbar level is involved; scanning, explosive, and monotone speech may occur when the cerebellar level is affected; and agnosia (failure to understand symbols) and aphasia (failure to understand the spoken word or to speak) may occur when the cerebral level is affected.

Speech that is monotonous in tone, with poor, unusual, or unexpressive prosody, is found in many children with pervasive developmental disorders. Complex vocal tics may occur in more severe cases of Tourette's syndrome and may include repetitive syllables or repetitively ejaculated words or phrases, including out-of-context obscenities (coprolalia), pallilalia (repetition of one's own words), and bursts of abnormal prosody; however, such complex tics are rare in the absence of a clear history of prominent simple vocal tics (e.g., sniffing, throat clearing, grunting).

Temporary speech problems may occur during regressive episodes (infantile speech patterns may reappear), during drug intoxication (dysarthria and slurred speech may occur), during anxiety (a high-pitched, tight voice may inhibit speech), and when the child refuses to talk (so-called selective mutism).

When one or more of the foregoing clinical findings are present, a full diagnostic evaluation is indicated. This evaluation may include a complete physical examination, neurologic examination, hearing assessment, reading assessment, comprehensive language and speech tests, and an educational test battery ( [Chapter 45](#) and [Chapter 49](#)).

## INTELLIGENCE

An approximate idea of the child's intelligence may be assessed by an evaluation of the following:

1. General vocabulary, responsiveness, and level of comprehension and curiosity are evaluated.
2. In young children, the ability to identify the parts of the body is evaluated. For example, at age 5 years, the normal child may be able to identify the jaw, temples, forearms, and shins.
3. Drawing ability is assessed. The child is asked to draw a person (see later).
4. The ability to subtract serial sevens or serial threes is assessed.

## MEMORY

At age 8 years, the normal child can count five digits forward and two or three digits backward; at age 10 years, the child can count six digits forward and four digits backward. Very poor performance on the digit span test may indicate difficulties with attention or problems with working memory because of organic factors. Minor difficulties may simply reflect anxiety. The child should also be able to repeat three items 5 minutes after they have been presented.

## QUALITY OF THINKING AND PERCEPTION

Traditionally, the clinical assessment of thought includes two major clinical dimensions: (a) actual thought content and (b) the form, flow, and organization of thought. A variation in any of these dimensions may be of such a degree and duration as to constitute a thought disorder. In actual practice, the distinction between form and content of speech is not always sharp.

*Disordered thought content* may take the form of unusual beliefs (delusions) or perceptions (hallucinations). Other unusual thought contents that also reflect

deficiencies in the formal quality of thought are neologisms and idiosyncratic logic, including developmentally inappropriate transductive reasoning (things that are related in time or space are believed to be related causally), difficulty in discerning differences and similarities, difficulty in distinguishing the relevant from the irrelevant, and excessive concreteness. *Disordered flow of thought* may take the form of slowness of thought (as in primary obsessional slowness) or a press of thought and speech with flight of ideas. Disorder of flow may take the form of blocking, muteness, or excessive repetition of words and sentences. A child may experience any of these manifestations subjectively as being alien, out of his or her control, and sometimes frightening. Loosening of associations entails poorly connected shifts in topic, with the speaker unaware of the incoherence of his discourse. Closely related to loosening of associations is tangential thinking, in which speech veers from one topic to another.

Some of these psychopathologic concepts are difficult to apply to young children without clear developmental criteria. To help distinguish among developmentally normal immaturities in discourse, Caplan and colleagues developed the Kiddie Formal Thought Disorder Rating Scale, which provides operational definitions of illogical thinking, incoherence, loosening of associations, and poverty of speech content applicable to children ( [Caplan et al., 1989, 1990](#)). These authors find that loose associations and illogical associations are rare or absent in normal children after age 7 years, and these features differentiate children with schizophrenia or schizotypal personality disorder from normal children. Children with complex partial seizure disorder sometimes exhibit illogical thinking without loosening of associations.

The causes of a thought disorder may be classified clinically as follows:

1. Genetic (e.g., inborn errors of metabolism, such as Hartnup's disease, Kufs' disease, and schizophrenia)
2. Traumatic (e.g., postconcussion syndrome)
3. Infective (e.g., viral encephalitis and brain abscesses)
4. Neoplastic (e.g., brain tumor)
5. Toxic (e.g., amphetamines, corticosteroids, bromism)
6. Deficiency related (e.g., pellagra)
7. Endocrine (e.g., thyrotoxicosis)
8. Metabolic (e.g., electrolyte disturbance and delirium)
9. Idiopathic (e.g., pervasive developmental disorder, schizophrenia)
10. Posttraumatic (e.g., acute and massive psychological stress reaction)
11. Seizure related (e.g. fugue state, partial complex seizures)

The symptoms that constitute a thought disorder should lead to a systematic review of the foregoing possible causes. Obviously, some causes are easily ruled out, and others immediately appear to be likely possibilities. Once the field has been narrowed in this way, a more detailed study can lead to further narrowing. For example, the associated presence of hallucinations may give a cross-differential diagnosis of specific syndromes.

### *Hallucinations*

The clinician should ask about auditory and visual hallucinations as though he or she were taking a medical history of the eyes and ears. The clinician may ask, "Do you have any trouble with your ears?" "Do your ears ever hurt you?" "Do your ears ever play tricks on you?" "Do you ever think you hear something, but nothing is there?" A similar sequence can be designed for inquiring about visual hallucinations.

One can follow up by asking, "Do you hear it inside your head or outside?" and "Do you think it (or they) are really there, or is it just your imagination?" It is important to try to distinguish between true hallucinations and other phenomena, such as obsessions or compulsions, which children may sometimes describe metaphorically as "a voice telling me to do [some compulsive action]." Dissociative phenomena (including vivid flashback phenomena and intrusive imagery), such as are found in children with posttraumatic stress disorder, may also be difficult to differentiate from hallucinations.

It is also usually relatively easy to distinguish the phenomenon of imaginary companions from true hallucinations by the following features. The child with an imaginary companion is usually normal in other respects and shows no other signs of a thought disorder. The imaginary companion can be imagined or dismissed at will, it is experienced as nonthreatening, comforting, and enjoyable, and it has functions and characteristics assigned at the child's volition. Unlike hallucinations, the imaginary companion is not ego-alien, and the child can freely talk about his or her "friend" in elaborate detail. The natural history of the imaginary companion and its possible relation to dissociative identity disorder ( [Chapter 70](#)) require further study.

Persistent hallucinations in childhood are frequently associated with psychopathology, but they are not necessarily pathognomonic of serious psychotic illness, such as schizophrenia, mania, or melancholic depression with mood congruent or self-reproachful hallucinations (including command hallucinations to hurt oneself) ( [Volkmar et al., 1995](#)). The following additional major clinical categories should also be considered.

**Drug Intoxication.** Many illicit drugs are potentially hallucinogenic; they include marijuana, psychedelics, cocaine, amphetamines, and barbiturates. Furthermore, children and adolescents who abuse drugs may also have an antecedent psychiatric disturbance. However, many legitimately prescribed medications, such as steroids and antihistamines or other atropine-like drugs, can produce hallucinations either when taken in therapeutic quantities or as a result of deliberate or inadvertent overdose or interaction with other medications. The timing and form of the hallucinations (e.g., florid visual hallucinations) sometimes suggest the possibility of drug ingestion. Other symptoms of drug ingestion may be present, including drowsiness, paranoid behavior, confusion, restlessness, excitement, violence, dilated pupils, ataxia, dysmetria, tremor, dysarthria, dyskinesia, akathisia, and hypotensive signs. The clinician must ask about drug ingestion. Urine and blood samples must be tested when drug ingestion is suspected.

**Seizure Disorder.** Hallucinations, particularly hypnagogic hallucinations, may occur in narcolepsy and seizure disorders. Hallucinations may be the first symptom of degeneration after a previous encephalitic illness. A neurologic examination and an electroencephalogram are required.

**Metabolic Disorders.** The metabolic disorders that may give rise to hallucinations include adrenal cortical hypofunction, thyroid and parathyroid disease, hepatolenticular degeneration, porphyria, beriberi, and electrolyte or mineral imbalance (secondary to prolonged parenteral fluid replacement therapy, diuretic therapy, excess vitamin D intake, or diabetic acidosis). Signs of the primary metabolic disorder are usually present.

**Infection.** Encephalitis, meningitis, and acute febrile illnesses (especially in young children) may give rise to hallucinations.

**Immaturity, Stress, and Anxiety.** Hallucinations in children are not always indicators of a serious psychiatric disorder or an organic cause. Hallucinations may also occur transiently in young children overwhelmed by anxiety ( [Volkmar et al., 1995](#)). These hallucinations may begin at night as either hypnopompic or hypnagogic phenomena and may be accompanied by the illusion or hallucination of insects crawling on the skin (formication), a sign of intense somatic anxiety. Young children who are under severe stress and who resort to the defense mechanisms of repression, projection, and displacement may also have hallucinations. Such hallucinations appear to be part of a regressive phenomenon, in which the distinction between fantasy and reality is temporarily lost. In the pediatric intensive care unit, sensory deprivation may combine with intense anxiety, medication, and metabolic factors to produce hallucinations.

In children exposed to too much stimulation or abuse, hallucinations may accompany a broader constellation of dissociative symptoms. Acute grief reactions after the death of a parent may also give rise to hallucinations. Usually, these hallucinations are auditory and consist of admonitions and prohibitions attributed to the dead parent. In all these cases, the content of the hallucination may suggest the underlying psychological conflict.

In older children, external conflicts rarely, if ever, give rise to hallucinations. However, if the stress is massive and overwhelms the child, it can lead to profound regression. The circumstances in which this occurs include severe and sudden illness.

In some instances, severe cultural deprivation, together with a disturbed parent-child relationship, may result in hallucinations. The hallucinations in this situation are often localized, orderly, and related to reality, and they may consist of forbidding voices and overt wish fulfillments. Often, such hallucinations are consistent with the superstitions of the parents. The child may appear to be well organized in other ways. However, often there is evidence of an associated personality disturbance in the child and psychosis in the parent, findings suggesting at least the possibility of a genetic or organic component, as well as powerful sociocultural influences. For example, in some Pentecostal sects, a high value is placed on being possessed by the Spirit. Hysterically inclined children and youths may lend themselves to this

experience and may hear voices.

**Schizophrenia.** When hallucinations are more fragmented, incoherent, and bizarre in content, there is a greater likelihood that schizophrenia is present ( [Bender, 1954](#); [Volkmar et al., 1995](#)). Bodily complaints and paranoid delusions may be associated with the psychosis. The child is often frightened and secretive about the hallucinations, which are often bizarre and out of the child's control. Other signs of a thought disorder, including disordered, illogical thought processes and inappropriate affect, are usually present. A history of psychiatric disturbance in the family and maternal deprivation during infancy may be obtained. Sometimes the child shows delinquent behavior. Psychological tests, particularly projective tests, are indicated.

#### FANTASIES, FEELINGS, AND INFERRED CONFLICTS

The clinician may evaluate the following:

1. The child's spontaneous play is assessed.
2. The child's response is assessed when asked, "Do you have good dreams or bad dreams? Tell me one of your dreams."
3. The child can be asked, "If you could have three wishes—you can have anything you want, or can change the world or yourself in any way you want—what would you wish for?" ([Winkley, 1982](#)).
4. The child's productions in the game of squiggles are evaluated ( [Berger, 1980](#); [Winnicott, 1971](#)). The squiggles game is a way of establishing contact with the child. The clinician briefly explains to the child that he or she will make a squiggle with a pencil or crayon on a sheet of paper and the child will then turn it into something, and then it will be the child's turn to make a squiggle and the clinician's turn to make it into something. As they take turns, a theme may emerge in the sequence of squiggles and constructions. The clinician uses the drawings, the child's approach to the game, and what the child says about the squiggles to help both of them gain some insight into the child's mind.
5. The child's drawings of a person or whatever he or she wants to draw are assessed.

The child's drawings, particularly the child's drawings of a person, are useful in assessing the child's intelligence ( [Harris, 1963](#)) fantasies, and feelings ([Burns, 1982](#); [DiLeo, 1973](#); [Klepsch and Logie, 1982](#)), and various systems have been developed for assessing these aspects of children's drawings ( [Naglieri, 1988](#); [Naglieri et al., 1991](#)).

Because human beings are the objects of most intense interest to the child, the child's developing conceptual abilities may be readily seen in his or her drawings of a person. Thus, a general course or line of progression can be seen in children's drawings at different ages. As long ago as 1921, Burt was able to discern the following sequence ([Burt, 1921](#)):

1. Scribbling (2 to 3 years): The circular motor activity itself is pleasurable to the child as the child increasingly adapts his or her hand to the crayon and also tries to imitate the actions of others.
2. Single lines (4 years): The child soon draws a single line and tends to juxtapose parts.
3. Symbolic representation (5 to 6 years): The child can now draw a person consisting mostly of circles and ellipses representing head and body, "stick" lines representing arms and legs (and an indeterminate number of digits), and some curvilinear lines to represent eyes, mouth, and ears (hair arrangement usually distinguishes the sexes) ([Fig. 41.4](#)).

**Figure 41.4.** Drawing of a person by a 4-year-old child.

4. Descriptive drawing (7 to 10 years): The child now pays more attention to detail, and clothing details appear ( [Fig. 41.5](#)).

**Figure 41.5.** Drawing of a person by an 8-year-old child.

5. Visual realism (11 years onward): The child can draw in profile and attempts a realistic visual representation. The child may subsequently show a tendency to inhibition, with a preference for geometric designs, although later a true artistic talent may emerge ( [Fig. 41.5](#)).

A more precise assessment and measurement of the child's drawings can be obtained through formal psychological testing ( [Chapter 43](#)). The child's drawings may also reveal clinically useful information about his or her feelings and fantasies. However, the scientific reliability and validity of studies of this aspect of children's drawings are modest at best.

Clinically, it is often useful to invite a child to draw a person and then to make up a story about the drawing ("Pretend the boy or girl has just finished doing something, is doing something now, and is going to do something soon").

In observing the child while he or she is drawing, one may notice the following:

1. Motivation and self-esteem: The child may be eager to draw or may be self-effacing ("I'm no good at drawing" or "I can't draw very well").
2. Motor skill and activity: Observe how the child holds the crayon and how careful or slapdash is the child's approach. Does the child erase frequently, perseverate, or confine the drawing to a small corner of the paper? Neurologic impairment may reveal itself in the execution of the drawing.
3. Sex of the figure drawn: In general, children prefer to draw their own sex first and, initially, will identify whether it is a boy or girl "by the hair."
4. Special features of the child's drawing:
  - a. Heavy pressure may suggest tension, assertiveness, aggression, or organicity; light pressure may suggest indecisiveness, timidity, depression, and low self-esteem.
  - b. Large drawings may suggest aggressiveness or perhaps compensatory expansiveness to cover feelings of inadequacy; small drawings may suggest withdrawal, insecurity, or depression.

- c. Drawings placed low or on the edge may suggest insecurity or dependency.
- d. Very enlarged drawings of the head may suggest preoccupation with symptoms related to the head or possibly concern about intelligence.
- e. Omission of facial features may suggest evasiveness; large eyes may suggest anxiety or suspiciousness; small eyes may suggest guilt or a self-absorbed tendency. Sometimes the size of a part (e.g., ear, nose, or mouth) may be related to a possible handicap. Bared teeth may suggest aggression.

Numerous other inferences have been suggested (DiLeo, 1973; Hammer, 1980; Handler, 1985; Koppitz, 1968; Machover, 1949), but again, it must be noted that the scientific validity of these inferences is often low.

## AFFECTS

During the interview with the child, the clinician has the opportunity to observe directly the child's mood, range of affect, and the possible predominance of certain affects, such as anxiety, depression, apathy, guilt, or anger. In addition to observing the child's speech content, facial expression, and other nonverbal cues, the clinician will want to inquire directly about depression, suicidal thoughts or behaviors, and anxiety.

### Depressive Affect, Depression, and Suicidality

Depression is a particularly important affect that must not be overlooked. Depression affect is often accompanied by low self-esteem (e.g., "I can't do that," "I'm no good at drawing"), as well as fatigue, loss of interest and pleasure, guilt, difficulty in concentrating, and disturbances in sleep, appetite, and motor activity. These symptoms constitute a diagnosis of major depression.

The child may be asked: "Do you ever feel really down—sad, upset, or like crying?" "Do you ever feel like no one loves you or cares about you?" "Do you every get really down on yourself, blame yourself a lot, or feel you're no good at things or dumb or ugly?" "Are there ever times when it seems like nothing is any fun any more?" or "Do you ever feel like life sucks?" If the child answers any of these in the affirmative, one should ask "Have you ever felt things are so bad you've wished you were dead?" and "Have you ever done anything to hurt yourself?" In addition to low self-esteem and anhedonia, it is important to inquire about neurovegetative signs, such as changes in sleep or appetite, fatigue or loss of energy, psychomotor retardation, and difficulty concentration.

Suicidal risk may be part of a major depressive disorder and should be specifically investigated. When there is overt suicidal ideation or suicidal behavior, one assesses the events and circumstances leading up to the episode, whether the act was planned or impulsive, lethal in the child's mind, an act of desperation or depression, and whether the child's reaction to his or her suicide attempt was one of continuing desperation and depression or abhorrence and fright. If a child has made a suicide attempt or other nonsuicidal form of self-injury or ingestion, one may, for example, ask the questions in Table 41.8. A more detailed set of questions to ask in the evaluation of suicidal risk in children (Table 41.9) is provided by Pfeffer (1986) (Chapter 65).

1. Present episode:
a. Tell me what happened. And what happened next?
b. Motivation:
1. Were you feeling sad or depressed and frustrated?
2. Did someone approach you and talk to you?
3. Did you have something you'd change afterwards?
4. Did you have something you'd like to do now?
5. Did you have suicidal thoughts or thoughts of suicide?
6. Did you ever do anything to hurt yourself in the past?
7. Have you ever done anything to hurt yourself?
8. What was the reason for it?
9. What did you do?
10. What were the reasons for it?
11. Did anything change for you then, or did things just stay the same?
2. Recurrent episodes:
a. Do you know of anyone else, either in the past or more recently, who has thought about or tried to kill himself or herself?
b. What did you think or feel when you heard about it?
c. Did it make you sad?
3. Concomitants:
a. When you (e.g., had the idea), did you think you would die?
b. Did you hope someone would find you?
4. Symptoms of depression:
a. How is your appetite?
b. Do you have any trouble going to sleep or sleeping through the night?
c. Do you feel tired all of the time?
d. Do you feel sad or down all the time?
e. Do you feel like you're not doing as well as you used to?
f. Do you feel like you're not doing as well as you used to?
g. Have anyone close to you left you or died?
h. How do you feel about your school?
i. How do you feel about your parents?
j. How do you feel about your friends?
k. Do you worry that your parents will be disappointed with you?

**Table 41.8. Questions to Ask About Suicidality**

1. Present episode:
a. Tell me what happened. And what happened next?
b. Motivation:
1. Were you feeling sad or depressed and frustrated?
2. Did someone approach you and talk to you?
3. Did you have something you'd change afterwards?
4. Did you have something you'd like to do now?
5. Did you have suicidal thoughts or thoughts of suicide?
6. Did you ever do anything to hurt yourself in the past?
7. Have you ever done anything to hurt yourself?
8. What was the reason for it?
9. What did you do?
10. What were the reasons for it?
11. Did anything change for you then, or did things just stay the same?
2. Recurrent episodes:
a. Do you know of anyone else, either in the past or more recently, who has thought about or tried to kill himself or herself?
b. What did you think or feel when you heard about it?
c. Did it make you sad?
3. Concomitants:
a. When you (e.g., had the idea), did you think you would die?
b. Did you hope someone would find you?
4. Symptoms of depression:
a. How is your appetite?
b. Do you have any trouble going to sleep or sleeping through the night?
c. Do you feel tired all of the time?
d. Do you feel sad or down all the time?
e. Do you feel like you're not doing as well as you used to?
f. Do you feel like you're not doing as well as you used to?
g. Have anyone close to you left you or died?
h. How do you feel about your school?
i. How do you feel about your parents?
j. How do you feel about your friends?
k. Do you worry that your parents will be disappointed with you?

**Table 41.9. Questions to Ask in the Evaluation of Suicidal Risk in Childrenk values) of the Instruments Considered in This Chapter (Where Available)**

## Anxiety

It is also important to inquire directly about *anxiety*, for example: "Are there any things that get you really nervous or scared, to the point of making you really uncomfortable or keeping you from doing things, such as play dates or sleepovers at friends' houses?"

## RELATIONSHIPS

The clinician may explore the following areas:

1. With the family: The clinician may ask the child who is in the family and which family members the child gets along with best and worst. One can also ask the child to describe the different members of their household, how the child gets along with each of them, and whether there are any "rough spots" in how they get along.
2. With peers: The clinician may ask the child who his or her friends are and whom he or she likes the most and the least. Asking the child what he or she likes about various friends gives some picture of how the child sees others and what aspects of people are most salient to the child. Again, having asked first about whom the child gets along best with, the clinician turns to ask, "Are there any kids you don't get along with?" "Do you ever have any trouble with how you and other kids get along?" and if so, to ask the child's impression of how those difficulties come about. For a child who feels ostracized or unpopular, one can inquire whether there are any things the child is teased about.
3. With teachers: The clinician may ask the child which teachers he or she likes and dislikes and why.

## SEXUAL AND AGGRESSIVE CONCERNS AND BEHAVIORS

1. Sexual: Is the child seductive or inappropriate toward other children or adults? Does the child engage in overt or covert masturbation or other autoerotic behaviors? Does the child have romantic interests, and, if so, what are their nature and object? Does the child have concerns over gender identity or sexual orientation? Is the child sexually active, and, if so, with whom?
2. Aggressive: Does the child have a problem with his or her temper? If so, who are the objects of the child's anger and what provokes it? How does the child express his or her anger—through appropriate verbal means, through verbal abuse, or through physical assaultiveness? Is the child provocative, irritable,

destructive, or violent? For example, does the child have a history of weapon carrying or use or of engaging in serious physical fights? Is there a history of cruelty to animals, fire setting, vandalism, or bullying? What is the child's attitude toward his or her expressions of aggression (e.g., contrition, lack of remorse)? Is the child overly inhibited in expressing aggression?

### DEFENSE ORGANIZATION

What are the child's modes of coping with conflicts or problematic urges (e.g., finding alternative or socially permissible means of satisfying them)? What coping strategies does the child use when anxious, frustrated, or angered? Does the child become phobic, avoidant, or overly inhibited? Does the child resort to counterphobic measures, provoking or deliberately risking what he or she fears? Does the child become overly perfectionistic or resort to denial (saying that there are no problems?)

### POSITIVE ATTRIBUTES

It is also important to make note of the child's positive attributes. For example, does the child have special talents or interests of which he or she is able to make adaptive use? The clinician will want to make note, when present, of the following: physical robustness and attractiveness; intelligence; emotional and cognitive flexibility, good affective coping skills and stability; psychological mindedness, amiability, cooperativeness, and social fluency; stable, supportive, and appropriate relationships with peers, family, and teachers; durable and realistic self-esteem; positive work habits and academic achievement; and reasonable and useful ethical values.

### FORMULATION

The complete psychiatric assessment of the child or adolescent should enable the clinician to formulate a useful description of how and why the particular child or adolescent presents in the way he or she does ([Shapiro, 1989](#)). Thus, the *formulation* is, in essence, an integrated summary of the unique way in which organic factors, environmental stresses, and inner conflicts have interacted over time for a particular child or adolescent in a particular family. Through the formulation, one obtains a full, multidimensional picture of the child or adolescent that goes far beyond the diagnostic label and provides a sound basis for devising an appropriate comprehensive treatment plan. The formulation attempts to spell out the internal and external factors that have brought about and maintained the child's difficulties, as well as protective and ameliorative factors that may have mitigated these difficulties and may serve as potential avenues for remediation. The clinician's focus on the child and family's strengths and adaptive capacities, as well as their areas of difficulty, helps to identify resources in the child, family, and school that may facilitate any therapeutic measures to be undertaken.

### CONCLUDING THE EVALUATION

In the course of the evaluation of the child, the clinician establishes a trusting relationship with the child and the parents. Consequently, the clinician considers the feelings of the child and the parents during the conclusion phase of the evaluation. For example, the clinician informs the child ahead of time as to when the last session will take place. Then, during the final interview, he or she ensures that the child knows what will take place next by asking the child or adolescent: "Are there any things you would particularly like me to tell your parents?" "Are there any things you don't want me to say to your parents?" "This is what I plan to say to your parents. How does that sound to you?" "Do you have any questions?" Sometimes a child will express feelings about the ending. These feelings should be recognized, acknowledged, and dealt with sympathetically and realistically.

At the final review meeting with the parents, the clinician may start by asking how the child reacted to coming for his or her interviews. Sometimes information comes to light that may help the clinician in assessing the child's capacity to form a relationship and engage in psychotherapy. The clinician can then give the parents an account of the child's strengths. Every child has some strengths (e.g., the child may be attractive, intelligent, delightful to be with, well coordinated, able to think clearly), and it is important that the clinician tell the parents about such qualities.

Next, the clinician talks with the parents about his or her assessment of the child's difficulties. The assessment should be discussed in clear language and documented with vignettes from the clinical interviews or from any of the special tests that help to illustrate and clarify the nature of the difficulty. If psychological tests have been performed, the psychologist may wish to participate in the review meeting with the parents.

The parents should be given every opportunity to ask questions. Their reactions should be recognized and understood; the parents need the support of the clinician. They need an explanation of the possible causes of their child's condition. They should also be reassured about all the good things they have done to help the child. Finally, treatment options and recommendations should be discussed with the parents. The parents should not be rushed, and they should be invited to telephone or return if they so wish.

Documentation of the basis for the findings is particularly important when a written report has to be submitted, for example, to a court for evidence in a custody dispute ([Lewis, 1974b](#)). When appropriate, and with the parents' permission, the clinician should also send a report to the referring person. The limits of confidentiality, again, must be clearly understood by the child, the parents, and the clinician, and the clinician must exercise special care to safeguard this confidentiality.

Finally, the psychiatric evaluation of the child and the child's family goes beyond the diagnosis. Each child and each family member has his or her own private experience of life. In a good psychiatric evaluation, the clinician is privileged to enter that private experience momentarily and to empathize with that person's feelings, hopes, and fears. One tries to capture this aspect of a person's life in the descriptive diagnostic formulation that follows the formal diagnosis.

### STRUCTURED INTERVIEWS, QUESTIONNAIRES, AND RATING SCALES

*Structured and semistructured psychiatric interviews*, questionnaires, and rating scales for children and parents have been devised to improve the reliability and validity of information and observations regarding psychiatric diagnosis. Currently, the greatest use for these instruments is in research. However, many of these instruments have been used successfully for screening purposes and as diagnostic aids in the clinical situation. They have also proven useful in providing a quantitative metric for measuring the impact of an intervention on a given set of symptoms. In turn, their use has sharpened clinical inquiry in such areas as the assessment of mood disorders, cognitive functions, attention, and thinking processes.

Structured interviews have the advantage of focusing on important areas and therefore do not leave to chance observations of important items that may not come to light in an unstructured interview. Structured interviews provide comprehensive and systematically obtained and rated data with respect to a specific set of diagnoses; they thus have the advantage that the data elicited by reliably trained interviewers can be compared across subjects, as, for example, in gathering epidemiologic data. One further advantage is the relatively short training period required to be able to administer a structured interview.

Structured interviews are more or less rigid, however, and do not admit much in the way of clinical judgment. Sometimes the conclusions do not correspond to the complexity of the clinical diagnosis. Furthermore, structured interviews pay little attention to the personal, historical, or adaptive context of the child's difficulties and hence are of limited utility in planning treatment interventions. Structured interviews for preschool children are generally unreliable. Questionnaires that have long lists of questions—for example, the Diagnostic Interview for Children and Adolescents (DICA), which has 207 items—may exhaust a child. The clustering of items around symptoms may also be a limiting factor as far as rapport is concerned, because the focus on negative behavior may be too relentless for too long. Often, the rote manner in which the questions are posed conveys little sense to the child that the interviewer has any empathic interest in the child's responses. The lack of normative data, in some instances, is a handicap. Few structured interviews focus specifically on father-child interactions.

On balance, structured psychiatric interviews for children and adolescents supply a useful safety floor and a reliable screening mechanism. In general, children report better about feelings, whereas parents report better about behavior.

The number of schedules and scales now available is formidable and increasing steadily. [Chapter 42](#) and the relevant chapters on syndromes have more detailed descriptions and indications for the use of standardized instruments.

### STANDARDIZED TESTS

Standardized tests, such as developmental, psychological, neurologic, educational, linguistic, and biological studies, are described in Sections V and VI.

### BRIEF HISTORICAL INTRODUCTION

Interviews are necessary tools for all forms of clinical medical diagnosis, and they have a singularly prominent position in psychiatry because of the lack of other “tests” for psychiatric disorders. All structured interviews used in psychiatry have their roots in the phenomenologic clinical interview, although different interviews take rather different routes in the standardization of the collection of phenomenologic data relevant to diagnosis.

#### Limitations of Unstructured Diagnostic Interviews

It soon became clear that clinical training was sufficiently varied that colleagues of the same discipline, working in the same establishment, were often unable to agree about an individual patient's diagnosis, even when they were presented with exactly the same information ( [Cantwell, 1988](#); [Gould et al., 1988](#); [Prendergast et al., 1988](#); [Remschmidt, 1988](#)). An apparent difference in rates of schizophrenia between New York and London proved to be almost entirely the result of differences in diagnostic criteria applied to observed phenomena ( [Cooper et al., 1972](#)). Observations such as these motivated the development of the formalized sets of diagnostic criteria familiar to us today from the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ( [American Psychiatric Association, 1994](#)) and the 10th edition of the *International Classification of Diseases* (ICD-10) ( [World Health Organization, 1992](#)).

The literature on medical decision making had already shown that clinicians suffer from certain detrimental information collection biases: (a) they tend to come to diagnostic determinations before they have collected all the relevant information, (b) they tend then to focus on collecting information to *confirm* that diagnosis (“confirmatory bias”), (c) they tend to ignore disconfirmatory information, (d) they combine information in idiosyncratic ways, and (e) they tend to make judgments based on the most readily available cognitive patterns: the “availability heuristic.” Further problems arise because of a tendency to see correlations where none exist (“illusory correlation”) and, contrariwise, to miss real correlations ( [Achenbach, 1985](#)). Added to all these problems is that, even today, standard diagnostic manuals do not provide very detailed descriptions of how to assess psychopathology at the symptom level. All the criteria for oppositional defiant disorder, for instance, begin with the word “often,” but how often is often? There is a great deal of room for clinicians to adopt very different decision rules about when to regard such symptoms as being present.

In the presence of all these difficulties, it became apparent that means were required to standardize the collection, quantification, and combination of diagnostic information. As a result, all structured interviews aim to (a) structure information coverage so all interviewers will have collected all relevant information (both confirmatory and disconfirmatory) from all subjects, (b) define the ways in which relevant information is to be collected, and (c) structure the process by which relevant confirmatory and disconfirmatory information is combined to produce a final diagnosis.

#### Early Structured Diagnostic Interviews

In the early days of structured interviews, it was supposed that *clinicians* would be using them because it was believed that only they had the necessary training and experience to be able to decide about the presence or absence of symptoms, even when quite detailed definitions were provided. The interview schedule served as a tool to guide the clinician interviewer in determining whether symptoms were present, but the interviewer made the decisions, on the basis of information provided by the child or adult. Interviews of this sort, like the Present State Examination (PSE) ( [Wing, 1974](#)) and the Reynard ( [Guze et al., 1969](#)) for adults and the Isle of Wight interview for children ( [Graham and Rutter, 1968](#), [Rutter and Graham, 1968](#)), were the first to be developed because they sprang naturally from clinical practice. They were called *semistructured* because the interviewer was allowed latitude in the specific form of the questions used.

Although the PSE and Isle of Wight interviews were used extensively in community surveys, it was clear that the use of clinician interviewers created both logistic and budgetary problems. Very large-scale epidemiologic studies, such as the Epidemiologic Catchment Area studies ( [Regier et al., 1984](#)), mandated the use of nonclinician (“lay”) interviewers. Some investigators believed that such interviewers would be incapable of making the judgments about symptoms, so, following methods used by political and marketing surveys, interviews were developed that required only that the interviewer ask a set of fixed questions in a preset order and collect the simple answers to those questions. In such interviews, the *questions* put to the subject are structured, and the interviewer makes no decisions about the presence of symptoms. Hence they came to be called “highly” or “fully” structured interviews. The Diagnostic Interview Schedule was the paradigmatic example of this sort of interview in adult psychiatry ( [Robins et al., 1979](#)), whereas the original Diagnostic Interview Schedule for Children and Adolescents (DICA) was the first child-oriented example ( [Herjanic and Campbell, 1977](#); [Herjanic et al., 1975](#)).

## Emergence of the Diagnostic Interview with the Child and the Need for Multiple Informants

Until the late 1960s, interviews and questionnaires directed to a parent or teacher about a child's behavior and *observation* of the child's behavior were the predominant methods of assessment in child and adolescent psychiatry. Verbal information from the child was typically regarded as being only supplemental or as material for psychodynamic interpretation ([Lapouse, 1966](#)). More attention was paid to playing with the child than to the collection of information through direct questioning. In 1968, a key transitional article reported on the reliability and validity of the Isle of Wight interview with the child ([Rutter and Graham, 1968](#)). The behavior of the child in a face-to-face interview was examined directly, but little was made of the factual content of the child's reports. In 1975, Herjanic and her colleagues asked whether children are "reliable reporters" of factual information and presented evidence that they are ([Herjanic et al., 1975](#)). Since then, a great deal of work has confirmed the importance of children's self-reports as a source of factual information, with the result that fact-finding (as opposed to interpretative) interviews with both parents and children are now regarded as being of equal weight in the diagnostic process, at least from late childhood. The one exception is in the evaluation of symptoms of attention deficit hyperactivity disorder, in which child reports have been found to be of little help ([Lahey, 1990](#); [Loeber et al., 1991](#)). However, the recent growth of interest in attention deficit hyperactivity disorder in adolescence and adulthood has led to the development of new measures in this area ([Conners, 1977](#)).

## Disagreement Among Informants and Its Implications for Combining Information from Multiple Informants

Until the 1980s, agreement between child and parent reports of symptoms was widely regarded as being a test of the *validity* of *child* reports ([Herjanic et al., 1975](#); [Rutter and Graham, 1968](#)). However, it soon became apparent that only low levels of agreement among informants (correlation coefficients around 0.3 for agreement among children, parents, and teachers) could be expected ([Reich et al., 1982](#); [Stanger and Lewis, 1993](#)). It is now considered that low levels of agreement among different informants about the child's clinical state are to be expected and do not invalidate the reports of any of them. Rather, each key informant presents a particular view of the child's problems. Indeed, it is precisely because agreement among informants is low that multiple informants are needed. Were agreement very high, taking the history from more than one informant would be redundant.

The problem is that disagreement among informants means that one has to decide how to weight the information from each informant in arriving at a diagnosis. Because it is uncommon for informants to invent fictitious symptoms, the simple rule of regarding a symptom as being present if any informant reports it usually suffices. When symptoms are combined to make diagnoses, the usual procedure is to "ignore" the source and to add up all positive symptoms from any source. Thus, a diagnosis of a major depressive episode (which requires the presence of at least five symptoms) may be made on the basis of three relevant symptoms reported by the child (say, depressed mood, anhedonia, and excessive guilt), with two other relevant symptoms (perhaps sleep and appetite disturbances) reported by the parent. Although some interview developers recommend *reconciliation*: discussions involving the interviewer, the parent, and the child to clear up discrepancies among their reports, such a discussion is problematic. Reconciliation requires that one informant must modify his or her story, and that means admitting being wrong or at least uninformed. The knowledge that such a discussion will occur could cause informants (e.g., drug-using adolescents) to withhold important information that they did not wish other informants (e.g., their parents) to hear about. Finally, in most research applications, one wishes to assure informants that what they say will not be revealed to anyone else, and this rules out a reconciliation interview.

The remainder of this chapter is concerned with the description of key points relating to "general" psychiatric diagnostic interviews, that is, those that cover a broad range of the common disorders of childhood and adolescence. Some interviews and observational systems exist for more specialized tasks, for instance, the Diagnostic Interview and the Autism Diagnostic Observation Schedule ([Lord et al., 1989, 1994](#)), but such instruments are not considered further here.

## TYPOLOGY OF INTERVIEWS

### Respondent-Based Interviews

As we have already seen, a distinction between semistructured and highly structured interviews has found its way into the description and discussion of diagnostic interviewing techniques. However, these terms are not very helpful for two reasons. First, they imply that the key difference between different types of interview concerns the *amount* of structure they impose. The problem is that the real issue is not one of amount of structure, but rather who makes the final decision on whether a symptom is present. In interviews in which the questions are absolutely prespecified, the respondent makes the final decision (typically by answering "yes" or "no" to each question). The interviewer makes no such decisions, but merely reads the questions. Because the decisions about the presence or absence of psychopathology lie with the respondent in such interviews, we refer to these interviews as *respondent based*. The Diagnostic Interview Schedule for Children (DISC) ([Shaffer et al., 2000](#)), the computer-assisted version of the DICA ([Reich, 2000](#)), and the Dominic-R (Valla et al., 2000) are three representatives of this approach.

### Interviewer-Based Interviews and Glossary-Based Interviews

We call interviews that require the interviewer to make an informed decision based on what the respondent says *interviewer based*. The interviewer is expected to question until he or she can decide whether a symptom meeting the definitions provided by the interview (or known to them from their training) is present. This group of interviews includes the Anxiety Disorders Interview Schedule (ADIS) ([Silverman and Rabian, 1995](#)), the Child and Adolescent Psychiatric Assessment (CAPA) ([Angold and Costello, 2000](#)), the Child Assessment Schedule (CAS) ([Hodges, 1993](#); [Hodges et al., 1982b](#)), the paper and pencil (not the computerized) versions of the DICA ([Reich, 2000](#)) and its close relative the Missouri Assessment of Genetics Interview for Children (MAGIC), the Interview Schedule for Children and Adolescents (ISCA) ([Sherrill and Kovacs, 2000](#)), the various versions of the Schedule For Affective Disorders and Schizophrenia for School-Age Children (Kiddie-SADS or K-SADS) ([Ambrosini, 2000](#)), and the Pictorial Instrument for Children and Adolescents (PICA-III-R) ([Ernst et al., 2000](#)). Three of these interviewer-based interviews (the K-SADS-P IVR, the DICA, and the CAPA) provide extensive sets of definitions of symptoms or detailed guidance on the conduct of the interview, and we call these *glossary based*. Such glossaries are particularly important when an interviewer-based interview is to be used by nonclinician interviewers because they provide detailed guidance about what the interviewer is supposed to be looking for in making symptom ratings. Nonclinician interviewers have been shown to be able to make such "clinical" judgments with high reliability when they have received adequate training with such glossaries ([Angold and Costello, 1995](#)).

The distinction between interviewer- and respondent-based interviews is not hard and fast in actual practice, because there is considerable cross-fertilization between these approaches. For instance, the CAPA, which has its roots in the interviewer-based tradition, includes a subset of questions that are to be asked verbatim of all subjects, as in a respondent-based interview, but then it allows further questioning for clarification. Conversely, the DICA, which had previously been a respondent-based interview, now requires interviewers to question much more flexibly and is now an interviewer-based instrument ([Reich, 2000](#)). Although the distinction between interviewer- and respondent-based interviews provides a useful rough-and-ready typology, it is really better to consider interviews as lying at various locations along three dimensions: (a) degree of specification of questions, (b) degree of definition of symptom concepts, and (c) degree of flexibility in questioning permitted to the interviewers. Interviews that provide extensive definitions and require interviewers to make judgments lie in the interviewer-based region of that three-dimensional space, whereas those that specify every question and allow no interviewer deviation from those questions lie in the respondent-based region.

### Pictorial Interviews

More recently, respondent-based child self-report interviews that add *pictorial* cues have been added as assessment tools. The most highly developed pictorial interview at this time is the Dominic-R ([Valla et al., 2000](#)), which is intended for use with 6- to 11-year-old children. Pictures representing psychopathology relevant to seven diagnoses are shown to the child, and questions about whether each symptom is present are read at the same time. Because no frequency, duration, or onset data are collected, it is not yet clear how such information should be combined with diagnostic information from other sources. This is, however, a general problem for interviews with younger children, because before the age of 8 or 9 years, they simply cannot provide all the frequency, dating, and timing information that full diagnostic interviews require. Although diagnostic test-retest reliabilities cannot be reported for the Dominic-R, its item reliabilities are respectable in comparison with those reported from studies of older children with other interviews.

The PICA-III-R, for children 6 to 16 years of age, adopts a somewhat similar approach, but the questions to be asked with the pictures are more loosely specified, and the test is intended to be used by clinicians. It covers a broader range of diagnoses than the Dominic-R, but no test-retest reliability data are yet available ([Ernst et al., 2000](#)).

## Screened Interviews

The Children's Interview for Psychiatric Symptoms (ChIPS) ([Weller et al., 2000](#)) was designed as a *screening* tool covering 20 DSM-IV Axis 1 disorders. "Cardinal questions" concerning symptoms most often seen in children with a particular disorder are asked at the beginning of each section. If the answers to these screening questions are in the negative, then the rest of that section is skipped. No test-retest reliability data are yet available for the ChIPS. A similarly "screened" version of the CAPA is also available, but in practice it has been found to save only about 10 minutes of interview time, so the loss of information resulting from not asking about all symptoms may not really be worth the time saving.

## BRIEF INTRODUCTION TO THE INTERVIEWS

Here we present a brief introduction to each of the diagnostic interviews, with a focus on their characteristic *response formats*.

### Schedule for Affective Disorders and Schizophrenia for School-Age Children

The K-SADS "family" of interviews consists of a group of very diverse assessments. Indeed, the only features that all the current versions of the K-SADS share in common are the name, the ability to make DSM-IV diagnoses, and the fact that all were designed to be administered *by clinicians*. The original version of the K-SADS (K-SADS-P) ([Puig-Antich and Chambers, 1978](#)) was a downward extension of the adult Schedule for Affective Disorders and Schizophrenia (SADS) and focused on the Research Diagnostic Criteria ([Spitzer et al., 1978](#)). The "P" in its title stands for *present* (not parent). It was designed for use with children aged 6 to 17 years, but it covered only a relatively limited range of symptoms and diagnoses. It was revised to cover DSM-III-R ([Ambrosini et al., 1990](#)) and DSM-IV.

#### K-SADS-P IVR

The version of the K-SADS-P most recently developed by Ambrosini and colleagues is called the K-SADS-P IV-R. This version is closest conceptually to the original K-SADS-P in including quite detailed definitions of severity codings for each symptom. The modal form for these symptom codings is a six-point scale, involving judgments about various combinations of intensity, duration, frequency, environmental responsiveness, psychosocial impairments, and observed behavior.

#### K-SADS-E

The K-SADS-E (E for epidemiologic) collects ratings of the present episode of any disorder *and* the *worst* past episode ([Orvaschel et al., 1982](#)). This interview is not even remotely similar in format to the K-SADS-P, because it rates only the presence or absence of symptoms, rather than employing the carefully defined severity codings of the K-SADS-P. The latest edition is DSM-IV compatible, and it allows the current *episode* (not individual symptoms) to be rated as mild, moderate, or severe.

#### K-SADS-PL

A group in Pittsburgh developed the K-SADS-PL (present and lifetime), as a sort of cross between the K-SADS-P and the K-SADS-E ([Kaufman et al., 1997](#); [Shanee et al., 1997](#)). Symptom ratings are reduced to three-point scales (typically "not at all," "subthreshold," "threshold"), and fairly minimal anchoring definitions of each point are provided. An initial 82-item screen interview, which allows skipping of substantial symptom areas, is also available.

#### WASH-U-K-SADS

Rather brief definitions of symptoms are given, and the level of severity is coded, but the severity codings are idiosyncratic and bear little relation to those in other versions of the K-SADS.

#### COLUMBIA K-SADS

The symptom definitions provided are often simply restatements of the DSM-IV criteria. Sometimes, particularly in relation to depression, a little more guidance is given. Symptom severity is typically rated on what appears to be a six-point scale like the K-SADS-P and K-SADS-P IVR, but closer inspection reveals that two of the points are usually defined only as being "intermediate" between two other points. Thus, only four points (one being symptom absence) are really defined. Although K-SADS interviews were developed for use by clinicians, some are also used with lay interviewers ([Hodges et al., 1987](#); [Lewinsohn et al., 1993](#)).

The K-SADS family differs from most interviews (but not the ISCA) in directing that the parent should be interviewed first and then the child should be seen by the same interviewer, who is then expected to resolve any discrepancies between the child's reports and those of the parent. The interviewer then completes a record representing his or her summation of the two interviews. This procedure is highly dependent on clinical judgment, and it means that the process of combining the information is not structured. It also seems likely to bias the results of the interview in favor of the parental reports ([Angold et al., 1987](#)), and some workers instead score the interviews with the parent and the child separately ([Weissman et al., 1987](#)).

## Child and Adolescent Psychiatric Assessment

The CAPA is one of an integrated group of instruments developed to assess a variety of risk factors for, manifestations of, and outcomes of child and adolescent psychiatric disorders. In addition to the usual symptom and impairment assessments, it also includes extensive ratings of the family environment and relationships, family psychosocial problems, and life events (including traumatic events and physical and sexual abuse). A separate module called the Child and Adolescent Impact Assessment (CAIA) ([Angold et al., 1998](#); [Messer et al., 1996](#)) measures the impact of the child's problems on the family, whereas the Child and Adolescent Services Assessment (CASA) ([Ascher et al., 1996](#); [Farmer et al., 1994](#)) covers service use for mental health problems in multiple sectors and settings. Psychosocial impairment in 17 domains of functioning is measured at both the syndromic level and overall. In the interview with the child, 62 items reflecting the child's observed behavior are also coded.

To facilitate completion of the interview by nonclinicians, the CAPA provides a more molecular approach to symptom codings. Extensive symptom definitions are given in a glossary and on the schedule, and rules are specified to allow nonclinicians to make separate codings of the intensity, frequency, duration, date of onset of symptoms, and psychosocial impairment resulting from them. The CAPA emphasizes obtaining descriptions and examples of possible pathologic features to ensure that codings are not based on the informant's misunderstanding of what was being asked ([Angold and Costello, 1995, 2000](#); [Angold et al., 1995](#); [Costello et al., 1998](#)).

A version of the CAPA has been developed for use with *young adults* (the Young Adult Psychiatric Assessment; YAPA), and a substantially modified version is now available for use with the *parents of preschool children* (the Preschool Age Psychiatric Assessment; PAPA). The latter includes assessment of certain areas not included in the CAPA. In addition, a version with empirically derived screen items is available, and this allows sections to be skipped if screen symptoms are absent. A streamlined version for collecting data for twin studies has also been developed ([Simonoff et al., 1997](#)).

## Diagnostic Interview for Children and Adolescents

The DICA started out as a respondent-based interview in the 1970s ([Herjanic and Campbell, 1977](#); [Herjanic and Reich, 1982a](#); [Herjanic and Reich, 1982b](#); [Herjanic et al., 1975](#); [Reich and Earls, 1987](#); [Reich et al., 1982](#); [Welner et al., 1987](#)). Since then, it has been progressively modified, so its *paper and pencil version* is now an interviewer-based interview ([de la Osa et al., 1997](#); [Ezpeleta et al., 1995](#); [Ezpeleta et al., 1997](#); [Reich, 2000](#)). However, there is also a *computer-based version* of the DICA that remains fully respondent based ([Reich et al., 1995](#)). In addition, the group responsible for the development of the DICA has produced a modification, the MAGIC. The major difference between the DICA and the MAGIC is that the MAGIC has a specifications manual, which includes a great deal of guidance on how to elicit key features of symptoms and a variety of clarifications of coding instructions ([Reich, 2000](#)).

The DICA and the MAGIC provide alternate versions for self-reports from children 6 (or 7) years old to 12 (and 13) to 17 years old, with differently worded questions. The DICA has also been used with even younger children, but special training is required for its administration in children younger than 6 or 7 years old, and the

instructions to interviewers essentially tell them to ignore the usual questioning format laid out in the schedule and to use their own questions.

Symptoms are typically coded on a three-point scale (no, sometimes/somewhat, yes) for items about emotional symptoms, and a two-point scale (no, yes) for disruptive behaviors, with additional information of frequency sometimes added. Impairment is measured at the syndrome level by three items asking about symptoms that make it hard to "get along" with the family, friends, and at school, rated on four-point scales (not at all, not too much, somewhat, quite a bit).

### Child Assessment Schedule

The CAS is organized around thematic topics and provides ratings of many items that are not required if all one wants to do is make ratings of the DSM criteria for disorders ([Hodges and Saunders, 1989](#); [Hodges et al., 1982a](#); [Hodges et al., 1982b](#); [Hodges et al., 1987](#); [Hodges et al., 1989](#); [Hodges et al., 1990](#)). The CAS now exists in child (7 to 12 years), adolescent, and parent report versions. Although originally developed for use by experienced clinicians ([Hodges et al., 1982a](#)), the CAS has now been used by lay interviewers in several studies. Symptoms are scored on a four-point scale (yes, no, ambiguous, not scored). This is followed by questioning about the onset and duration of positive symptoms. The items to be coded are defined in brief sentences that outline each symptom concept. The interviewer is expected to make a judgment about the coding based on the answer to the questions on the schedule (plus any additional questions that may be thought necessary).

The CAS also has a 56-item section for recording observations of the child's behavior during the interview. Diagnoses can be generated manually by interviewers using algorithms provided by the developer of the interview, but computerized scoring is recommended. The algorithms also generate symptom scales pertaining to certain areas of psychopathology.

Psychosocial impairment is measured using a separate instrument, the Child and Adolescent Functional Assessment Scale (CAFAS), which can also be used alone or with another diagnostic interview ([Hodges and Wong, 1996, 1997](#); [Hodges et al., 1998](#)).

### Anxiety Disorders Interview Schedule

Notwithstanding its title, the ADIS also provides brief ratings of symptoms pertinent to other disorders, but its coverage of the anxiety disorders is more thorough ([Silverman, 1991](#); [Silverman and Eisen, 1992](#); [Silverman and Nelles, 1988](#); [Silverman and Rabian, 1995](#)). The interview is designed for *clinician* use, and it is derived from the adult ADIS ([di Nardo et al., 1993](#)). Questions that *should* be asked are provided, and guidance is given about when to use additional questions. Most symptoms are scored on a simple three-point scale (yes, no, other). However, in the anxiety section, a good deal of use is also made of nine-point scales (represented by a thermometer) ranging from "not at all" to "very, very much." Similar scales are used to rate *interference*, which is the ADIS term for psychosocial impairment resulting from disorders. Skip structures are frequently employed, so many persons are not asked about all symptoms.

### Interview Schedule for Children and Adolescents

The ISCA mandates administration by experienced clinicians with extensive structured interviewing training and full understanding of the principles of diagnosis and its application to children with psychopathology. Interviewers must be able to combine the symptom information from both parent and child into diagnoses themselves, because formal algorithms for this process (other than the official diagnostic manual itself) do not appear to be available ([Sherrill and Kovacs, 2000](#)). Questions are clearly specified, but much additional clarification is expected of interviewers, who are not expected slavishly to stick to the written questions. Sixty-nine "major" symptoms and 10 "mental status" items are covered, and they are typically coded on a nine-point severity scale that incorporates judgments about associated distress, functional impairment, and the amount of effort required to counteract symptoms. "Subsidiary information" about many symptoms is also collected, typically in a yes-no format. In addition, 17 intrainterview behavioral observation items are assessed. A version of the interview for use with young adults (the Follow-up Interview Schedule for Adults; FISA) has also been developed.

### Diagnostic Interview Schedule for Children

As already indicated, the questions on a respondent-based instrument are designed in a fixed, ordered sequence and require very simple responses (typically yes or no). Symptom severity is defined by similar yes-no answers on subsidiary questions (asked only if a positive response is obtained to a superordinate question) and forced choices from short sets of frequency ranges. All data combination is performed by computerized algorithms. The DISC covers a wide range of childhood and adolescent disorders and is suitable for use with 9 to 18 year olds. A version for use with the parents of preschoolers is currently under development.

## INTERVIEW TIME FRAMES

The K-SADS interviews, the ADIS, the CAS, the Dominic, the PICA-III-R, and the ISCA all focus on the child's "current" status or the "current episode" of disorder, although the definition of "current" is largely unspecified, except in the case of the ISCA, in which the assessment period is specified (e.g., 2 weeks for irritability). The Columbia K-SADS adds a past 2-week time frame to the "current" frame. The K-SADS-PL, the Columbia K-SADS, and the K-SADS-E explore lifetime histories of "worst" episodes, whereas the ISCA also provides for assessment of lifetime disorder, and an "interim" version provides an assessment of current status and the child's status in the interim between the current assessment and the last assessment for use in follow-up studies. The DICA and MAGIC focus on the whole lifetime, but for some disorders an additional shorter time frame is also included. For instance, in the depression section, the MAGIC asks about the "past month" as well as whether the child has "ever" had symptoms. The CAPA covers a "primary period" of 3 months, but it also notes whether certain uncommon symptoms (such as suicide attempts) have ever occurred, and a version that provides lifetime coverage of major episodes of certain syndromes is also available ([Simonoff et al., 1997](#)). The full DISC-IV can be used to assess either the last month or the last year, and it also offers a module to determine whether certain syndromes that did not occur during the preceding year had occurred at any point since the age of 5 years.

## SPECIFICATION OF QUESTIONS, INTERVIEWER FLEXIBILITY, AND THE DEFINITION OF SYMPTOMS

In a fully respondent-based interview such as the DISC, or the computerized version of the DICA, all questions are completely specified, and no others may be used. In other words, the questions are fully specified, there is no interviewer flexibility, and no need exists to provide definitions of symptoms. All variability in these features concerns the interviewer-based interviews.

The ADIS, CAPA, DICA, and MAGIC all contain questions that, under most circumstances, should be asked as written in the schedule. Additional questions are then asked as necessary to allow the interviewer to determine exactly whether the symptom is present. Many such questions are provided on the schedule of the CAPA, and fewer questions are provided by the CAS schedule (but it is not clear to what extent the "set" questions of the CAS are mandated for use). Most guidance on this process for the DICA and MAGIC is provided in the MAGIC's specifications manual. All these interviews provide at least some additional instructions about when to probe further. The K-SADS group of interviews provides a range of suggested questions but no formal rules about when they are to be used or skipped. Interviewers are also expected to ask any additional follow-up questions that may be necessary to clarify responses.

By *interviewer flexibility*, we mean the degree to which the interviewer is expected or encouraged to use judgment in asking additional clarifying questions. In this respect, the K-SADS and ISCA (and perhaps the ADIS) interviews may be seen as providing most flexibility because they demand that judgments based on clinical experience be made, and in the case of the K-SADS they do not mandate the use of any particular questions. The problem question is "flexible to do what?" The answer is relatively clear in the case of the K-SADS-P IV and the CAPA, in which detailed coding rules are provided for each symptom. The task of the interviewer is to determine whether those coding criteria are met. With the other interviewer-based instruments, it often seems that the interviewer's task's job is to obtain the answer to the *original question*. Variable amounts of guidance on how to do so are provided, in considerable detail in the MAGIC's specifications manual, with brief symptom definitions in the CAS, but with little or no guidance in the K-SADS-E or ADIS.

The K-SADS-P IV and the CAPA provide detailed *definitional* glossaries covering each symptom; this means that the task of the interviewer is quite clearly specified at the level of the *definition* of symptoms. The CAPA glossary also contains many procedural instructions relating both to questioning in general and to questioning about specific symptoms, but these are presented as being secondary to the definitional issues. The MAGIC's specifications manual can also be seen as being a glossary, but it is, first and foremost, a *procedural* manual. It is primarily about *how* to collect the information. In the course of this discussion of procedure, it also includes a good deal of definitional material, but it does not provide formal definitions of items such as found in the K-SADS-P IV or CAPA.

## RELIABILITY OF STRUCTURED DIAGNOSTIC INTERVIEWS

A difficulty with the literature on *reliability* is that the term is applied to several very different sorts of design and statistical approaches. Three of these are commonly seen in the literature on structured interviews, but only one presents a useful test of what one ultimately requires in a diagnostic interview. For instance, one often sees reports of *interrater* reliabilities in the interview literature. However, interrater reliability is not a very useful index of interview performance. With respondent-based interviews, it tests nothing but whether one interviewer can read aloud adequately while another codes a schedule. With such interviews, if interrater reliability is not in the high 0.9's, one should retrain or fire one's interviewers! In an interviewer-based interview, the questions are not fixed, and so different interviewers could use different questions to elicit the same information. Because the interrater reliability paradigm uses multiple raters to score the same interview, this major source of potential unreliability is eliminated, with the result that the interrater reliability is likely to substantially overestimate the reliability of the interview in actual use. However, if interrater reliabilities fall below about .8, that is an indication either that something is wrong with interviewer training or that the interview needs to be revised to provide greater clarity about what is supposed to be rated. The point is that if very high interrater reliability coefficients cannot be obtained, we can be certain that test-retest reliability will be poor.

*Internal reliability* is sometimes reported for scales resulting from diagnostic interviews. Typically, the statistic given is Cronbach's  $\alpha$ . This statistic provides a measure of the degree to which the items in the scale are correlated with one another. There are two problems with the use of such a statistic here. First, it has nothing to do with whether raters are coding items "reliably," but rather, it concerns the degree to which the items in a scale are all measuring the same thing. Second, a perfectly good diagnosis could be associated with low correlations among the symptoms that signal the presence of that diagnosis. Most medical (and psychiatric) diagnoses are more concerned with pattern recognition than with scalar values. For instance, in the general population, it is unlikely that dry eyes, dry mouth, and arthritis are very highly correlated with one another but that does not mean that Sjögren's syndrome is a bad diagnosis. Of course, if the task is to develop a scalar measure of some construct, then the scale's  $\alpha$  is important information. However, from the perspective of a diagnostic interview, low  $\alpha$  values are not necessarily a bad thing, nor are high  $\alpha$  values necessarily a good thing. It is entirely possible to have a perfect measure of a diagnostic entity where Cronbach's  $\alpha$  for the symptoms constituting that entity was close to zero.

Table 42.1 shows the results of studies of the *test-retest* reliabilities ( $k$  values) of diagnoses measured by the instruments considered in this chapter. Test-retest reliability is what is needed in judging an instrument. In the absence of reasonable test-retest reliability, all other reliabilities are moot. It can be seen that all the interviews that have been tested do a reasonably good job, and there is not much to choose among them, as far as test-retest reliability of diagnosis is concerned. These reliability coefficients are similar to those reported for psychiatric interviews with adults. Reliabilities for scale scores derived from these interviews are typically rather higher than they are for diagnosis, but that is nearly always true of comparisons between scale score reliabilities and the reliabilities of categories generated by imposing cut points on the same scales. Moreover, some of the unreliability of diagnostic measures is the product of the diagnostic system itself, thanks to its requirement that numerous unmemorable details about past psychopathology be considered. Particular problems have been identified with the reliability of responses concerning the duration of symptoms and the dates of their onsets (Angold et al., 1996a; Breton et al., 1995).

Table 42.1. Diagnostic Test-Retest Reliabilities (k values) of the Instruments Considered in This Chapter (Where Available)

Despite enormous efforts on the part of interview developers, it cannot be said that the reliability of diagnostic interviews has increased much over the years. We now have a fairly mature interview technology that has been repeatedly refined in the hope of increasing the reliability of assessments. The current arsenal of diagnostic interviews probably offers reliability that is as good as can be achieved unless quite different means of arriving at psychiatric diagnoses appear.

A problem with the test-retest assessment of reliability is that it requires that the interview be repeated within a short period of time. With both questionnaires and interviews, one typically finds that fewer symptoms are endorsed at the second interview than at the first (Angold et al., 1996b; Lauritsen, 1998; Lucas et al., 1999; Piacentini et al., 1999). There are many possible explanations for this effect (Jensen et al., 1992), but some evidence suggests that the results of the first interview are probably the most accurate representation of reality. The usual interpretation of test-retest reliability statistics, such as Cohen's  $k$  for categorical data (e.g., diagnoses) and the intraclass correlation coefficient for continuous data (e.g., scale scores), involves the supposition that the relationship between scores at the first interview and those at the second involves two components, agreement and random error. The presence of a *consistent difference* between first interviews and second interviews indicates that such statistics underestimate the "true" (and ultimately unmeasurable) reliability of both interviews and psychopathology scales.

## VALIDITY OF STRUCTURED DIAGNOSTIC INTERVIEWS

The problem with trying to assess the validity of psychiatric interviews is that there is no non interview test for most psychiatric disorders. The structured interview itself is the closest approximation we have to a current standard. So how are we to *validate* the diagnoses obtained from such interviews? This is a version of a problem that psychologists have been grappling with for decades; one that led to the concept of *construct validity*. The central idea here is that the validity of an instrument for the measurement of a psychological construct inheres not in some single agreement coefficient with one external standard, but in the instrument's performance within the *nomologic net* of theory and data concerning the construct or constructs that the instrument purports to measure (Anastasi, 1950, 1986; Cronbach and Meehl, 1955; Gulliksen, 1950; Jenkins, 1946; Novick, 1985; Peak, 1953; Wallace, 1965; Weitz, 1961). As Gulliksen pointedly remarked in 1950, "at some point in the advance of psychology it would seem appropriate for the psychologist to lead the way in establishing good criterion measures, instead of just attempting to construct imperfect tests for attributes that are presumed to be assessed more accurately and more validly by the judgment of experts" (Gulliksen, 1950).

Structured interviews were developed because of the dismal psychometric properties of unaided clinical diagnosis, so comparisons with unstructured clinical judgment (as may be found for instance in chart diagnoses) are hopelessly flawed tests of diagnostic interview validity. That has been obvious to interview developers for a long time, so validity studies have sometimes provided the clinicians with all the information from the interviews to be validated, in addition to allowing them to collect further information should they desire. In such a circumstance, it is often the case that *most* of the information available to the clinician comes from the interview under test. It will hardly be surprising, then, if there is good agreement between clinician and interview, but no real test will have been done.

In considering the validity of any interview, we should take a construct validation approach and describe what we currently know about it in relation to the nomologic net pertaining to child and adolescent psychiatric diagnosis. So far, only the developers of the CAPA have explicitly laid out the evidence for the validity of the CAPA using this approach, but most of the interviews considered here can point to similar chains of evidence. To give a flavor of the sort of evidence relevant to construct validation, the following findings have been adduced as construct validators of the CAPA:

1. Diagnostic rates and age and gender patterns of disorder given by the CAPA are consistent with those found using other interviews.
2. Patterns of diagnostic comorbidity are consistent with those found by other interviews.
3. Symptomatic diagnoses are associated with psychosocial impairment.
4. Parent and child reports of psychopathology on the CAPA are related to parent and teacher reports of problems on well-established scales for detecting psychopathology.
5. Children with CAPA-identified disorders use more mental health services than children without such diagnoses.
6. CAPA diagnosed children tend to come from families with a history of mental illness.

7. There is genetic loading for certain CAPA scales scores and diagnoses.
8. CAPA diagnoses show consistency over time.
9. CAPA diagnoses predict negative life outcomes ([Angold and Costello, 2000](#)).
10. Different CAPA diagnoses are differentially related to the physiologic changes of puberty ([Angold et al., 1999](#)).

There is, of course, a big drawback to this approach. No new interview will be able to point to such chains of evidence until it has been in use for quite a time. How then is any new instrument ever to be developed? The answer lies in the application of common sense and the well-established assessment principles. When a new assessment is needed, it is perfectly proper to use the best available information about the nature of the phenomena to be measured to design what seems, on the face of it, to be an adequate measure. Attention needs to be given to keeping questions short and focused on single constructs and to defining the task of the interviewer clearly and providing good definitions of the constructs to be studied in the case of interviewer-based interviews. If initial test-retest reliability is adequate, then, in general, it is unlikely that the interview will prove to be utterly invalid. Because it is very unusual to try to assess a construct that has been utterly unmeasured before, or about which nothing whatever is known, it is also usually possible to include in the test-retest study other measures that will give some indication of the concurrent, predictive, or divergent validity of the new instrument.

## ADVANTAGES AND DISADVANTAGES OF INTERVIEWER-BASED AND RESPONDENT-BASED INTERVIEWS

Neither interviewer- nor respondent-based interviews are ideal tools, and there is simply no answer to the question of which type is best. In this section, we list the general advantages of each type of interview, and the lack of each advantage can be regarded as a disadvantage of the other type. However, it is worth noting here that it has sometimes been said that respondent-based interviews are more appropriate for general population studies. Because it has now been shown that lay interviewers can provide reliable and valid ratings using interviewer-based interviews, this position is no longer tenable. Indeed, some larger-scale general population studies have used and are still using interviewer-based interviews ([Costello et al., 1996](#); [Lewinsohn et al., 1993](#); [Simonoff et al., 1997](#)).

### Advantages of Interviewer-Based Interviews

Interviewer-based interviews have four theoretical and practical advantages: (a) if the interview has been conducted and coded properly, the meaning of the ratings is precisely known; (b) they provide opportunities to cross-check discrepant or confusing information; (c) they enable the use of efficient open-ended questioning strategies and allow the use of redundant questioning, which has been shown in adults to improve the quality of responses; and (d) they appear to be less prone to overdiagnosis on the basis of symptom reports, so arbitrary impairment scale cutoffs do not have to be employed to produce reasonable diagnostic rates in unselected community samples.

#### WHAT DO THE CODINGS MEAN?

In an interviewer-based interview, a positive coding for a symptom means that it has been determined that the symptom, as defined in the schedule, is present. In a respondent-based interview, one knows only that a child or parent responded positively to a particular question. One does not know exactly what the child or parent understood the question to mean. This problem has been documented with unusual symptoms that most children never experience, such as obsessive-compulsive or psychotic symptoms. Such symptoms are greatly overreported using the DISC ([Breslau, 1987](#)). When clinicians review what the children said, it is obvious that what is being reported is not obsessive-compulsive disorder or psychosis. However, if an unstructured clinician review is added to the diagnostic process, one no longer knows exactly what factors have gone into the final rating, and one great advantage of the respondent-based interview is lost.

#### CROSS-CHECKING DISCREPANT OR CONFUSING INFORMATION

It is common in clinical practice to find that certain answers appear to contradict previously given information or lead to uncertainty about whether a symptom is present. In an interviewer-based interview, one simply attempts to clarify the contradiction or confusion. The respondent-based approach provides no such mechanism for resolving such difficulties, because interviewers are not allowed to exercise their judgment about such matters.

#### USE OF OPEN-ENDED AND REDUNDANT QUESTIONS

The distinction between open and closed questions is not absolute, but open questions are those that offer the chance to provide a wide range of answers or free-recall descriptions of phenomena, whereas closed questions call for one of a limited set of responses. For example, an open question in response to being told by a child that he had received a bad school report may be "How did you feel about your bad grades?" whereas "Did your bad grades make you feel unhappy?" would be a closed question. If a child had just admitted to stealing, responding with "Tell me more about that" involves an open question, whereas "What did you steal?" is a closed question. Basically, closed questions call for a yes or no answer or a date, frequency, duration, or other quite specific piece of information, whereas open questions give the opportunity for the child to provide a description of his or her feelings, which may or may not involve sadness or hostility. The work of Rutter and Cox and their colleagues offers some direct guidance on the best ways to use these different sorts of questions with adults, and in the light of the literature on children's memory, there is little reason not to use a similar approach with children. These investigators conclude that, in general, most factual information is collected when a systematic approach that relies heavily on open questions is used. This approach is also conducive to parental expressions of emotion, because it involves less talking on the part of the interviewer and gives more time for parents to discuss their concerns. Conversely, a noninterventionist approach results in the provision of less relevant information, whereas challenging interpretations and a confrontational style prove less effective in eliciting emotions ([Cox et al., 1981a, 1981b, 1981c](#); [Hopkinson et al., 1981](#); [Rutter and Cox, 1981](#); [Rutter et al., 1981](#)). Thus, open questions can be effective in collecting information efficiently, but, of necessity, respondent-based interviews must rely on closed questions. Conversely, closed questions are necessary to elicit information that is otherwise not forthcoming, and respondent-based interviews have been a substantial help to the developers of interviewer-based interviews in establishing well-thought-out logical structures for series of closed questions.

A redundant question is one that is asked more than once in different ways, that is, questions that contain two presentations of the same item, as in "Have you been more irritable than usual?" followed by "or made angry more easily?" The adult survey literature ([Cannell et al., 1977](#)) suggests that such redundancy is actually helpful in providing both additional time for thought and a second chance to detect symptoms. If the answer to one question is positive and the other is negative, that is no problem for an interviewer-based interview, in which follow-up questions can be used to clarify the situation. However, this cannot be done in a respondent-based interview, in which specific chains of questions in response to initially discrepant information are required. Collapsing the two questions into one is no help because this generates a "multiple question" that requires the respondent to remember and process the two parts of the question simultaneously.

#### REASONABLE RATES OF DISORDER ARE IDENTIFIED IN COMMUNITY SAMPLES WITHOUT RESORTING TO ARBITRARY IMPAIRMENT CUTOFFS

Rates of diagnosis based only on symptom reports have been found to be unreasonably high with the DISC. To correct this tendency, it is now usual to require that a diagnosis be allocated only when the score on the Child Global Assessment Scale (CGAS) is less than 60 (or sometimes 70, i.e., when notable psychosocial impairment is present). However, in most cases, the DSM-IV requires that either impairment or distress be present, not that significant impairment always be present. Furthermore, the typical impairment cutpoint of 60 was established because it generated what appeared to be sensible rates of diagnosis, not because anyone with a score of more than 60 is necessarily unimpaired. Because the K-SADS-P and the CAPA employ exacting definitions at the individual symptom level, community studies using these instruments do not need to apply additional rules about impairment to generate sensible rates of diagnosis.

### Advantages of Respondent-Based Interviews

We can also identify four advantages of respondent-based interviews: (a) less intensive training needs to be provided to interviewers, (b) a lesser level of quality control is required, (c) computer assisted and computer-administered interviews can more readily be developed, (d) computerized interviews offer the prospect of providing "preclinical" screening for use in clinical settings.

#### INTENSITY OF TRAINING

There is no doubt that an interviewer-based interview makes greater demands on an interviewer than does a respondent-based interview. For instance, training on the full CAPA package takes a month, compared with a few days for the DISC.

## QUALITY CONTROL

*Interviewer drift* occurs with respondent-based interviews and necessitates continuing quality control throughout a study, but it is unarguable that there is much more to check with an interviewer-based interview. Care must be taken not only that the interview is being conducted and coded properly, but also that mechanisms must be in place to ensure that interviewers continue to interpret the responses of interviewees correctly. Whether this additional burden is worth the effort depends on the situation in which the interview is being used.

## COMPUTERIZATION

A great advantage of the respondent-based approach is that it lends itself easily to computerization. Questions are arranged in unvarying logical sequences in such an instrument, with stem questions, followed by sequences of further questions contingent on the answers to the stems. Software is available to allow the presentation of such interviews on a personal computer. Computerization can be achieved at two levels. Computer-*assisted* psychiatric interviews (CAPI) employ an interviewer to read questions from the screen and to enter the appropriate codes into the computer as the interview progresses. The machine takes the interviewer to the appropriate stem questions and stores the responses in a database. There is no need for bulky interview schedules to be copied and carried around, and data entry is completed during the interview. Furthermore, the computer will not accidentally skip parts of the interview or vary the order of its presentation. The next level of computerization is referred to as computer-*administered* survey interviewing. Here, no interviewer is used at all. Rather, digitized audio recordings of the questions (sometimes even with digitized video of an interviewer) are played back by the computer as the written form of the question is displayed. The respondent enters a response to the question, which is saved to the database. The DISC has become progressively more complex since the 1980s (largely because of the ever-increasing complexity of the DSMs), and the DISC-IV is now supposed always to be completed in its CAPI format, because it is too difficult to administer it effectively in a paper-and-pencil format. There is also a CAPI version of the DICA, but this differs from paper-and-pencil version of the interview in being fully respondent based (Reich et al., 1995).

## PRECLINICAL SCREENING

We have reached the point at which it is feasible to have parents and children complete a diagnostic interview such as the DISC-IV before they see a clinician. The possible output from the DISC-IV is almost infinitely flexible and requires only programming to allow the production of reports tailored to particular clinical needs that can be generated immediately the interview is finished. Equipped with such a report, a clinician familiar with one of the interviewer-based interviews would then be starting with a very respectable initial diagnostic formulation to guide further elucidation of the clinical status of the child.

## AN APPROACH TO SELECTING A STRUCTURED INTERVIEW FOR RESEARCH OR CLINICAL PURPOSES

As we have already seen, reliability and validity quotients are little help in selecting the “best” interview, because there is little to choose among interviews in this regard. Similarly, all the interviews considered here take quite a long time to complete, and the length of all these interviews is proportional to the symptoms manifested by a child. None has been shown to be notably shorter than any other in practice, and so reported mean interview durations are also no help in selecting an interview for any particular application. Rather, the key to selecting an interview is to be very clear about what that application demands. This means having thought through what the ideal interview for that application would be like, so the characteristics of each can be matched against that criterion. It is also worthwhile to prioritize these demand characteristics in advance. It may not be possible to have everything, so it is a big help to have thought through the relative impact of different tradeoffs. In the following sections, we consider some questions that prospective interview users should ask themselves as part of the process of selecting an interview:

### Question 1: What Content Areas Need to Be Covered?

All interviews do not cover all diagnoses. (Indeed, none covers all possibly relevant diagnoses.) It is essential in the first instance to decide what areas must be covered and what additional areas would be nice to have, but are not essential.

### Question 2: What Assessment Time Frame Is Needed?

The addition of a lifetime frame involves either compromising the assessment of current or recent symptoms (as with the K-SADS-PL) or combining a short time frame interview with a separate lifetime interview, which results in a very long assessment. If one is conducting a 3-month follow-up assessment after treatment, an interview that focuses on diagnostic status over the last year will not be very helpful.

### Question 3: What Sort of Interviewers Will Be Available?

In general, clinicians are not enthusiastic about using a respondent-based interview because they have to follow a fixed schedule of questions, and it provides no means to collect more detailed information that may be relevant to a variety of treatment decisions. So it makes sense for them to use one of the interviewer-based interviews. Such interviews can also be very useful clinical training tools, because they provide excellent models for the clinical interviewing process.

If lay interviewers are to be used, then the K-SADS family of interviews may not be the best choice because these interviews have all been developed for use by clinicians and provide less guidance for the training of lay interviewers. No reliability data on their use with lay interviewers are available. Conversely, the CAS, CAPA, DICA, and ADIS were all developed for use with trained lay interviewers and have been shown to have acceptable reliability in their hands. All these interviews are also acceptable to clinicians.

### Question 4: What Are the Age and Developmental Levels of the Children to Be Assessed?

It is clear that “adult-style” diagnostic interviews (all the interviews considered in this chapter fall into this category) with preschool children are a waste of time, because they simply cannot provide all the information required by the DSM-IV or ICD-10 diagnostic criteria. Several groups are working on this problem at present, but none of the instruments reviewed here is of any use for very young children. The K-SADS and DICA are said to be suitable for face-to-face use with children down to the age of 6 years, but others doubt that a *full* diagnostic interview really works with children younger than 8 or 9 years old, unless the interviewer simply “goes off interview” to obtain a relatively impressionistic view of the child’s symptoms. Even the interview with the parent requires substantial modification for preschoolers. We do not recommend the use of any of these instruments in face-to-face interviews with children less than 8 or 9 years old. Special versions of the DICA and CAPA for use with younger children are currently under development, but their feasibility and reliability remain to be determined. Picture-enhanced interviews such as the Dominic-R may be suitable for children as young as 6 years old, but even here, reliability appears to be somewhat lower with younger children, and such interviews do not generate full diagnoses. The same problem applies to older persons with substantial intellectual deficits. When an individual’s IQ is less than 70, it becomes very difficult to complete a full diagnostic interview. Interviews with parents and teachers may still be conducted, but we know little about their performance characteristics in such circumstances.

At the other end of the “juvenile” age range (late adolescence and early adulthood), the researcher or clinician has the choice of shifting to an “adult” measure or using an age-appropriate modification of a child interview (e.g., the YAPA).

### Question 5: How Much Can I Afford to Spend on Training and Quality Control?

“Spend” here refers to both time and money. If less than a week is available, then none of the interviewer-based interviews is suitable, because good training for them demands a greater time investment. However, DISC training can be provided in as short a time as this because the DISC requires far less of interviewers. Conversely, when amortized over the life of a study or clinical program, initial costs for training usually turn out to be only a small percentage of the total costs, so good training on an interviewer-based interview may constitute a good investment.

Once the interview is over, the DICA and CAPA both expect that it will be reviewed for appropriateness of codings. In addition, regular (both recommend weekly) continuing training sessions for interviewers are required to prevent interviewer drift. Are funds and personnel available to support such continuing quality control and training procedures? The CAS and K-SADS interviews do not appear to have standard recommendations for quality control and continuing training, but there is no

reason to suppose that data quality and consistency are any easier to maintain with these instruments. Because the DISC-IV is computerized and the DISC interviewer's task is much less arduous than that required of interviewers using any of the interviews considered in this chapter, it demands less effort to control interviewer drift.

### **Question 6: What Needs and Resources Do I Have for Data Entry and Manipulation of the Data?**

The K-SADS family of interviews produces diagnoses through the medium of score sheets completed by the interviewer and scored by that person to produce diagnoses. The CAS provides formal algorithms for making diagnoses that can be implemented either by the interviewer or by a computer. The CAPA offers only computerized algorithms because its developers (like those of the DISC) believe that the process of producing a final diagnosis from a large array of symptom data is of such complexity that errors are bound to occur if humans do it unaided. These different approaches to producing a final diagnostic formulation have very different implications for data entry and manipulation. If the computer is to make the diagnoses, then all the symptom information must be entered (this task easily runs to hundreds or thousands of variables per case), and diagnostic algorithms must be available. If the clinician makes the final diagnosis, then one could simply enter only that information (or not computerize any data at all in a clinical setting in which the interview is being used just as a clinical assessment whose results appear only in the medical record). The CAPA is probably the interviewer-based instrument that makes the most demands on data entry (because of its molecular approach to symptom severity), so it has extensive data entry, checking, and diagnostic programs. Even so, one must budget for setting up and training people in the use of these programs. Once these demand characteristics have been determined, one can begin the task of actually selecting an interview:

#### **Action 1: Review the Available Instruments and Make a Shortlist**

It may seem surprising that we place a review of available measures so late in the process. There are two reasons for doing this. First, the choice of measure should depend on the nature of the application, not the other way around, so until the application has been well defined, the issue of instrumentation is moot. Second, once one has answered questions 1 to 6, a brief review of instruments may indicate that only one is even remotely suitable. To put it another way, it is more efficient to decide which interview to use relatively late in the process, because one may be able to save a lot of time that would otherwise have been spent in considering instruments that cannot meet the needs of the study. If there seem to be several possibilities, one has at least reduced the number of instruments that need to be considered to a shortlist for further evaluation.

#### **Action 2: Obtain Copies of the Instruments on the Shortlist and Conduct a Detailed Evaluation**

Unfortunately, there is absolutely no substitute for obtaining copies of the instruments still left on the shortlist and reviewing them in detail. The manifold differences among instruments make it impossible to provide more than a flavor of what an interview is like in a review chapter such as this. It is worth remembering that you will be asking the interview developers to send several hundred pages of schedules, glossaries, instruction manuals, and the like, and these will need to be paid for. At this stage, it should be possible to make a final choice, but if there are still questions that have not been answered in all these materials, a telephone call to someone in the relevant interview development group can be very helpful. If this "homework" is been done, it is also likely to be well received.

#### **Action 3: Plan Training Well Ahead of Time**

It is not unknown for an interview developer to receive a request such as the following: "Hello, I put the \_\_\_\_\_ in a grant proposal, and the funding has just come through. I need you to train my interviewers next month." Interview developers have busy research and clinical lives, and they cannot provide training programs at a moment's notice. The time to be setting a hopeful date for training is *when the grant proposal is submitted*, not after it has been reviewed and funded.

## **FUTURE DIRECTIONS**

A great deal of work has gone into producing the interviews we have today, and there is little sign that recent efforts to "improve" such measures further have had much effect on their reliability. Of course, as we learn more about psychopathology, we will need to modify our measures' content to reflect what we need to measure, but the basic principles used to design new or revised modules will not change in the foreseeable future (and will work just as well or poorly as they do today). What is needed now is to extend the range of structured assessments down to younger ages. There is astonishingly little research on preschool psychopathology, for instance, and it was only in 2000 that the first structured parent-report diagnostic interview specifically designed for use with this age group became available. It remains to be seen how information from the child and caretakers other than parents can usefully be integrated into diagnostic assessments, but work has begun in this area. Newer "self-report" assessments of the mental status of the child that do not tie themselves rigidly to current diagnostic criteria show great promise for the future. For instance, with the MacArthur Story-Stem Battery ([Warren et al., 1996, 2000](#)), the interviewer uses toys to act out the beginnings of stories, which the child is then asked to complete. The videotapes of these interactions are then scored to provide indices of a variety of internal states. The Berkeley Puppet Interview employs two puppets to express two moods or states, and the child indicates the puppet most like himself or herself, thereby providing self-report assessments of perceived academic functioning, social relationships, depression, anxiety, and aggression or hostility. Some simpler questionnaires with pictures have also shown promise with preschoolers in relation to the assessment of depression and anxiety ([Ialongo et al., 1993](#); [Martini et al., 1990](#)).

Now that many diagnostic measures are available, it is likely that they will move progressively into ordinary clinical practice. It seems strange that the unstructured clinical interview has been almost entirely supplanted for research purposes because of its well-documented inadequacies as a diagnostic procedure, but it continues to be the main assessment tool in clinical practice, in which good phenomenologic assessment is surely of the greatest importance. All clinicians dealing with psychopathology can benefit from training on an interviewer-based structured interview (particularly one of the glossary-based interviews), and it is to be hoped that such training will soon become part of all training programs for psychiatric clinicians. However, it must be admitted that the time to conduct a full psychiatric assessment is not always available, and when that is the case, it would be helpful to have shorter interviews available to serve as screening tools. At the time of writing, work is happily beginning on a version of the DISC to fulfill this function. The idea here is not to force slavish dependence on any particular structured interview on clinicians, but to use the strengths of standardized interviews to underpin their explorations of the nature and meaning of psychopathology. Our understanding of psychopathology and of its measurement has come a long way, and it is time to bring the benefits of what are still typically regarded as being research assessment methods to all of our patients and clients.

[Chapter References](#)

Psychological testing conducted by a trained clinical psychologist is a method of obtaining developmentally informed, concrete, and standardized data regarding a person's capacities and behavior in a wide variety of domains (Allison et al., 1968; Sparrow et al., 1985, 1995). The domains that are most pertinent to the assessment of children and adolescents include intellectual ability, educational accomplishment, language skills, visual-motor coordination, adaptive behaviors, and personality functioning (Sparrow et al., 1985). (See Chapter 40 for further information on infant assessment.)

In clinical practice, psychological assessment constitutes an important type of inpatient or outpatient consultation. Historically, when done as an inpatient procedure, psychological testing has often been part of a comprehensive, multidisciplinary workup aimed at facilitating long-term treatment. In such circumstances, referral questions may be broad, to contribute to the overall understanding of a patient. Test data are typically integrated with findings from other relevant disciplines. Although such long-range inpatient treatment is still conducted in some sites, recent developments in national health care practices have dramatically reduced the typical length of inpatient stay. To keep pace with these developments, psychologists in these settings have had to respond with flexible, creative approaches to more time-efficient assessment. Careful choices must be made among the test instruments discussed in this chapter to answer highly specific referral questions. More comprehensive psychological assessment often must be deferred until after the patient has been discharged to a less restrictive treatment setting.

Although the foundation of inpatient psychological assessment has been modified, as noted earlier, the basic approach to outpatient assessment has remained fairly constant. Therefore, to articulate most clearly the discrete phases of a comprehensive psychological evaluation, this chapter is organized to reflect the typical flow of an outpatient consultation. Accordingly, the chapter first addresses the identification of appropriate referral questions and the preparation of the child or adolescent patient and of the parents. Choice of assessment procedures and of instruments and test administration are then discussed, with emphasis on recent contributions to the test library. This discussion particularly reflects recent activity in the psychoeducational evaluation of attention deficit hyperactivity disorder (ADHD) and in infant assessment. The chapter then focuses on developments in test interpretation and concludes with a discussion of issues involved in the communication of findings.

### REFERRAL QUESTIONS

To ensure that psychological assessment is most efficacious, the testing should be directed at specific referral questions. Appropriate referral questions facilitate the psychologist's choice of test instruments and, on analysis of the test data, help to determine which are the relevant issues. When not guided by particular questions, the testing often yields general information that lacks the precision necessary to be of clinical utility. Relevant referral questions are often formulated by the referring clinician. When the referring clinician is uncertain about the focus of the testing, consultation with the psychologist may help to articulate referral questions. For children and adolescents, the referral questions are also often designated by parents who make direct requests for psychological assessments.

The many different suitable referral questions for psychological assessment may be grouped into several areas. First, for the very young child, clinical psychological testing offers answers to pressing questions regarding the progress of development. Many times, parents, pediatricians, educators, and mental health professionals form impressions and concerns about the rate and nature of a youngster's development. Testing compares the individual child to age-mates, provides a reliable indicator of developmental level, and permits the substantiation or modification of such assumptions. Such assessment is most useful in the identification of developmental disorders and the sequelae of neurobehavioral insult from sources such as lead poisoning. It also highlights the need for early interventions that may greatly improve a child's and a family's long-term quality of life.

Second, for the school-age child and adolescent, psychological testing provides a more reliable estimate of intellectual capacity than does clinical impression. Often, a clinical estimate of a child's intelligence level based on self-presentation can be misleading. Interpersonal behaviors may be confusing or disturbing if they seem discrepant with the person's apparent level of intelligence. This is particularly true when a youngster's verbal skills are quite different from his or her other intellectual abilities. Intellectual assessment also serves as a foundation on which to base evaluation of other areas of functioning. In this regard, intellectual capacity, as defined by most intelligence measures, is both a global characteristic and the interaction of several specific subdomains. As elaborated on later in regard to choice of test procedures, each intelligence test is constructed based on a particular characterization of global intelligence and the more specific skills of which it is composed. Although some children's intellectual endowment is relatively consistent across these diverse areas, many children display quite striking intellectual strengths and weaknesses. Psychological testing makes a major contribution to clinical care by elucidating the child's strengths and weaknesses and by identifying the ways in which they are manifested in behavior.

In clinical work with children and adolescents, it is often most useful to compare and contrast measured intelligence with results of individualized academic achievement testing. Appropriate academic achievement testing samples accomplishments in reading, arithmetic, spelling and written language, and more specialized skill areas as they may pertain to individual patients. Comparison of intellectual with academic test results allows the psychologist to respond to referral questions regarding the presence of learning disabilities. It is to be expected that academic achievement levels will be commensurate with intelligence levels (Kaufman and Kaufman, 1983; Sattler, 1988). When these levels are inconsistent, with academic achievement statistically significantly higher than intellectual levels, it is likely that the person has expended extreme effort to attain educational goals. It is also possible, although less common, that the person's true intellectual potential is greater than his or her measured intelligence. In contrast, when academic achievement levels are significantly lower than intelligence levels, the child may be considered learning disabled in one or more areas of academic functioning. It is critical to note that diagnosis of a learning disability denotes an inborn information-processing problem requiring particular special educational techniques (Kaufman and Kaufman, 1983; Sparrow and Blackman, 1985). In cases of learning disability, psychological test findings form the basis for educational placement and programming recommendations.

Clinical psychological assessment may also respond to questions regarding psychodiagnosis and psychotherapeutic treatment of children and adolescents. Use of projective test materials and of projective indicators on other instruments makes it possible to elucidate specific areas of psychopathology to aid in diagnosis. Very specific differential diagnoses can be considered, such as documentation in an adolescent of a thought disorder or an affective disorder, or differentiation between psychotic functioning and extreme anxiety in a younger child.

Once a diagnosis has been established, psychological assessment can also assist in treatment. Psychological test results can assist in the selection of the type of therapy to be attempted. For example, information regarding the integrity of a child's thought processes would be helpful in determining the appropriate level of the therapist's supportive activity in promoting the child patient's psychological insight (Pine, 1985). For a case in which testing provides assurance of solid, realistic thinking, intensive therapy may be attempted with confidence. In contrast, therapy would best be approached more cautiously and combined with more comprehensive services after testing that indicated frankly compromised reality orientation.

Similarly, test findings may help to predict the course of treatment. Test data about a youngster's degree of relatedness would help to foresee the child's likely response to a developing therapeutic alliance. For example, documentation of a child's association of intimacy with aggression would prepare a therapist for that youngster's psychological distancing after establishment of a close therapeutic relationship. Test results may also help to address a treatment impasse. Frequently, psychological assessment identifies patient characteristics that were less prominent earlier, attention to which would facilitate progress in otherwise stalled treatment.

Such identification is most helpful in highlighting the severity of disturbances that were previously considered less serious or remained unrecognized.

Psychological testing is also useful to answer very practical questions regarding disposition planning and program eligibility. Many programs designed to meet the special needs of certain children and adolescents, such as classes for the intellectually gifted, services for the retarded, and residential treatment centers, require documentation of need based on psychological assessment results. For children with less unusual needs, psychological test results can also assist with grade placement decisions. With disposition planning in mind, a psychological test battery can be designed efficiently.

## **PREPARATION OF PATIENT AND PARENTS**

For psychological testing to be most useful, the patient should be prepared adequately. With children and adolescents, such preparation typically begins with the parent. When the testing referral comes from another educational or mental health professional, the preparation should be initiated by the referring professional and should be completed by the psychologist.

The referring professional's preparatory function can be divided into three parts. First, the purpose of the testing should be explained to the parents in a clear, forthright manner. Referral questions should be discussed in nontechnical language so parents have a good understanding of the need for consultation. Second, the referring clinician should clarify his or her own ongoing relationship with the patient and parents, apart from the work with the testing psychologist. If the referring professional will continue to work with the child and family after the testing, this should be explained. If the testing referral actually constitutes a transfer to the psychologist for care, this, too, should be explained carefully. The usefulness of psychological testing is compromised severely when parents are confused about the psychologist's role in the provision of care. Finally, pragmatic directions should be provided about how to make contact with the psychologist for the assessment consultation. This sort of direction increases the likelihood that the referral will proceed smoothly.

Preparation of the young patient follows directly from parental preparation. Parents should be encouraged to share the preparatory information with their child and should present information in an honest, open manner appropriate to the child or adolescent's developmental level. In many cases, it is most helpful if the referring clinician assists the parents with this task. Several factors should be emphasized. First, it should be stressed that the testing is being pursued in an effort to provide relevant interpersonal or educational help to the child or adolescent, rather than as a means of being derogatory or punitive. Second, especially with younger children, it is helpful to assure the patient that the psychologist is a "talking doctor" who will not perform any physically invasive procedures. Preparation of the youngster best concludes with assurance that the psychologist will provide complete instructions, guidance, and assistance throughout the assessment.

Even when the patient is well and fully prepared, he or she usually meets the psychologist for the first time with considerable anxiety and denies receiving any information about the assessment to be completed. As part of establishing the necessary testing rapport, the psychologist should reiterate the preparatory information, instruct the child about testing procedures, and move on to carrying out the assessment. In most cases, careful preparation and establishment of initial rapport provide sufficient comfort to enable the youngster to cooperate easily in the collection of reliable and valid test data.

## **PSYCHOLOGICAL TESTING IN RELATION TO CHANGES IN THIRD-PARTY PAYMENT**

In referring patients for psychological testing and in carrying out that testing, clinicians must be aware of changing regulations governing third-party payment. With the more traditional indemnity insurance plans that were prevalent in previous years, decisions about provider, timing, and extent of testing rested with the relevant professionals and the youngster's parents. Likewise, the financial aspect of the psychological testing remained a matter to be agreed on between parents and provider, with the parents later seeking insurance reimbursement as dictated by the terms of their specific insurance policy. Referring clinicians were rarely involved in any financial negotiations regarding psychological testing.

In contrast, with the advent of health maintenance organizations and a wide variety of managed-health care plans, many administrative and financial decisions central to the testing process came under the control of insurance company representatives. Provider choice, preapproval of particular test instruments, specification of number of hours allowed for testing, access to confidential information, and regulation of allowable fees came to be dictated by the insurance companies and their managed-care associates.

In the current insurance climate, it is necessary for clinicians to be cognizant of insurance regulations when they make testing referrals. If use of insurance support is essential to the performance of the testing, clinicians must conform to rules governing choice of psychologist and referral procedures. To be granted access to insurance benefits, referring clinicians must also formulate highly specific referral questions and must specify how the questions will be addressed and to what use the answers will be put.

In some cases, useful psychological testing can be conducted under current insurance conditions. In many cases, however, more current insurance regulations constitute undue interference in the clinical testing process. The most qualified psychologists may not participate in a given plan. Instruments and number of hours approved may not allow for a sufficient response to referral questions. Confidentiality may be sacrificed in potentially damaging ways. If it is at all possible for a family to pursue testing without using insurance coverage, the referring clinician may do well to recommend a private agreement between parents and psychologist to ensure a higher quality of care.

## **TEST ADMINISTRATION**

This section reviews salient test procedures, psychometric issues, and examples of commonly used assessment instruments for each of the functional domains noted earlier. Although it is not an exhaustive list, the instruments included are those that the relevant literature and clinical experience have demonstrated to be of value in constructing test batteries that respond to most referral questions for psychological assessment.

### **Procedures**

#### *BATTERY COMPOSITION*

After clarification of the referral question, the child psychologist is faced with the task of making an initial determination about which instruments will comprise the assessment battery. In rendering this determination, the psychologist must weigh the wish to obtain the most comprehensive possible data with such realistic matters as the need for expeditious completion of the battery, the child's developmental capacity to withstand the rigors of testing, and developmental variables pertaining to the individual child's functioning across domains to be assessed ( [Goldman et al., 1983](#); [Siegel, 1988](#)). The psychologist then must consider adjusting the battery composition as emerging test data refine the known referral question or suggest new questions ( [Sattler, 1988](#)). For instance, if a child's performance on screening measures of academic achievement indicates deficits in acquisition of grade-appropriate reading skills, more intensive examination may be required to specify whether the child's deficits are more attributable to problems with reading decoding or reading comprehension.

#### *ADMINISTRATION*

The length of time required for a child to complete a test battery depends on certain variables, including the complexity of the referral question and the associated number of required test instruments, the child's capacity to sustain work on focused tasks, and the family's cooperativeness in keeping scheduled appointments. As a rule of thumb, experienced psychologists expect that the administration of a comprehensive psychoeducational assessment battery requires four to six sessions of from approximately 60 to 90 minutes each. Scoring test protocols absorbs an additional 1 to 2 hours of the psychologist's time.

Because the goal of testing is generally to obtain a picture of the child's maximum capacity, the psychologist must be certain of sufficient rapport to ensure the child's best effort. To accomplish this aim, the examiner employs the clinical skills, used by most clinicians in evaluating children, that serve to allay the child's anxiety and enlist cooperation in completing the tasks at hand. At the same time, however, the psychologist must bear in mind the distinguishing hallmarks of the psychological assessment enterprise, which are the acquisition of data in a structured setting using appropriate standardized measurements ( [Sparrow et al., 1985](#)). The psychologist must therefore be certain that the establishment of rapport does not violate standardized administration procedures permitting comparison of the child's test performance with those of the normative sample.

Although the principal focus of this chapter is on psychological assessment in outpatient settings, it was noted at the outset that changes in the current health care

climate have compelled psychologists working in inpatient settings to address creatively the need for more time-efficient testing that does not sacrifice the integrity of the testing process. In constructing appropriate test batteries in such settings, it is critical to define the limited number of specific questions to be addressed and to confine inferences accordingly. Typically, appropriate questions for testing under these conditions focus on ruling out major intellectual and psychiatric deficits or disorders (e.g., mental retardation and psychosis). A sample battery to fulfill these needs may include five subtests (Information, Vocabulary, Similarities, Block Design, and Picture Completion) from the Wechsler Intelligence Scale for Children, third edition (WISC-III) (Wechsler, 1987b), the Vineland Screener ( [Sparrow et al., 1994a, b](#)), and the Rorschach test ( [Rorschach, 1921](#)). Each of these instruments is discussed later in this chapter.

## Psychometric Issues

An extensive literature exists pertaining to technical and methodologic principles associated with psychological assessment ( [Anastasi, 1988](#); [Sattler, 1988](#); [Sparrow et al., 1984](#)). To judge the utility of assessment instruments, this literature can be distilled to three concepts: validity, reliability, and standardization.

### VALIDITY

An instrument's *validity* concerns the extent to which it measures what it purports to measure. In summarizing the Standards of Educational and Psychological Testing ( [American Psychological Association, 1985](#)), [Anastasi \(1988\)](#) found that the many methods for determining validity can be organized into three principal groups. An instrument possesses *content-related validity* to the extent that its item content covers a representative sample of the measured domain, a validation issue typically considered in evaluating achievement tests ( [Anastasi, 1988](#)). If an instrument is effective in predicting an person's performance in specified activities, it is said to possess *criterion-related validity*. This form of validity is determined by checking test performance against a direct and independent criterion measure of that which the test is supposed to measure, for instance, by comparing scholastic aptitude test scores with grades obtained in college. Finally, a test's *construct-related validity* refers to the test's capacity to measure a theoretical construct on which the test is based. Derived from documented interrelationships among behavioral measures, this form of validation requires the accumulation of various types of information, including correlations with other tests and statistical techniques such as factor analysis and measurements of the test's internal consistency.

### RELIABILITY

An instrument's *reliability* refers to the degree to which results obtained from the instrument can be reproduced within acceptable levels of agreement. The most commonly required measures of consistency for a psychological test are that its scores can be reproduced over time (*test-retest reliability*) and across examiners (*interrater reliability*). An additional estimate of reliability that is frequently reported is *interitem consistency*, or the consistency of responses to all items in the test ( [Anastasi, 1988](#)). This form of reliability provides information about the degree of homogeneity of the domain which the test is purported to sample and is typically reported in the form of reliability coefficients (either the Kuder-Richardson coefficient for dichotomous responses or Cronbach's coefficient  $\alpha$  for continuous responses) ( [Cronbach, 1951](#); [Kuder, 1937](#); [Novick and Lewis, 1967](#)).

### STANDARDIZATION

To be well *standardized*, an instrument should be pretested on a large, demographically representative sample of subjects. Comparison of a given child's performance on a test with an appropriate standardization group can occur only if such standardization has been conducted ( [Sparrow et al., 1985](#)). Such comparisons provide a context for understanding the child's test performance from a developmentally informed perspective and permit more powerful inferences about strengths or deficits documented in the child's testing.

## Commonly Used Assessment Instruments

The tests presented in this section ( [Table 43.1](#)) are organized according to the functional domain assessed (i.e., intellectual ability, academic achievement, visual-motor functioning, adaptive behavior, attentional capacity, personality organization, neuropsychological functioning, and developmental status). The discussion of each test includes a description of its purpose, format, and appropriate subjects, as well as commentary about the types of scores derived, administration time, psychometric properties, and unique features.

**Table 43.1. Commonly Used Child and Adolescent Psychological Assessment Instruments**

### MEASURES OF INTELLECTUAL ABILITY

#### *Wechsler Intelligence Scale for Children, Third Edition (WISC-III)*

Like its two predecessors, the original WISC ( [Wechsler, 1949](#)) and the WISC-R ( [Wechsler, 1974](#)), the WISC-III ( [Wechsler, 1991](#)) is a downward extension of adult intelligence scales ( [Wechsler, 1955, 1981](#)). In its revision published in 1991, it remains the most widely used individually administered intelligence test for children in the age range for which it was designed, 6 years to 16 years, 11 months. The WISC-III provides several welcome improvements, including updated and more culturally sensitive test items, more user-friendly materials (such as larger color, as opposed to black-and-white, stimulus cards for the Picture Arrangement subtest), and a restandardization providing more contemporary and psychometrically sound norms and standard cores. The WISC-III consists of 13 subtests divided into a six-subtest Verbal scale and a seven-subtest Performance scale (for a description of the 12 subtests retained from the WISC-R and capacities tapped by each, see [Sattler, 1988](#)). The Verbal Scale is composed of the Information, Similarities, Arithmetic, Vocabulary, Comprehension, and Digit Span subtests, and the Performance Scale includes the Picture Completion, Picture Arrangement, Block Design, Object Assembly, Coding, Symbol Search, and Mazes subtests. Symbol Search is a subtest developed for the WISC-III and is designed to measure processing speed. Administration time for the total instrument is approximately 60 to 90 minutes.

The instrument was constructed on the notion that intelligence may be defined as a person's overall capacity to understand and cope with the world ( [Wechsler, 1991](#)). The author emphasizes that this definition requires an assessment instrument that appreciates the global nature of intelligence and that avoids placing undue emphasis on any one ability in assessing overall intellectual capacity. The subtest tasks therefore attempt to challenge a child's abilities in a broad variety of ways, to provide a fuller estimate of capacity. Tasks require children to answer verbal queries and to work several types of visual or visual-motor puzzles.

The test generates Full Scale, Verbal, and Performance intelligence quotient (IQ) scores, individual subtest scaled scores, and test-age equivalents. Factor analytic research has been conducted and summarized in the manual ( [Wechsler, 1991](#)), and it reveals four principal factorial underpinnings of the WISC-III: Verbal Comprehension (Information, Similarities, Vocabulary, and Comprehension), Perceptual Organization (Picture Completion, Picture Arrangement, Block Design, and Object Assembly), Freedom from Distractibility (Arithmetic and Digit Span), and Processing Speed (Coding and Symbol Search). To facilitate scoring and interpretation, the WISC-III provides easy computation of Index Scores for each of these factors.

Interpretation of the test protocol requires several levels of analysis ( [Kaufman, 1979](#); [Sattler, 1988](#)), including placing of the global IQ scores into ranges of intellectual functioning ( [Table 43.2](#)), calculating the significance of any difference between Verbal and Performance IQ scores, comparing the Verbal Comprehension, Perceptual

Organization, Freedom from Distractibility, and Processing Speed index scores, determining the presence of significant individual relative subtest strengths and weaknesses, conducting comparisons of individual subtest scores, and appreciation of the quality of individual item responses. This approach to profile analysis permits generation of hypotheses about cognitive strengths and weaknesses based on statistically significant differences among scores.

Standard Score	Level
130+	Very superior
120-129	Superior
110-119	High average
90-109	Average
80-89	Low average
70-79	Borderline
50-69	Mild retardation
40-49	Moderate retardation
20-39	Severe retardation
Below 20	Profound retardation

**Table 43.2. Commonly Used Intelligence Classification**

The psychometric properties of the WISC-R have been extensively researched, and this research base provides a foundation for the psychometrics of the WISC-III. Reliability is reportedly outstanding (Sattler, 1988; Wechsler, 1974; Wechsler, 1991), with steadily strong internal consistency reliability coefficients (Sattler, 1988; Wechsler, 1974). Sattler also summarizes the plethora of research studies that, collectively, document the instrument's satisfactory concurrent, criterion, and construct validities (Sattler, 1988).

*Wechsler Intelligence Scale for Children, Third Edition as a Process (WISC-III PI)*

A newer test instrument, the WISC-III as a process (WISC-III PI) is designed for use along with or after completion of the WISC-III (Kaplan et al., 1999). Aiming to provide greater insight into the processes by which children or adolescents (ages 6 years, 0 months to 16 years, 11 months) carry out cognitive functions, the WISC-III PI consists of a variety of subtests. Some of these subtests are essentially alternate scoring or administration procedures for standard WISC-III subtests. Others are variations of WISC-III subtests intended to illuminate a range of ways to gain access to cognitive information. Finally, some new subtests are designed specifically for the WISC-III PI to measure cognitive operations related to those on existing WISC-III subtests. Coauthored by well-respected experts in the fields of neuropsychology and psychological assessment, the WISC-III PI makes it possible to investigate low WISC-III scores, to obtain a more detailed summary of a child's strengths and weaknesses, to assist with diagnostic decisions, to help monitor progress, and to support intervention planning. The examiner chooses those parts of the WISC-III PI most relevant to a specific youngster. Standardized scores, percentiles, and age equivalents are derived and are normed to be comparable to most psychoeducational tests in common use. Reliability and validity of the WISC-III PI are good and allow for confident use of the instrument. As educators increasingly request information about students' cognitive processing abilities, in addition to their cognitive levels, the WISC-III PI should gain wider usage.

*Wechsler Adult Intelligence Scale, Third Edition (WAIS-III)*

As noted earlier, the WISC-III represents a downward extension of Wechsler's theories of assessing adult intelligence. The most recent revision of the adult instrument is the Wechsler Adult Intelligence Scale, third edition (WAIS-III), published in 1997 (Wechsler, 1997a). The WAIS-III retains the formulations of the original WAIS but provides more current normative data, updated test content and materials, and improved administration procedures. The format of the WAIS-III is similar to that of the WISC-III in that the test yields Verbal, Performance, and Full-Scale IQ scores along with four Global Index Scores, Verbal Comprehension, Perceptual Organization, Working Memory (a score comparable to the WISC-III Freedom from Distractibility Index), and Processing Speed. These Global Indices are, in turn, based on scores on 14 subtests. Eleven of these subtests are retained from the WAIS-R; three subtests are new. Like the WISC-III, the WAIS-III now also has a Symbol Search subtest to measure efficiency of visual scanning and recognition. The WAIS-III also now includes Matrix Reasoning, a test of nonverbal inferential reasoning ability, and Letter-Number Sequencing, a measure of auditory attention and working memory. Test profile analysis on the WAIS-III is similar to that on the WISC-III. Like the WISC-III, the WAIS-III has excellent statistical properties (Wechsler, 1997a).

The WAIS-III is appropriate for use with persons between the ages of 16 and 89 years. This instrument may therefore be employed in testing adolescents who are more than 15 years old. The age ranges of the WISC-III and the WAIS-III overlap between the ages of 16 years and 16 years, 11 months. Sattler states that a more thorough sampling of ability can be obtained with the children's instruments when it is used with children of below-normal ability in the overlapping age range (Sattler, 1988). For normal and gifted children, however, both instruments provide adequate sampling.

*Wechsler Preschool and Primary Scale of Intelligence—Revised (WPPSI-R)*

Published in 1989, the Wechsler Preschool and Primary Scale of Intelligence—revised (WPPSI-R) (Wechsler, 1987) is a revision of the original WPPSI (Wechsler, 1967), a further downward extension of the Wechsler scales for use with children between the ages of 3 years and 7 years, 3 months. Several significant improvements have been incorporated in the revision to address concerns and limitations raised about its predecessor. For instance, the WPPSI-R age range represents an extension of approximately 1 year both upward and downward. To provide greater comparability to the WISC-III, the WPPSI-R adds a 12th subtest (Object Assembly) to the WPPSI's 11 subtests. Eight of the subtests (Information, Vocabulary, Arithmetic, Similarities, Comprehension, Picture Completion, Mazes, and Block Design) are also found on the WISC-III, whereas three subtests (Sentences, Animal House, and Geometric Design) were developed exclusively for the WPPSI and have been retained in the revision. New items and changes in design intended to enhance interest among young children have made the revision more user friendly. In the tradition of the other Wechsler scales, the WPPSI and WPPSI-R possess well-documented reliability and validity and are standardized adequately (Anastasi, 1988; Sattler, 1988; Sparrow et al., 1985; Wechsler, 1967; Wechsler, 1987). The interpretation of results follows the same course as noted earlier.

*McCarthy Scales of Children's Abilities (MSCA)*

As noted by Kaufman and Kaufman (1977), the McCarthy Scales of Children's Abilities (MSCA) (McCarthy, 1972) comprise a welcome instrument appropriate for the assessment of children between the ages of 2 years, 6 months and 8 years, 6 months. Its 18 subtests are clustered into five domains (Verbal, Perceptual-Performance, Quantitative, Memory, and Motor), and also allow for the calculation of a General Cognitive Index, which serves as the equivalent of the Full-Scale IQ on the Wechsler scales. Administration time is approximately 45 to 60 minutes, depending on the subject's age. Particular advantages of the MSCA are its fine standardization and psychometrics, ease and enjoyment of administration for both examiner and subject, and direct measurement of fine and gross motor skills and acquisition of eye, hand, and leg dominance, which are of particular importance in this age group (Sattler, 1988; Sparrow et al., 1985). The MSCA does not include tasks tapping social judgment. To compensate for this shortcoming, Kaufman and Kaufman encourage administration of the appropriate subtest of the WPPSI-R or WISC-III (Kaufman and Kaufman, 1977; Kaufman and Kaufman, 1983).

As discussed, the MSCA has had a well-earned place among good measures of children's intelligence. At this point, however, the test is quite old and is not widely used. To return to wider use, a thorough revision of the test would be required.

*Kaufman Assessment Battery for Children (K-ABC)*

The Kaufman Assessment Battery for Children (K-ABC) (Kaufman and Kaufman, 1983) measures the cognitive abilities of children between the ages of 2 years, 6 months and 12 years, 5 months. The K-ABC differs from other assessment instruments in its purpose and its theoretical basis. The test attempts to distinguish between a child's acquired knowledge (Achievement) and intellectual capacity as understood from the perspective of cognitive processing abilities. The K-ABC is firmly rooted in theories of cognitive psychology and neuropsychology, which posits that intelligence should be understood in terms of a child's relative facility in processing simultaneously or sequentially presented information. The processing of these different forms of information is understood to require different cognitive styles and to draw from different lateralized hemispheric brain functions, with sequential processing primarily associated with left-brain functioning and simultaneous

processing with activities in the right hemisphere. Reliability levels are highly acceptable and numerous validation studies have appeared in print. The standardization sample closely matches the 1980 U.S. Bureau of the Census data for age, gender, race, geographic region, community size, and socioeconomic status.

The K-ABC requires approximately 45 to 75 minutes of administration time. Its 10 mental processing subtests are divided into Sequential Processing (Hand Movements, Number Recall, and Word Order) and Simultaneous Processing (Magic Window, Face Recognition, Gestalt Closure, Triangles, Matrix Analogies, Spatial Memory, and Photo Series) Scales. A Mental Processing Composite score can be derived from these subtest scores that is equivalent to a Full-Scale IQ score on the Wechsler scales. Six subtests (Expressive Vocabulary, Faces and Places, Arithmetic, Riddles, Reading/Decoding, and Reading/Understanding) contribute to the Achievement Scale. The number of subtests administered varies according to the child's age.

Clinical experience indicates that because of its Mental Processing and Achievement scale construction, the K-ABC provides an efficient means of comparing a child's intellectual capacity and level of academic achievement, a comparison at the core of assessment of learning disability. Conversely, although research has suggested possibilities for richer profile interpretation ( [Kamphaus and Reynolds, 1987](#)), K-ABC profile interpretation does not possess the same heuristic value as the Wechsler scales to generate hypotheses about the interplay between intrapsychic conflict and selective ego deficits. Additionally, critics have labeled the distinction between mental processing ability and acquired knowledge faulty because of the test's artificial distinction between the ways in which children acquire and process information ( [Sattler, 1988](#)).

Since its first publication, the K-ABC has proved to be a well-accepted and useful test instrument for children and adolescents. Over time, several of the items have become outdated, however. In particular, items on the Faces and Places subtest, a test of general factual knowledge, have fallen out of popular awareness and are no longer commonly recognized. At the time of this writing, the K-ABC is being updated to allow it to remain a valuable test instrument.

#### *Kaufman Adolescent and Adult Intelligence Test (KAIT)*

As outlined in an interview with Alan Kaufman presented in Kamphaus' *Clinical Assessment of Children's Intelligence* ( [Kamphaus, 1993](#)), the Kaufman Adolescent and Adult Intelligence Test (KAIT) is an instrument that derives its theoretical foundation from three sources: the Cattell–Horn theory of fluid and crystallized intelligence; Piaget's concept of formal operational thinking; and Luria and Golden's articulation of the planning functions of the prefrontal lobes ( [Kaufman and Kaufman, 1993a](#)). The Cattell–Horn theory is the primary of these three sources and guides the test's organization into Fluid and Crystallized scales. These scales measure novel problem-solving skills and knowledge derived from acculturation and education, respectively. This theoretical construction is developmentally informed and has received strong empirical support, because research has consistently demonstrated that crystallized skills are maintained throughout the life span, whereas fluid skills plummet after peaking in young adulthood. As is true of the Kaufmans' other published tests, the KAIT is well standardized and reports very strong reliability coefficients. Additionally, the authors report construct validity through correlations with other commonly used intelligence tests (WISC-R, WAIS-R, K-ABC), and through studies with a variety of adult clinical populations.

The KAIT is designed to be administered efficiently, requiring only 60 minutes for its Core Battery of six subtests. An Expanded Battery, including four additional subtests, can be used for further clinical or neuropsychological assessment, and customized assessment can be obtained by selecting from among any or all of these additional subtests. The Core Battery's three-subtest Fluid Scale consists of Rebus Learning, Mystery Codes, and Logical Steps, and the Crystallized Scale is composed of Auditory Comprehension, Double Meanings, and Definitions. The Expanded Battery subtests are Memory for Block Design, Famous Faces, Rebus Recall, and Auditory Recall. The 10 subtests provide age-based scaled scores, and global IQ scores are generated for the Fluid Scale, Crystallized Scale, and Composite Intelligence.

Preliminary clinical experience with the KAIT indicates that the instrument is challenging to both administrator and subject and should not be administered without substantial practice on the part of the examiner. Test items often prove difficult for adolescents with less intellectual ability, and examiners may wish to administer another instrument in conjunction with the KAIT, to be most confident of test findings.

#### *Kaufman Brief Intelligence Test (K-BIT)*

Requiring an administration time of 15 to 30 minutes, the Kaufman Brief Intelligence Test (K-BIT) ( [Kaufman and Kaufman, 1990a, b](#)) is designed to provide a quick estimate of intelligence, either as an indicator for, or alternative to, a comprehensive intelligence test. The individually administered test can be used across a very wide age span, ranging from 4 to 90 years, and can be administered by trained nonpsychologists. The K-BIT consists of a Vocabulary subtest, which measures word knowledge. The first part of the subtest is administered to all ages and requires an oral label for pictured objects. The second part of the Vocabulary subtest requires the subject to name a word based on a brief description and partial spelling of the word. This second part of the subtest is administered only to persons age 8 years and older. The K-BIT also contains the Matrices subtest, which measures nonverbal intellectual reasoning ability. A strength of the test, which it shares with the K-ABC, is that the examiner is allowed to teach during administration of the early items, to ensure that the subject's best abilities are tapped. The K-BIT yields standard scores normed to be comparable to the major, commonly used full intelligence and academic achievement tests and is easily interpretable. As is true for other tests authored by the Kaufmans, the K-BIT norms are derived from a representative normative sample stratified to conform to the U.S. Bureau of the Census figures. Furthermore, the test rests on a very sound statistical foundation and boasts excellent reliability and validity. Clinical practice bears out the test authors' assertions regarding the utility of the test. The K-BIT serves a very useful purpose in providing easy access to a trustworthy estimate of a person's intellectual ability level. This easy access is particularly valuable among persons who find it difficult to tolerate full administration of a longer intelligence measure.

#### *Leiter International Performance Scale—Revised (Leiter-R)*

Development of the original Leiter International Performance Scale ( [Roid and Miller, 1997](#)) began in the 1920s. Developed by Dr. Russell Graydon Leiter, the first commercial version of the test was published in 1940. Designed to provide a comprehensive measure of nonverbal intelligence, the original Leiter Scale was used widely for the assessment of diverse populations. Over the years, however, the test materials became outdated, and comparability of Leiter scores with scores on other major test instruments was limited. In addition, it became clear that the Leiter Scale could benefit from application of more modern statistical methods of test construction. Accordingly, Gale H. Roid, Ph.D., and Lucy J. Miller, Ph.D., revised the test. As currently constructed, the revised Leiter Scale (Leiter-R) is designed to measure nonverbal intelligence in persons from 2 years to 21 years of age. On the Leiter-R, nonverbal intelligence is defined as fluid reasoning, visualization, visuospatial memory, attention, and memory. Presented in a tabletop easel format and consisting of attractive, contemporary materials, the Leiter-R is made up of two main groups of subtests, Visualization/Reasoning and Attention/Memory. The test also includes behavior rating scales that capture behavioral observations made during testing. Administered on an individual basis, the Leiter-R can be used in whole or in part, depending on individual needs. The full battery of Leiter-R subtests requires approximately 90 minutes for completion. A full range of standardized scores and percentiles can be derived on the Leiter-R. Standardized on a nationally representative sample, the Leiter-R has good reliability and validity. Given its long history of valuable use and the integrity of its current construction, the Leiter-R should be considered as a valuable tool for the assessment of persons with significant verbal communication difficulties associated with cognitive disorders, developmental disorders, hearing impairments, motor impairments, traumatic brain injury, attentional disorders, learning disabilities, and examiner–subject language incompatibility. The Leiter-R has particular utility for lower-functioning persons on the autistic spectrum. Because the test requires no verbal output from the subject and a minimum of interpersonal interaction, persons on the autistic spectrum are often able to demonstrate more ability on the Leiter-R than they would on other, more traditional instruments.

#### *Stanford-Binet Intelligence Scale, Fourth Edition (SB:FE)*

The Stanford-Binet Intelligence Scale, fourth edition (SB:FE) ( [Thorndike et al., 1986](#)) represents the latest revision of an instrument whose modern history dates back to 1916 and whose roots extend back to at least 1905. This version represents a significant departure from the 1937 Forms L and M and the 1960 Form L-M, for which revised norms were provided in 1972. A three-level theoretical model guided the construction of the instrument and postulated the following: a general intelligence factor (g) at the highest level of inference; a second level of factors, including crystallized, fluid, and short-term memory; and a final level comprising more specific factors such as verbal, quantitative, and abstract visual reasoning. Traditionally, a major advantage of the Stanford-Binet test has been its broad age range, permitting more accurate assessment of persons functioning at either extremely low or high cognitive levels. A significant criticism of the SB:FE is its lack of a comparable battery throughout the scale's age range, meaning that scores obtained by children at different ages are based on different subtest combinations ( [Sattler, 1988](#)).

Administration time for the SB:FE may be quite long, in some cases exceeding 2 hours, because the instrument includes only a single timed subtest. This is a significant drawback for use of the test. The 15 subtests of the SB:FE are divided into four larger areas: Verbal Reasoning (consisting of the Vocabulary, Comprehension, Absurdities, and Verbal Relations subtests); Abstract/Visual Reasoning (Pattern Analysis, Copying, Matrices, and Paper Folding and Cutting); Quantitative Reasoning (Quantitative, Number Series, and Equation Building); and Short-Term Memory (Bead Memory, Memory for Sentences, Memory for Digits,

and Memory for Objects). Standard scores are generated for the subtests, the four areas, and a Composite Score similar to the Wechsler IQ score. Because later factor analytic studies did not support the original factorial structure of the test, [Sattler \(1988\)](#) suggests an alternate, more valid set of factor scores and means of computation. The psychometric properties of the test are very good, with excellent reported reliability. The SB:FE is well standardized on a population similar to that of the 1980 U.S. Bureau of the Census, and weighting procedures are used to ensure maximum conformity to census data. Many validation studies summarized by [Sattler \(1988\)](#) conclude that the SB:FE and the Wechsler scales yield similar scores for subjects in the average range of cognitive functioning, but the SB:FE may produce lower scores for gifted or mentally retarded subjects. Because of the limitations noted, clinical experience suggests that the employment of other instruments (Wechsler scales, MSCA, and K-ABC) be ruled out before using the SB:FE.

#### *Peabody Picture Vocabulary Test, Third Edition (PPVT-III)*

A revision of the earlier PPVT-R ([Dunn and Dunn, 1981](#)), the PPVT-III was designed for persons between the ages of 2½ and 9< years. The Peabody Picture Vocabulary Test, third edition (PPVT-III) ([Dunn and Dunn, 1997](#)) is an individually administered, untimed test intended to measure receptive vocabulary and to serve as a screening instrument of verbal ability. The test is available in two forms: PPVT-III-A and PPVT-III-B. Each form includes four training items and 204 test items. Each of the test items consists of four black-and-white pictures arranged on a page contained in a tabletop easel. For each item, the examiner states a word, and the test subject must designate the picture that best matches the spoken word. Thus, the test is very easy to administer, requires only about 11 to 12 minutes to complete, and is easily scored. The PPVT-III yields standard scores, percentiles, normal curve equivalents, stanines, and age equivalents. Well standardized on a nationally stratified representative sample, the test has excellent reliability and validity. When it is used in conjunction with the Expressive Vocabulary Test (EVT), discussed later, it is possible to derive comprehensive information about a person's single-word vocabulary. Finally, because the PPVT-III is brief, simple to administer, and requires only a pointing response from the subject, it often serves as a good "ice-breaker" when a full test battery is to be administered.

#### *Expressive Vocabulary Test (EVT)*

The EVT ([Williams, 1997](#)) is a measure of word retrieval and expressive vocabulary designed for use with persons between 2½ and 9< years of age. Administered on an individual, untimed basis, the test consists of teaching items and 190 test items. Contained in a tabletop easel, items are divided into an early picture labeling section and a larger, later section that requires the subject to supply a synonym for a stated word accompanied by a picture. Like the PPVT-III, the EVT is simple to administer, requires only 10 to 25 minutes to complete, and is easily scored. The statistical properties of the test are excellent in that it is normed on a nationwide sample stratified to conform to the latest U.S. Bureau of the Census figures, item bias is analyzed and inappropriate items are eliminated from the test, reliability and validity are very good, and the test yields standard scores, percentiles, normal curve equivalents, stanines, and age equivalents that are comparable to those of most other major intellectual measures. The EVT is a very useful tool for screening expressive language problems, determining school readiness, gaining a better understanding of reading difficulties, monitoring development, and assessing progress in mastering English as a second language. In addition, because of its wide age range, the test has great utility for research.

An added attraction of using the EVT is that it is conormed with the PPVT-III. This conorming allows for direct comparison of expressive and receptive vocabulary skills. A significant difference between PPVT-III and EVT scores is to be understood as an index of word retrieval skill.

### *MEASURES OF ACADEMIC ACHIEVEMENT*

#### *Kaufman Survey of Early Academic and Language Skills (K-SEALS)*

The Kaufman Survey of Early Academic and Language Skills (K-SEALS) ([Kaufman and Kaufman, 1993b](#)) fills an important need in the assessment of 3- to 6-year-old children. Although little formal academic knowledge is expected of such young children, it is often useful to assess youngsters' progress in acquiring a foundation of preacademic knowledge. The K-SEALS serves exactly this function. Individually administered in approximately 15 to 25 minutes by both professional and trained nonprofessionals, the K-SEALS consists of three subtests: Vocabulary, a measure of word knowledge; Numbers, Letters, and Words, a test of early recognition of letters and numerals, knowledge of relative quantity and size, and early reading and math skills; and Articulation, a test of skill at pronouncing words correctly. All subtests use pictorial cues on a tabletop easel and require oral responses. Across subtests, the test distinguishes between receptive and expressive skills, as well as between letter and word, as opposed to number, skills. To facilitate easy comparisons between K-SEALS scores and other commonly used intelligence and achievement tests, the test yields standard scores, percentiles, classifications, and age equivalents normed in the same way as most of the other measures. The K-SEALS boasts excellent psychometric properties, that is, good reliability, fine validity, and relative lack of racial, ethnic, or gender bias.

#### *Woodcock-Johnson Psycho-Educational Battery—Revised*

The revised form of the Woodcock-Johnson Battery was published in 1989 ([Woodcock and Johnson, 1989](#)). The revision offers organizational, procedural, psychometric, and scoring improvements as well as new subtests. Although this revised version, like the original Woodcock-Johnson Battery, was published to provide an estimate of both intellectual capacity and academic achievement, it is not currently viewed as a major competitor with the cognitive assessment instruments listed earlier ([Sattler, 1988](#)). Rather, the Tests of Achievement comprising Part II of the Battery are more commonly used to estimate levels of scholastic accomplishment. The Achievement section of the battery measures reading decoding and comprehension skills, math reasoning and calculation skills, written language skills, and knowledge of specific subject areas (science, social studies, and humanities). In clinical practice, most extensive use is made of the Reading, Mathematics, and Written Language Clusters. Although efficient to administer, the instrument is cumbersome to score and, for many psychoeducational purposes, has been supplanted by the Kaufman Test of Educational Achievement (K-TEA) and the Wechsler Individual Achievement Test (WIAT), as discussed later. A third edition of the Woodcock-Johnson Battery has been published too late for review in this chapter.

#### *Wide Range Achievement Test, Third Edition (WRAT 3)*

Earlier versions of the Wide Range Achievement Test (WRAT), the original WRAT and the WRAT-R ([Jastak and Wilkinson, 1984](#)), were used for many years as brief screening instruments for identifying academic skills deficits ([Anastasi, 1988](#); [Sattler, 1988](#)). The current version of the test, the WRAT 3, was published in 1993 ([Wilkinson, 1993](#)). The 1993 restandardization aimed at retaining the ease of administration and reliability of the earlier editions of the test while updating the norms and making it possible to use the WRAT 3 for pretesting and posttesting of academic accomplishments. Accordingly, two equivalent forms of the test were designed for use with persons from 5 years, 0 months through 74 years, 11 months of age. Each form can be administered separately or in conjunction with one another. Both forms consist of three subtests: Reading, a quick measure of decoding skills; Spelling, a test of the ability to write letters and words from dictation; and Arithmetic, a test of basic computational skill. The test requires 15 to 30 minutes to complete and yields standard scores, grade equivalents, percentiles, and normal curve equivalents. The statistical properties of the WRAT 3 are sound, allowing the test to be used with confidence. The strength of the WRAT 3 is that it requires only a brief time to provide a solid assessment of academic skills. Because of its brevity, however, some academic domains receive shorter shrift; that is, there are no measures of reading comprehension or grasp of math word problems. As a result, the WRAT 3 is best used when administration time is a critical factor or when only a basic estimate of academic functioning is required.

#### *Kaufman Test of Educational Achievement (K-TEA), Brief and Comprehensive Forms*

The K-TEA ([Kaufman and Kaufman, 1985](#); [Kaufman and Kaufman, 1998a, b](#)) is a well-standardized screening instrument for assessing academic achievement in children 5 through 18 years of age. It is easy to administer and score, and it takes approximately 30 minutes to complete. Five subtests are included: Reading Decoding, Reading Comprehension, Mathematics Applications, Mathematics Computation, and Spelling. The Comprehensive Form provides a systematic approach for evaluating errors, which is of potential use to clinicians interested in devising curricular interventions to address skills deficits but which is also cumbersome for most examiners. The Brief Form, with a reduced item sample, is appropriate for most psychoeducational applications. Because it provides data about a child's functioning across domains of most general interest, possesses a reasonable item sample and good psychometric properties, and is easy to administer and score, the K-TEA has proven to be the academic achievement screening instrument of choice for children in its age range, especially when the test is used in conjunction with the MSCA or the appropriate Wechsler scale. Although there is some overlap of items between the K-ABC and the Achievement section of the K-TEA, each test does make a unique contribution to the assessment of a child's level of educational accomplishment. For instance, the K-TEA Reading subtest provides a wide range of item difficulty and permits a more refined assessment of reading skills. Conversely, the K-ABC Faces and Places and Riddles subtests assess aspects of acquired knowledge not tapped by the K-TEA.

The K-TEA has become a widely used academic achievement test. In 1997 and 1998, the test norms were updated to improve the statistical properties of the test further and to address intervening changes in curriculum and educational practices, demographics of the population, and overall cultural transitions. In comparing

original and updated norms, it appears that overall student performance improved in the years after the first publication of the K-TEA. As a result, a higher performance level is required to earn a particularly high score using updated K-TEA norms.

#### *Wechsler Individual Achievement Test (WIAT)*

An addition to the available library for the individual assessment of academic achievement, the WIAT ([Wechsler, 1992](#)) is designed to accompany the Wechsler intelligence scales. The instrument was developed for use with children in kindergarten through grade 12, and aged 5 years through 19 years, 11 months. The test requires approximately 30 to 60 minutes to administer the comprehensive battery, depending on age, although a briefer core battery can be administered as a screening instrument in approximately 15 minutes. The WIAT is well standardized and has the advantage of being conormed on the populations used to standardize the Wechsler intelligence scales, thus enhancing the psychologist's confidence in inferring discrepancies between intellectual ability and level of achievement. The Screener comprises three subtests: Basic Reading, Mathematics Reasoning, and Spelling. In conjunction with these three subtests, five additional subtests are included in the Comprehensive Battery: Reading Comprehension, Numerical Operations, Listening Comprehension, Oral Expression, and Written Expression. The last three subtests provide welcome data not typically available in academic achievement tests, and they permit a richer sample of a child's receptive, expressive, and written language functioning that may be contributing to academic performance deficits. Because of these unique aspects and its conorming with the most commonly used intelligence tests (the Wechsler scales), the WIAT has become a significant alternative to the K-TEA.

#### *Oral and Written Language Scales (OWLS)*

The OWLS ([Carrow-Woolfolk, 1996](#)) comprise a measure of receptive and expressive language, both oral and written, in children and adolescents. The test consists of three scales: Listening Comprehension, a measure of receptive understanding; Oral Expression, a test of skill at answering questions, completing sentences, or generating original verbal expression; and Written Expression, a measure of skill at using both the conventions of written language and linguistic forms, as well as skill at communicating meaningful ideas. Whereas tests such as the PPVT-III and EVT assess single-word vocabulary, the OWLS test also examines connected language and linguistic concepts. The oral language scales are for use with persons from the age of 3 through 21 years, whereas the written language scale is for use with subjects 5 through 21 years old. Administered individually, all scales can be used, or the examiner can select the specific scale needed to understand a particular youngster best. Administration time varies according to number of scales completed but generally ranges from half an hour to 1 hour. The OWLS test is standardized on a representative national sample and possesses good reliability and validity. It can be used with confidence to identify learning disabilities, to guide educational interventions, to monitor academic progress, and to contribute to research. The Written Expression Scale is particularly useful. Although there are many easily administered and easily scored measures of oral language, written language measures other than the OWLS tend to be more cumbersome, time consuming, and uninteresting to the subject. In contrast, the relative brevity, ease of administration, and variable item type of the OWLS makes it a much more pleasant instrument to use in assessing written language skill.

### **MEASURES OF ADAPTIVE BEHAVIOR**

#### *Vineland Adaptive Behavior Scales*

A revision of the Vineland Social Maturity Scale ([Doll, 1965](#)), the Vineland Adaptive Behavior Scales ([Sparrow et al., 1984](#)) assess personal and social sufficiency. A semistructured interview is conducted by a trained examiner with a respondent familiar with the subject. Four functional domains are assessed: Communication, Daily Living Skills, Socialization, and Motor Skills (up to age 4 years, 11 months). Domain scores, in turn, generate an Adaptive Behavior Composite. An additional checklist taps behaviors typically construed as maladaptive. The three forms of the instrument are the Survey Form, the Expanded Form, and the Classroom Edition. The Survey Form contains approximately half the items of the Expanded Form, requires approximately 1 hour to administer, and has proved sufficient for the purposes of most clinicians. The Expanded Form divides many of the skills on the Survey Form into discrete steps to be mastered and thus offers valuable programming assistance for work with low-functioning persons. The Classroom Edition is designed to be completed by a child's teacher in approximately 20 minutes and does not require an interview with the teacher. The strongest criticism leveled to date against the Vineland Scales is that there is apparently substantial fluctuation of means and standard deviations across age groups, thus limiting the extent to which the instrument can be used for longitudinal comparisons ([Silverstein, 1986](#)). In clinical practice, however, the scales have proved to provide an excellent estimate of adaptive behavior, which is of significant value in developing a fuller picture of a child's psychosocial functioning. As development of the *Diagnostic and Statistical Manual of Mental Disorders* proceeds toward publication of the fifth edition, it is anticipated that assessment of adaptive functioning will become even more central in psychiatric diagnosis. Thus, it should be expected that the utility of the Vineland Scales in clinical practice will increase.

With this anticipated increase in demand in mind, and to meet current demands for expedited assessment, the Vineland Screener was developed ([Sparrow et al., 1994a, b](#)). Although aimed at research needs with large subject pools, the Vineland Screener's high correlation with the full Vineland test and clinical requirements have led to its increasing use in clinical settings as well. The Screener is administered in the same semistructured interview format as the Survey and Expanded forms of the Vineland Scales. Key items have been selected from the full instrument to allow for speedier administration. Screener raw scores are then equated with raw scores on a fuller version of the Vineland Scales to serve as the basis for the calculation of derived scores. Although in use for a relatively short period, the Vineland Screener has demonstrated its usefulness both in research and in inpatient treatment settings, in which accommodation to shortened hospitalizations has become mandatory.

In the tradition of the original Vineland Social Maturity Scale, the Vineland Adaptive Behavior Scales have become a highly valued instrument in assessing a wide variety of referral questions. The Vineland Adaptive Behavior Scales have been translated into numerous languages and used around the world to document levels of personal and social self-sufficiency. As technology and societal practices change, however, types and standards of adequate adaptive functioning also change. For the Vineland Scales, changes such as the increasing academic, job, and leisure use of personal computers and widespread ownership of cellular phones have necessitated updating and revision of many items. As this chapter is written, a comprehensive revision of the Vineland Adaptive Behavior Scales is under way.

#### *Scales of Independent Behavior (SIB)*

The Scales of Independent Behavior (SIB) ([Bruininks et al., 1984](#)) comprise an individually administered measure of personal and social sufficiency across a broad age range. As opposed to the Vineland Scales, this test is not administered by a semistructured interview and permits estimates of the adaptive behavior functioning of nonretarded adults. In most cases, data are collected from an informant, but the person being assessed may also serve as the respondent. The SIB test was developed to be used in conjunction with the Woodcock-Johnson Broad Cognitive Ability Cluster Score to provide an efficient estimate of both adaptive ability and intellectual capacity. Research questioning the validity of the Cluster Score ([Sattler, 1988](#)), however, requires that clinicians proceed with caution in using these two instruments for the purposes advocated by the authors. The SIB test consists of 14 subtests that produce four adaptive behavior (Motor, Social Interaction and Communication, Personal Living, and Community Living) and three maladaptive behavior (Internalized, Asocial, and Externalized) clusters. The adaptive behavior clusters, in turn, generate a Broad Independence summary Cluster Score. The full SIB test requires approximately 1 hour of administration time, but a 15-minute Short Form has also been developed.

### **MEASURES OF ATTENTION AND CONCENTRATION**

Most recently, increased research and clinical attention have been aimed at gaining a more comprehensive understanding of ADHD. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* ([American Psychiatric Association, 1994](#)) summarizes much of the current thinking about this multifaceted disorder.

Advancement in knowledge about this disorder has been accompanied by a need for psychological test data to assist with differential diagnosis. Often, clinical psychologists have relied on indicators embedded in a traditional test battery to help confirm or rule out the diagnosis of ADHD. Such indicators have included behavioral observations in the test setting, Hand Movements performance on the K-ABC, Digit Span scores on the WISC-R, and, more recently, the Freedom from Distractibility Scale on the WISC-III. More currently, however, instruments have been developed that can allow for more direct determination of the accuracy of the ADHD diagnosis. The rationale for administering a variety of instruments is to ascertain the subject's capacity to marshal attention and concentration in response to stimuli presented through different sensory input modes and requiring different forms of response. This cluster should be administered and interpreted as part of a standard, thorough, psychoeducational assessment. Findings of attentional difficulty should be used to place a child accurately in an attentional, behavioral, academic, or emotional diagnostic category or to make the diagnosis of comorbid difficulties.

Given that ADHD is a difficulty in attending to a focused task on demand amid competing stimuli, it should not be surprising if ADHD symptoms do not manifest in the

controlled atmosphere of the psychologist's office. Accordingly, in addition to direct evaluation of the child or adolescent, data must be gathered from multiple observers in settings where the child encounters situational demands that make the emergence of ADHD symptoms more probable. To accomplish this task, relevant instruments can be administered to parents, teachers, and the identified child or adolescent. These instruments are discussed here, organized according to the particular informant or subject.

#### *Child and Adolescent*

**Controlled Word Association Test.** This test ([Benton and Hamsher, 1978](#)) was designed originally as part of the Benton Battery and was used for assessment of aphasia. In a 1-minute period, the subject is required to say as many acceptable words as possible beginning with a specified letter (i.e., F, A, or S). Successful completion requires continued attention. Average response scores are tabulated for each of the three specified letters and for the test as a whole. Normative data are available for children and adolescents ([Gaddes and Crockett, 1975](#)). Percentile scores can be calculated. To make valid interpretations of attentional capacity on this test, accurate information must also be available about the subject's level of knowledge about letter-sound combinations.

**Trail Making Test.** Derived from the Army Individual Test Battery ([U.S. Army, 1944](#)) and revised by [Reitan \(1971\)](#), this is a widely used and popular instrument ([Reitan, 1971](#)) requiring the subject to connect a series of numbered circles in Part A and a series of alternating numbers and letters in Part B under timed conditions. Most pertinent to assessment of ADHD, the test requires sustained concentration for successful completion. Normative information is available in the neuropsychological literature ([Spreen and Gaddes, 1969](#)), including means, standard deviations, medians, and score ranges.

**Wisconsin Card Sorting.** Designed originally in the 1940s and modified in the 1980s ([Heaton, 1981](#)), this test ([Berg, 1948](#); [Grant and Berg, 1948](#)) requires the subject to sort given cards into appropriate piles. The criteria for proper assignment must be determined by the subject using feedback provided either by the examiner directly or by a computer program. Attention to relevant card attributes, sustained concentration, and mental flexibility are all essential for successful task completion. Percentiles, T scores, and standard scores may all be derived from the raw scores.

**Computerized Tests.** Assessment of a child's or adolescent's ability to maintain attention and concentration on a somewhat monotonous, continuous performance task is helpful in the diagnosis of ADHD. Such computerized tests as VIGIL ([Cegalis and Volin, 1991](#)) and PASAT ([Cegalis and Birdsall, 1992](#)) are appropriate choices for this purpose.

#### *Parent*

**Behavior Assessment System for Children (BASC), Parent Rating Scales.** A relatively new addition to the collection of instruments available for assessment of childhood behavior, the BASC ([Reynolds and Kamphaus, 1992](#)) offers a comprehensive, structured assessment of a child's behavioral functioning across a variety of domains. Most salient in this discussion, the BASC contains an Attention Problems and a Hyperactivity Scale, as well as other clinical scales to help provide greater certainty in differential diagnosis. Test authors assert that the BASC is useful in diagnosing attentional deficit disorders with and without hyperactivity (Reynolds and Kamphaus, 1993). Parents are asked to rate 131 behaviors as occurring never, sometimes, often, or almost always. A full range of derived scores, including standard scores, percentiles, and age equivalents, may be derived.

**Home Situations Questionnaire—Revised (HSQ-R).** One of several behavior checklists popularized by Barkley and his colleagues ([Barkley, 1991](#)), the HSQ-R ([DuPaul, 1991a](#)) is a 14-item list of behaviors denoting attentional or concentration problems as they may manifest in home activities, such as riding in a car, playtime, social visiting, and attending religious services. Parents are asked to rate each behavior as either present or absent. If the behavior is rated as present, the parent is asked further to rate its severity. The scale yields total scores as well as factor scores differentiating between difficulty in compliance versus leisure situations. Means and standard deviations are provided. Scores more than 1.5 standard deviations above the mean for the age and sex of the child are considered indicative of diagnosable attentional difficulty.

**Attention Deficit Hyperactivity Disorder (ADHD) Rating Scale.** Another of the scales popularized by Barkley and his colleagues ([Barkley, 1991](#)), the ADHD scale ([DuPaul, 1991b](#)) is composed of 14 items. Each item refers to a problematic behavior suggestive of attentional problems. The parent is asked to rate the degree to which each behavior noted describes the individual of concern. Rating choices are not at all, just a little, pretty much, and very much. Again, the scale yields a total score and factor scores. Factors on this scale are Inattentive-Hyperactive and Impulsive-Hyperactive. Means and standard deviations are provided. These values are interpreted just as they are on the HSQ-R discussed earlier.

#### *Teacher*

**Behavior Assessment System For Children (BASC), Teacher Rating Scales.** The teacher form of the BASC ([Kamphaus and Reynolds, 1993](#)) is quite similar to the parent form in aim, format, scoring, and psychometric properties. The content of the scales is directed to relevant school-based situations, such as adjustment to new teachers, completion of assigned tasks, and disruptiveness of others.

**School Situations Questionnaire—Revised (SSQ-R).** Completed by teachers, this test ([DuPaul, 1991c](#)) is a parallel instrument to the HSQ-R described earlier. One of the instruments used by Barkley and those working with him (1991), the SSQ-R is an 87-item scale. Items refer to school-based settings and ask the rater to note the presence or absence of attentional difficulty in each setting and to rank the severity of the difficulty from mild to severe. Total scores and mean severity ratings are derived, and these scores are then compared with normative means and standard deviations. As on the other Barkley scales, scores more than 1.5 standard deviations above the mean are considered significant for ADHD.

**Attention Deficit Hyperactivity Disorder (ADHD) Scale.** This instrument ([DuPaul, 1991b](#)) is described earlier and is appropriate for use by teachers as well as parents. Whereas the parent completes the form to describe behaviors witnessed at home, the teacher targets school-based behaviors in completing the form.

**Child Attention Profile (CAP).** The CAP ([Edelbrock, 1991](#)) is a 10-item scale also popularized by Barkley and his group of colleagues ([Barkley, 1991](#)). The items refer to behaviors indicative of problems with attention and concentration relevant to completion of structured work. The rater is asked to designate each behavior as not true, somewhat or sometimes true, or very or often true of the child in question. The test yields a total score and two factor scores, Inattention and Overactivity. Means and standard deviations are provided. Scores more than 1.5 standard deviations above the mean are understood as clinically significant.

#### *PROJECTIVE TESTS*

##### *Rorschach Inkblots*

The Rorschach test ([Rorschach, 1921](#)) enjoys great popularity among clinicians ([Erdberg and Exner, 1984](#)). First described in 1921, the Rorschach test consists of 10 inkblots, each printed on a separate rectangle made of heavy cardboard. Five of the cards are monochromatic, two are black and red, and three are polychromatic. Standard administration consists of two phases: free association, in which the subject simply states what each blot may represent; and inquiry, in which the clinician seeks clarification from the subject about what aspects of the blot contributed to the percept identified in the free-association phase. Clinicians typically allow approximately 1 hour for administration time. Although some administration and scoring systems have been developed for use with the Rorschach test ([Beck, 1944](#); [Klopfer, 1954](#)), the work of Exner and colleagues ([Exner, 1978, 1986](#); [Exner and Weiner, 1982](#); [Wiener-Levy and Exner, 1981](#)) represents the most ambitious effort to establish a psychometrically sound basis for scoring this instrument ([Anastasi, 1988](#)). The Rorschach test is primarily used as a clinical device for assessing personality organization and, with children, also provides data regarding the developmental status of such organization ([Zlotogorski, 1986](#)). Particularly significant data are generated regarding a child's developmental capacities for reality testing, integration of affect, and maturational level of object relations. The Rorschach test has been subjected to extensive research that establishes its satisfactory reliability, particularly since the introduction of Exner's Comprehensive System ([Anastasi, 1988](#); [Zlotogorski, 1986](#)).

Computer software has been developed for scoring Rorschach protocols according to the Exner system. The computer scoring yields both quantitative and qualitative interpretive information. The computer scoring facilitates efficiency and objectivity in scoring Rorschach protocols. The comprehensive information provided by the scoring program offers the broadest information possible. Computerized scoring is not, however, a good substitute for the careful sequential analysis of responses carried out by an experienced examiner.

### *Thematic Apperception Test (TAT)*

The Thematic Apperception Test (TAT) ([Murray et al., 1938](#)) consists of 20 picture cards, one of which is blank and 19 of which vary in their degree of ambiguity. Cards are presented one at a time, and the child is asked to tell a story, as opposed to simply stating what the card portrays. The story is to include a beginning, a middle, and an end and is to describe something about the thoughts and feelings of the characters. The story is recorded verbatim by the clinician who may actively request clarification of the story as it is being told. After administration of the test, the clinician analyzes the story to determine the identification of the story's hero, the hero's attributes, and the conflicts, defenses, and adaptations evidenced in the hero's individual and interpersonal functioning. The underlying assumption of this analysis is that the respondent makes particular use of the hero as the object for unconscious projections and identifications.

According to many authors (e.g., [Anastasi, 1988](#); [Siegel, 1987](#); [Siegel, 1988](#)), the TAT is appropriate for use with older children, adolescents, and adults. Other investigators ([Goldman et al., 1983](#)) point out that Murray originally intended his method for use with persons who are more than 4 years of age. Although thematic assessment instruments have been developed for use with younger children, between approximately the ages of 3 and 10 years (e.g., Children's Apperception Test, [Bellak and Bellak, 1961](#); Roberts Apperception Test for Children, [McArthur and Roberts, 1982](#)), in clinical practice the TAT is generally used as the apperception test of choice. This is because the TAT, by virtue of its greater stimulus ambiguity, is considered to elicit more efficiently the subject's projections, and because greater examiner familiarity with the TAT engenders more of an internal frame of reference and face validity. The publication of a version of the Children's Apperception Test in which stimulus cards depict human as opposed to animal figures has generated enthusiasm among clinicians. These pictures appear more developmentally appropriate and better preserve the valuable ambiguity that is a hallmark of the TAT.

Typically, clinicians administer eight to 10 cards selected for the individual child or adolescent being tested. Although this approach reduces the instrument's reliability, it generates a rich lode of clinical data for use in deriving clinical hypotheses that may be confirmed or denied elsewhere in the test battery.

### *Machover Draw-A-Person Test (DAP)*

In this commonly used projective test ([Machover, 1949](#)), the subject is provided with a piece of standard-size, 8½" x 11" paper and a pencil with an eraser and is instructed to draw a person. The only constraints placed on the figure are that it portrays the entire body and that it not be drawn as a "stick figure." On concluding this drawing, the subject is then asked to draw a person of the opposite gender from that of the initial drawing. The examiner notes the subject's behavior, verbalizations, and demeanor while drawing and the sequence in which body parts are drawn. The productions are then subjected to a qualitative analysis, focusing on such variables as figure size, page placement, arm position, clothing, significant omissions and disproportions, shading, and erasures ([Anastasi, 1988](#)).

[Machover \(1949\)](#) provides a guide for interpretations of drawings without providing data in support of those interpretations. Research has been conducted that fails to validate Machover's diagnostic inferences ([Klopfer and Taulbee, 1976](#)). In clinical practice, the Machover Draw-A-Person Test (DAP) is typically used as a source for generating clinical hypotheses. It may be helpful to conceptualize two broad categories of such hypotheses, which may be derived from qualitative analysis of the DAP: (a) hypotheses pertaining to the subject's perception of and feelings about the self, particularly ego development and bodily integrity; and (b) hypotheses pertaining to the subject's perception of and feelings about interactions with the social environment, particularly with primary nurturing caregivers.

### *Kinetic Family Drawing (KFD)*

The Kinetic Family Drawing (KFD) test ([Burns, 1982](#)) is frequently administered by clinicians to generate hypotheses regarding the subject's perceptions of and feelings about family structure and sentient environment, particularly the subject's own sense of connectedness to individual family members and the family as a whole. Administration and interpretation are similar to that of the DAP. The subject is provided with paper and pencil and is asked to draw a picture of the family doing something. It is important that this latter instruction not specify "doing something *together*," because this instruction would contaminate data regarding perceived family cohesion.

One manual for KFD interpretation ([Burns, 1982](#)) cites references for inferences drawn about KFD productions. Machover is one of the most frequent citations, however, and this reduces the reliability of the citations because of the previously noted research failing to support her diagnostic inferences. KFD interpretation is therefore subject to the same caution as other projective data, and it is best used as a source of clinical hypotheses requiring confirmation or denial elsewhere.

### *Rotter Incomplete Sentences Blank*

The Rotter test ([Rotter and Rafferty, 1950](#)) is one of many sentence completion tasks that are widely used by clinicians and researchers ([Goldberg, 1965](#)). The Blank consists of 40 sentence stems, which the subject is instructed to complete to express true feelings. A scoring manual permits ratings of each response on a seven-point scale assessing degree of adjustment or maladjustment. Other more recently developed sentence completion instruments (e.g., Incomplete Sentences Task, [Lanyon and Lanyon, 1980](#)) provide forms for school- and college-age children.

As with many of the instruments noted earlier, many clinicians use a more clinical approach to sentence analysis. Such clinicians often work from a theoretical position that holds that sentence completion protocols can provide a particularly rich source of heuristic data about a child's level of ego development ([Loevinger, 1977](#)).

## PERSONALITY TESTS

### *Behavior Assessment System for Children (BASC), Self-Report*

The BASC ([Reynolds and Kamphaus, 1992](#)), discussed earlier among parent and teacher measures, also includes two editions of a self-report form, one for 8 to 11 year olds and one for 12 to 18 year olds. The instrument contains numerous self-referent statements. The child or adolescent is asked to classify each statement as either a true or false self-descriptor. For youngsters who have difficulty reading, the examiner can provide assistance. A range of standardized scores and percentiles is derived along dimensions pertaining to school, family, and personal functioning. Clinically, the Self-Report Form of the BASC is very useful as a straightforward, time-efficient, easily scored measure of a youngster's self-concept. The drawback of the instrument is that, despite its inclusion of checks on the truthfulness of the youngster's self-report, the test seems to elicit unrealistically positive self-appraisals. Clinical use suggests that only very extreme levels of behavioral and emotional disturbance are likely to be reflected fully on the BASC Self-Report.

### *Minnesota Multiphasic Personality Inventory, Adolescent (MMPI-A)*

The Minnesota Multiphasic Personality Inventory (MMPI) ([Hathaway and McKinley, 1940](#); [Hathaway and McKinley, 1943](#)) has been the most widely used personality inventory ([Anastasi, 1988](#)). A revision, the MMPI-2, was published in 1989 ([Butcher et al., 1989](#)). Like its predecessor, the MMPI-2 is a self-report, criterion-keyed instrument, which means that the instrument's items are selected according to an external criterion, in this case the item's ability to discriminate a group carrying a clinical diagnosis from a normal control group. Although the original MMPI and MMPI-2 were designed for use with an older adolescent and adult population, there has always been caution about the validity of MMPI-based clinical inferences as applied to a broad adolescent population. To address this caution and to provide more valid data regarding adolescents, the MMPI-A ([Butcher et al., 1992](#)) was published in 1992. The MMPI-A is standardized on a school-based national adolescent population. Some possible limitations that exist in the normative population are its relative weighting toward better-educated families of higher socioeconomic status.

The MMPI-A consists of 478 forced-choice, true-false items provided in a test booklet. Answers are recorded on a separate answer sheet and then may be scored by hand or by computer. The MMPI-A includes several validity scales (lie, validity, correction, and variability scores) designed to check on such test-taking variables as carelessness, misunderstanding, malingering, and special response sets, 10 original clinical scales (hypochondriasis, depression, hysteria, psychopathic deviance, masculinity-femininity, paranoia, psychasthenia, schizophrenia, hypomania, social introversion), 15 content scales specifically related to adolescent development (anxiety, obsessiveness, depression, health concerns, alienation, bizarre mentation, anger, cynicism, conduct problems, self-esteem, aspiration level, social discomfort, family problems, school problems, and negative treatment indicators), and supplementary scales to measure anxiety, repression, alcoholism, and immaturity. A profile is generated in which raw scores are converted to standard Z-scores, and interpretation is based on consulting available references providing descriptions of clinical populations consistent with different MMPI-A profiles.

### *Millon Adolescent Personality Inventory (MAPI)*

The Millon Adolescent Personality Inventory (MAPI) ([Millon et al., 1982](#)) consists of 150 true-false items and was designed to be completed in approximately 20 minutes by adolescents between the ages of 13 and 18 years. The instrument's two forms (MAPI-C and MAPI-G) are intended for clinical and guidance applications, respectively. Twenty scales are produced, clustering into measures of personality style (introversive, inhibited, cooperative, sociable, confident, forceful, respectful, sensitive), expressed concerns (self-concept, personal esteem, body comfort, sexual acceptance, peer security, social tolerance, family rapport, academic confidence), and behavioral correlates (impulse control, social conformity, scholastic achievement, attendance consistency). The MAPI is intended specifically for use with adolescents and is standardized on relevant normative populations.

### *Children's Personality Questionnaire (CPQ)*

The Children's Personality Questionnaire (CPQ) ([Porter and Cattell, 1972](#)) represents one attempt to provide a measure of personality functioning in younger children, in this instance ages 8 through 12 years. The test is grounded in the theoretical work of Cattell, which led to the development of the Sixteen Personality Factor Questionnaire (16PF) ([Cattell et al., 1970](#)). Consisting of 140 forced-choice questions that may be broken into short forms of 70 items each, the test's administration time generally does not exceed 45 minutes.

The CPQ generates factor scores tapping 14 hypothesized primary personality traits, including emotional stability, self-concept, excitability, and self-assurance. Consistent with the 16PF, second-order, broad trait factors may be derived, including extraversion, anxiety, tough poise, and independence. Critiques support the instrument's research utility but raise questions regarding its clinical applicability ([Goldman et al., 1983](#)). The relative dearth of theory-based instruments for this age group, however, leads many clinicians to include the CPQ in assessment batteries for children of elementary school age.

## **NEUROPSYCHOLOGICAL SCREENING TESTS AND TEST BATTERIES**

### *Developmental Neuropsychological Assessment (NEPSY)*

The Developmental Neuropsychological Assessment (NEPSY) ([Korkman et al., 1998](#)) is an individually administered, comprehensive assessment instrument that examines a youngster's functioning from a neuropsychological perspective. Ideal for use by clinicians well grounded in developmental theory but not necessarily identified primarily as neuropsychologists, the NEPSY uses a broad range of Core and Expanded subtests to measure abilities in five main Domains: Attention/Executive Functioning, which is the capacity to focus attention, to sustain concentration, and to carry out planning, monitoring, self-regulation, and problem-solving; Language, which comprises verbal labeling, phonologic analysis, verbal efficiency, and verbal comprehension; Sensorimotor Functions, comprising fine motor dexterity, precision, and discrimination; Visuospatial Processing, which is visual-motor integration, judgment of spatial orientation, and nonverbal abstract reasoning; and Memory and Learning, the ability to remember faces, names, isolated bits of verbal data, and fuller narrative information. Subtest materials and procedures are somewhat novel and maintain the interest of young subjects. Because the examiner has some discretion about the number of subtests needed to be administered, administration time varies from about 20 minutes to about an hour. The test is designed for children between the ages of 3 and 12 years. The NEPSY is standardized on a representative national sample. Standardized scores, percentiles, and age equivalents are derived and allow for direct comparison with scores on other mainstream psychoeducational test instruments. Although its statistical properties are thus far superior to many of the poorly standardized but widely used neuropsychological tests, reliability and validity of the test are much better between the ages of 5 to 12 years than in younger children. At the younger ages, normal developmental progress makes it very difficult to measure reliably the functions assessed by the NEPSY. Because of its comprehensive nature and relatively good statistical foundation, the NEPSY is a valuable tool in psychological assessment with children. It should never substitute for a full neuropsychological battery, however.

### *Wide Range Assessment of Memory and Learning (WRAML)*

Intended for use with children and adolescents between the ages of 5 and 17 years, the Wide Range Assessment of Memory and Learning (WRAML) test ([Sheslow and Adams, 1990](#)) is designed to offer a comprehensive measure of the youngster's ability to acquire and remember a variety of types of information. Administered on an individual basis, the WRAML takes approximately 45 minutes to 1 hour to complete. The WRAML has three scales, each of which has three subtests. The first is the Verbal Memory Scale, measuring the ability to complete a rote memory task involving single letters and numbers as well as more complex verbal tasks. The second scale is the Visual Memory Scale, assessing the ability to reproduce a simple visual pattern and to recall more complex visual information. The third scale is the Learning Scale, composed of subtests that measure the impact of repeated trials in remembering verbal, visual, and cross-modal information. Some subtests include a Delayed Recall task to gain preliminary information about intermediate-term memory. The WRAML is standardized using a representative national sample corresponding to the most recent available U.S. Bureau of the Census data. Reliability is good and validity is reasonably good. Accordingly, the WRAML can be used with moderate confidence as part of a more comprehensive test battery.

### *Developmental Test of Visual-Motor Integration (VMI)*

First introduced in 1964, the Developmental Test of Visual-Motor Integration (VMI) has since been renormed twice, in 1981 and again in 1989 ([Beery, 1989](#)). The VMI was developed for use in both academic and clinical settings, and it can be administered either individually or in groups to children between the ages of 2 and 15 years, inclusive. The child is presented with a booklet containing 24 geometric designs and is simply instructed to copy each with no erasures permitted. Designs are scored on a pass-fail basis, according to criteria and examples provided in the manual. Testing is discontinued when the child fails to reproduce three consecutive designs accurately. Administration time is approximately 10 to 15 minutes.

The VMI enjoys satisfactory psychometric properties ([Beery, 1989](#); [Polubinski et al., 1986](#)), and it is commonly employed by clinicians as a measure of children's perceptual-motor ability. Such a measure is an important component of assessment batteries constructed to rule out the presence of learning disabilities ([Jansky, 1988](#)). Because it requires minimal interaction with the examiner, the VMI is often administered early in the assessment battery as a means of introducing children to the task of testing.

### *Benton Visual Retention Test*

The Benton Visual Retention Test ([Benton, 1974](#)) is used as a measure of visual-figural memory in adults and in children beginning at the age of 8 years. The test consists of 10 cards on each of which is reproduced one or more geometric designs. The manual outlines several different administration procedures. In the recommended standard administration, the subject is told that each card will be presented for 10 seconds, after which the card will be removed and the subject will reproduce the figure from memory. Reproductions are scored on both a pass-fail basis ("number correct" score) and in terms of the total number of errors ("error" score). Using tables provided in the manual, both these scores are then compared with the anticipated "normal" score for each age and intellectual level (typically determined by the IQ score obtained on the cognitive instrument used in the assessment battery). Scores deviating from this expected score by a significant number of points are considered to either "raise the question" or "suggest" the presence of a visual-figural memory deficit.

Used together, the VMI and the Benton test provide well-standardized data about a child's visual-motor and visual-memory functioning. Depending on the data obtained, hypotheses about perceptual, motor, or memory deficits can be further explored by administering additional instruments (e.g., Jordan Left-Right Reversal Test, [Jordan, 1973](#); Motor-Free Visual Perception Test, [Colarusso and Hammill, 1972](#)).

### *Bender Visual Motor Gestalt Test (Bender-Gestalt)*

Widely used by clinical psychologists to rule out the presence of brain damage ([Anastasi, 1988](#); [Sattler, 1988](#)), each of the nine Bender-Gestalt cards ([Bender, 1938](#)) presents a geometric design that the subject is asked to copy with the card remaining in sight. This Copy phase is typically followed by the Recall phase, in which the child is next asked to reproduce from memory as many of the figures as possible after they have been removed from sight. Although Bender did not develop objective and standardized scoring criteria and normative data, such systems have subsequently been developed. The best-known scoring system for children is that of Koppitz ([Koppitz, 1964, 1975](#)), which provides norms for subjects in kindergarten through fourth grade.

Similar to the VMI and the Benton test, the Bender-Gestalt provides an efficient screen for detecting brain damage. In the past, clinicians also used the

Bender–Gestalt as a source of projective test data, a practice that has received little validation support ( [Sattler, 1988](#)).

#### *Reitan–Indiana Neuropsychological Test Battery for Children and Halstead–Reitan Neuropsychological Test Battery for Older Children*

These two batteries ([Reitan and Davison, 1974](#); [Reitan and Wolfson, 1985](#); [Selz, 1981](#)) are discussed together because of their conceptual, structural, and clinical similarities. The batteries are designed to assess a broad range of functions, and their content is somewhat flexible, permitting different degrees of emphasis on various aspects of the child's functioning. Most clinicians administer 11 tests including sensorimotor and perceptual tasks as well as an aphasia screening test ([Anastasi, 1988](#)). In addition, the complete battery also includes administration of an intelligence test, typically the WISC-III. Administration time for the full battery can therefore be as long as 6 hours.

The utility of these batteries is compromised by virtue of limited available reliability, validity, and normative data ( [Sattler, 1988](#)). In the hands of sophisticated and well-trained neuropsychologists, the derived data can be employed to differentiate brain-damaged children ( [Reitan and Herring, 1985](#); [Selz and Reitan, 1979](#)) and children with specific associated syndromes and to assist in rehabilitation planning by articulating behavioral deficits related to central nervous system disorders ([Anastasi, 1988](#)).

#### *Luria–Nebraska Neuropsychological Battery, Children's Revision (LNNB-C)*

Similar to the Reitan batteries noted earlier, the Luria–Nebraska Neuropsychological Battery, Children's Revision (LNNB-C) ( [Golden, 1987](#)) was developed to investigate a wide variety of neuropsychological functions, to assess cognitive deficits, and to provide data to guide rehabilitation in children aged 8 to 12 years. This battery differs from the Reitan instruments, however, in its abbreviated administration time (approximately 2½ hours) and greater standardization of content, materials, administration, and scoring ([Anastasi, 1988](#)). The battery's 149 items are grouped into 11 clinical and two optional scales (assessing sensorimotor, perceptual, and cognitive abilities), three summary scales (discriminating brain-damaged from normal children), and 11 factor scales (assessing specific neuropsychological functions and requiring caution in interpretation). All items receive scores of 0, 1, or 2, with higher scores indicating greater evidence of brain dysfunction. A companion 57-category qualitative scoring system permits further evaluation of error items.

The LNNB-C is a downward extension of an adult version of the battery ( [Sattler, 1988](#)), an approach to neuropsychological assessment that has been the focus of substantial controversy and criticism ( [Adams, 1980](#); [Delis and Kaplan, 1983](#); [Sattler, 1988](#); [Sparrow et al., 1985](#); [Stambrook, 1983](#)). The manual provides more substantial standardization, reliability, and validity data than are available for the Reitan batteries, but concern has been raised about the adequacy of the battery for each of these psychometric issues ( [Nolan et al., 1983](#); [Sattler, 1988](#); [Sparrow et al., 1985](#)). Given these concerns, pending completion of further research caution is required in the clinical interpretation of data generated by this battery.

#### *Wechsler Memory Scale, Third Edition (WMS-III)*

More than simply intending to replace its predecessor in measuring simple memory functions, the third edition of the Wechsler Memory (WMS-III) ( [Wechsler, 1997b](#)) was designed to make a major contribution to a comprehensive test battery by measuring the complex interaction between memory and learning. Based on current research in the neurosciences, the test consists of six primary subtests and five optional subtests. The subtests are divided into three main groups: immediate memory, general memory (delayed), and working memory. In all groups, both visual and auditory modes are evaluated. Further scores can be derived to delineate the learning process in acquiring auditory information. The test is administered on an individual basis, requires approximately 30 to 45 minutes for completion, and is appropriate for those between the ages of 16 and 99 years. The age span covered by the WMS-III, thus, makes it a useful instrument for the assessment of older adolescents. A full range of standardized scores can be derived and easily compared with other well-used cognitive test instruments. The statistical properties of the test are sound, so the instrument can be used with confidence.

### **MEASURES OF INFANT AND PRESCHOOL DEVELOPMENT**

#### *Bayley Scales of Infant Development, Second Edition (BSID-II)*

The Bayley Scales of Infant Development, second edition (BSID-II) ( [Bayley, 1993](#)) is a revision of the Bayley Scales of Infant Development ( [Bayley, 1969](#)). Like its predecessor, the BSID-II assesses the developmental functioning of infants and toddlers with the aim of detecting developmental delay and pointing the way toward appropriate intervention strategies. The revision was undertaken to update the normative data, to extend the age range beyond what was covered by the original BSID, to improve the content coverage to make the test more useful clinically, to enhance the test materials to increase their attractiveness for subjects, to improve the psychometric properties of the test, and to improve the clinical utility of the test by including standardization data on such special populations as those with Down's syndrome, prematurity, and prenatal drug exposure, all while preserving the original basic focus of the BSID on deriving sound developmental information from stimulating, standardized interaction with an infant or young child. The test consists of Mental, Motor, and Behavior Rating scales. The Mental scale focuses on the infant's early ability to direct his or her attention to appropriate people and objects in the environment and then on the development of age-appropriate interactive, language, conceptual, and memory skills. The Motor scale focuses on early development of both fine and gross motor skills, as well as sensory integration and visual–motor coordination. Both the Mental and Motor scales are completed using a flexible administration format. Test materials are attractive and resemble captivating toys. Test subjects are offered the materials, along with stimulating guidance about the developmentally adequate way of interacting with the materials. The subject's actual use of the materials is then evaluated. Rather than relying on the type of direct assessment used for administration of the Mental and Motor scales, the Behavior Rating scale is completed based on informal observation of the infant or preschooler during the testing. Styles of interpersonal relating, attunement to others, and accessibility to limit setting are examples of the types of behaviors assessed. Test sessions are typically fast paced, to maintain the very young child's interest, and they require considerable creativity, as well as test familiarity from the examiner. For these reasons, the BSID-II is often considered a challenging instrument for examiners to master. Once mastered, however, the test can be administered in a smooth, systematic, enjoyable manner. The BSID-II is standardized on a representative national sample that conformed to the 1988 update of the 1980 national census reported by the U.S. Bureau of the Census. The sample is designed to conform to racial, ethnic, and socioeconomic proportions in the national population. At each age level, there is equal representation of males and females. Reliability and validity data for the BSID-II are provided in the test manual. The data indicate that the test is a reliable and valid instrument that can be used with confidence. The reliability and validity data pertain to documentation of current developmental status. Early developmental data do not serve to predict long-term intellectual ranking. In clinical practice, the BSID-II provides very valuable information about the status of the youngest of patients. One drawback, however, is that the test does not provide a discrete measure of language development. Such a measure is often needed in the assessment of potential developmental delay.

#### *Mullen Scales of Early Learning (MSEL), American Guidance Service Edition*

The original version of the Mullen Scales of Early Learning (MSEL) was developed by Eileen Mullen, an expert in early childhood development and education (Mullen, 1988). Although the test was useful and well-received, the small, private basis on which the test was constructed compromised its statistical properties. In 1993, the MSEL was purchased by the American Guidance Service (AGS), a well respected publisher of psychoeducational tests. Under the auspices of the AGS, the MSEL was standardized on a nationally representative sample of children between the ages of 2 days and 69 months, 0 days ( [Mullen, 1995](#)). The reliability and validity of the measure are now quite good.

In the original version, there were separate Mullen scales for infants and preschoolers. In the AGS edition, the MSEL has become a single test designed for use with children from birth through 68 months of age. The test is administered individually without time limits. Administration time varies from 15 minutes at the youngest ages to approximately an hour for 5-year-old youngsters. The MSEL is divided into five scales: Gross Motor, a measure of central motor control and mobility; Visual Reception, a test of visual discrimination, memory, organization, sequencing, and spatial awareness; Fine Motor, a measure of visual–motor ability; Receptive Language, a test of auditory comprehension, memory, organization, sequencing, and use of spatial concepts; and Expressive Language, a test of speaking ability, language formation, and the ability to verbalize concepts. Standardized scores, percentiles, age equivalents, descriptive categories, and developmental stages are all derived on the MSEL. The test is particularly useful for determining eligibility for early intervention and special education services, for assessing children with special needs, and for helping to design individualized psychoeducational programs.

### **PSYCHOLOGICAL TEST RESULTS**

As discussed earlier, psychological testing yields a wealth of data regarding a child's or an adolescent's functioning. It is important to address both the nature of the data gathered and the means by which it is most usefully communicated to young patients and their parents.

## Nature of the Data

Consistent with the multifaceted test battery described earlier, psychological assessment provides data on a youngster's cognitive, behavioral, and personality functioning. For each domain assessed, test findings place the youngster at a particular level of functioning overall. To obtain the most sophisticated benefit of psychological testing, however, it is critical to go beyond a summary analysis of each distinct domain to analyze both the interrelationships among the domains assessed and, further, the profile of individual strengths and weaknesses within each global domain ( [Novick and Lewis, 1967](#)). This is because an identical performance in one area of functioning by several youngsters may have vastly different implications depending on how each one of them performs in other areas. For example, projective evidence of highly original, complex, rich, reality-oriented internal mental processes is reassuringly unremarkable for a child with a high IQ. The same projective data from a child with a low-average or borderline IQ, though, raises important questions about the accuracy of measurement of that child's intelligence. Once the individual features of a youngster's test profile have been analyzed, the psychologist provides a formulation that integrates the diverse findings into a comprehensive view of the patient. The data analysis concludes with the offer of recommendations on how best to address the needs noted in the assessment.

## Communication of the Findings

To facilitate appropriate interventions on behalf of the child or adolescent assessed, psychological test results must be communicated in understandable language and with interpersonal sensitivity appropriate to the recipient of the information. If the results are communicated in overly technical language or without regard for their impact on parents, clinicians, and others invested in the child or adolescent patient, the test data are likely to be ignored, and the benefits of testing will be negated.

Assessment findings should also be shared in a particular order to facilitate their incorporation into clinical care. The initial step of this sequence depends on the referral source. If the test referral came from another professional, test data and recommendations should be communicated initially to the referring clinician. By communicating first with this colleague, appropriate primary responsibility for patient care and relationships to the patient are safeguarded. The psychologist and referring clinician can then decide together how best to proceed with further communication of the test findings to those concerned. In some instances, the referring clinician and testing psychologist may elect to present the findings together. The advantage to this presentation mode is that all concerned can develop a shared, multidimensional understanding of the child or adolescent. In other cases, it may be best for the psychologist to present the assessment data alone. The data can then be brought back to the clinical relationship with the referring professional. This method is best when time constraints make a joint meeting difficult. The method also has special advantages for those cases in which the psychological test data may be at odds with clinical expectations. Separate communication of the data by the psychologist allows the referring clinician to maintain better a therapeutic alliance with the patient and family. Together, the clinician and family can then begin to incorporate the data obtained from the testing. Finally, for those cases in which fragile patient functioning highlights the importance of the relationship with the referring clinician, it is often best to have that clinician relay the test findings to those concerned. For these patients and their families, the information may be best accepted and understood in the context of a supportive, therapeutic relationship.

For cases of the type discussed earlier, findings and recommendations should then be communicated to the parents in the most efficacious presentation style. If the parents themselves initiated the referral, sharing these findings and recommendations with the parents constitutes the first step in the interpretive process. Just as good rapport is necessary in the testing situation to guarantee testing accuracy, so is it necessary in consulting with parents to facilitate their willingness to make good use of the data. Care should be taken to demonstrate some empathy for the parents' understanding of the child or adolescent so they can feel confident about the veracity of the test results. Findings should be communicated in a forthright but tactful manner, with particular sensitivity to shared family traits and for parental attitudes toward the youngster involved.

With children of elementary school age and with adolescents, it is always important to then consider providing the test findings directly to the patient. The offer of an interpretive meeting for the child or adolescent should be made pending parental approval. If the child or adolescent requests such an interpretive meeting, a careful clinical decision should be made by parents and professionals regarding the best setting and participants for this meeting. Some children prefer to safeguard their self-esteem by hearing the results privately from their parents. Those who have developed an initial attachment to the testing psychologist often want to hear about their test performance from him or her. Still others, who have therapists to whom they are closely attached, request that their therapists communicate the test results. These latter two formats may or may not include the parents. With the patients themselves, test findings should also be shared in a straightforward, honest manner. The child's or adolescent's strengths should be emphasized, his or her weaknesses discussed in an empathetic manner, and hopeful recommendations offered.

At times, other interested parties also need to share in the assessment findings. For children and adolescents, the school is the likeliest other recipient of the information. It may also be helpful to communicate the test findings to programs for young people with special needs as well as to other caregivers. Parents should make informed decisions with the psychologist and, when relevant, the referring clinician about the format in and extent to which the findings are to be shared with outside parties. These decisions should balance protection of family privacy with sufficiently full communication of findings to allow for appropriate interventions on behalf of the child or adolescent.

## 44 NEUROLOGIC MEANING OF SOFT SIGNS

Jonathan H. Pincus, M.D.

[Origin of Soft Signs](#)  
[Chapter References](#)

The term *soft signs* has become a subterfuge for clinicians who are avoiding hard scientific thinking. It is almost a slang expression, like “stroke,” which can mean cerebral thrombosis, embolus, hemorrhage, convulsion, or even heart attack. The term *soft signs* has been used to refer both to *historical evidence* of events that can be associated with brain damage and certain kinds of behavior (e.g., hyperactivity, impulsiveness, poor attention span) and to *physical findings* elicited by examination of the patients. Many different symptoms and signs are subsumed under the title soft signs. Some of these are maturational and probably represent variants of normal. Others relate to hereditary conditions and diseases, and still others refer to acquired disorders of the brain. Hyperactivity, emotional lability, disorders of attention, and impulsiveness have been considered soft signs by some. Children certainly may have motor, perceptual, linguistic, adaptive, social, and educational problems of various types as the result of brain abnormality. To identify useful evidence of organic brain dysfunction, there must be a search for other findings that will reliably reflect neurologic abnormality. This has only partly been accomplished, hence the term “soft.”

Asymmetrical physical and neurologic findings are clearly reliable indicators of disease. Still, there are certain “hard” neurologic findings, on which neurologists rely daily in the performance of physical examinations that have not actually been subjected to careful scientific scrutiny. For example, it is not known how often patients who are free of nervous system diseases have Babinski reflexes, especially when these patients are tired or stressed. Not only do we not know how many neurologically normal persons manifest this sign, we also do not know exactly how many people with demonstrable brain damage—even those with corticospinal tract damage—fail to manifest this sign.

Despite this failure, great and appropriate emphasis is placed on the significance of the neurologic examination in general and on the Babinski reflex in particular, even though the neurologist may be influenced in his or her interpretation by the fact that patients have been referred because of their failure to conform to some normal behavioral pattern and are therefore abnormal almost by definition. It is up to the neurologist to discover independent evidence of abnormality. Therefore, the signs the neurologist elicits are taken as confirming the presence of lesions in the brain.

Exactly the same thing can be said of soft signs. There have been relatively few systematic studies of large populations of children in whom meticulous neurologic examinations have been performed. The Isle of Wight Study ([Rutter et al., 1970](#)) suggests that there is not as close an association between the presence of abnormal neurologic findings and behavioral abnormalities as may have been assumed from earlier publications. Neurologic findings do not always predict behavioral distortions, and behavioral abnormalities do not always predict physical abnormalities; yet there is a statistical correlation between the two. Other studies confirm the lack of specificity of some motor and sensory signs in the neurologically impaired and in neurologically normal persons ([Werry and Aman, 1976](#)).

When a soft sign is identified as reliably indicating the presence of brain dysfunction, it is no longer soft. If it reflects brain damage in some patients and can be seen in others who have no evidence of brain dysfunction, then it is soft indeed and is probably not very helpful in determining whether a patient has brain dysfunction. Signs and symptoms that are found in neurologically normal persons more frequently than in people with brain damage are not soft signs of abnormality but, rather, are within the normal range. To determine which signs are truly soft—that is, those that can be associated with organic damage but need not be—requires correlational statistical studies in patients who are known to be abnormal and in people who are known to be normal, with the recognition that the former is easier to establish than the latter. This has not been completed for each of the physical signs that are called soft.

Consistency has been considered important in determining the long-term significance of soft signs in children. Although follow-up studies can provide considerable information, the finding that minor or major neurologic abnormalities may disappear in the course of development does not necessarily mean that the findings originally elicited were not significant or should be considered “merely maturational.” Mild hemiparesis or diapaesis may disappear, hypotonia may become normotonia, seizures may stop, but the importance of these findings as evidence of encephalopathy in the past remains. Such historical encephalopathy may still be relevant to contemporary cognitive and behavioral disturbances.

One of the most common clinical settings in which learning and behavioral disturbances turn up is that of seizures originating in the temporal lobe. The etiologic dilemma of this association has not been fully resolved. Are the learning and behavior problems secondary to the emotional trauma of susceptibility to seizures? Does the uncontrolled seizure disorder, or the medication that is used to control it, lead to a partial functional disruption of the system that is sufficient to cause defects of attention and learning? The weight of evidence indicates that, in most cases, seizures and behavior problems are coincident symptoms of the same basic neurologic abnormality. This explains why the seizures often resolve while the behavior and learning problems remain.

The search for validating correlations among various findings requires a standard against which to compare them. There is a tendency to ascribe certainty to tools that are used by an allied profession. Child psychiatrists may tend to regard the physical examination of a child neurologist with greater respect than do neurologists themselves. Consistency of findings and interrater reliability can be a problem. The electroencephalogram (EEG) may provide borderline or frankly paroxysmal abnormalities in a certain percentage of patients with learning disability who have no clinical seizures. This may be a soft finding to many neurologists, but it may not be to some psychologists. Conversely, psychological tests, especially the Wechsler Intelligence Scale for Children and Bender tests, may provide evidence that to neurologists is less equivocal than it may be to psychiatrists or even to psychologists. All groups are somewhat in awe of computed tomography (CT) and magnetic resonance imaging (MRI) of the brain, although findings such as cerebral atrophy and enlarged ventricles are quite soft because they do not reliably predict behavioral or cognitive dysfunction ([Shaywitz et al., 1983](#)). The truth is that we lack an acceptable standard against which to measure each of the multitudinous symptoms and signs included in the vague expression, soft signs. This being the case, we have been forced to make correlations among tests of unproven value ([Barlow, 1974](#)).

### INVESTIGATION OF PARTICULAR SOFT SIGNS: MOTOR AND SENSORY

[Precht and Stemmer \(1962\)](#) first pointed out the significance of choreiform movements. This phenomenon consists of random, quick, irregular movements, most prominently seen in the fingers of the supinated outstretched forearms. Precht and Stemmer correlate this phenomenon with perinatal distress and neonatal abnormality. Wolff and Hurwitz report an overall incidence of the choreiform syndrome of roughly 10% in elementary school children aged 10 to 12 years, with a significant difference between boys (17%) and girls (5%) ([Wolff and Hurwitz, 1966](#)). The incidence of choreiform signs drops from 50% at age 10 years to 3% among 12 year olds. Additional studies document that boys with choreiform twitches have more reading and spelling difficulties than boys without such twitches, but there is no such correlation in girls ([Wolff and Hurwitz, 1973](#)).

Development of the ability to appreciate simultaneous touch to face and hand (the face–hand test, a test of attention to sensory stimuli, a useful measure of frontal cortical function in adults) is clearly age related. Most neurologically normal children achieve this ability by age 7 years. This is also the age during which concepts of body image enlarge to include a body under the large head of children’s drawings ([Bender et al., 1951](#)). [Kraft \(1968\)](#) basically confirms these findings but finds no

correlation with the scored Goodenough Draw-a-Man test, a test that measures parietal lobe functions. Kraft finds that 30% of 7-year-old nonreaders give an immature response to the face–hand test, whereas 20% of normal readers give an immature response, a difference that is neither impressive nor useful. In adults, none with normal cortical function, as defined by the Halstead–Reitan battery, have an abnormal face–hand test, and 91% of those with abnormal cortical function are abnormal on the face–hand test ( $p < .01$ ), (Jenkyn et al., 1985). No one knows at what age failure on the face–hand test becomes a reliable indicator of cerebral cortical dysfunction.

In a longitudinal study of 66 prematurely born children from advantaged homes, neurologic examinations were performed at 8 years of age. Thirteen of these children had localizing neurologic findings, and 20 were found to have two or more nonlocalizing (soft) signs of central nervous system (CNS) dysfunction. These included tests of speech, balance, coordination, gait, sequential finger–thumb opposition, muscle tone, graphesthesia, stereognosis, and choreiform movements. These 33 neurologically abnormal children were significantly more likely to have sustained perinatal complications than were children whose neurologic examinations were normal. Although children with soft signs were at a consistent disadvantage—in relation to posterior cerebral cortical functioning as shown by intelligence quotient (IQ), reading, and arithmetic achievement test score levels—compared with those who were neurologically normal, these differences did not reach conventional levels of significance. However, the children with soft signs were significantly more likely to have received special education and to have been referred for psychiatric consultation than were the neurologically normal children. Almost half of the children with two or more of the physical soft signs elicited by the investigators required special educational intervention to reach the same overall level of academic school performance achieved by the neurologically normal children. Ninety percent of the neurologically normal children made satisfactory progress without any modification of the school program. This finding, coupled with the high frequency of psychiatric consultations and continuing intervention in the group with soft signs, provided support for the view that children with soft signs at 8 years old are, indeed, at greater risk for the emergence of behavioral or school learning problems (Hertzog, 1981). Soft signs tend to reflect frontal lobe dysfunction, whereas difficulty with reading, writing, and arithmetic represents parietal, temporal and occipital dysfunction. The association of soft signs with behavioral disorders and not with abnormal reading, writing, and arithmetic could be understood as the result of premotor frontal dysfunction.

## RELIABILITY AND STABILITY OF SOFT SIGNS

Any conclusion regarding the validity of soft signs assumes a satisfactory interrater reliability, internal consistency, and retest stability of subtle signs. Although this has not been studied extensively, some information is available (Stokman et al., 1986). The Physical and Neurological Examination for Soft Signs (PANESS) was used with 54 psychiatric patients and 25 neurologically normal children aged 5 to 17 years. Acceptable interrater reliability was found for most of the items tested. Test-retest reliability at 2 weeks was not satisfactory for some of the categorically scored items. However, continuous items, such as the time needed to perform 20 consecutive movements, remained relatively stable at retest (Vitiello et al., 1989).

To assess the persistence of soft signs outside a referred sample, 159 members of a local birth cohort of the United States National Collaborative Perinatal Project were traced, and their performance on six neurologic test scales was measured at age 17 years by examiners who were unaware of the status of these children when these patients were 7 years old. A comparison group was also formed that had been free of signs at age 7 years. On four of the six tests (dysdiadochokinesia, mirror movements, dysgraphesthesia, and motor slowness), index boys did significantly worse than the comparison boys. In contrast, index girls scored significantly worse than comparisons only on motor slowness. The consistency of neurologic test performance through the years contradicts the idea, at least in boys, that soft signs are only maturational lags destined to fade with age. The worse the boy's neurologic score at age 17, the stronger is the relationship with his status at age 7.

This important study makes another observation of great significance. Analysis of the data that categorizes findings as either absent or present, rather than of varying intensity, would have shown almost no statistically significant relationship in the 7- to 17-year data. If neurologic test performance is intrinsically a continuous function, such categorical analysis, which was used in most of the earlier studies, would be likely to underestimate the true strength of relationships (Shafer et al., 1986). Unfortunately, the large population studies that have been interpreted as casting doubt on the usefulness of abnormalities found on neurologic examination have used a categorical approach to describing them.

## SOFT SIGNS AND ATTENTION DEFICIT HYPERACTIVITY DISORDER

The literature on this subject is somewhat confusing. Wikler et al. (1970) and Camp et al. (1978) find no difference in the prevalence of signs between children with and without *attention deficit hyperactivity disorder* (ADHD), but every possible sign is not individually validated. Nichols and Chen (1981) analyze a large sample drawn from all 7-year-old participants in the National Collaborative Perinatal Project and find only a small excess of overactivity and inattention among children with neurologic soft signs. Shaffer et al. (1985) find no relationship between early soft signs and attention deficit or conduct disorders in 63 male and 27 female adolescents known to have had neurologic soft signs at the age of 7 years, but the same group does relate three signs (motor slowness, motor inaccuracy, and dysgraphesthesia) to poor IQ and poor attention span (Schonfeld et al., 1989). Castellanos et al. (2000) report abnormal frontal oculomotor function in girls with ADHD. Lucas et al. (1965), Mikkelsen et al. (1982), and McMahon and Greenberg (1977) all find soft signs to be more common in generally younger groups of children with ADHD than in controls (Wikler et al., 1970).

There is, thus, considerable evidence that, although soft neurologic signs reflect organic brain dysfunction, they are rather inconsistently seen in the syndrome of ADHD, once called minimal brain damage. This does not mean that ADHD is unrelated to brain dysfunction. If ADHD or any cognitive–behavioral syndrome were associated with soft neurologic findings, this would presumably constitute evidence in favor of the organic nature of such a cognitive–behavioral syndrome. If a cognitive–behavioral syndrome were not associated with soft neurologic findings, it would not necessarily mean that the disturbance arose from some source other than brain dysfunction. In fact, dysfunction confined to the premotor portion of the frontal lobes is likely to produce a major distortion in behavior, attention span, and personality without concomitant major motor signs, difficulty with reading, writing, arithmetic, or a drop in IQ.

The frontal lobes have increasingly been targeted as the possible source of abnormality in ADHD (Benson, 1991). Quantitative analysis of MRI scans of 18 boys with ADHD and 18 carefully matched controls supports the theory of abnormal frontal lobe disturbance in ADHD (Giedd et al., 1994). Semrud-Clikeman et al. (2000) report similar findings. MRI studies of the cross-sectional area of the corpus callosum also reveal that the anterior regions are smaller in boys with ADHD (Giedd et al., 1994; Hynd et al., 1991). A similar study using positron emission tomography (PET) identifies hypometabolism in the left anterior frontal lobe as a significant correlate of ADHD severity in adolescents (Zametkin et al., 1993). Functional MRI studies are consistent with the foregoing, showing abnormality in the putamen, a portion of the frontal-basal ganglia-thalamic circuit (Teicher et al., 2000). Event-related potentials also indicate abnormal frontal function in ADHD (Pliszka et al., 2000). Brain mapping reveals abnormal premotor processing in ADHD (Steger et al., 2000).

Reports of psychological tests that generally reflect frontal dysfunction generally support the linkage of ADHD with frontal lobe dysfunction. Deficits in verbal fluency are found in male ADHD inpatients compared with inpatient controls (Koziol and Stout, 1992). Other tests reflecting frontal lobe dysfunction distinguish children with ADHD from controls, although general cognitive impairment as measured by the IQ is not found in the former group (Shue and Douglas, 1992). Some measures of frontal lobe dysfunction do not reliably distinguish attention deficit disorder (ADD) with and without hyperactivity, but the Continuous Performance Test and the Stroop Test do distinguish groups with ADHD from neurologically normal groups (Barkley et al., 1992). Others (Loge et al., 1990) report impaired Wechsler Intelligence Scale for Children performance in ADHD but no difference from controls in the Wisconsin Card Sorting Test or tests of verbal and design fluency (Grodzinsky and Barkley, 1999; Doyle et al., 2000).

Clearly, the preponderance of evidence (MRI, PET, psychological tests) favors the concept that frontal dysfunction explains some of the behavior in ADHD, even though none of these tests is specific enough to provide a reliable diagnosis, absent other data. We must now ask: Are there physical neurologic signs that reflect frontal lobe dysfunction? The answer is yes, but none of them are part of the ordinary neurologic examination of school-age children, and, for the most part, they have not been standardized and validated in these age groups as they have been in adults (Jenkyn et al., 1977, 1985). These are the snout reflex (Paulson and Gottlieb, 1968), suck and grasp reflexes (Shahani et al., 1970), paratonia, persistent glabellar reflex (Damasio, 1985), abnormal visual tracking movements (Rodin, 1964), abnormal response in performing reciprocal coordination of the hands, and three-step motor sequences of the hands (Luria, 1962; Ozeretski, 1930). The presence of three frontal signs discriminated between subjects with normal and abnormal MRIs with 93% accuracy, and normal and abnormal neuropsychological testing with 85% accuracy, when applied to 31 murderers whose average age was 32 years. Half had been diagnosed as having ADHD in their youth: Grasp reflex, suck reflex, and paratonia were the best discriminators (Blake et al., unpublished data). Three or more abnormal signs on the battery of tests performed by Jenkyn and his colleagues reliably distinguish normal subjects from mildly, moderately, and severely impaired adults, using the Halstead–Reitan battery (Jenkyn et al., 1977, 1985). If ADHD were, in fact, a reflection of frontal lobe dysfunction, we would predict that physical signs of frontal lobe dysfunction of the type validated by Jenkyn et al. and Blake et al. would be more prevalent among children with ADHD than controls. The age at which findings on these tests become abnormal must be known. Clearly, normal 2 year olds would not be able to perform tests of complicated motor sequences. At what age does the inability to accomplish these tasks become abnormal? Are abnormalities on these tests characteristic of children with ADHD? It is disappointing that no study has yet answered these questions.

## Clinical Examination of the Brain

The neurologic examination is a way of determining whether various parts of the brain and spinal cord are functionally intact. It is easiest to test the lower, phylogenetically more primitive parts of the nervous system and then progress to more complex functions.

The human brain is organized in layers of interacting regions. At the base, just behind the mouth, is the brain stem, which controls most elemental functions such as breathing, blood pressure, and swallowing. It also controls the cranial nerves subserving eye movement, facial movement, and the muscles of the throat, mouth, and neck. The brain stem mediates sensation in the head, face, and neck and, through the cerebellum, general motor coordination. Above the brain stem, behind the nose and its sinuses, is the diencephalon. This controls body temperature, appetite, sleep, and wakefulness. Circling around that central region of the brain is the limbic system and amygdala–hippocampus complex, the seat of the primitive emotions involved in sexual behavior, fear, anger, and aggressive attack, as well as memory. Virtually, all mammals share these features. Over all this, covering the entire surface of the brain and lying just below the skull, is the cerebral cortex, the thick layer of gray matter that is the source of intelligence. The cortex is anatomically and functionally distinct from the rest of the brain. Complex perceptual and cognitive functions take place in the cortex. Vision registers and is integrated at the back of the brain in the occipital lobes. Somatosensory information like touch, pain, and position in space is interpreted in the parietal lobes; smell and taste are interpreted in the temporal lobes. Speech and the understanding of language are usually identified with the left perisylvian region and in the transcortical areas surrounding that. Voluntary movement derives from the motor strip in the posterior part of the frontal lobes. Voluntary movement is modified by deep subcortical centers called the basal ganglia. Almost all mammals have well-developed occipital, parietal, and temporal lobes and motor control systems that are very similar to the human ones.

To determine whether the brain is intact, the examiner must test reflexes and sensorimotor functions, must compare the patient's right and left sides, and must observe stance and gait. The head circumference should be measured with a tape measure and compared with a table of normal standards. If the circumference is more than two standard deviations below the mean, the patient is microcephalic and will have an 85% chance of being cognitively impaired.

Tests of motor coordination include skipping, hopping, and walking a straight line forward and backward. The patient should be asked to spread the fingers apart and hold the hands apart while the examiner looks for discontinuous, involuntary, jerky movements of the fingers and arms, called *choreiform movements*. The patient should be tested to see whether he or she is right handed and right footed. If dominance is mixed, it may mean that his nervous system has not developed the way that it should.

Abnormality on a single test usually does not mean that the person is brain damaged, but a pattern of abnormalities does indicate that the brain is malfunctioning. Asymmetrical (lateralized) abnormalities are likely to reflect structural abnormalities of the CNS, but severe damage to the brain can be present in patients whose sensorimotor functions, coordination, and reflexes are normal.

### COGNITIVE FUNCTIONS

Because the brain is the organ of cognition, cognitive functions must also be tested in the neurologic examination. The Mini-Mental Status Examination (MMSE) is a standard tool for the investigation of the cognitive status. The patient must be able to identify the day, date, time of day, and location. The patient is asked to name several objects that have just been presented (pen, wristwatch). The patient is given three words and is asked to repeat the three words immediately and to remember them, is asked to subtract seven from 100 and to perform five serial subtractions of seven, and is asked to spell the word "world" forward and backward. The examination requires patients to be able to read, repeat, and write a sentence, copy a standard diagram, follow a three-step command, and recall the three words he or she was instructed to remember earlier. The MMSE is an excellent screening test for cognitive disorders that affect the posterior two-thirds of the brain, but the frontal lobes can be damaged or even surgically removed without causing any abnormality in speech, arithmetic ability, reading, writing, or memory. Although these functions, tested by the MMSE and IQ tests, often remain intact, frontal lobe dysfunction can cause profound and devastating changes in the patient's social life.

### EVALUATION OF THE FRONTAL LOBES

Fibers from the frontal lobes project to other regions of the brain such as the corpus striatum and the dorsomedial nucleus of the thalamus. Lesions in the dorsomedial thalamus can cause the kinds of abnormalities that frontal lesions can produce. For this reason, it is a mistake to conceptualize the functions that are mediated by the frontal lobes as residing exclusively within this area of the brain, but for the sake of brevity, we refer to them as *frontal functions*.

Judgment and the ability to deal with complexity are crucial functions of the frontal lobes. Unfortunately, there is no reliable, objective standard or test for measuring judgment that is sufficiently sensitive and specific. Asking a patient what he or she would do with a stamped addressed envelope found lying in a street is not an adequate test of frontal lobe function. It is insensitive and nonspecific. There are, however, several simple physical tests of frontal lobe function that rely on motor and sensory functions. Neurologists and psychiatrists can easily assess them.

Regressive reflexes (e.g., snout reflex; suck, nuchocephalic) ([Jenkyn et al., 1977](#)) are associated with diffuse cerebral dysfunction (e.g., delirium, dementia). These reflexes are called *regressive* because they are normally present in very young children and infants but not in adults ([Jenkyn et al., 1985](#)). When interpreting these reflexes, it is wise to recall that neuroleptic medications can cause regressive reflexes.

The most useful of these reflexes engages the extensive *frontal eye fields*, the portion of the frontal lobes that enables the eyes to track a moving object. The examiner asks the patient to follow the examiner's smoothly moving finger as it goes slowly from left to right horizontally in front of the patient. An abnormal response would be visual tracking in brief, staccato, discontinuous (saccadic) jerks or inattentiveness with brief deviations of the patient's eyes from the examiner's finger rather than smooth movements. A normal response would be smooth visual tracking of the moving finger. The patient should also be able to stare for 30 seconds at the examiner's stationary finger without deviating his or her gaze. This helps to demonstrate an ability to concentrate.

Tapping gently on the bridge of a patient's nose normally elicits *blinking*. If the blinking persists for more than three taps, it means that the patient cannot accommodate to a benign stimulus. After three taps, it should be clear that there is no potential threat to the patient's eyes. If the patient cannot suppress the urge to blink even though there is no threat, it shows that he or she cannot adapt to a new situation. This inflexibility reflects dysfunction in a frontally mediated pathway ([Jenkyn et al., 1977](#)).

Paying attention to two sensory stimuli simultaneously can be difficult for frontally damaged people. They tend to disregard the more distal of two unilaterally applied stimuli. For example, if the examiner touches the patient's right cheek and right hand simultaneously while the patient's eyes are closed, the patient may report having been touched only on the cheek. This is called the *face–hand test*. If the patient extinguishes (pays no attention to) the more distal stimulus, it shows that his or her attention to somatosensory stimuli by the frontal lobes is attenuated.

To see whether a patient can concentrate and suppress an urge, the examiner creates a visual urge and then asks the patient to ignore it. The examiner faces the patient, holds his or her hands to either side of the patient's eyes, and asks the patient to look at the examiner's nose. He or she instructs the patient to deviate his or her eyes to the side of the examiner's briefly raised index finger and then return his or her gaze to the examiner's nose. Alternately, the examiner moves his or her right and then left index fingers. The patient looks towards the moving finger and then back at the examiner's nose. Once it is clear to the examiner that the patient has mastered this and looks to the moving finger and then back to the examiner's nose, the examiner asks the patient to look toward the opposite side, toward the side that *does not* move. Patients with frontal damage have trouble suppressing the urge to look at the moving finger and first look there before correcting. This test uncovers impulsivity and inattentiveness. It is called the *antisaccade test*. It is performed five times, twice to the left, twice to the right, and then once to the left. Two or more failures count as an error.

Frontally damaged patients often cannot perform two- and three-stepped motor sequences repetitively even though their strength and coordination are normal. This makes complex, repetitive motor tasks sensitive indicators of frontal function. The patient is asked to strike his or her thighs repeatedly, simultaneously, with the right palm and the left fist, then with the right fist and left palm, alternating with each blow. Patients should be able to perform three sets perfectly on their own after having been taught how to perform this by the examiner. This is the *two-stepped Luria test*. Then the examiner shows the patient how to strike the thigh successively with the right palm, fist, and the edge of the hand. The patient attempts it alone after being shown how to do this by the examiner. The patient is then asked to perform the task with the left hand, striking the palm, the fist, and the side of the hand in sequence. This is called the *three-stepped Luria test*. Frontal lesions often interfere with the proper sequencing of this task. Abnormality on either the two- or three-stepped Luria test indicates frontal dysfunction.

Patients with frontal disturbances often cannot relax their limbs when asked to do so and allow them to remain suspended in the air when one is raised and then is dropped by the examiner. This is the *placement test*. Sometimes patients try to help by anticipating the position the examiner wishes them to assume after the examiner instructs them to be "limp as a rag doll." The abnormality is called *paratonia*. When this sign is severely abnormal, the limb will remain in any position in which it was placed. This phenomenon is called *waxy flexibility or catatonia* and can also be encountered in psychotic states of depression and schizophrenia.

Upward gaze is another frontally mediated function. When asked to look upward, the patient should be able to move the outer limbus of the iris upward at least 5 mm and downward 7 mm. The examiner must place a ruler vertically in front of the patient's eyes to measure the extent of movement.

Testing the *nuchoccephalic reflex* reveals the patient's ability to adapt to postural change. It is often helpful in diagnosing frontal disease. With the patient's eyes closed, the examiner places his or her hands on the patient's shoulders and quickly turns the patient to the right or to the left. Normally, the head follows the shoulders. Some frontally impaired patients do not move their heads with their shoulders. They cannot adapt to this postural change.

The *snout reflex* is tested when the examiner uses the middle phalange of his or her flexed index finger and firmly presses the patient's relaxed lips and then draws the finger away. Any contraction of the orbicularis oris to this stimulus results in a puckering of the lips or the chin.

The *suck reflex* is similar. The examiner firmly places the knuckle of his or her flexed index finger between the subject's lips. There should be no response from either stimuli. Any pursing or sucking motion by the subject's lips or movement of the chin is recorded as a disinhibited reflex and an abnormal response.

The *grasp reflex* is tested both with and without distraction. First, the patient is told to relax his or her hand while the examiner uses his or her own finger to stroke the palmar surface of the subject's hand. Next, the patient is distracted by being instructed to spell a simple word such as "fist" both forwards and backwards. Each hand is stroked without distraction and then with distraction. The addition of a second task ("spell 'fist' backward") to the first task ("relax your hand") increases the stress on the person and allows a disinhibited reflex to become manifest in frontal lobe dysfunction. Absence of any flexion of the subject's fingers is normal. Any flexion of the fingers represents disinhibition and is abnormal.

The results of each of these tests are not abnormal in every case of frontal damage. A pattern of abnormality, that is, three or more abnormal tests, sustains the conclusion that the frontal lobes are damaged. Three abnormal test results reliably correlate with abnormalities in both the MRI of the brain and neuropsychological testing with the Halstead-Reitan battery ([Blake et al., 1995](#)). The correlation is significant but not absolute. We have found that the most sensitive and specific of these frontal neurologic tests are the inability to perform smooth visual pursuit and the inability to perform accurately the three-step Luria test. MRI scans of patients who fail both these tests have a great likelihood of being abnormal. ([Bae et al., 1998](#)).

#### COGNITIVE ASPECTS OF THE FRONTAL LOBE EVALUATION

The *word fluency test* examines frontal function by testing the ability to generate words that are not in a context. In this test, the examiner asks the patient to name as many words as possible in 60 seconds that begin either with the letter "F" or "M." A normal score is 14 plus or minus five. It is abnormal to name fewer than nine words. This is not an intelligence test but a test of improvisation. A person with frontal damage may perform normally on an IQ test or the MMSE. Because frontally damaged people have trouble improvising or in using old knowledge in a new way, the word fluency test provides an indication of frontal dysfunction.

The "king story" can be very useful in separating patients with attentional deficits from those with memory deficits. The story has a familiar sound but contains no familiar details:

Once upon a time there lived a king who was very ill. His physicians could not help him, so he sought the advice of his wise men. His wise men advised him to obtain the shirt of a happy man. The king sent out messengers who scoured the kingdom and finally found a happy man, but the happy man did not own a shirt.

Before this story is recited, the patient is asked to pay close attention to the details and to repeat it, including as many details as possible. When patients are unable to provide all the details of this story, it indicates inattention. Sometimes the inattention is the result of frontal damage, and sometimes it reflects nervousness, depression, mania, schizophrenia, obsessiveness, or intoxication. After the examination has been completed and 15 minutes have elapsed, the patient is asked to repeat the story. If the patient recalls the details that *he or she* included in his initial repetition of the story, the examiner can conclude that the patient's memory is intact. The combination of poor attention span and intact memory is frequently seen in patients with frontal dysfunction.

The abnormalities on the physical and cognitive tests described earlier are age dependent. What is abnormal in adults may not be abnormal if found in children. Unfortunately, there are no studies of normal children that indicate at what age a frontal sign is abnormal.

The psychological tests that most reliably reflect frontal dysfunction are those that assess executive functions. These are mediated in large part through the frontal lobes. The most sensitive tests are the Wisconsin Card Sorting test, Trail Making Tests A and B, the Categories subtest of the Halstead-Reitan battery, and tests of continuous performance such as the Stroop Color and Word Test. The pediatric psychologists and school psychologists, who are ordinarily the ones who test children with behavioral, cognitive, and learning disorders, rarely use these tests of frontal, executive functioning, although many of these tests have been standardized to age 6 years. No psychological evaluation is complete that does not evaluate executive functioning, especially in attentional disorders.

The other tests that are available for the evaluation of the brain include static and dynamic imaging and tests of body fluids. MRI is much superior to CT for identifying brain abnormalities, but even MRI can be misleadingly negative in patients suffering from devastating diseases such as epilepsy, mental retardation, cerebral palsy, torsion dystonia, chorea, and a variety of dementing disorders.

The dynamic tests such as single photon emission CT, PET, and functional MRI are misapplied when used just to see whether the brain is abnormal. All these reflect cerebral blood flow, which is greater in those portions of the brain that are being used. The radiologists who perform the tests usually ask the subjects to remain still, eyes closed, and thinking of nothing, in other words with their brain not working. It is not possible to be sure whether a person is thinking or about what he or she may be thinking. The most trivial thoughts represent brain activity and can result in a change in the regional blood flow as measured by these sensitive tests. For this reason, it is difficult to determine what activity on the imaging test is normal and what is abnormal. Patients with severe frontal dysfunction or severe dyslexia may seem normal on scans performed when these patients are not trying to perform a task with which they have trouble. In other words, when they are not using their brains, their defective brains can seem normal. Only during a task that normally engages a particular defective region of the brain is the abnormality identified. Patients with dyslexia would have to be studied while they are reading. Those with attentional difficulties would have to be studied while they are attempting to attend. So variable are the details of testing that the normal control values of one laboratory cannot be used by another.

The mind and the brain can be disordered by conditions whose presence can only be detected by examinations of body fluids, namely, endocrine, infectious, metabolic, and toxic disorders. These conditions generally require investigation by blood tests such as toxicology screens, complete blood count, sedimentation rate, urea, electrolytes, glucose, tests for syphilis or human immunodeficiency virus, and endocrine functions. Vitamin B<sub>12</sub>, folate, calcium, phosphorus, magnesium, porphyrin screens, lead levels, antinuclear antibodies, and other laboratory tests may be required as clinically indicated. Lumbar punctures have become less necessary as imaging has improved, but suspected inflammatory conditions still require cerebrospinal fluid examination for diagnosis.

#### Differential Diagnosis of Attention Deficit Hyperactivity Disorder

The most common form of ADHD is probably the result of a lag in the rate of normal maturation of the brain. The brain does not complete its growth until early in the third decade, and an important factor in brain growth is myelination of the frontal lobes, the last part of the cortex to join the electrical grid that operates the brain. Such maturational ADHD may largely reflect genetic factors (Wilcutt et al., 2000).

The large male preponderance in children with ADHD ([Arnold, 1996](#)) may be explained if the growth and development of the brain and the frontal lobes are generally slower and more variable in boys. This concept has some experimental support (Benes et al., 1994, [Bachevalier and Hagger, 1991](#)) and clinical support as well ([Flannery et al., 2000](#); [Castellanos et al., 2000](#)). ADHD may often be the reflection of the slow but normal development of frontal circuits. Behaviorally, this would

appear as social immaturity, hyperactivity, and short attention span. ADHD as a manifestation of immaturity is a condition that many would outgrow.

There is a marked predilection of cognitive-behavioral disorders such as ADHD, autism, dyscalculia, developmental disorders of motor execution, and some forms of mental deficiency for boys by margins of four to one. These abnormalities may be X-linked traits such as the fragile X syndrome. Sex steroids may affect early brain maturation. Testosterone could slow the development of certain cortical functions, usually associated with the left hemisphere, and it may speed the development of other functions. This could explain the superiority of girls for verbal tasks and boys for visual-spatial tasks ( [Rapin and Allen, 1988](#)).

Increasingly, ADHD is being recognized not as a separate disease entity but as a behavioral syndrome that has many causes with differing prognoses and treatments that depend on the origin. Neurologic diseases of frontal circuits may produce the same behavioral distortions in a school-age child as immaturity, but these would be less likely to resolve with time. Examples of such disorders may be lead poisoning and traumatic brain injury.

Mental illnesses can also produce symptoms of ADHD in school-age children. Of the mental diseases, mania has received a great deal of attention ( [Carlson, 1998](#); [Geller et al., 1998](#); [Giedd, 2000](#)). Obsessive-compulsive disorder (OCD) ( [Clayton et al., 1999](#); [Moll et al., 2000](#)), Tourette's syndrome ( [Freeman et al., 2000](#)), and schizophrenia ( [Erlenmeyer-Kimling et al., 2000](#)) are other possible causes of ADHD in children. Experiential factors can produce ADHD, often with conduct disorder and oppositional defiant disorder. The symptoms of ADHD can be thought of as one of the childhood expressions of these conditions, rather than being considered another, unrelated, comorbid disease.

## NEUROLOGIC SOFT SIGNS AND OTHER PSYCHOPATHOLOGY

Neurologic soft signs have been described as being overrepresented in patients carrying a diagnosis of childhood autism, Tourette's syndrome, schizophrenia, borderline personality disorder, or anxiety and withdrawal.

### Autism

Like ADHD, *autism* is not a disease entity itself but, rather, a behavioral syndrome of childhood that can result from many different disorders of the CNS that cause bilateral dysfunction. Defective speech is a hallmark, but autistic children often have varying deficits in comprehension, symbolic thinking, and the formation of abstract concepts that reflect varying degrees of CNS dysfunction and the diseases that cause it. This is consistent with the variegated pattern of cognitive functioning in autism, which is often uneven in an individual case, with preserved "islets of intelligence." Autism is often seen in children who show strong independent evidence of neurologic abnormality. It may be associated with phenylketonuria, tuberous sclerosis, and infantile spasms during the first year of life. Many autistic children have multiple cognitive deficits, and perhaps half have, or once had, electroencephalographic abnormalities or a history of seizures or both. The symptoms of autism resemble those of congenital aphasia. Permanent aphasia can be produced in children only by bilateral cerebral lesions.

Hardly any information on the neuropathologic correlates of autism has been published. It is a nonprogressive, nonfatal syndrome, and brain biopsies cannot usually be justified. Some defects in cerebral myelination and myelination of the cerebellum have been reported, but it seems highly unlikely that these constitute the root of the disturbance, which symptomatically resembles more a problem of the gray matter and cerebral cortex than of the white matter or the cerebellum.

Children with autism were compared with neurologically normal children matched for both chronologic and mental ages on two tests of motor imitation and on the Herzig battery for nonfocal neurologic signs ( [Jones and Prior, 1985](#)). The latter includes tests of speech, balance, coordination, double simultaneous stimulation, gait, sequential finger-thumb opposition, muscle tone, graphesthesia, astereognosis, and choreiform movements. Performance was rated as normal, mildly impaired, or markedly impaired. Imitation ability was defective in the children with autism who showed an average of four soft signs. All had two or more such signs, the most frequent of which were choreiform movements (100% markedly impaired); imbalance (70% markedly, 30% mildly impaired); extinction to double simultaneous stimulation (60% markedly impaired); incoordination (40% markedly, 50% mildly impaired); finger-thumb opposition (40% markedly, 30% mildly impaired); and speech disarticulation (40% markedly, 40% mildly impaired).

The significant prevalence of soft signs in this group of 6- to 10-year-old children with autism was marked, universal, and excessive, compared with both chronologically and mentally age-matched controls. Yet some of the soft signs were also seen among the controls. The lack of true, normative developmental data makes it difficult to use the soft signs to support the theory of the organic pathogenesis of autism. The lack of complete understanding of autism makes it unsound to use the supposed organic pathogenesis of autism to validate the meaningfulness of soft signs ( [Jones and Prior, 1985](#)).

### Tourette's Syndrome

*Tourette's syndrome* is a familial neuropsychiatric disorder of unknown origin that is characterized by waxing and waning multiform motor and phonic tics and a range of complex and intriguing behavioral symptoms. Typically, it is a lifelong disorder that can be disabling and that usually begins in the first decade. In addition to the motor and phonic symptoms, several behavioral symptoms are often seen in patients with Tourette's syndrome, including diminished ability to concentrate, impulsiveness, impaired regulation of activity, and disabling obsessions and compulsions. As many as half of the children with Tourette's syndrome satisfy the diagnostic criteria for ADHD. Although most do not have primary learning disabilities, their conduct disturbance can substantially impair school performance. Many patients with Tourette's syndrome do have specific learning disabilities as well, however. Obsessive-compulsive symptoms seen in patients with Tourette's syndrome usually appear late in the developmental course of the syndrome. These include obsessive doubting of decisions, concern about touching objects or persons, and elaborate compulsive rituals.

Family studies and twin data support the notion that Tourette's syndrome and multifocal tics are inherited as an autosomal dominant trait on a single major gene locus ( [Shapiro et al., 1978](#)). The finding that Tourette's syndrome is genetic strongly implicates brain dysfunction as the source of the symptoms. The relationship between Tourette's syndrome and ADHD is controversial. Some studies suggest that ADHD is etiologically related to Tourette's syndrome, whereas other reports are more consistent with the hypothesis that ADHD is a comorbid condition and that the high prevalence of ADHD in a clinical population of patients with Tourette's syndrome may result from an ascertainment bias ( [Cohen et al., 1982](#)). If so, ADHD is still the most common "comorbidity" in Tourette's syndrome ( [Freeman et al., 2000](#)). Increased rates of obsessive-compulsive symptoms in patients with Tourette's syndrome and the finding that about 20% of first-degree relatives of Tourette's probands display prominent obsessive-compulsive symptoms have led to the provocative hypothesis that some forms of OCD may be an alternate phenotypic expression of the Tourette's gene.

### Obsessive-Compulsive Disorder

Obsessive-Compulsive disorder (OCD) has been linked to altered neurologic function after head trauma, encephalitis, abnormal birth events, and Tourette's syndrome. Abnormalities in CT scans, EEGs, PET scans, and evoked potentials have been described in this disorder, but they are neither consistent nor pathognomonic of OCD. Forty-one medication-free patients with OCD who met the criteria of the third revised edition of the *Diagnostic and Statistical Manual of Mental Disorders*, as well as 20 normal controls matched for age, sex, and handedness, were studied on 20 individual tasks that involved fine motor coordination, involuntary movements, and sensory and visual-spatial function. There were significantly more signs of CNS dysfunction in the OCD group, as shown by abnormalities in fine motor coordination, involuntary and mirror movements, and visual-spatial function. An excess of findings on the left side of the body and abnormalities in drawing cubes may suggest right hemispheric dysfunction in a subgroup of patients with OCD. Soft signs correlated with the severity of obsessions. There was also a correlation between abnormalities in visual memory and recognition on neuropsychological testing and total soft signs. These findings provided additional evidence for a neurologic deficit in some patients with OCD. We lack understanding both of the neurologic basis of soft signs and of OCD ( [Hollander et al., 1990](#)), but both may derive from subcortical dysfunction, either within the frontal lobe or in the basal ganglia and thalamic gray matter that communicate with the frontal lobe ( [Cummins, 1993](#)).

### Schizophrenia

Minor neurologic abnormalities and physical anomalies are commonly found in *schizophrenia*. This is not what one would expect in a "functional" disease, and, for this reason, such signs have often been overlooked or considered epiphenomena. One has only to walk through the chronic wards of a large state hospital to be impressed by the number of patients who suffer from neurologic dysfunction, in terms of impaired equilibrium, gait, and coordination, and even gross mental retardation. The effects of medication, malnutrition, and multiple electrical shock treatments may have something to do with these abnormalities. Certainly, many of the studies of neurologic changes in state hospital populations, for which both the cause for admission and original symptoms often have been long forgotten, are suspect when a high incidence of neurologic findings in patients with schizophrenia is cited. The few such studies done on patients with acute illness, however, have

documented a significant degree of neurologic dysfunction. Abnormalities include minor motor and sensory (soft) neurologic signs on physical examination, EEG abnormalities, and abnormal CT scans.

[Rochford et al. \(1970\)](#) examined 65 hospitalized, untreated psychiatric patients for the presence of the following minor signs: (a) motor impersistence; (b) stereognosis; (c) graphesthesia; (d) extinction during bilateral simultaneous stimulation; (e) bilateral marked hyperreflexia; (f) coordination defects; (g) disturbance of balance and gait; (h) cortical sensory abnormalities; (i) mild movement disorders; (j) speech defects; (k) abnormal motor activity; (l) defective auditory–visual integration; (m) choreiform movements and adventitious motor overflow (tremor); (n) cranial nerve abnormalities, such as slight anisocoria, esotropia, auditory deficit, and visual field and retinal defects; and (o) unequivocally abnormal EEGs. They found neurologic abnormalities in 36.8% of the psychiatric patients (all diagnostic groups). This was significantly different from an age-matched, normal control population (5%). Neurologic soft signs were found in 65.5% of the patients with schizophrenia. By way of comparison, there were no soft signs in patients with primary affective disorders.

Neurologic deficits have been included in descriptions of schizophrenia since Kraepelin first defined dementia praecox. One group of studies reported a greater-than-normal overall number of neurologic signs in patients with adult and childhood schizophrenia and in the children of patients with schizophrenia ([Rieder and Nichols, 1979](#)). Another group reported more neurologic signs in the schizophrenic twin of identical twins discordant for schizophrenia. A third group of studies found deficits in a broad range of specific neurologic areas, including psychomotor integration, vestibular reactivity, lateralization, and involuntary muscle coordination and tone ([Marcus et al., 1985](#)). In fact, the presence of neurologic signs in schizophrenia is so strong a finding that a congenital neurointegrative defect is now believed to be at the base of at least some subtypes of the illness.

[Fish et al. \(1965\)](#) reported in detail on 10 infants, each of whom had a parent with schizophrenia. During the neonatal period, these children showed poor muscle tone and an unusually torpid biological state, and, later, they showed irregular or uneven rates of physical growth and motor development.

The original neurologic examination for the Israeli study of children of patients with schizophrenia ([Marcus et al., 1985](#)) was constructed in 1966 and used child neurology scales. Results showed a subgroup of children of parents with schizophrenia who had poorer cumulative scores than controls.

Five years after the original data were collected, another neurologic assessment was made of the same children using a similar examination. Several statistically significant group differences in neurologic functioning were found. In the original assessment, neurologic signs were more severe in boys than in girls. This sex difference is consistent with the higher incidence of many kinds of major and minimal brain dysfunction and developmental delay observed in boys. A group of children with multiple areas of neurologic deficits was identified, consisting almost exclusively of the children of parents with schizophrenia. In contrast, children with good neurologic functioning were a mixture of index and control cases. This pattern of results is consistent with the model described previously: Only a subgroup of the children of parents with schizophrenia would show biological deficits, whereas others would be indistinguishable from neurologically normal children. Forty-four percent of the children of parents with schizophrenia in this study had signs of a neurointegrative defect during at least one of the time periods. This result is consistent with the hypothesis that approximately half of the children of parents with schizophrenia have neurologic deficits.

The types of neurologic signs most typical of the children of parents with schizophrenia were perceptual–sensory signs, poor motor coordination, poor right–left orientation, poor balance, and motor overflow (the last especially at the older ages). Such minor deficits in attention and inhibition suggest a strong resemblance between this subgroup of children of parents with schizophrenia and children with ADHD. Although many of the children of parents with schizophrenia had other neurologic signs, such as dyskinesias, abnormal reflexes, and facial asymmetries, it was the foregoing group of motor and sensory signs that best defined the poorly functioning subgroup and probably represents the genetically determined dysfunction.

If there are soft signs that correlate with psychosis, they may derive from the same brain abnormality that causes the psychosis. Premorbid deficits in verbal memory, gross motor skills, and attention during childhood were characteristic of the children of parents with schizophrenia who ultimately became psychotic when they reached adulthood ([Erlenmeyer-Kimling et al., 2000](#)).

Reports of EEG abnormality in patients with schizophrenia who were referred at random range from 5% to 80%, with an average of 25%, but the vagaries of EEG interpretation and the variability in diagnosing schizophrenia obscure the meaning of these data. Patients diagnosed as having catatonic schizophrenia seem to show consistently higher rates of EEG abnormality, usually manifested as nonspecific slowing. Because catatonic states are often acute and have a relatively good prognosis, one wonders whether all cases so labeled are really catatonic schizophrenia. The higher rate of EEG abnormality in catatonic schizophrenia raises some question about the diagnosis.

Yet EEG abnormalities are seen in patients with schizophrenia, especially catatonic schizophrenia, more often than in the general population. This statement seems valid even when allowances are made for an occasional misdiagnosis and the effect of drugs and shock therapy. It is not known whether the schizophrenic process or an underlying or associated brain defect causes these EEG abnormalities. One possibility is that brain damage, which may be reflected in the EEG, could facilitate the development of schizophrenia in persons with a genetic tendency to the disease. The theory that brain damage makes it more likely that the gene for schizophrenia will be expressed clinically would also explain the inconsistent but significant association of soft signs on the physical examination with schizophrenia.

CT and, more recently, PET have opened exciting possibilities for studying the structure and function of the CNS in patients with schizophrenia. Since 1976, there have been persistent reports of ventricular enlargement, hemispheric asymmetry, and cerebellar atrophy in patients with schizophrenia. [Rieder et al. \(1983\)](#) and [Shelton et al. \(1988\)](#) have shown ventricular changes in schizophrenia and have shown that these ventricular changes correlate with other findings, such as increased neuropsychological impairment, poor response to treatment, and poor premorbid adjustment. The ventricular enlargements demonstrated would not be called abnormal by radiologists but, rather, are subtle variations within the normal range, and even these are not present in all the patients with schizophrenia who are studied. Other investigations have not confirmed the findings of ventricular enlargement. Almost all the studies in this area, whatever their results, suffer from serious methodologic problems, such as the following: (a) the study populations have been disparate, ranging from old to young, chronic to acute, rigidly diagnosed to less rigidly diagnosed; (b) the techniques of measuring ventricular size in each study are not standardized and vary from manual measurements to computer measurements, thus leading to a great variation from study to study in the incidence of abnormal findings and in their comparability; and (c) the control populations have varied from none, to reported norms in the literature, normal populations, or neurologic patients with headaches who are referred for evaluation. Very few of these studies have compared other chronic psychiatric patients to the patients with schizophrenia, and none has used a blind technique for reading CT scans.

PET is now being used to study schizophrenia, and this technique is so sophisticated that we may be able to observe dynamic changes of cerebral function in patients with schizophrenia during different psychopathologic states and to follow these changes through the course of illness. The PET studies seem to show some decrease of blood flow in the frontal lobes of patients with schizophrenia. Minor asymmetrical hemispheric differences have been noted as well ([Berman et al., 1988](#); [Buchsbaum et al., 1984](#)). These studies, however, have involved so few patients with such varying diagnoses and drug regimens that we must await larger studies and more standardization of the research methods to lend them more weight.

### **Borderline Personality Disorder**

Extensive investigation of patients with *borderline personality disorder* suggests that underlying organic factors may play a role in this complex disorder that consists of affective, behavioral, and cognitive abnormalities. One area of focus has been neurologic and neurophysiologic dysfunction. Findings in patients with borderline personality disorder of abnormal EEG results, histories including head trauma, seizures, and learning disabilities, and similarities to patients with episodic dyscontrol syndrome and adult ADHD have led several authors to postulate that a neurophysiologic dysfunction of the CNS may be responsible for mediating some of the symptoms experienced by patients with borderline personality disorder ([Gardner et al., 1987](#)).

Patients with borderline personality disorder were found to have a significantly greater number of soft-sign neurologic abnormalities when compared with a group of normal control subjects. The presence of two or more soft signs differentiated the two groups statistically. The authors speculated that the nonfocal, soft-sign neurologic abnormalities may reflect underlying CNS dysfunction, which may, in turn, be associated with the development of borderline personality disorder.

### **Anxiety and Withdrawal**

In their study of soft signs, [Shaffer et al. \(1985\)](#) find an odd correlation of early soft signs with *anxiety and withdrawal*. Sixty-three male and 27 female adolescents at 17 years of age, known to have had neurologic soft signs at the age of 7 years, were compared with controls with no soft signs at age 7 years. Adolescents with early soft signs had significantly lower IQs and were more likely to have a psychiatric disorder characterized by anxiety, withdrawal, and depression. All the girls and 80% (12 of 15) of the boys with a diagnosis of anxiety and withdrawal showed early soft signs. There was no relationship between early soft signs and attention deficit or

conduct disorders. Examination of relative contributions of anxiety at age 7 years, IQ, and social and family disadvantage to later diagnosis showed that most of the variance was accounted for by soft signs, independently of IQ. Soft signs and anxious, dependent behavior at age 7 were strongly predictive of persistent psychiatric disorder characterized by anxiety and withdrawal.

### Origin of Soft Signs

The origins of soft signs remain obscure. It is widely held that they have a developmental origin, by which it is usually meant that they diminish in prevalence or severity with age. This hypothesis is supported to some extent by cross-sectional studies that find a higher prevalence of individual signs among younger than older children. However, there have been relatively few longitudinal studies. [Shaffer et al. \(1985\)](#) find that a large proportion of children who have soft signs at age 7 years continue to show such signs at age 17. [Hertzog \(1981\)](#), studying a neurologically deviant population, finds that although there is diminution in amplitude and range of signs in an individual child, children with a sign at one age are likely to show signs, not necessarily the same ones, 5 years later. Further, the notion of signs being "developmental" does not elucidate the problem. The study by [Nichols and Chen \(1981\)](#) on the cohort of children aged 7 from the entire National Collaborative Perinatal Project finds few prenatal predictors, other than maternal smoking or diabetes and chorionitis, to be related to soft signs. Although the relative risk of having soft signs given one of these maternal factors is significantly increased, it is nevertheless low. Postnatal infections, illnesses, and injuries do not predict soft signs.

Nichols and Chen have also studied concordance for signs among the monozygotic and the dizygotic twins in the study population. The difference between them was statistically significant, with greater concordance found in the monozygotic twins. This finding, coupled with observations on the ratio of concordance between full siblings and first cousins, is compatible with a genetic origin of soft signs.

One is led to the conclusion that soft signs on the neurologic examination do reflect brain dysfunction in most cases and are influenced by age and heredity. They do not reliably predict ADHD or any other mental-behavioral-cognitive syndrome. In all likelihood, many soft signs reflect premotor frontal lobe underdevelopment or abnormal frontal development. The prevalence of soft signs is greatest in disorders that have been linked to frontal lobe disease, such as ADHD and schizophrenia, or to basal ganglia disorders of frontally mediated circuits, such as OCD and Tourette's syndrome.

*Psychoeducational evaluation* refers to the use of standardized psychological and educational tests and other procedures to evaluate the aptitudes, abilities, skills, knowledge, attitudes, and behaviors that affect school performance and adjustment. This chapter overviews test use in the schools. It begins with a synopsis of some of the debate provoked by school-based testing. Next comes an examination of the implications of U.S. federal law for psychoeducational evaluation. With these overviews providing a context for discussion, the chapter continues with a presentation of testing goals, types of tests, and domains of functioning typically assessed through school-based testing. The chapter ends with conclusions and implications for the child psychiatrist. (For a general discussion of psychological testing, see [Chapter 43](#).) [Chapter 43](#) presents information about psychological assessment that is essential to a full understanding of psychoeducational evaluation in the schools. All the chapters in the Section VIII B contribute information for understanding the purposes of school-based assessment and the circumstances under which it occurs. Several of the chapters on syndromes in Section VI detail disorders such as mental retardation, developmental learning disorders, and attention deficit hyperactivity disorder (ADHD) that may be first identified through school-based psychoeducational evaluation ([Chapter 120](#) and [Chapter 122](#) provide further essential information).

### SCHOOL TESTING CONTROVERSIES

A long history of controversy has surrounded the use of standardized tests in schools ([Bolon, 2000](#); [Sattler, 2001](#)). More recently, proponents and opponents of testing have rekindled debate. The catalysts for renewed argument include high levels of illiteracy, unacceptable rates of school dropout, increasing proportions of students identified as disabled, and young adults unprepared for certain sectors of the economy ([Broadfoot, 1996](#); [U.S. National Commission on Excellence in Education, 1983](#)). The disparate rates of illiteracy, dropout, disability, and vocational unpreparedness evident among communities that differ with regard to social, cultural, and economic variables add intensity to the discussion ([Duncan and Brooks-Gunn, 1997](#); [Kozol, 1991](#); [McDonnell et al., 1997](#); [Utley and Mortweet, 1999](#)).

At the level of mandatory large-scale testing, supporters reason that measuring academic progress with uniform, objective procedures is the only way to hold students and educators accountable for achievements. These same proponents adhere to the premise that standardization of educational goals and objectives will lead to equality of educational opportunity and therefore will enhance outcomes for all ([Bolon, 2000](#); [Pullin, 1994](#)). Foes of mandatory testing note the questionable reliability and validity of group-administered measures. Opponents maintain that situational factors can idiosyncratically and capriciously affect a student's test scores, thereby reducing reliability and making interpretation difficult. Further, opponents point out that concretizing achievement criteria into paper-and-pencil formats necessarily narrows the scope of the skills, behaviors, and knowledge that tests can tap. This limits test validity by reducing the correlation between test performance and classroom learning (concurrent validity) and future academic and vocational outcomes (predictive validity). Arguments opposing uniform standards regarding the measurement of educational goals and objectives also emphasize the tremendous diversity of the students and communities in the United States. Many educators worry that testing programs can lead to "teaching to the test" at the expense of comprehensive and integrated curricula that take into account the diverse backgrounds, expectations, needs, and goals of students and their families ([Cizek, 1998](#); [Madaus, 1991](#); [Pullin, 1994](#); [Sacks, 1999](#)).

At the level of individual testing, educators and policy makers who support the frequent use of psychoeducational evaluation highlight the importance of understanding individual learning styles when designing instruction and planning curriculum ([Gardner, 1993](#); [Sattler, 2001](#); [Sternberg and Grigorenko, 1997](#)). Educators who back comprehensive individualized psychoeducational assessment also point out that rates of educational disability requiring special education have increased over the past 2 to 3 decades. Nationally, rates of disability exceed 10% ([Reschly, 1996b](#); [U.S. Department of Education, 1999](#)). Thus, high rates of disability justify putting significant resources into identifying and planning for students with special needs. This approach assumes that any attempt at intervention or remediation requires a thorough analysis of the problems to be solved. In essence, accurate diagnosis must precede effective intervention, especially for remediating deficits that are associated with disability. Critics of the regular use of psychoeducational assessment respond that extensive evaluation takes resources away from instruction. Further, they argue that few data support the idea that matching instruction and curriculum with learning style leads to improved learning and performance ([Englemann and Carnine, 1982](#)). Finally, they note that norm-referenced tests have historically been used to justify the exclusion of poor and minority students from mainstream classrooms ([Artiles and Zamora-Duran, 1997](#); [Lopez, 1997](#); [Oswald et al., 1999](#)).

### FEDERAL GUIDELINES ABOUT PSYCHOEDUCATIONAL EVALUATION

State and federal regulations regarding education and disability directly affect the use of educational and psychological tests in the schools, at both large-scale and individual levels ([American Psychological Association, 1999](#)). The U.S. Individuals with Disabilities Education Act (IDEA), most recently amended and reauthorized in 1997, contains many principles and guidelines that govern assessment and evaluation. The IDEA succeeded Public Law 94-142, the historic act passed by Congress in 1975 that transformed public education in this country for all persons ([Martin et al., 1996](#)) (an overview of this law is presented in [Chapter 121](#)). This section covers only those aspects of the act that bears directly on test use and the psychoeducational evaluation process.

Federal law, as amended in 1997, promotes six principles designed to ensure that all students receive a Free and Appropriate Public Education. The six principles are (a) zero reject, (b) nondiscriminatory evaluation, (c) appropriate education, (d) least restrictive environment, (e) procedural due process, and (f) parent participation ([Turnbull et al., 1995](#)). Each of these principles has implications for the regulation of psychoeducational assessment in the schools. *Zero reject* means that no student will be denied an education. Therefore, all students are entitled to evaluations that will yield useful educational data. No students may be judged "untestable" or unable to benefit from education. *Nondiscriminatory evaluation* refers to adhering to standards and maintaining procedures that guarantee that no student will be incorrectly categorized in the special education identification process. This principle puts into place safeguards such as seeking parent permission, assessing in the student's primary language, employing tests that meet professional standards, interpreting test scores in the context of the student's cultural and social background, and using multiple measures. *Appropriate education* refers to the development of an Individual Education Plan (IEP) that takes into account the student's strengths and weaknesses and provides services that ensure that a student will actually benefit from the instruction delivered. For special education students, the goal of psychoeducational evaluation is always development or modification of an IEP. Appropriate education, by definition, leads to measurable increases in the skills, knowledge, attitudes and behaviors that are the target of a student's IEP. *Least restrictive environment* means that instruction must occur in "normative" or "inclusive" settings whenever possible. The implication of this mandate for psychoeducational evaluation is that findings and recommendations must be applied to the regular classroom setting or must provide clear data about the justification for a more restrictive setting. *Procedural due process* principles put in place steps that assure parents that they may challenge educational decisions. Parents have the right to challenge findings from school-based evaluations, either by having findings from their own experts considered by the student's team or by requesting an independent evaluation. *Parent participation* means that parents take part in all aspects of their child's educational planning, including serving as informants in the evaluation process.

The IDEA defines several categories of disability including (a) autism, (b) mental retardation, (c) specific learning disability, (d) serious emotional disturbance, (e) speech and language impairment, (f) orthopedic impairment, (g) traumatic brain injury, (h) other health impairment, (i) visual impairment including blindness, (j) hearing impairment including deafness, and (k) multiple disabilities. Further, the law requires identification of preschool children as developmentally delayed or as having a diagnosed disorder or disability that interferes with education. Gifted and talented students are to be identified, but service is not mandatory ([Wehman, 1997](#)). Psychoeducational evaluation may be an important component of the evaluation of any special education student. It is an essential component of the identification, classification, and program planning process for students with autism, mental retardation, learning disability, serious emotional disturbance, other health impairment (when identified because of ADHD), and developmental delay. It is also usually a critical component of program planning for students with traumatic brain

injury and other neurologic impairments ([Anastasi and Urbina, 1997](#); [Sattler, 2001](#)).

## PURPOSES AND TYPES OF PSYCHOEDUCATIONAL EVALUATION

School-based psychoeducational evaluation serves three major functions. The first, and the one that applies universally to all students, involves the measurement and documentation of academic progress. Almost all students participate in some kind of large-scale, standardized testing of scholastic competencies. These mass testing programs aim at documenting that students have achieved curricular goals, ensuring that schools are adequately serving their communities, and screening for students who are experiencing academic difficulty. Large-scale programs do not, and cannot, employ the kind of assessment procedures needed for diagnosis and special education identification.

The second major purpose of psychoeducational evaluation is the identification of disabled students in need of special education. Psychological and educational tests provide crucial information for establishing differential diagnoses and appropriate educational classification. The third goal of psychoeducational assessment is the development of IEPs. The use of standardized instruments by psychologists and educational specialists can elucidate neuropsychological profiles, learning styles, and cognitive strengths and weaknesses that may give teachers keys to adapting curricula for individual students. Testing may also be one of the methods used to document progress toward IEP goals.

Tests differ on several different dimensions including group versus individual, norm-referenced versus criterion-referenced, and domains of functioning assessed. Group-administered tests may be helpful screening devices. Only individual tests, administered by certified or licensed professionals, are appropriate for diagnosis and special education classification ([American Psychological Association, 1999](#)). Norm-referenced measures compare a student's performance with a specific group. Typically, the normative sample consists of age or grade peers. Supplemental samples may include special populations. If a student's background diverges from that of the normative sample, interpretation of test scores may be compromised. Inappropriate application of scores derived from normative data is one of the major criticisms leveled against test use in the schools. Criterion-referenced measures evaluate a student's performance against absolute and objective measures of skill ([Cohen and Spruill, 1990](#)). Criterion-referenced measures may delineate prerequisites for entry into a program. They may specify successful exit criteria. They may also serve as instructional benchmarks that document progress through a curriculum or course of study. Criterion-referenced measures may also be used as a part of classifying students for special education in certain circumstances and for certain disabilities.

## DOMAINS OF FUNCTIONING ASSESSED

The set of skills, abilities, and behaviors that may be assessed for educational planning is essentially infinite. For practical purposes, domains may be categorized in terms of aptitude, achievement, development during early childhood, and behavior.

### Aptitude and Achievement

Psychological and educational theories have traditionally distinguished between aptitude and achievement and have treated them as orthogonal constructs, even though considerable research documents their complex entanglement ([Ceci, 1991](#); [Daniel, 1997](#); [Hunt, 1995](#)). *Aptitude* refers to the abilities and endowed capacities that a student brings to instruction. *Achievement* refers to the repertoire of acquired knowledge and skill that a student demonstrates as a function of educational experience. In the United States, school-based testing developed during the 20th century as a reflection of these seemingly dichotomous streams. Those measuring aptitude followed in the tradition of Alfred Binet, Theodore Simon, Lewis Terman, Robert Yerkes, and David Wechsler, in search of pure measures of intelligence and other specific abilities ([Anastasi and Urbina, 1997](#)). Other researchers and pedagogues attempted to objectify and quantify achievement through development of standardized measures that could be used on a broad scale ([Bolon, 2000](#)). The press to measure aptitude and to document academic progress in the service of enhancing achievement intensified in the 1950s with the Cold War and the race for space ([Rickover, 1959](#)). In this climate, [Cronbach \(1957\)](#) advanced the still popular tenet that focus on aptitude-by-treatment interactions would increase the efficacy of all educational interventions. The idea that careful assessment of the unique individual characteristics that a student brings to the classroom is a requisite to appropriate instruction continues to guide psychoeducational assessment today.

Assessment strategies that distinguish between aptitude (or ability) and achievement remain a fixture of school-based testing today. However, researchers have typically failed to find aptitude-by-treatment interactions ([Ayers and Cooley, 1986](#); [Good et al., 1993](#); [Reynolds, 1986](#)). Search for aptitude-by-treatment interactions continues apace, however, bolstered by the knowledge that it is not possible to test the null hypothesis and the faith that it is right to fit interventions to individual circumstances and characteristics ([Naglieri, 1997](#)).

### Assessing Aptitude

Certain group-administered tests of ability or aptitude continue to be used in schools today. Group measures may tap some problem-solving aptitude that is different from the academic skills that are targeted by educational curricula. Group aptitude measures may also screen for students who are not achieving up to potential or for students who are intellectually gifted. However, interpreting scores from these tests as measures of intelligence or intelligence quotient (IQ) is *not* appropriate. Determining a student's intellectual potential is typically an integral part of most comprehensive, individual psychoeducational evaluations. In the school setting, individually administered intelligence tests are typically used for three purposes. First, scores are used to predict academic potential and to make judgments about underachievement. Second, scores from intelligence tests are used to determine criteria for disorders such as mental retardation and specific learning disability and to make special education classification decisions. Finally, patterns of strength and weakness evident on intelligence tests may be used to make inferences about learning style.

Intelligence measures can be derived from a variety of psychometric instruments; however, several tests are most commonly used in educational settings. Perhaps the most widely used test today is the Wechsler Intelligence Scale for Children, third edition (WISC-III). The WISC-III yields an overall measure of intelligence or IQ, referred to as a Full-Scale IQ, as well as quotient scores that describe verbal and nonverbal (performance) intellectual abilities. The WISC-III is most commonly used in educational settings to establish a baseline for the child's intellectual functioning. Other standardized measures, such as achievement tests or tests of language ability, can then be compared with IQ scores. Large discrepancies between intelligence and achievement, or between verbal and nonverbal abilities, may indicate potential learning disabilities or language impairments.

Another widely used measure of intelligence is the Kaufman Assessment Battery for Children (K-ABC). Similar to the WISC-III, this test provides a measure of the child's overall intellectual ability. On the K-ABC, this summary score is referred to as a Mental Processing Composite. Compared with the WISC-III, the K-ABC relies less on the child's verbal abilities and acquired knowledge and focuses more on problem solving. Based on Luria's neuropsychological model of intellect and cognition, the K-ABC provides measures of a child's sequential and simultaneous processing. In addition, it attempts to separate academic achievement and acquired knowledge from processing ability. The K-ABC can be a useful tool for determining intellectual potential when one works with children who are very young, who evidence delayed language acquisition, or who come from culturally different or culturally impoverished backgrounds. Historically, many school systems have used another measure of intellectual ability, the Stanford-Binet test. This test was one of the earliest widely used measures of intelligence and is still used by many school systems nationally. However, the more rigorously designed and widely normed WISC-III and K-ABC have become the instruments of choice for many evaluators.

Children with unique learning problems or severe disabilities often present a challenge to psychologists who wish to assess the intellectual aptitude of these children. Many children with severe motor, visual, hearing, or emotional problems may require alternative forms of assessment. Structured clinical interviews, classroom observation, behavioral and play assessments, and curriculum-based assessment are examples of alternatives often used when assessing challenging students. Alternate tests of cognitive functioning abound. When one is confronted with challenging students, perhaps the most important assessment tool is a well-trained professional who has had experience and specialized training in clinical child assessment as it relates to school performance.

### Assessing Achievement

The assessment of academic achievement remains the cornerstone of comprehensive psychoeducational evaluation and provides important information about student skill levels in various areas related to specific programs of instruction. Achievement test results are also used in conjunction with other data to determine eligibility for special education services, gifted and talented programs, and other academic curricula. As mentioned previously, results of achievement testing are also used to measure the effectiveness of individual teachers, schools, and school districts, although this practice is controversial and is fraught with difficulty. More broadly, the goal of achievement testing is to facilitate the process of learning through the assessment of academic progress.

Academic achievement can be measured in several ways. Most commonly, acquired skill and knowledge are assessed using a survey or general achievement battery. These group tests are administered by school personnel in the classroom setting and are designed to assess a range of academic competencies. At the elementary school level, measures of achievement typically focus on the academic skills of reading, mathematics, and written language. At the secondary level, advanced reading comprehension, mathematics, and writing skills continue to be measured, and achievement in content areas becomes another aspect of academic progress to be evaluated. Achievement batteries typically allow for comparison of student scores within a particular grade or age range and permit tracking of individual achievement as a student progresses from grade to grade. Typically, these tests have good psychometric properties and offer norm-referenced scores. However, these tests do not provide the detailed diagnostic and prescriptive level of assessment that is necessary for the identification of strengths and weaknesses necessitating alternative educational programming.

In contrast to general achievement batteries, diagnostic achievement tests are designed to assess specific areas of knowledge, skill, or cognitive processes thought to underlie essential academic competence. These tests are typically individually administered and allow for the identification of problem-solving deficits or gaps in knowledge or skill that may contribute to learning problems. Diagnostic tests may also tap advanced skill levels or cognitive strengths suggesting the need for enriched or accelerated education. Diagnostic tests generally focus on the assessment of basic reading skills such as decoding and phonemic awareness, reading comprehension, mathematical reasoning, arithmetic calculation, and spelling. Tests such as the Wechsler Individual Achievement Test and the Kaufman Test of Educational Achievement assess multiple academic areas, whereas other tests such as the Woodcock–Johnson Reading Mastery or the Key Math Test—Revised allow for a more detailed examination of a single skill area. Generally, diagnostic achievement tests have excellent psychometric properties, are administered by a psychologist or certified educational specialist, and are part of a comprehensive psychoeducational evaluation. Norm-referenced standard scores, percentiles, and grade and age equivalents describe academic performance relative to the cognitive abilities of the individual or to the skill levels of individuals in a normative comparison group.

### Early Childhood Development and Maladaptive Behavior

Perhaps the greatest change in school-based psychoeducational evaluation in the 1990s was the increasing emphasis on the assessment of early childhood development and on the assessment of behavioral disturbances that influence learning. Focus on these domains reflects changes in federal law and recognition that students often present with difficulties more pervasive or complex than traditional aptitude and achievement constructs can characterize. Reauthorizations of the IDEA have mandated special education for children from birth to the age of 5 years. Special education classifications now include autism as a distinct category. When revised in 1997, the IDEA established new standards for educating seriously emotionally disturbed students. Further, it clarified some issues regarding children with disruptive disorders, such as ADHD who may have special education needs. These revisions in federal law emerged from the combined wisdom of educators, researchers, and policy makers about the diverse and pressing needs of students today.

The advent of mandatory special education for preschool students has demanded the use of psychometric instruments to document developmental delay and the need for special services. Federal guidelines delineate five spheres of development requiring consideration: cognitive, language (including receptive and expressive), adaptive (meaning self-help skills), motor (including gross and fine), and personal and social. Numerous instruments have been developed for assessing these areas of functioning. The Bayley Scales of Infant Development, the Mullen Scales of Early Learning, and the Vineland Adaptive Behavior Scales are the three with the most psychometric rigor and developmental breadth ([Chapter 43](#)). These tests are not designed to assess social, emotional, and behavioral difficulties or problems with attention and state regulation that may adversely affect education. Federal guidelines and the instruments used to document preschool special education needs have been criticized for their emphasis on the criterion of developmental delay ([Meisels and Shonkoff, 1990](#)). At times, preschoolers with significant behavioral, attentional, social, and affective needs do not meet eligibility criteria based on delay. This is an area in which child psychiatry expertise can add essential methods to evaluation in the schools.

The need to assess social, attentional, and emotional disabilities that adversely affect education has increased. Children in educational settings are often identified by teachers and other school staff as having potential social, emotional, and behavioral problems that compromise their adjustment or the adjustment of others. Assessment tools can be useful for providing evidence of disabilities requiring special education. They also can be useful for identifying goals and objectives that may be the focus of a student's IEP. The most commonly used measures for assessing social, emotional, and behavioral difficulties are checklists or survey questionnaires that require informants to rate the frequency or intensity of a large number of specific behaviors. Two comprehensive inventories that are used most often in the school setting are the Achenbach Child Behavior Checklist and the Behavior Assessment Scales for Children (BASC). Extensive studies by researchers have documented the excellent reliability, validity, and functional utility of the BASC and the Achenbach test. Both the Achenbach test and the BASC have versions for parents and teachers. The BASC also has a self-report version for children older than 8 years. Responses on these inventories are converted to standardized scores on numerous different dimensions relating to internalizing, externalizing, and school-related difficulties. These data can help educators and clinicians to determine whether a student's behavior deviates significantly from age norms.

Disruptive behavior is often the presenting problem that leads to a student's referral for psychoeducational evaluation. The most widely diagnosed disruptive disorder affecting a child's academic functioning is ADHD. An integral part of the assessment of ADHD is structured observation of the child's behavior in school with formal rating scales. Parent, teacher, and self-report versions of scales measuring symptoms of ADHD are available. The most commonly used scales are Connor's Scales and the Barkley Scales ([Fennerty et al., 2000](#)). These scales allow the observer to quantify difficulties with attention, activity level, and impulsivity and to compare ratings to normative data. Although clinically significant elevations on behavior ratings are a necessary part of making the diagnosis of ADHD, they are not sufficient in and of themselves. History, clinical interview, and, at times, other tests should be employed to establish this diagnosis. In most communities, school personnel do not make this diagnosis alone. Rather, they provide data to psychologists, psychiatrists, or pediatricians that will help to establish this complex diagnosis. ADHD alone is not usually sufficient to meet the requirements for special education services. Children diagnosed with ADHD often have comorbid learning disabilities or psychiatric disorders that can interfere with their academic functioning. At times, students with severe ADHD meet special education criteria for Other Health Impairment. Thus, ratings of attention are often included as part of a comprehensive psychoeducational assessment.

Children who present with behaviors that indicate broad, atypical disturbances in development or seriously impaired social skills may evidence pervasive developmental disorders such as autism or Asperger's disorder. These children often present unique challenges in school and may puzzle and frustrate teachers and clinicians struggling to assess and remediate aspects of the disorder that compromise learning. Although school-based psychoeducational assessment may be useful for describing behaviors and aptitudes, a thorough assessment by a child psychiatrist or clinical child psychologist who specializes pervasive developmental disorders and social disabilities is essential for these students. Finally, students may present with debilitating psychiatric symptoms or behavioral disturbances that impede their academic progress. Disorders such as anxiety, depression, Tourette's syndrome, obsessive–compulsive, and psychosis may profoundly compromise academic adjustment. Again, school-based psychoeducational assessment is always an essential component of any comprehensive evaluation of a student's functioning. For these students, appropriate psychoeducational evaluation typically includes collaboration with clinical professionals outside of school who may use structured clinical interviews or projective tests to establish diagnosis and treatment goals.

### OTHER ASSESSMENT TECHNIQUES

Discussion of psychoeducational evaluation must include note of assessment techniques that augment, and often substitute for, standardized testing. The current trend emphasizes *functional* assessment ([Reschly, 1996a](#)). Functional assessment requires taking an empirical approach to studying students by intervention interactions. In functional assessment, the educational milieu is as much a subject of evaluation as is the student. Assessment identifies environmental, curricular, and interpersonal barriers to academic progress, as well as student attributes. *Classroom observations* that highlight the relation of antecedents, consequences, and student progress are essential methods of functional assessment, as are structured parent and teacher reports. *Portfolio assessment*, which entails the collection and analysis of work samples and the recording of critical incidents, is an increasingly respected method that can provide essential qualitative data that standardized measures cannot generate ([Black, 1993](#)). In *diagnostic-prescriptive teaching*, different instructional methods, materials, and modifications are tested for success. This procedure has become a staple of comprehensive psychoeducational evaluation. In this approach, assessment and intervention are dynamically linked, with student progress serving as both the outcome measure and the standard by which instruction is judged ([Arter and Jenkins, 1979](#)). Finally, clinical judgment and opinion, based on professional consultation, have important roles in school-based evaluation.

### CONCLUSIONS

Various purposes and influences determine the nature of psychoeducational evaluation in the schools. The urgency of improving outcomes for all, the demand for accountability, and federal and state mandates regarding the special education of disabled students all converge to shape the goals, methods, and philosophies of school-based evaluation programs. Historically, psychoeducational assessment has emphasized psychometric testing of aptitude and achievement. More recently, the

domains assessed have widened to include early childhood development, disruptive disorders such as ADHD, and developmental and psychiatric disorders causing social disabilities and emotional dysfunction. The assessment techniques used have also broadened to include functional assessment, classroom observation, parent and teacher report, portfolio assessment, diagnostic prescriptive teaching, and professional clinical judgment. Child psychiatrists can play an essential role in school-based evaluation. When providing case-oriented consultation regarding individual students, psychiatrists will enhance their effectiveness by considering the unique purposes of evaluation in the schools and the unique societal and legislative influences that have shaped its process and products.

## DEFINITION

The *perverse developmental disorders* (PDDs) comprise a group of neuropsychiatric disorders characterized by specific delays and deviance in social, communicative, and cognitive development, with an onset typically in the first years of life. Although commonly associated with mental retardation, these disorders differ from other developmental disorders in that their developmental and behavioral features are distinctive and do not simply reflect developmental level (Rutter, 1978). Although better definitions of the syndrome of *autism* continue to be needed, the validity of autism as a diagnostic category is now well established. The validity and definition of other proposed PDDs are more controversial (Volkmar and Cohen, 1988), but several of these conditions are included in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association, 1994).

Present definitions of the disorder remain profoundly influenced by Leo Kanner's original and phenomenologic description of the disorder (Kanner, 1943), as well as its subsequent modification by Rutter (1978). Of the various PDDs, autism has been the most intensively studied. Both categorical and dimensional approaches to diagnosis have been used (Parks, 1983; Volkmar and Cohen, 1988). Categorical approaches have typically emphasized three different areas of disturbance: social dysfunction, communicative deviance, and certain unusual behavioral features often subsumed under the rubric of *insistence on sameness*. Typically, the characteristic social and communicative deficits are believed to be aberrant relative to the person's developmental level (Volkmar et al., 1995). The development of truly operational definitions has been hindered by various factors: (a) issues of continuity with other disorders, such as schizophrenia; (b) the broad range of syndrome expression; (c) changes in syndrome expression with age; (d) the frequency of autistic-like symptoms in persons with severe mental retardation; and (e) the relative infrequency of the disorder (Volkmar and Cohen, 1988). Autism was not accorded official diagnostic status in the American Psychiatric Association's DSM until 1980, when it was included within a new class of disorders, the PDDs.

The criteria of the third edition of the DSM (DSM-III) for infantile autism included pervasive social deficits, gross deficits in language development, unusual speech patterns (when speech was present), bizarre responses to the environment, and an absence of the delusions or hallucinations typical of schizophrenia. By definition, autism was apparent by 30 months of age. A "residual" category was included for those persons who had once met criteria for autism but no longer did. Even in the relatively short period of time between the DSM-III's appearance (American Psychiatric Association, 1980) and its revision (DSM-III-R) (American Psychiatric Association, 1987), problems with the DSM-III system were apparent (Volkmar and Cohen, 1988). It lacked a developmental focus, criteria were overly restrictive, and language problems rather than broader *communication* problems were emphasized. In response to the criticism that the DSM-III criteria for autism were too "infantile" (i.e., most appropriate to younger and more severely impaired children), major revisions were made in the DSM-III-R.

The DSM-III-R provided a series of 16 individual criteria for autistic disorder. These 16 criteria were grouped into three categories (impaired social interaction, impaired communication, and restricted repertoire of activities). To achieve a diagnosis of autism, a person had to exhibit at least eight of the 16 criteria, with a specified distribution across categories. Age of onset was no longer an essential diagnostic feature, although onset (before or after 36 months) could be specified. These changes gave the DSM-III-R a greater developmental orientation, but at the apparent cost of a broadened diagnostic concept, that is, in comparison with other systems and with the substantial revisions made in the DSM-IV (Volkmar et al., 1988).

In the DSM-IV (American Psychiatric Association, 1994), the definition of autism was developed on the basis of a very large, international, multisite field trial. The final DSM-IV definition (Table 46.1) retains historical continuity with previous definitions of autism, that is, in relation to the requirements for disturbance in three broad areas of developmental dysfunction. It differs from DSM-III-R in that age of onset is included as a necessary diagnostic feature. More important, this definition is conceptually identical to that employed in the tenth edition of the *International Classification of Diseases* (ICD-10) (World Health Organization, 1994) (Chapter 39), as are the definitions of other disorders in this class; aspects of the historical development of these diagnostic concepts are discussed subsequently.

Table 46.1. DSM-IV Criteria for Autistic Disorder (299.0)

In addition to autism, other diagnostic categories are included within the PDD class in the DSM-IV. Although research on these conditions is less advanced than that on autism, there appears to be sufficient justification for their inclusion as specific diagnostic categories.

In *childhood disintegrative disorder* (also sometimes referred to as Heller's syndrome or disintegrative psychosis) (Table 46.2), children develop a condition that resembles autism but arises only after a relatively prolonged period, usually 3 or 4 years, of clearly normal development (Volkmar, 1994). This condition apparently

differs from autism in the pattern of onset, course, and outcome ([Volkmar and Cohen, 1989](#)).

- 
- A. Apparently normal development for at least the first 2 years, as manifested by the presence of age-appropriate verbal and nonverbal communication, social relationships, skills and adaptive behavior
- B. Clinically significant loss of previously acquired skills in at least two of the following areas:
- (1) Expressive or receptive language
  - (2) Social skills or receptive language
  - (3) Bowel or bladder control
  - (4) Play
  - (5) Motor skills
- C. Abnormalities of functioning in at least two of the following areas:
- (1) Qualitative impairment in social interaction (e.g., impairment in nonverbal behavior, failure to develop peer relationships, lack of social or emotional reciprocity)
  - (2) Qualitative impairments in communication (e.g., delay or lack of spoken language, inability to initiate or sustain a conversation, stereotyped and repetitive use of language, lack of varied make-believe play)
  - (3) Restricted, repetitive and stereotyped patterns of behavior, interests and activities, including motor stereotypies and mannerisms
- D. Not better accounted for by another specific Pervasive Developmental Disorder or by Schizophrenia
- 
- From American Psychiatric Association, Diagnostic and Statistical Manual, 4th ed. (DSM-IV), Washington, DC, American Psychiatric Association Press, 1994, with permission.

**Table 46.2. DSM-IV Criteria for Childhood Disintegrative Disorder (299.10)**

In *Rett's disorder* ([Table 46.3](#)), a very brief period of normal development is usually followed by a period of decelerated head growth, loss of purposeful hand movements, onset of characteristic hand-washing stereotypies, and development of severe psychomotor retardation ([Tsai, 1994](#)). This condition has, to date, been observed only in girls. Although the course of this condition differs markedly from that of autism, there is a period of time, particularly in the preschool years, when confusion with autism may occur.

- 
- A. All of the following:
- (1) Apparently normal prenatal and perinatal development
  - (2) Apparently normal psychomotor development through the first 6 months
  - (3) Normal head circumference at birth
- B. Onset of all of the following between 5 and 48 months:
- (1) Deceleration of head growth
  - (2) Loss of previously acquired purposeful hand movements, with the development of stereotyped hand movements (e.g., handwringing or handclapping)
  - (3) Loss of social engagement early in the course (although often social interaction develops later)
  - (4) Appearance of poorly coordinated gait or trunk movements
  - (5) Marked delays and impairment of expressive and receptive language with severe psychomotor retardation
- 
- From American Psychiatric Association, Diagnostic and Statistical Manual, 4th ed. (DSM-IV), Washington, DC, American Psychiatric Association Press, 1994, with permission.

**Table 46.3. DSM-IV Criteria for Rett's Disorder (299.80)**

Of the various disorders potentially included with the PDD class, the validity of Asperger's disorder as separate from autism has probably been the most controversial. Given the absence of "official" definitions, the term has been used in markedly different ways ([Klin, 1994](#)). It appears that the condition differs from autism in that it is associated with higher levels of cognitive and communicative skills and an absence of signs of central nervous system (CNS) dysfunction. Unusual preoccupations (e.g., with train schedules) and high degrees of egocentrism are common, as are motor delays ([Klin, 1994](#)). Similar traits are sometimes noted in family members. The DSM-IV and ICD-10 definitions of this condition are compatible ([Table 46.4](#)).

- 
- A. Qualitative impairment in social interaction of the type described for autism ([Table 46.1](#))
- B. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities of the type described for autism ([Table 46.1](#))
- C. Lack of any clinically significant general delay in language (e.g., single words used by age 2, communicative phrases used by age 3)
- D. Lack of any clinically significant delay in cognitive development, as manifested by the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment
- E. Does not meet criteria for another specific Pervasive Developmental Disorder
- 
- Adapted from American Psychiatric Association, Diagnostic and Statistical Manual, 4th ed. (DSM-IV), Washington, DC, American Psychiatric Association Press, 1994, with permission.

**Table 46.4. DSM-IV Criteria for Asperger's Disorder (299.80)**

The term Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS), also referred to as atypical personality development, atypical PDD, or atypical autism, is included in the DSM-IV to encompass "subthreshold" cases, such as when marked impairment of social interaction, communication, interest, or a stereotyped behavior pattern is found, but full criteria for autism or another explicitly defined PDD are not met. This *subthreshold* category is, thus, defined implicitly; that is, no specific guidelines for diagnosis are provided, and the concept has been broadened compared with the DSM-III-R. Although deficits in peer relations and unusual sensitivities are typically noted, social skills are less severely impaired than in classic autism. The lack of definition for this relatively heterogeneous group of children presents problems for research into this condition.

In addition to categorical diagnostic systems, various dimensional approaches to diagnosis have also been employed ([Parks, 1983](#)). These approaches are based on parent or teacher report or direct observation. Typically, deviant behaviors are rated or sampled with attendant issues of standardization and reliability. Changes in syndrome expression over the course of development and the prevalence of high levels of "autistic-like" behaviors in severely retarded persons also pose problems for the development of such instruments. Some work ([Lord et al., 1991](#)), focused on the development of diagnostic and assessment instruments specifically keyed to diagnostic criteria, offers particular advantages for research studies.

## HISTORICAL NOTE

In the 20th century, various diagnostic concepts were proposed to encompass severe psychiatric disturbances of childhood onset. The history of diagnostic concepts illustrates the pitfalls of simple extension of concepts derived from work with psychotic adults; indeed, children's changing conceptions of reality and normative beliefs in fantasy figures suggest the need for considerable caution in such attempts ([Volkmar et al., 1995](#)).

Diagnostic concepts proposed for childhood "psychosis" are presented in [Table 46.5](#). Of particular note is the early interest in the extension of Kraepelin's description of dementia praecox to children. Early assumptions of continuity between severe childhood psychiatric disturbance and adult schizophrenia were based, in large part, on the severity of the disorders. The term *childhood schizophrenia* became synonymous with *childhood psychosis*. In 1943, Leo Kanner described 11 cases of "early infantile autism" and noted various ways in which this disorder appeared to be distinctive ([Kanner, 1943](#)). These children exhibited an apparently congenital inability to relate to other people (in contrast to an apparent ability to relate to objects); their language (when it developed at all) was remarkable for echolalia, pronoun reversal, and concreteness. Behaviorally, these children engaged in repetitive, apparently purposeless activities (stereotypy), were highly responsive to the inanimate environment, and were intolerant of change. Kanner's use of the term *autism* was meant to convey the unusual, self-centered quality that his cases exhibited, but it was also suggestive of the autism associated with schizophrenia. Although Kanner's description has been remarkably enduring, his speculations about certain

aspects of the condition (e.g., normal levels of intelligence, lack of association with other medical conditions, unusual levels of parental education) proved incorrect (Cohen et al., 1994). The validity of Kanner's concept as distinct from schizophrenia was established over the next several decades only, as various lines of evidence became available.

Diagnostic Concept (Current Terminology)	Originator
Dementia praecox	DeSanctis, 1906
Dementia infantilis (disintegrative disorder)	Heller, 1928
Early infantile autism (autistic disorder)	Kanner, 1943
Autistic psychopathy (Asperger syndrome)	Asperger, 1944
Atypical personality development	Rank, 1949
Rett syndrome	Rett, 1966

**Table 46.5. Development of Diagnostic Concepts: Childhood “Psychosis”**

Heller proposed the term *dementia infantilis* to account for children who develop normally for some period before profound developmental regression (Heller, 1930/1969). His concept, also known as *disintegrative disorder*, is now included in the DSM-IV. In 1944, Asperger proposed a novel concept, *autistic psychopathy*, which resembled Kanner's concept in some ways (Asperger, 1944). This disorder, now usually known as *Asperger's syndrome* or disorder to avoid the confusion produced by the word *psychopathy*, has been described particularly in the European literature; in the United States, such persons are more likely to be termed autistic (Cohen et al., 1994). The continuity of Asperger's disorder with autism remains debated; the disorder is of some interest, to the extent that it may establish areas of continuity between autism and other disorders.

## PREVALENCE AND EPIDEMIOLOGY

Since the first epidemiologic study of autism placed the rate in the population at around four per 10,000 (Lotter, 1966), more than 20 studies have been published in the English language. In a review of these studies, Fombonne (1999) reports prevalence estimates that ranged from 0.7 per 10,000 to 21.1 per 10,000, with a median prevalence estimate of 5.2 per 10,000. Not surprisingly, the most important factor accounting for these differences is the nature of the definition used for autism (Wing, 1993), with broader definitions yielding higher rates. Other factors accounting for differences include differences in screening and ascertainment procedures and the size of target populations. Consistent with widespread views that the rate of autism may have been on the increase since the early 1980s (Fombonne, 1996), prevalence rates have significantly increased with publication year, with a median rate of 7.2 per 10,000 for surveys conducted since 1989 (Fombonne, 1999). However, even though this increase in reported rates may reflect an actual increase in the incidence of autism owing to specific environmental or other processes, data to date indicate that this increase has been primarily related to case definition (i.e., more recent studies are more likely to adopt broader definitions of autism and to include conditions that are similar to autism) and case recognition (i.e., there is increased awareness of autism and related conditions in both the general population and the mental health community). Moreover, estimates of prevalence may be affected by issues of diagnosis in the extreme ranges of the condition, that is, the severely mentally retarded and the nonretarded persons with autism. For example, in a study by Honda and colleagues (1996), about half of the identified sample with autism had intelligence quotients (IQs) of at least 70, a finding contrasting with the rate of about 20% reported in most studies for intellectual functioning within the normative range. Although increased awareness and better detection techniques for identification of cases in the extreme ranges may contribute to the more recent prevalence rates, it is also the case that diagnosis is most difficult, and less reliable, in these cases (Klin et al., 2000). Consistent with gender proportion found in clinically referred samples (Lord et al., 1982), Fombonne (1999) reported that the average male:female ratio across studies was about four males for every female. However, this ratio varied according to the absence or presence of mental retardation: in the moderately to severely retarded range, the median gender ratio was less than two males to one female, whereas the median gender ratio in the normative IQ range was more than six males to every female. Although, over the years, potentially causal medical associations have been reported for autism, the strongest connection appears to be with tuberous sclerosis; approximately 20% of patients with this disorder may also appear to exhibit autism (Baker et al., 1998; Hunt and Shepherd, 1993). Tuberous sclerosis is observed in only a small number of cases of autism.

Estimate rates for conditions marked by severe social impairments that fall short of stricter diagnostic criteria for autism (i.e., PDD-NOS) have typically been two to three times higher than the rate of autism (maybe one per 600 or so), although issues of definition and ascertainment become even more acute with this group. Similar methodologic issues question the very high rates reported in a few studies of Asperger's syndrome (Fombonne, 1997). The other PDDs are less common than autism. For example, childhood disintegrative disorder is perhaps 10 times less common than more strictly defined autism (Volkmar and Rutter, 1995), and Rett's disorder or syndrome is similarly uncommon (Leonard et al., 1997). With the exception of Rett's syndrome, which affects female patients almost exclusively, a male predominance has been reported in the other nonautistic PDDs.

## CLINICAL DESCRIPTION

### Age of Onset

In most cases, the apparent onset of autism occurs within the first or second year of life. Age of onset (more properly termed age of recognition) of the PDDs has been important in differentiating these disorders from others (e.g., childhood schizophrenia) and in making distinctions within the PDD class. Studies of large series of cases of “psychotic” children have generally revealed a bimodal distribution of age of onset; children with disorders developing in the first or second year of life are more likely to have autism, whereas those with disorders developing later in childhood, particularly during adolescence, are more likely to exhibit problems more typical of schizophrenia (Chapter 60).

Although Kanner (1943) believed that autism was present from, or shortly after, birth, subsequent work has suggested that the disorder sometimes can be observed after some months, or even a few years, of relatively normal development (Volkmar, 1985). Figure 46.1 illustrates the age of apparent onset (i.e., recognition) of 103 persons with DSM-III diagnoses of infantile autism or childhood-onset PDD and suggests that most cases are recognized in the first or second year of life. Data from detailed parental reports (Volkmar and Cohen, 1988) and from retrospective analyses of videos made during infancy (Osterling and Dawson, 1994) suggest that many children who do not receive diagnoses of autism until later show some differences in social responsiveness and communication, for example, not responding when called by name, at or around their first birthday. Certain factors (e.g., status as a first-born child, parental denial, bilingual household, relatively high intellectual level in child) may act to delay case detection. For example, Asperger's disorder may be detected somewhat later than more typical autism, given the relatively higher intellectual levels and the relative preservation of communicative skills reported to be associated with the disorder (Klin, 1994). In addition, parents of about one-fourth of children with autism spectrum disorders report that their children had a few meaningful words and then stopped talking completely for more than a month, and sometimes for years. Often the loss of words is accompanied by, or preceded by, loss of social skills such as playing patty cake or waving goodbye. This pattern of behavior appears to be quite specific to autistic spectrum disorders, although it is not universal.

**Figure 46.1.** Age of recognition of autism/childhood onset PDD. (From Schopler E, Mesibov G (eds): *Diagnosis and Assessment in Autism*. New York, Plenum Press, 1988, p. 80.)

Children with apparent disintegrative disorder develop an autistic-like condition after a longer period (2 or more years) of unequivocally normal development ( [Volkmar, 1994](#)), which includes the spontaneous use of meaningful phrases, and it often involves loss of toileting, use of utensils, and other adaptive and motor skills. In contrast, in Rett's syndrome, the period of normal development is quite short, usually a few months ( [Tsai, 1994](#)), and it involves the specific loss of directed use of the hands, as well as the development of repetitive behaviors of the hands around the midline.

### Social Disturbance

Autism was initially described by Kanner as a disturbance of affective contact. Social dysfunction in autism is distinctive; it is not explicable in terms of mental age delay in itself and is a, if not the, central defining feature of the disorder. Social features, along with level of language skills and nonverbal intelligence, are the greatest predictors of independence and long-term diagnosis ( [Venter et al., 1992](#)).

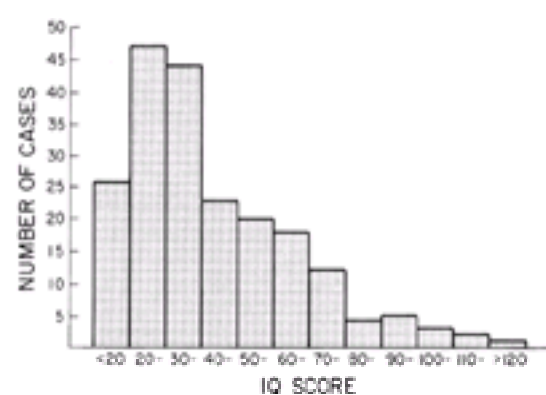

In part, this is testimony to the rapidity and complexity of development of social skills in typically developing children. Normally developing infants are remarkably social, even in the first few months of life. They exhibit an apparent predisposition to form social relationships; this predisposition appears to be an important foundation for the development of other skills ( [Stern, 1987](#)). The social development of autistic children is distinctive in many ways. The human face holds little interest for the autistic infant; lack of eye contact, fewer socially directed behaviors such as facial expressions, vocalizations, or pointing and a lack of interest in other children are typical. Deficits in social interaction in autism change somewhat over the course of development but remain an area of great disability even for the highest-functioning, nonretarded autistic adults. The social deficits in childhood disintegrative disorder and Asperger's disorder are similar to those observed in persons with autism with comparable language and intellectual levels.

### Communicative Disturbance

Deficits in the development of expressive language are the most common source of initial concern for parents of children later diagnosed with autism. Communication problems appear to be a central aspect of the syndrome. Epidemiologic studies have indicated that approximately half the patients with autism never use speech as their primary method of communication, although this number may be decreasing with earlier, more effective intervention ( [Dawson and Osterling, 1997](#); [Rogers, 1998](#)). Those who do speak exhibit language that is distinctive in numerous ways ( [Paul, 1987](#)). The speech of autistic persons is remarkable for the use of stereotyped phrases and delayed echolalia (saying, "Time for bed, honey" as a request to leave the office); pronoun reversal; failure to use appropriate cadence and intonation; impaired semantic development; extreme literalness; and failure to use language for social interaction. Immediate echoing (i.e., repeating right back what someone just said) is observed in normally developing children who are acquiring language, as well as children with autism and those with language impairments, and both types of echolalia may be positive communicative features that can be used to help build a child's language further. Deficits in pragmatic communication, particularly the ability to have a back-and-forth conversation, are common. The language and communicative deficits in autism differ from those seen, for example, in the developmentally language-disordered child ( [Paul, 1987](#)), primarily in the social difficulties that they reflect and in the degree of severity of delay in both receptive and expressive language ( [Lord 1995](#)). The communicative development of persons with apparent Asperger's disorder appears to be less severely impaired than that observed in persons with more classic autism and may represent an area of strength, at least in certain respects ( [Klin, 1994](#)). Children with more fluent, although delayed, language are also more often diagnosed with PDD-NOS or atypical autism. (Towbin, 1997) In Rett's disorder and childhood disintegrative disorder, communication skills, particularly expressive language skills, are usually very limited ( [Tsai, 1994](#); [Volkmar, 1994](#)).

### Cognitive Development

Kanner's initial impression that children with autism exhibited normal levels of intelligence was based on their intelligent appearance and the observation that they performed quite well on certain parts of traditional tests of intelligence; this initial characterization proved incorrect, because most, although not all, persons with autism have since been shown to have significant delays across a range of behaviors concordant with mental retardation. Although attempts were made to account for poor test performance on the basis of "negativism" or "untestability," it became clear that, when developmentally appropriate tests were employed, most (approximately three-fourths) persons with autism scored in the mentally retarded range ( [Fig. 46.2](#)). IQ scores are relatively stable and predictive of outcome ( [Klin and Shepard, 1994](#)). Conversely, marked scatter in performance on tests of intelligence is common and differs from the usual pattern observed in retarded nonautistic children. Islets of unusual ability (e.g., rote memory or block design) may be present ( [Klin and Shepard, 1994](#)). A few autistic persons exhibit truly remarkable abilities, for example, in musical or drawing ability or in exceptional feats of memory, such as the ability to name days of the week corresponding to dates several years in advance ("calendar calculators"). Autistic persons exhibit persistent deficits in abstract thinking and in sequencing and processing information. Lower levels of intelligence are associated both with a greater risk of developing a seizure disorder in adolescence and with a worse outcome. The pattern of verbal versus nonverbal (performance) IQ appears to differentiate persons with autism from those with Asperger's disorder. As may be expected, given that relative preservation of early language skills is the major differential feature of the two conditions, persons with Asperger's disorder often have markedly higher verbal IQ scores, whereas there is more variation in higher functioning persons with autism ( [Klin, 1994](#)).

**Figure 46.2.** Full-scale IQ distribution for 203 autistic individuals, Child Study Center sample. (From Volkmar FR, Cohen DJ: Classification and diagnosis of childhood autism. In: Schopler E, Mesibov G (eds): *Diagnosis and Assessment in Autism*. New York, Plenum Press, 1988.)

Cognitive deficits may be apparent in infancy, and scatter in developmental examination is apparent during the preschool years. In general, autistic children do best with tasks that involve motor and perceptual-motor skills and worst with tasks that involve symbolic information and verbal skills ( [Klin and Shepard, 1994](#)).

### Behavioral Features

The contrast between the response of a child with autism to the inanimate environment (e.g., seeing the credits flash by on television) and the lack of response to social cues (e.g., the voice of a parent) is often quite striking. A child may show relatively little differentiation of his sibling from other children but be particularly attached to an unusual object, such as a spongy puzzle piece. Although parents may initially be concerned that their child with autism is deaf, often the child is quite sensitive to certain nonspeech sounds (e.g., the vacuum cleaner or a jingle on the radio). Interest in nonfunctional aspects of objects (e.g., taste or feel) and stereotyped (purposeless and repetitive) movements are common and include hand flapping, toe walking, spinning objects, and the like. Such activities appear to be preferred modes of behavior and can consume much of the child's time. Unusual affective responses are also common; a child may become panicked in response to new situations, such as having to walk across a porch to a door or regularly recurring stimuli such as singing in church. Play skills are typically quite deviant, accompanied by deficits in imaginative play. These aspects of the disorder are shared with many children without autism who have severe or profound mental

retardation, but they appear to be more common in autism and occur even in children with autism who have normal intelligence ( [Volkmar and Cohen, 1988](#)).

## Developmental Changes

As with other children, significant changes occur over the course of development ( [Rutter, 1970](#)). Typically, preschool children with autism exhibit the more classic syndrome picture previously referred to as infantile autism, with marked lack of interest in other people, absent or severely delayed communication, and cognitive delays. Delays in case detection remain, unfortunately, relatively common because parents are often initially reassured that the child is “just a late talker.” Although parents often report earlier concerns about the child's development, usually delayed language development is the cause for referral. Many children with autism do not show clear repetitive behaviors at the age of 2 years, even though they do show clear social and communicative deficits; behavior may become more obviously stereotyped and unusual as the child enters the later preschool years ( [Lord, 1995](#)). By school age, many children with autism become more responsive socially, develop some response to joint attention (e.g., become able to follow a point), and, in some cases, become more socially directed to familiar people. Language skills and simple gestures may improve considerably, although other skills may be quite deviant. Self-stimulatory and other problematic behaviors, such as self-abuse, also become more common and more difficult to manage. In adolescence, a few persons with autism make marked developmental gains; another subgroup shows very problematic deterioration in behavior. The onset of seizures in adolescence is relatively common, particularly in more severely retarded persons ( [Rutter, 1970](#)). As adults, many of these patients remain severely impaired. Those persons who are able to achieve personal and occupational self-sufficiency still exhibit residual difficulties in interpersonal interaction; typically, these are persons with the highest levels of cognitive and communicative skills.

In Asperger's disorder, the higher intellectual levels, in general, suggest a somewhat better long-term prognosis. Conversely, patients with this condition have been reported to be at increased risk of other psychiatric disturbance, such as psychosis ( [Klin, 1994](#)). The limited data available suggest that the outcome in childhood disintegrative disorder is even worse than that of autism: minimal levels of developmental recovery are typical after the developmental regression. In Rett's disorder, the course of the condition is quite characteristic. Various unusual behaviors (e.g., breath holding, air swallowing) and motor problems (e.g., ataxia, apraxia) are observed, and the patient becomes severely or profoundly mentally retarded ( [Tsai, 1994](#)).

## ETIOLOGY AND PATHOGENESIS

### Biological Mechanism

As the validity of the autistic syndrome became more firmly established, various lines of evidence converged to suggest the importance of neurobiological factors in the pathogenesis of this and similar conditions. Although the variety and consistency of this evidence are impressive, neither specific biological markers for autism nor precise pathogenic mechanisms have been identified. Autistic persons exhibit an increased frequency of physical anomalies, persistent primitive reflexes, and various neurologic soft signs, as well as increased abnormalities on electroencephalograms (EEGs) ( [Golden, 1987](#)). Brain imaging studies reveal various associated abnormalities. Autistic persons are at increased risk of developing seizure disorders ( [Rutter, 1970](#)). The autistic syndrome is observed more commonly (although by no means invariably) in an apparently diverse group of medical conditions, such as tuberous sclerosis, phenylketonuria, maternally inherited deletions (Angelman's syndrome) and duplications of chromosome 15q11-q13, and fragile X syndrome, but much less commonly with others, such as Down's syndrome ( [Cohen et al., 1994](#)). Autism has also been associated with diverse prenatal and perinatal risk factors ( [Tsai, 1987](#)). Similar, although less extensive, data suggest the importance of neurobiological factors in Rett's disorder and childhood disintegrative disorder. The DSM-IV classified pervasive developmental disorder, Rett's syndrome, has been found to result from mutations in a specific gene, *MECP2* ( [Amir et al., 2000](#)). The role of genetic mechanisms in autistic disorder is suggested by the observation that siblings of affected persons are at a 45-fold or greater risk of autism than the general population and are at higher risk of developing various language and cognitive problems; studies of monozygotic and dizygotic twins have shown an increased concordance for autism in monozygotic twin pairs ( [Cook, 2001](#); [Rutter et al., 1997](#)). The apparent genetic component is likely to be more robust in Asperger's disorder ( [Volkmar et al., 1998](#)).

### Family Factors

Kanner's initial report of the autistic syndrome emphasized the apparently congenital nature of autism but also noted the remarkable degrees of occupational success observed in the parents of these first patients, as well as evident deficits in parent-child interaction. These latter observations were subsequently taken to suggest some role of parental psychopathology in syndrome pathogenesis. During the 1950s and 1960s, considerable efforts were made to remediate the effects of deviant caregiving practices of cold (“refrigerator”) parents through, for example, extensive child and parent psychotherapy. Various lines of evidence now make it clear that deviant child-rearing practices do not account for autism. Parents of autistic children resemble parents of children with other developmental problems; they do not exhibit specific deficits in child-rearing practice, nor do they have unusual personality traits ( [Cohen et al., 1994](#)). In retrospect, it appears that early notation of deviant patterns of parent-child interaction may just as well have reflected deviance contributed by the child rather than by the parent; similarly, early studies showing an association of autism with higher social class appear to be artifacts introduced by ascertainment bias; for example, more successful and well-educated families are more likely to seek treatment ( [Schopler et al., 1980](#)). It is clear that the parents of autistic children may be understandably stressed by the experience of caring for a severely impaired child and may suffer from depression and anxiety. In childhood disintegrative disorder, parents often observe some psychosocial or medical event in association with the onset of the condition, such as the birth of a sibling, the death of a grandparent, or hospitalization for elective surgery. It seems likely that such events are simply chance, rather than causal, associations, given their frequency in this age group ( [Volkmar, 1994](#)).

### Environmental and Social Influences

The word *autism* suggests the self-contained quality exhibited by autistic persons. Although evocative, this description tends to minimize the significant impact that the environment can have on persons with autism and related disorders. Early psychodynamic views tended to overemphasize the maladaptive qualities of certain deviant behaviors; for example, poor performance on IQ tests was thought to result from intentional “negativism,” and echolalia was seen as a maneuver used by the child to distance himself or herself from social interaction. Experimental and other data have led to a significant revision of this view. It is clear, for example, that autistic children are not unduly negativistic; they may behave oddly in certain situations, but many aspects of behavioral functioning can be understood as adaptive attempts to cope with a confusing environment. Levels of appropriate behavior are, for example, highest in more highly “structured” situations, and treatment programs that emphasize specific educational goals in the context of highly regulated interactions are more commonly associated with behavioral improvement ( [Lockyer and Rutter, 1969](#)).

## LABORATORY STUDIES

### Biological Studies

Autism and related conditions have been observed in association with certain other conditions ( [Anderson and Hashino, 1997](#); [Golden, 1987](#)). As part of a comprehensive examination, it is important to conduct a careful medical and family history. Genetic screening for various inherited metabolic disturbances is indicated, because some inherited disorders are associated with autism (e.g., phenylketonuria). Chromosome analysis and, possibly, genetic consultation are indicated in the presence of mental retardation or signs of inherited disorders, such as the fragile X syndrome. Hearing tests have often been conducted by the time a child is referred for specialized evaluation; when usual audiologic assessment procedures cannot be employed, brain stem auditory evoked response testing is indicated. Neurologic consultation should be obtained if the child has signs suggestive of overt seizure disorder or other evidence of gross neurologic dysfunction or if unusual features are present (e.g., late onset). EEGs may be helpful in such cases. Computed tomography or magnetic resonance imaging scans may be indicated and sometimes reveal disorders such as tuberous sclerosis or degenerative CNS disease. A history of prenatal or postnatal infections (e.g., congenital rubella) is sometimes elicited. The nature of medical conditions associated with autism and other PDDs remains somewhat controversial. Some investigators suggest a very high frequency of associated medical conditions ( [Gillberg, 1990](#)), but such estimates may be artificially inflated by methodologic and other problems. It appears that the frequency of autism is probably higher than expected in relation to certain medical conditions, although such instances account for only a small proportion of cases of autism ( [Bailey et al., 1993](#)). In general, it seems appropriate to conduct a reasonable search for such conditions, keeping in mind the relative costs of laboratory and other procedures; that is, the choice of laboratory tests or consultations should be guided by the history and examination.

### Psychological Studies

By definition, persons with PDDs have developmental problems in multiple areas of functioning. It is particularly important to approach aspects of psychological assessment, as broadly defined, in a systematic fashion. Problems in assessment are often posed by the difficulties in engaging affected persons, by the need to employ developmentally appropriate assessment methods, and by the degree of developmental scatter commonly associated with these conditions. Commonly, multiple evaluation sessions and the efforts of an interdisciplinary treatment team (including a psychiatrist, a psychologist, and a speech and communication

specialist) are needed. Services of neurologists, as well as physical and occupational therapists, may also be appropriate, such as regarding management of seizure disorder or motor problems.

Intellectual functioning can be assessed by the administration of various standard tests of intelligence or development ( [Klin and Shepard, 1994](#)). To the extent possible, it is helpful to obtain estimates of both verbal and nonverbal or performance IQ. Typically, nonverbal skills are less severely impaired than more abstract verbal skills, which involve sequencing and coding of information. For very low-functioning persons, administration of tests developed for infants and very young children may be appropriate. Adaptive behavior should be systematically evaluated; this is relevant both in terms of documenting degrees of associated mental retardation and for program planning. Speech and communication assessment, not simply limited to evaluation of expressive language or articulation, should be conducted. Psychiatric assessments should include both direct observation and consultation with parents and schools; careful evaluation of reported autistic-like symptoms is indicated. Various rating scales and checklists may aid the diagnostic process but do not replace the need for careful and thoughtful clinical assessment. Associated behavior problems are best evaluated in light of careful developmental assessments. [Table 46.6](#) summarizes evaluation procedures.

1. Historical information (Age development and characteristics of development Age and nature of onset Medical and family history)
2. Psychological and communicative examination (Estimate of intellectual level (particularly nonverbal IQ) Communicative assessment (receptive and expressive language use of nonverbal communication, pragmatic use of language) Adaptive behavior Evaluation of social and communicative skills relative to nonverbal intellectual abilities)
3. Psychiatric examination (Nature of social responsiveness (eye contact, attachment behaviors) Behavioral features (stereotypy/self-stimulation, resistance to change, sensory sensitivities to the environment, etc.) Play skills (nonfunctional use of play materials, developmental level of play activities)
4. Medical evaluation (Associated medical conditions (infectious, genetic, prenatal and perinatal risk factors, etc.) Genetic screen (chromosome analysis and genetic consultation if indicated) Hearing test (if indicated) Consultation (neurologic/pediatric/occupational or physical therapy) as indicated by history and current examination (e.g., EEG, CT/MRI scan)

**Table 46.6. Evaluation Procedures: Autism and Pervasive Developmental Disorders**

## DIFFERENTIAL DIAGNOSIS

Autism and related disorders must be differentiated from other conditions, such as language and other developmental disorders and sensory impairments, particularly deafness. Mental retardation often coexists with autism, and the frequency of autistic-like symptoms increases with more severe retardation ( [Wing and Gould, 1979](#)). Disagreements regarding diagnosis are most pronounced at both ends of the IQ distribution, that is, among very low-functioning and high-functioning persons (Volkmar et al., 1997). Because of the multiple areas of impairment, a multiaxial, developmentally based approach is particularly useful. Specific behavioral features are best viewed in the context of measures of both intellectual and communicative capacities ( [Table 46.6](#)). Individual tests and assessment instruments should be selected as appropriate to the individual patient; measures of adaptive skills in communication and socialization can be viewed in relation to overall cognitive skills and also serve a valuable function in guiding remedial programs. The degree of any associated mental retardation should be noted. Associated medical conditions should be identified; audiologic evaluation is indicated if there are concerns about the child's hearing ability.

Provision of historical information can aid the diagnostic process. The diagnosis of autism is more straightforward when the parents report no history of apparently normal development and when the behavioral deviation is of long standing. Less commonly, some period of apparently normal development precedes the apparent onset of the illness. Questions about specific developmental skills or about development at times of usually well-remembered events (e.g., the child's first birthday) may help to clarify aspects of the early history. Although a few autistic children appear to have had some period of reasonably normal development, such a history suggests that elective mutism, Rett's disorder, childhood disintegrative disorder, language disorder, schizophrenia, and degenerative CNS disorder should be considered in addition to autism. Although some children with histories of severe neglect exhibit deficits in attachment, such deficits typically remit with adequate care, and other features of autism are not typically present. The limited available evidence suggests that children with PDD-NOS probably come to professional attention rather later than is the case with autistic children, and intellectual deficits are less common ( [Dahl and Cohen, 1986](#)). The pattern of onset in disintegrative psychosis is distinctive, although, behaviorally, such patients may be indistinguishable from more typically autistic ones. Both abrupt and gradual developmental regressions have been noted, and intensive neurologic examination does not necessarily reveal a specific cause. Reports of cases of apparent Asperger's disorder suggest that language skills are relatively more preserved, whereas motor delays are more common than in autism. Unusual features (e.g., rapid deterioration in an otherwise normally developing child) suggest the need for thorough medical evaluation. The diagnostician's task is particularly complex when dealing with younger and more severely impaired patients. In some cases, the exact nature of the disorder becomes most clear only over the course of development.

## TREATMENT

Given the severity of these conditions and the relatively poor prognosis, it is not surprising that many varied treatments have been used, including various pharmacologic treatments, somatic treatments (such as electroshock therapy and "patterning"), behavior modification, educational intervention, psychotherapy, dietary change, and the like ( [DeMyer et al., 1981](#)). Unfortunately, until relatively recently, problems in study design and in sample description or selection have made it difficult to assess many treatments systematically. Short-term changes may reflect nonspecific effects and be neither sustained nor clinically significant. It is just such changes, which may be associated with various novel and unproven treatments that are reported, on average, approximately every 6 months in the lay press. Sadly, such reports, usually of amazing successes, are hardly ever rigorously conducted or evaluated. For example, it was suggested that very low-functioning persons with autism were able to communicate through a special modality (facilitated communication) in which the hand of another person (the facilitator) guided that of the person with autism to type out messages on a keyboard or letterboard ( [Cohen et al., 1994](#)). Although the utility of various augmentative communication skills in autism is well established, and although some persons with autism do indeed have particular facility with written (as opposed to oral) expression, systematic study revealed that the alleged communications were most often the product of the facilitator rather than the child ( [Eberlin et al., 1993](#)). Unfortunately, this occurred after some school systems and families had completely reorganized their treatments and goals for these children.

At present, the best available evidence points to the importance of appropriate educational interventions to foster the acquisition of basic social, communicative, and cognitive skills ( [Committee on Educational Interventions for Children with Autism, 2001](#); [Rogers, 1998](#)). Appropriate intensive education not only teaches children with autism spectrum skills that they need to learn and helps them to make more sense of the world, but also it should provide support and training for parents. Behavior modification procedures may be helpful in increasing appropriate and decreasing inappropriate behaviors and may facilitate involvement in educational programming ( [Lovass, 1987](#)). It is clear that early and continuous intervention is highly desirable and has measurable effects on later intellectual and communicative functioning, although initial claims ( [Lovass, 1987](#)) of specific programs resulting in "recovery" from autism in a substantial minority of children with autism have not been replicated ( [Smith and Antolovich, 2000](#)). Educational interventions are best provided over a full day of school (unless a child is very young) on a year-round basis; the usual pattern of summer school vacations is typically not well tolerated by autistic children. Professionals should work with parents to advocate the availability of appropriate educational placements and ancillary services, such as respite care. Because there are often many professionals involved in an evaluation, it is vital that fragmentation of effort be avoided by ensuring that information among professionals and to the parents is conveyed in a timely and responsible fashion. Engagement with persons with autistic spectrum disorders and their families can be lifelong and entails attention to educational interventions, group living situations, and involvement in community-based day and vocational programs, as well as to aspects of family support. Advocacy groups such as the Autism Society of America and similar groups in the United States and other countries have been helpful in this regard; these groups may offer important sources of support to parents as well. Psychotherapy is not usually indicated for children with autism, although it may be useful in higher-functioning adolescents or adults with fluent language, including those with Asperger's syndrome. In such cases, therapy should be carefully focused on specific goals, whether behavioral or emotional and supportive ( [Riddle, 1987](#)). Cognitive-behavioral therapy that is specifically tailored to the individual strengths and difficulties of the person with an autistic spectrum disorder may be helpful with adolescents and adults, as may social groups that provide opportunities for learning and practice of social skills with peers and relevant to work.

Although none of the pharmacologic agents used in the treatment of autism and related conditions have proven curative, certain medications, particularly the major tranquilizers, have been shown to have an important, limited role in the management of certain cases ( [Tanguay, 2000](#)). Careful double-blind studies using haloperidol have demonstrated enhanced learning and improved behavioral adaptation. The major tranquilizers may act to decrease activity levels, increase relatedness and task involvement, and increase accessibility to remediation programs. Patients who receive pharmacologic treatments should be carefully monitored for side effects, and major tranquilizers should be used in the lowest effective dose for the shortest possible period of time. Oversedation should particularly be avoided. Reports suggest the potential usefulness in autism and related conditions of other agents, such as those used in treatment of compulsive behavior ( [McDougle et al., 1994](#)). Studies of

additional agents, such as fenfluramine ([Campbell, 1988](#)) or naltrexone ([Campbell et al., 1990](#)), have not revealed particular benefit. Although considerable interest has centered on the possibility that dietary or vitamin treatments may produce behavioral change, efficacy data from controlled trials are notably absent. The nonspecific increases in activity levels autistic persons sometimes exhibit may be taken to suggest a trial of stimulant medications. In general, stimulants worsen behavioral functioning; this result is not surprising, given that stimulants can induce stereotypes in animals by facilitating the action of the neurotransmitter dopamine. Various somatic treatments have not proven clinically useful. Pursuit of unproven treatments at the expense of educational interventions should be avoided.

## OUTCOME AND FOLLOW-UP DATA

Numerous methodologically sound follow-up studies of autism have been conducted ([Howlin and Goode, 1998](#); [Lotter, 1978](#)). As adults, about two-thirds of persons with autism exhibit very significant limitations in the ability to care for basic personal needs, whereas about one-third of these patients achieve some level of personal and occupational independence, with a smaller number of persons becoming able to live fully independently. The two most important predictors of adult outcome are level of intellectual functioning and communicative competence, even though these do not guarantee a positive outcome because even the highest-functioning individuals continue to exhibit residual and debilitating impairments in social interaction ([Howlin, 2000](#)). Persons with IQs in the moderately and severely retarded range are more likely to have worse outcomes as adults, including the presence of seizure disorders and more severely encompassing language and communication impairments. An important trend has been observed, however; in post-1980 studies, the percentage of persons with better outcomes has significantly increased, whereas the percentage of persons with the poorest outcomes (e.g., living in long-stay institutions) has markedly decreased ([Howlin, 1998](#)), a finding apparently reflecting not only general trends in mental health care but also, and importantly, the fact that older outcome studies focused on persons who had not benefited from any meaningful or systematic intervention. Even more important, with improved earlier identification of children with autism ([Rogers, 2001](#)) and the substantial impact that early intervention services appear to have on the natural course of the condition ([Dawson and Osterling, 1997](#)), the trend toward better outcome overall in autism is very likely to continue as outcome studies are performed on the cohort of children who benefit from empirically proven early, intensive, and structured forms of intervention. It is still the case, however, that curative claims made by proponents of unestablished forms of intervention on the basis of anecdotal or very small studies are unwarranted, and at this time autism is likely to continue to be a lifelong disorder. What is hoped for, however, is the continuation of the current trend suggesting that more and more persons with autism will have a meaningful form of communication and higher levels of independent living skills.

Although fewer follow-up data are available for other forms of PDD, the outcome appears to be worse in the case of both childhood disintegrative disorder ([Volkmar and Rutter, 1995](#)) and Rett's syndrome ([Ellaway and Christodoulou, 1999](#)). In contrast, the outcome for patients with Asperger's syndrome appears to be better ([Howlin, 2000](#); Tantam, 2000; [Volkmar and Klin, 2000](#)), presumably because of better communication and cognitive skills, but possibly also because of great social motivation. The same considerations probably apply to persons with PDD-NOS, although data on these patients are difficult to interpret because of issues of diagnostic definition.

Follow-up studies have illustrated some intriguing aspects of autism that remain poorly understood. For example, it is clear that persons with autism are at higher risk of seizures throughout childhood and particularly in adolescence, a pattern quite unlike that of the normal population, in whom the risk of seizures decreases with age ([Volkmar and Nelson, 1990](#)). A few persons with autism exhibit a pattern of behavioral deterioration during adolescence, whereas another small group appears to improve during this period ([Rutter, 1970](#)). Early outcome studies reported progress in language as "poor" or "very poor." More recently, there have been reports of much greater improvement ([Rumsey et al., 1985](#)), although how much more is difficult to determine, given the variability in measures used in different studies ([Howlin and Goode, 1998](#)). Nevertheless, given the current emphasis on early intervention services and the general focus of these services on fostering communication skills in a very intensive and aggressive fashion ([Dawson and Osterling, 1997](#)), the prospect for better language outcomes in the future is very realistic. As for social competence, despite improvement over the course of a person's life, it is still the case that persons with autism continue to be particularly impaired in this realm, and it is indeed quite rare that such persons are able to achieve romantic or sexual relationships or marriage.

## DIRECTIONS FOR RESEARCH

Considerable progress in understanding the biological basis of autism has occurred since the 1950s. The validity of the disorder has now been established, and attempts to provide more precise definitions have facilitated research studies. Knowledge regarding the validity and definition of other PDDs remains quite limited, however. Continued research is needed to establish their validity, and the development of truly operational definitions for these disorders and autism remains an important research priority. It is now clear that the term infantile autism was, in many ways, a misnomer because autistic infants grow up to be autistic adults. Studies of adults with PDDs remain relatively uncommon. Diagnostic techniques such as positron emission tomography and magnetic resonance imaging scanning may help to elucidate underlying pathophysiologic mechanisms. The study of conditions such as childhood disintegrative disorder may be particularly appropriate to attempt to clarify underlying pathologic mechanisms. At present, it appears that the final behavioral syndrome known as autism may well represent the effects of multiple insults on the developing CNS acting through one or more mechanisms. The explication of underlying CNS substrates for social behavior is particularly important. Similarly, the development of testable hypothesized mechanisms of CNS dysfunction will significantly advance our understanding of these complex disorders.

---

### CASE ILLUSTRATION: AUTISM

John was the second of two children born to middle-class parents after normal pregnancy, labor, and delivery. As an infant, John appeared undemanding and relatively placid; motor development proceeded appropriately, but language development was delayed. Although his parents indicated that they were first concerned about his development when he was 18 months of age and was still not speaking, in retrospect, they noted that, in comparison with their older child, John had seemed relatively uninterested in social interaction and the social games of infancy. Stranger anxiety had never really developed, and John did not exhibit differential attachment behaviors toward his parents. Their pediatrician initially reassured John's parents that he was a "late talker," but they continued to be concerned. Although John seemed to respond to some unusual sounds, the pediatrician obtained a hearing test when John was 24 months old. Levels of hearing appeared adequate for development of speech, and John was referred for developmental evaluation. At 24 months, motor skills were age appropriate, and John exhibited some nonverbal problem-solving skills close to age level. His language and social development, however, were severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. His play skills were quite limited, and he used play materials in unusual and idiosyncratic ways. His older sister had a history of some learning difficulties, but the family history was otherwise negative. A comprehensive medical evaluation revealed a normal EEG and computed tomography scan; genetic screening and chromosome analysis were normal as well.

John was enrolled in a special education program, where he gradually began to speak. His speech was characterized by echolalia, extreme literalness, a monotonic voice quality, and pronoun reversal. He rarely used language in interaction and remained quite isolated. By school age, John had developed some evidence of differential attachments to family members; he also had developed certain self-stimulatory behaviors and engaged in occasional periods of head banging. Extreme sensitivity to change continued. Intelligence testing revealed marked scatter, with a full-scale IQ in the moderately retarded range. As an adolescent, John's behavioral functioning deteriorated, and he developed a seizure disorder. Now an adult, he lives in a group home and attends a sheltered workshop. He has a rather passive interactional style but exhibits occasional outbursts of aggression and self-abuse.

---

### CASE ILLUSTRATION: ASPERGER'S SYNDROME

Tom was an only child. Birth, medical, and family histories were unremarkable. His motor development was somewhat delayed, but communicative milestones were within normal limits. His parents became concerned about him at age 4, when he was enrolled in a nursery school and was noted to have marked difficulties in peer interaction that were so pronounced that he could not continue in the program. In grade school, Tom was enrolled in special education classes and was noted to have some learning problems. His greatest difficulties arose in peer interaction; he was viewed as markedly eccentric and had no friends. His preferred activity, watching the weather channel on television, was pursued with great interest and intensity. On examination at age 13, Tom had markedly circumscribed interests and exhibited pedantic and odd patterns of communication with a monotonic voice quality. Psychological testing revealed an IQ within the normal range with marked scatter evident. Formal communication examination revealed age-appropriate skills in receptive and expressive language, but marked impairment in pragmatic language skills.

---

### CASE ILLUSTRATION: DISINTEGRATIVE DISORDER

Bob's early history was within normal limits. By age 2 years, he was speaking in sentences, and his development appeared to be proceeding appropriately. At age 40 months, he was noted to exhibit, abruptly, a period of marked behavioral regression shortly after the birth of a sibling. He lost previously acquired skills in communication and was no longer toilet trained. He became uninterested in social interaction, and various unusual self-stimulatory behaviors became evident. Comprehensive medical examination failed to reveal any conditions that could account for this developmental regression. Behaviorally, Bob exhibited features of autism. At follow-up at age 12 years, he still was not speaking, apart from an occasional single word, and he was severely retarded.

---

### CASE ILLUSTRATION: RETT'S DISORDER

Darla was born at term after an uncomplicated pregnancy. An amniocentesis had been obtained because of maternal age and was normal. At birth, Darla was in good condition; weight, height, and head circumference were all near the 50th percentile. Her development during the first months of life was within normal limits. At around 8 months of age, her development seemed to stagnate, and her interest in the environment, including the social environment, waned. Her developmental milestones then became markedly delayed; she was just starting to walk at her second birthday and had no spoken language. Evaluation at that time revealed that Darla's head growth had decelerated. Some self-stimulatory behaviors were present. Marked cognitive and communicative delays were noted on formal testing. Darla began to lose purposeful hand movements and developed unusual hand-washing stereotyped behaviors. By age 6, her EEG was abnormal, and purposeful hand movements were markedly impaired. Subsequently, she developed truncal ataxia and breath-holding spells, and her motor skills deteriorated further.

---

### CASE ILLUSTRATION: ATYPICAL PERSISTENT DEVELOPMENTAL DISORDER AND PERSISTENT DEVELOPMENTAL DISORDER NOT OTHERWISE SPECIFIED

Leslie was the eldest of two children. She was noted to be a difficult baby who was not easy to console but whose motor and communicative development seemed appropriate. She was socially related and sometimes enjoyed social interaction, but she was easily overstimulated. Leslie was noted to exhibit some unusual sensitivities to aspects of the environment and, at times of excitement, exhibited some hand flapping. Her parents sought evaluation when she was 4 years of age because of difficulties in nursery school. Leslie was noted to have problems with peer interaction. She was often preoccupied with possible adverse events. At evaluation, she was noted to have both communicative and cognitive functions within the normal range. Although differential social relatedness was present, Leslie had difficulty using her parents as sources of support and comfort. Behavioral rigidity was noted, as was a tendency to impose routines on social interaction. Leslie was enrolled in a therapeutic nursery school, where she made significant gains in social skills. Subsequently, she was placed in a transitional kindergarten and did well academically, although problems in peer interaction and unusual affective responses persisted. As an adolescent, she describes herself as a "loner" who has

## DEFINITION

It would be natural for a clinician or researcher to assume that the diagnosis of *reactive attachment disorder* refers fundamentally to a disturbance in the child–parent attachment relationship. Not only does the diagnostic label juxtapose the terms attachment and disorder, but also, during the past few decades, the term “attachment” has become virtually synonymous with the infant–caregiver relationship in psychiatry and psychology ( [Bowlby, 1951, 1969, 1980, 1982](#); [Provence and Lipton, 1962](#); [Spitz, 1946](#)). The reactive attachment disorder diagnosis, however, does not necessarily refer to a child's primary attachment relationship. Rather, it applies more broadly to a child's manifestation of disturbances in social relatedness across individuals and contexts.

The abnormal development of social behaviors is presumed to be in response to (hence the term “reactive”) early and profoundly pathological caregiving operationalized as “persistent disregard of the child's basic emotional needs for comfort, stimulation and affection,” “persistent disregard of the child's basic physical needs,” or “repeated changes of primary caregiver that prevent formation of stable attachment” ( [American Psychiatric Association, 1994](#)). The diagnosis therefore is an attachment disorder in the sense that disturbances in the early relationship *between* parent and child are thought to give rise to a diathesis for social dysfunction *within* the child. Thus, although the disorder is thought to arise from a relational context, it differs from V codes and other relational problems in that the behavioral constellation persists over time, is evident across situations, is manifested in contexts well beyond the confines of the child–caregiver relationship, and is therefore a disorder thought to reside within the child.

In its initial incarnation in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) ( [American Psychiatric Association, 1980](#)), reactive attachment disorder was described in general terms as a disorder marked by lack of developmentally appropriate social responsiveness and delayed physical development. With an age of onset *before* 8 months, the diagnostic criteria included detailed descriptions of socially unresponsive behaviors in infants, such as lack of visual tracking, lack of smiling response, lack of alerting and turning toward caregiver's voice, and abnormal physical development such as weak rooting, hypomotility, and failure to gain weight or exhibited weight loss (with no physical explanation).

The diagnosis was essentially a description of failure-to-thrive symptoms, but it was distinguished from this pediatric syndrome by its psychosocial or “nonorganic” cause. Locating the origin of the socioemotional disturbances in the context of the primary attachment relationship also served to differentiate reactive attachment disorder from the pervasive developmental disorders. Whereas abnormal social relatedness is the hallmark of children with these disorders, their defects are thought to be neurobiological, resulting in a lack of capacity for normal social development. Moreover, in contrast to the pervasive developmental disorders, marked improvement in the clinical picture subsequent to adequate caregiving is considered a diagnostic confirmation of the disorder.

The inclusion of reactive attachment disorder in the DSM-III was a significant step toward defining an important clinical phenomenon, but the criteria proved difficult to apply. Some aspects of the definition seemed overly detailed and applicable only to very young infants ( [Rutter and Shaffer, 1980](#)). Additionally, the inclusion of failure to thrive as an essential feature artificially narrowed the diagnostic concept. In response to these problems, the diagnosis underwent major changes in the revised DSM-III (DSM-III-R) ( [American Psychiatric Association, 1987](#)). The transformation of reactive attachment disorder included a dramatic shift from a diagnosis primarily for infants to a disorder more easily applied to young children and a broadening of the diagnostic concept to incorporate the diversity of clinical presentations. The unusual age of onset—before 8 months—was raised to 5 years of age, and the failure-to-thrive symptoms were converted from defining features to associated features documented on Axis III. Rather than a detailed list of symptomatic characteristics, the criteria incorporated two general descriptions of abnormal social relatedness: (a) excessively inhibited, ambivalent interactions, and (b) indiscriminate social behaviors. The psychosocial nature of the disorder was retained through the continued requirement for a history of grossly pathogenic care, diagnostic confirmation by reversed clinical presentation subsequent to exposure to adequate caregiving, and the exclusion criteria of children with infantile autism or mental retardation.

Although the criteria for reactive attachment disorder in the fourth edition of the DSM (DSM-IV) have undergone few substantive changes, they do provide a more accurate interpretation of the research findings. Those findings suggest that the relationship between grossly pathological care and reactive attachment disorder is not as direct as presupposed in DSM-III or DSM-III-R because children's responses to pathological care can be markedly different. The text now clearly states that some children, despite experiencing maltreatment, are able to develop selective attachments to caregivers and do not necessarily develop reactive attachment disorder. In addition, the revised definition deemphasizes the importance of *grossly* pathological care (stating in the text that it is usually but not necessarily present) in recognition that less severe environments can also give rise to the clinical syndrome. The criteria now require the presence of pathogenic care, rather than grossly pathogenic care.

Disturbances in social relatedness continue to be defining features of the disorder, but there are now two designated subtypes: *inhibited* and *disinhibited*. Children manifesting the *inhibited* type are characterized by “excessively inhibited, hypervigilant, or highly ambivalent and contradictory responses” and may exhibit resistance to comforting and “frozen watchfulness” ( [American Psychiatric Association, 1994](#)). The child with the *disinhibited* type, in contrast, exhibits diffuse attachments “manifest by indiscriminate sociability with marked inability to exhibit appropriate selective attachments” ( [American Psychiatric Association, 1994](#)). In addition, mental retardation is no longer an exclusionary criterion. These revisions essentially increase the diagnostic similarities between the DSM-IV and the 10th edition of the *International Classification of Diseases* (ICD-10) ( [World Health Organization, 1992](#)). An enduring difference between the two systems is that the ICD-10 does not require any specific origin, although the presence of pathogenic parental care is implied in the text.

## HISTORICAL NOTE

The recognition that an appropriately nurturing psychosocial environment is a necessary condition for the development of differential relatedness in infants is, surprisingly, a relatively recent phenomenon. Throughout most of history, the emphasis in the “nature–nurture” debate has been on the “nature” side. The presumption that development was largely unrelated to the quality of the psychosocial environment was reflected in institutional care practices for infants and young children and in early work, in the 20th century, that suggested that IQ could be assessed in infancy and was stable into adult life. (See [Boswell, 1988](#), and [Hunt, 1961](#), for interesting reviews of these issues.) The recognition of the profound impact of disruptions in the processes of attachment, by such factors as maternal deprivation, institutional rearing, and maltreatment, signaled a marked shift in the understanding of social developments in infants and young children ( [Ainsworth et al., 1985](#); [Bowlby, 1951](#); [Kempe et al., 1962](#); [Rutter, 1979, 1981](#)). Accordingly, only more recently have efforts been made to develop a diagnostic classification that would capture the clinical picture of children who have experienced pathologic care, particularly in the form of abuse, neglect, institutionalization, or repeated changes in caregivers. The clinical literature proffers an array of diagnostic labels for these children, some describing or emphasizing major signs and symptoms, such as nonorganic failure to thrive, psychosocial dwarfism, and anaclitic depression, whereas others have emphasized the major environmental circumstances of the child,

such as hospitalism, maternal deprivation, and maltreatment syndrome. Reactive attachment disorder is the label selected for the DSM in an attempt to capture both the context of the disorder (“reactive” in response to caregiving) and the sequela of the caregiving (problems in the child’s social relatedness). Diagnostic criteria for reactive attachment disorder incorporate the clinical presentations of children who have experienced various iterations of pathogenic care as they have been described in the maltreatment, failure-to-thrive, maternal deprivation, and institutionalization literature.

What has been curious in the development of the diagnostic category is the relative lack of influence from the field of attachment ( [Zeanah and Emde, 1994](#)). The apparent discontinuity between the DSM-IV definition and findings from the developmental literature is the basis for criticisms proffered by attachment researchers. It is their contention that the name of the disorder is somewhat misleading because the diagnostic criteria include social abnormalities that extend well beyond the infant–caregiver relationship. These developmentalists hold a more circumscribed definition of attachment disorder as residing within the child–caregiver relationship and would like to see the criteria reflect aspects of the attachment behavioral system more directly ( [Zeanah and Emde, 1994](#)).

The conceptualization of attachment disorders as a characterization of child–caregiver relationships has been formalized in a diagnostic classification system developed by [Zero to Three/National Center for Clinical Infant Programs \(NCCIP\) in their manual, \*Diagnostic Classifications of Mental Health and Developmental Disorders of Infancy and Early Childhood\* \(1994\)](#). Similar to DSM-IV, the NCCIP system provides an Axis I diagnosis, Reactive Attachment Deprivation/Maltreatment Disorder of Infancy and Early Childhood, to be applied when a child has experienced persistently inadequate basic emotional, physical, or psychological care and manifests a disturbance in social relatedness. However, the NCCIP diagnostic framework extends beyond DSM-IV by including a classification system for disordered parent–child relationships. Coded on Axis II, there are nine so-called Relationship Disorders in which the child presents with a disturbance specific to a primary attachment figure, but for which a history of grossly pathogenic basic care is not required; these include relationship problems characterized by overinvolvement or underinvolvement; anxiety; hostility; abuse (verbal, physical, or sexual); or mixed types. In contrast to reactive attachment disorder, in which the child necessarily presents with pervasive developmental delays in social relatedness, a child diagnosed with a relationship disorder may manifest symptoms that exist only in the context of the primary caregiving or attachment relationship. Through this classification system, NCCIP system has furnished a meaningful way to understand and address disorders specific to the quality of the child–parent relationship.

Although some applaud the NCCIP’s inclusion of relationship disorders in their classification system, the diagnostic category is still plagued by the same shortcomings as the DSM-IV and ICD-10, namely, the exclusion of criteria that describe disordered infant attachment behaviors, such as disturbances in comfort-seeking behaviors, secure-base behaviors, and exploratory behaviors ( [Zeanah et al., 2000](#)). Furthermore, these investigators suggest that the DSM-IV and its ICD-10 and NCCIP counterparts define a syndrome of nonattachment applicable only to children who have failed to develop selective attachments. The narrow focus of the current criteria, in their view, precludes the diagnosis of children who have formed severely disturbed attachment relationships. Their alternative classification system includes three types of attachment disorders: Disorders of Nonattachment (which are similar to DSM-IV inhibited and disinhibited subtypes), Secure-Base Distortions (which describe children with disturbed attachment relationships), and Disrupted Attachment Disorders (which include children who have experienced the loss of an attachment relationship). These classifications define attachment disorders as a syndrome that exists between individuals rather than within individuals, a significant departure from the theoretical framework of DSM-IV and ICD-10.

Despite these criticisms, research supports the validity of the attachment disorder construct and its viability as a clinical entity ( [Boris, Zeanah, Larrieu, 1998](#); [O’Connor and Rutter, 2000](#); [Volkmar, 1996](#)). Preliminary evidence also suggests that a distinction can be made between the disinhibited and inhibited subtypes, but questions remain about the reliability and usefulness of subtyping ( [Boris, Zeanah, Larrieu, 1998](#); [O’Connor and Rutter, 2000](#); 1994; [Volkmar, 1996](#)).

## PREVALENCE AND EPIDEMIOLOGY

To date, extensive literature searches reveal no epidemiologic studies of the prevalence and incidence of reactive attachment disorder as defined in the DSM-III-R. According to the DSM-IV, the disorder appears to be “very uncommon,” but exactly how uncommon it is and what is the empirical source for this estimate are not specified ( [American Psychiatric Association, 1994](#)). Cases reported in the literature have included children from all socioeconomic levels, although descriptions of children with associated disorders, such as failure to thrive, have reported relationships with variables such as poverty, family dysfunction, and parent psychopathology ( [Richters and Volkmar, 1994](#); [Skuse, 1984a](#) and [1984b](#)). The paucity of epidemiologic data results, in part, from the repeated changes in the diagnostic criteria and the absence of an established protocol for assessing attachment disturbances. To a certain extent, efforts to develop accepted research protocols have been hampered by a limited understanding of the relationship between attachment disorders and attachment classifications. Although researchers have consistently found perturbed patterns of attachment in maltreated children ( [Cicchetti and Barnett, 1991](#)), clearly, some children who are abused or who are institutionalized do form secure attachments to their caregivers ( [Chisholm, 1998](#); [Egeland and Sroufe, 1981](#); [O’Connor and Rutter, 2000](#)). Findings such as these raise questions about the sensitivity of the Ainsworth Strange Situation procedure to attachment disturbances at the level of clinical diagnosis ( [O’Connor and Rutter, 2000](#)). Currently, insecure or disorganized attachment behaviors are commonly understood as risk factors for the development of psychopathology and should not be confused with diagnostic criteria or evidence of clinical caseness ( [Zeanah, 1996](#)).

Given the etiologic requirements for the disorder, it may seem plausible to derive an estimate of affected children from the statistics on maltreated and institutionalized children. Researchers concede, however, that establishing rates of child abuse and neglect is fraught with difficulties. Such estimates depend not only on “reported cases,” the substantiation of reports, and variations in the content, interpretation, and enforcement of reporting laws, but also on our definition of “maltreatment,” which shifts with the prevailing cultural and political winds ( [Barnett et al., 1993](#)). In addition, although the [Panel on Research on Child Abuse and Neglect \(1993\)](#) suggested that 1,000,000 was a *conservative* estimate of the number of children who have been maltreated in the United States, it is not clear what proportion of these children would meet the DSM-IV criteria for experiencing grossly pathogenic care. Finally, there are no available estimates of the number of children experiencing multiple substitutions in caregivers for reasons such as court-ordered custody changes, prolonged parental absences resulting from military deployments, and extensive hospitalizations for illness.

## CLINICAL DESCRIPTION

Because the diagnostic category of reactive attachment disorder is relatively new and has undergone considerable revision, the data available to provide a complete clinical description are limited. Some of what follows, therefore, has been drawn from related literature on failure to thrive, child maltreatment, institutionalization, and attachment. In this context, it should be reiterated that the large body of literature on the development of attachment and, in particular, on attachment types as assessed in the Ainsworth Strange Situation ( [Ainsworth et al., 1985](#)) has only some relationship to attachment *disorder* as such.

### Age of Onset

The literature on maternal deprivation, maltreatment, and institutionalization suggests that children who suffer insults to their early attachment and bonding relationships subsequently exhibit pervasive and persistent defects in their social development. The current diagnostic requirement is that there be marked disturbances in social behavior *before* the age of 5 years (although the diagnosis can be applied as early as the first month of life). The reliability and validity of this specific age of onset have not yet been established, although it seems reasonably clear that, whereas the task of forming attachments continues throughout life, it is during the first years of life that the process is most prone to fundamental disruption ( [Volkmar, 1996](#)).

Empirical questions aside, from a practical standpoint, determining age of onset can be a remarkably challenging task. A review of the clinical literature suggests two common pathways to treatment for children with reactive attachment disorder: (a) pediatric assessments for failure-to-thrive symptoms in infancy and, more recently, for children adopted from international institutions and (b) psychiatric evaluations for behavioral and language delays in early childhood (often subsequent to changes in custody or entrance into school settings). Often it is someone other than the primary caregiver who brings the child in for an evaluation. As a result, ascertaining the quality of early social behaviors becomes almost impossible because the details of the child’s early history are often fragmented and incomplete, particularly for children who are assessed only after permanent removal from the home or after an international adoption. Further research is needed to establish the distribution of apparent onset ages as well as to determine the sensitivity and specificity that the criterion contributes to the diagnosis ( [Volkmar, 1996](#)).

### Social Disturbance

Social dysfunction is the central defining feature of children with reactive attachment disorder. The *inhibited* subtype is marked by the child’s persistent failure to initiate and respond to social interactions in an age-appropriate manner. Instead, the child appears wary and hypervigilant, excessively inhibited, and generally ambivalent in response to caregivers and social interactions. Additionally, caregivers find the child resistant to comforting or prone to exhibit “frozen watchfulness.” In the maltreatment and deprivation literature, these children are described as affectively withdrawn, apathetic, and unresponsive. They are often remarkable for their gaze abnormalities and idiosyncratic or atypical responses to social cues. This pattern of behaviors has been described as a perturbation of the attachment system

characterized by the inhibited development of normal comfort-seeking and social behaviors ([Zeanah et al., 2000](#)).

Children manifesting the *disinhibited* subtype, in contrast, seem to be quite interested in interacting with others but do not appear to make selective attachments. Rather, their relationships are marked by superficiality, “clinginess,” and indiscriminate sociability. In what some call a hyperactivation of the attachment system, these children may demonstrate a preference for a familiar individual but typically engage in diffuse attachments; they seek comfort from unfamiliar adults when they are distressed and willingly, even affectionately, approach strangers ([Chisholm, 1998](#); [O'Connor et al., 1999](#); [Zeanah et al., 2000](#)). Children suffering from the disinhibited subtype also exhibit impaired social behaviors including an inability to detect important social cues, a lack of awareness of interpersonal boundaries, and a failure to engage in social reciprocity ([Rutter et al., 1999](#)). Finally, these children also exhibit excessive aggressiveness and incompetence in their peer relationships ([Alessandri, 1991](#); [Erickson et al., 1989](#); [Hoffman-Plotkin and Twentyman, 1984](#); [Main and George, 1985](#); [O'Connor et al., 1999](#); [Salzinger et al., 1993](#)). For either subtype, the clinical picture may vary depending on chronologic age, developmental level, and early caregiving history.

### Communication Disturbances

Although not included in the diagnostic criteria, indirect evidence from the failure-to-thrive, maltreatment, and deprivation literature and case descriptions of children with reactive attachment disorder suggest that *some* affected children may evidence delays in language development ([Cicchetti, 1987](#); [Coster et al., 1989](#); [Harris, 1982](#); [Oates et al., 1985](#); [Richters and Volkmar, 1994](#); [Rutter and Garmezny, 1983](#); [Skuse, 1984a](#); [Vondra et al., 1990](#)). The linguistic disturbances, when present, appear to range from poor articulation to mild echolalia. The communication impairments among children with reactive attachment disorder appear to be more similar to those of language-disordered children and less similar to the severe forms often seen in children with autism. In addition, language development in these children appears to improve after intervention. Further research is needed to determine the nature and extent to which language disturbances are present among children with reactive attachment disorder.

### Cognitive Development

Because the emphasis of reactive attachment disorder is on abnormal social development, and because mental retardation was an exclusionary criterion before the DSM-IV, there is a paucity of data concerning cognitive impairments among affected children. Reports on children diagnosed with reactive attachment disorder and the indirect evidence from research on children raised in depriving and maltreating environments suggest that intellectual functioning is often below average or delayed at initial assessment. It is clear, however, that children with mental retardation also usually form attachments, albeit at a time commensurate with developmental level ([Berry et al., 1980](#)). [Zeanah and Boris \(2000\)](#) suggest that the diagnostic criteria could be improved by requiring a minimal mental age of 10 months to guard against normal delays in the development of selective attachments resulting from cognitive impairments. Again, reactive attachment disorder differs from other disorders by the presence of marked improvements after therapeutic intervention ([Crittenden, 1985](#); [Erickson et al., 1989](#); [Hoffman-Plotkin and Twentyman, 1984](#); [Richters and Volkmar, 1994](#); [Tizard and Rees, 1975](#)). Postinstitutionalized Romanian children who had experienced severe and global deprivation under the Ceausescu regime were found to have remarkable cognitive gains by the age of 4 years, a finding further supporting the contention that significant improvements in child-rearing conditions can effect dramatic developmental gains.

The cognitive deficits exhibited by some children with reactive attachment disorder are most accurately described as an associated feature. Researchers in the field of maltreatment and deprivation have identified multiple pathways to cognitive impairments, ranging from physical abuse to low economic status. More specifically, in these pathogenic environments intellectual deficits may be the result of brain damage from head injuries, neurologic insults stemming from malnutrition, depressed language development because of inadequate verbal stimulation, or the effects of heavy medication administered to exert behavioral control as seen in some of the Romanian institutions ([Herrenkohl et al., 1984](#); [Kaufman and Cicchetti, 1989](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#); [Skuse and Bentovim, 1994](#); [Terwogt et al., 1990](#)). Data from the series of studies on Romanian adoptees conducted by Rutter and his colleagues ([O'Connor et al., 1999](#); [O'Connor and Rutter, 2000](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#)) lead them to conclude that psychological deprivation appears to play a more powerful role than nutritional deprivation in subsequent cognitive development. This finding is consistent with the results of a population-based study in which children diagnosed with nonorganic failure to thrive in infancy were found to have no cognitive or educational disadvantages by the time they reached school age ([Drewett et al., 1999](#)). Moreover, in the studies on the Romanian adoptees ([O'Connor et al., 1999](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#)), the duration of deprivation seemed to have a more adverse effect on cognitive development than the severity of deprivation.

### Behavioral Features

Clearly, the most striking feature of children with reactive attachment disorder is their atypical social presentations. Yet other behaviors are frequently associated with the disorder. Disruptive, disorganized behaviors, along with poor affect regulation and low frustration tolerance, have been noted particularly among the *disinhibited* type. Some of these children also exhibit distractibility and attentional problems. Studies of the postinstitutionalized Romanian children continue to suggest a link between attachment disorders and the presence of externalizing behaviors, particularly inattention and hyperactivity, but the nature of that link remains uncertain ([Chisholm, 1998](#); [O'Connor and Rutter, 2000](#); [Zeanah, 2000](#)). Although institutionalized children appear to be at risk for developing both attachment and behavioral problems, it is unclear whether these problems share common, overlapping, or discretely different risk factors. Anecdotal clinical descriptions have also cited underdeveloped self-care skills and self-stimulatory behaviors ([Richters and Volkmar, 1994](#)). Among postinstitutionalized children from Romania, [Rutter and colleagues \(1999\)](#) document the presence of both isolated autistic features and what they term overall “quasi-autistic” behavior patterns. These researchers have adopted the latter term because, in sharp contrast to “ordinary” autism, there is almost no gender discrepancy among affected children, head circumference is not elevated, and the children show marked improvement over time. Furthermore, because the children’s behaviors are characterized by indiscriminate friendliness and other social abnormalities typical of attachment disorders, the investigators suggest that the “quasi-autistic” behavior pattern may be indicative of some form of attachment disturbance.

### ETIOLOGY AND PATHOGENESIS

To date, no known primary biological mechanisms underlie the development of the disorder. Evidence of the presence of a biological predisposition may be eventually revealed, given the considerable variation that has been reported among siblings raised together in extremely depriving and maltreating early environments as well as among postinstitutionalized children ([Hinshaw-Fuselier et al., 1999](#); [O'Connor et al., 1999](#); [Skuse, 1984a](#)). In the maltreatment literature, a transactional model has emerged as a way to understand such diversity in outcomes ([Cicchetti, 1987](#)). There may, for example, be biological factors, such as physical anomalies, persistent colic, or difficult temperament, that influence the likelihood that a child will be victimized by a caregiver. Moreover, certain factors, such as difficult temperament, may also influence the likelihood that a child will react pathogenically to maltreatment. Children with these biological risk factors who also experience pathogenic infant-caregiver relationships may consequently experience disruptions in their achievement of, or successful progression along, normal developmental lines. The formation of selective attachment relationships may be one of the normal developmental tasks that falters and thereby sets the stage for the emergence of reactive attachment disorder. More recently, researchers have been developing a psychobiological theory of attachment that looks beyond the natural unfolding of internal biological processes to examine how social experiences affect infant brain development ([Schore, 1997](#); [Zeanah and Boris, 2000](#)). The exact nature and role that the infant-caregiver relationship plays in the development of neural pathways, brain processes, and subsequent behaviors are still under investigation. However, the evidence is clear that the brain of the human child is genetically designed to assemble its own social, emotional, and personality characteristics by taking instruction from its local environment. Early environmental experiences therefore provide the initial scaffolding for social, emotional, and intellectual functioning and help to organize the child's understanding of the world, herself or himself, and others.

By definition, reactive attachment disorder arises in response to pathological caregiving. In fact, the growing body of literature on the effects of maternal deprivation, maltreatment, and institutionalization led to the recognition of reactive attachment disorder as a clinical phenomenon. Several family factors are thought to put attachment relationships at risk, including death of a parent, maternal depression, maternal substance abuse, marital discord, poverty, multiple early hospitalizations, and placement in foster care ([Boris and Zeanah, 1998](#)). Among institution-reared children, the lack of opportunity to form selective attachments appears to be an important contributing factor ([O'Connor and Rutter, 2000](#)). However, to date, there has been no systematic research published detailing significant family factors among affected children. The omission of *grossly* pathogenic care from the formal DSM-IV criteria (it has been replaced with, simply, “pathogenic care”) suggests a continuum of inadequate caregiving that may give rise to the disorder. Unfortunately, the etiologic requirement of adverse caregiving has rendered it impossible to determine whether the condition arises in the absence of such care. In addition, although it is clear in the maltreatment literature that severe abuse or neglect can give rise to disorders of attachment, there is still no definitive evidence on the effects of milder forms of disturbed caregiver-child interaction styles ([Volkmar, 1996](#); [Zeanah and Zeanah, 1989](#)). Researchers in the area of nonorganic failure to thrive describe some differences between mothers with and without infants with nonorganic failure to thrive ([Drotar et al., 1990](#)). In parent-child interactions, mothers of affected infants are observed to have less adaptive social interactions, less positive affect, and more arbitrary termination of feedings. In addition, researchers also report that mothers with nonorganic failure to thrive infants frequently complain of lack of perceived emotional support from family members ([Drotar, 1991](#)). No differences are found, however, on factors such as family size, maternal age, maternal

education, parent marital status, or sex of child.

Preliminary findings with institutionalized children suggest that disordered attachment behaviors are more related to the duration of deprivation than the severity of deprivation ([O'Connor and Rutter, 2000](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#)). Furthermore, although psychological deprivation and nutritional deprivation often coexist, psychological deprivation appears to have a more profound effect on the presence of disturbed attachment behaviors ([O'Connor et al., 1999](#)). In cases reported thus far, however, it appears that the symptoms of children with reactive attachment disorder are pervasive and are typically manifested across situations and across relationships. Our current understanding of the disorder also suggests that environmental and social influences play an essential role in reversing the clinical picture. In fact, the amelioration of symptoms subsequent to the introduction of adequate caregiving has often been used as a means for confirming the diagnosis.

## LABORATORY STUDIES

No specific laboratory studies exist for reactive attachment disorder.

## DIFFERENTIAL DIAGNOSIS

Various conditions or situations may give rise to problems in infant–parent attachment. For example, the separation of a young child from a primary attachment figure may be associated with the sequence of *protest*, *despair*, and *detachment* outlined by Bowlby. In some such instances, particularly with somewhat older children, depressive symptoms may predominate, and, if the reaction is prolonged, a diagnosis of depression may be indicated. Sometimes blind or deaf children may initially seem to have deficits in attachments, but, usually, once the sensory impairment is identified and the appropriate interventions are made, the apparent social deficit improves markedly.

Infants and young children with mental retardation that is not associated with autism or another pervasive developmental disorder develop attachments that are appropriate to their developmental level; such attachments may, however, be more prone to disruption, for example, as a result of unstable environments, and it is possible that such children are at greater risk of developing reactive attachment disorder. In the pervasive developmental disorders, deficits in reciprocal social interaction are, by definition, present and are usually observed from very early in life. Social deficits may be particularly profound in autistic disorder, especially in very young children. However, over time some selective attachments do develop, although these are usually highly deviant. The presence of other characteristic symptoms (e.g., marked deficits in communication and unusual behavioral responses to the environment, such as stereotypy and resistance to change) usually alerts the clinician to the diagnosis. Because autism and related conditions are usually associated with mental retardation, the child's overall mental age should be taken into consideration. A substantial body of evidence suggests that, in most cases, the psychosocial environment provided by parents of children with autism and related conditions is appropriately stimulating, and the failures in social development observed reflect a fundamental disturbance in the child. As would then be expected, changes in the environment do not typically result in major behavioral improvement or the development of more robust attachments.

Although some children with the disinhibited subtype of reactive attachment disorder may exhibit inattention or hyperactivity and poor concentration, their symptom picture differs from that of children with attention deficit hyperactivity disorder because of their lack of selective attachments. Although it is likely that the two disorders share common risk factors, they are nonetheless considered distinct clinical entities. As suggested in the DSM-III ([American Psychiatric Association, 1980](#)) criteria for this condition, some infants and young children with reactive attachment disorder may also exhibit disturbances in feeding (e.g., feeding disorder of infancy, rumination disorder, or pica) and in growth (e.g., psychosocial dwarfism).

## TREATMENT

Intervention should focus on the totality of the child's situation. Efforts should be made to support the child's development, the adequacy and responsiveness of the parents, and the provision of an appropriately stimulating and nurturing psychosocial environment. Treatment should emphasize the fostering of selective attachment relationships. Provision of appropriate pediatric and early intervention services should be made. Assessment by a pediatrician is particularly important for postinstitutionalized children because they have often experienced malnutrition and inadequate health care. Although foster placement is best avoided if possible, sometimes removal of the child is mandatory, for example, because the child has sustained life-threatening injuries or is in immediate danger. Although the usual presumption is that reunification of child and parents is the eventual goal, it is important to balance attempts at rehabilitation with the child's need for stability. Effective coordination and integration of services are critical for children living in foster care, and clinicians need to be aware of forensic issues such as confidentiality, permanency planning, and custody arrangements. Among children who have been recently adopted, clinicians should be sensitive to goodness-of-fit issues and should assess the degree to which the parent and the child are coping with the new relationship.

The attempt to produce major changes in the child–caregiver relationship often requires sustained, intensive, and highly structured work with the child, the caregiver, and the dyad. Appropriate additional support services should be made available to the caregiver. Pediatric monitoring is particularly critical if eating or growth problems are present.

## NATURAL HISTORY, OUTCOME, AND FOLLOW-UP DATA

As a diagnosis in its own infancy, there are as yet almost no longitudinal data on the developmental trajectory of children with reactive attachment disorder. The reduction or resolution of symptoms probably depends in large part on the nature, duration, and severity of pathogenic care experienced by the child, on the child's own constitutional factors, and on the interaction between these two. In the studies conducted with Romanian adoptees, early and lengthy deprivation appears to play particularly critical roles in the development of attachment disturbances 1999; ([O'Connor and Rutter, 1999, 2000](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#)). In general, the prognosis is less hopeful the earlier, more severe, and more prolonged the environmental deprivation and the later adequate caregiving and interventions are introduced. From the clinical descriptions and from studies on children from maltreating and depriving environments, a body of evidence suggests that the symptoms appear to be responsive to therapeutic intervention. Improvements in cognitive functioning, language development, and motor development are cited ([Hodges and Tizard, 1989a,b](#); [O'Connor and Rutter, 2000](#); [Rutter and the English and Romanian Adoptees Study Team, 1998](#)). In addition, there are reports of decreases in behavioral problems and increases in age-appropriate self-care skills ([Richters and Volkmar, 1994](#)).

Unfortunately, improvements in the quality of social relatedness are more difficult to measure. There are reports of improved social skills, but the concern is that these changes may be only superficial. For some children, atypical gaze patterns, idiosyncratic interactive styles, and poor integration of social and emotional cues appear to persist ([Richters and Volkmar, 1994](#)). In addition, among institutionalized children, the pattern of indiscriminate friendliness appears to be persist even after the development of preferred attachments ([Chisholm, 1998](#); [O'Connor and Rutter, 2000](#); [Zeanah, 2000](#)). Many investigators have hypothesized that problems with social development may endure throughout adulthood in the form of difficulty in establishing or maintaining meaningful relationships and persistence of idiosyncratic styles of relating. The question remains whether or to what extent social and emotional development in children with reactive attachment disorder will be systematically different from that in other children.

## PREVENTION

Various factors can be used in the prevention of reactive attachment disorders. These include avoiding institutional and multiple foster placements, adequate stimulation of infants and young children, and provision of adequate parental support. Unfortunately, out-of-home placement cannot always be avoided, and repeated foster placements are often made.

## RESEARCH DIRECTIONS

The relative absence of research on this condition is, in some ways, paradoxical, given both the history of work on the effects of maternal deprivation and orphanage rearing and the important social policy problems created by caring for children with reactive attachment disorders. Information on such basic aspects of the condition as clinical phenomenology, course, epidemiology, and response to treatment is lacking. Although the distinction, as in the DSM-IV, of subtypes of the condition seems generally reasonable, research on the potential importance of this distinction, such as for intervention and outcome, remains unclear. Furthermore, whereas preliminary evidence suggests that the construct of attachment disorder has validity and its importance as a clinical diagnosis is supported, the reliability of the diagnostic criteria remains largely untested. The requirement of pathogenic care as an essential feature continues to be widely criticized and warrants further investigation. Whether the sensitivity and specificity of the diagnostic concept could be improved by the inclusion of other symptoms also remains open for future

research.

### DEFINITION

*Mental retardation* (MR) is defined in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association, 1994](#)) on the basis of two essential features: subnormal intellectual functioning, characterized by an intelligence quotient (IQ) lower than 70, and commensurate deficits in adaptive functioning (capacities for social and personal sufficiency and independence). The measurement of intelligence is presumed, in most cases, to be based on the administration of an appropriate standardized assessment of intelligence. Deficits in adaptive skills can be measured on instruments such as the revised Vineland Adaptive Behavior Scales ([Sparrow et al., 1984](#)) or a similar scale. DSM-IV criteria are summarized in [Table 48.1](#).

A. Significantly subaverage intellectual functioning, on IQ of approximately 70 or below on an individually administered IQ test (for inform, a clinical judgment of significantly subaverage intellectual functioning)	
B. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety	
C. Onset before age 18 years	
Code based on degree of severity reflecting level of intellectual impairment:	
317 Mild Mental Retardation	IQ level 50-55 to < 70
318 Moderate Mental Retardation	IQ level 35-40 to 50-55
318.1 Severe Mental Retardation	IQ level 20-25 to 35-40
318.2 Profound Mental Retardation	IQ level < 20 or 25
319 Mental Retardation, Severity Unspecified	when there is a strong presumption of mental retardation but the person's intelligence is unmeasurable by standard tests

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV). Washington, DC: American Psychiatric Association, 1994.

Table 48.1. DSM-IV Diagnostic Criteria for Mental Retardation

Various levels of MR are specified in the DSM-IV: mild (IQ 50 to 70), moderate (IQ 35 to 49), severe (IQ 20 to 34), and profound (IQ <20). Borderline MR can be noted as a V code. Some flexibility is allowed for clinical judgment. Most persons with MR in childhood are those with mild MR (about 85% of cases); those with moderate (about 10%), severe (about 4%), and profound MR (1% to 2%) constitute the remainder of cases ([Fig. 48.1](#)). In the past, the distinction between educable (IQ 50 to 70) and trainable (IQ <50) was made. Although no longer commonly used, this distinction is important. Persons with mild MR have psychiatric difficulties that are fundamentally similar (if generally more frequent) to those seen in the general population; this is not true for more severely impaired persons. Similarly, specific medical conditions associated with MR are more likely in the group with an IQ lower than 50, whereas lower socioeconomic status is more frequent in the group with mild MR ([Szymanski and King, 1999](#)). The proportion of persons with severe and profound MR is higher than would be expected given the normal curve reflecting the impact of severe medical problems on development ([Dingman and Targan, 1960](#)).

Figure 48.1. Levels of mental retardation.

The tests chosen for assessment of intellectual functioning must be appropriate to the patient, should have reasonable reliability and validity, and should be administered in a standardized way by appropriately trained examiners. (See [Chapter 43](#) for a discussion of psychological assessment.) Unfortunately, in some situations, the selection of an appropriate test can be difficult, such as for a very low-functioning person. Other aspects of assessment can also be problematic, such as when some modification must be made in terms of administration given the specific circumstance. Such modifications may limit the validity of the results obtained. The examiner must make an informed decision in such circumstances depending on the nature of the issue at hand, for example, determination of eligibility for services versus information on levels of functioning that can guide remediation. Particularly in terms of eligibility for services, it is critical that the examiner administer the test in exactly the standardized fashion. Measures of adaptive skills are generally based on parent or caregiver report, although, in some cases, the person may be interviewed directly. In essence, the conceptual notion is that the term *adaptive skills* refers to capacities for personal self-sufficiency on a day-to-day basis.

The inclusion of adaptive skills in the definition of MR rests on the observation that some persons with IQ scores below 70 may, as adolescents or adults, have learned sufficient adaptive skills that they are able to function totally or largely independently as adults and, thus, would not technically meet criteria for MR. This is more typical of persons who, as children, score in the mildly retarded range ([Edgerton, et al. 1984](#)).

The approach to the definition of MR is fundamentally the same in the tenth edition of the *International Classification of Diseases* (ICD-10) (World Health Organization, 1992). However, the [American Association of Mental Retardation's \(AAMR\) \(1992\)](#) definition of MR discards the use of IQ in favor of a "needs-based" assessment relative to 10 different areas of functioning. This definition also gives the clinician leeway to extend the upper IQ bound to 75; this seeming small increase actually

would be the source of a considerable broadening of the diagnostic concept of MR potentially would double the total number of cases ( [MacMillan et al., 1995](#)). The AAMR definition has been much criticized, has had very little empirical support, and has proven difficult to use.

## HISTORICAL NOTE

Interest in MR can be traced to antiquity ( [Trent, 1994](#); [Zigler and Hodapp, 1986](#)). Modern interest in MR began at the time of the Enlightenment and increased greatly during the 19th century; this emphasis occurred at the time of great social upheaval and as infant and child mortality began to decline. There was increased interest in children, in education, and in the role of experience (nurture) versus endowment (nature). The interest in the “nature–nurture problem” is exemplified in the work of Itard with Victor, a child who was thought to be wild or “feral” but who probably had autism ( [Candland, 1993](#); [Simon, 1978](#)). Subsequently, educators such as Sequin began to develop specific educational methods for stimulating children's development. By the latter half of the 19th century, many facilities had been developed for the care of mentally retarded persons. Although the initial goal of such facilities was to provide a period of treatment before the child was returned to the family, these institutions began to be places for custodial care, a problem that has led to a strong counterreaction in recent years and to a renewed emphasis of caring for persons with MR in their homes and communities.

During the 19th century, various distinctions were made between levels of MR by using what now would be seen as rather pejorative terms such as imbecile, cretin, and idiot. Originally, the etiologic basis of any such distinctions was quite limited. On the one hand, there was little systematic information on intellectual functioning that could be used for purposes of categorization; on the other, there were few known etiologic causes of MR. Both these limitations began to be addressed toward the end of the 19th century and the beginning of the 20th century. Binet developed the first test of intelligence, which was translated into English and adapted in the United States by Terman ( [Binet and Simon, 1916](#); [Terman, 1911](#)); the Stanford–Binet test served as a model psychometric assessment instrument for many years. It allowed much more precise characterization of levels of intellectual disability. In addition, Terman had the brilliant notion of taking the mental age and dividing by the child's chronologic age and multiplying this quotient by 100 to yield the IQ. This simplified comparison across children of different ages. Although Binet had originally developed his scale to identify children who were delayed in order to help them, the IQ score quickly became the object of much study. *Faith* in the IQ as a predictor variable led to the extension of developmental testing in infants and young children and a *belief* that, when the test was properly administered, the resulting score from an IQ test was fixed and reflected a person's genetic endowment. This proved not to be correct, as [Skeels and Dye \(1939\)](#) and others began to demonstrate. In his classic study, Skeels demonstrated this practically by transferring infants and young children from an orphanage to a home for the “feeble minded” to make the children normal! This fantastic plan had been prompted by his clinical observation that children in the home for the feeble minded received considerably more stimulation than those in the orphanage. He reported major differences in outcome both in childhood and, later, in adult life ( [Skeels, 1966](#)). By the 1940s and 1950s, there was increased awareness that the IQ score was indeed the product of both experience and endowment, and therapeutic optimism for improving the functioning of mentally retarded children again increased.

In addition to intellectual functioning, it also became apparent that the person's capacities to engage in appropriate self-care or “adaptive” skills was a major determinant of outcome in MR. In the 1930s, the psychologist Edgar Doll developed the Vineland Social Maturity scale in an attempt to quantify such skills. This instrument has been revised ( [Sparrow et al., 1984](#)), and it continues to serve as an important tool in the assessment of children with MR. Deficits in adaptive skills are now required as part of the diagnosis of MR. In addition, and in contrast to IQ, adaptive skills can readily be taught.

Another major line of work centers on the origin of MR syndromes. This was exemplified in the 19th century by the work of Dr. Langdon Down, who reported on a syndrome that now bears his name and is currently recognized as being the result of trisomy of chromosome 21. At the time of his report, Dr. Down, of course, had no notion of chromosomes. His theoretical understanding, which was based on a mistaken idea of racial stereotypes combined with darwinism, was fundamentally flawed, but his clinical observation has been remarkably robust. As time went on, more and more specific syndromes of MR were identified. It became clear that MR could result from a range of risk factors, including problems related to the developing fetus ranging from genetic factors (Down syndrome) to exposure to toxins *in utero* (fetal alcoholism) to maternal infections (congenital rubella), for example. As noted subsequently, advances in genetics have led to an explosion in the recognition of such syndromes, often with a very precise understanding of their cause ( [Szymanski and King 1999](#)).

In recent years, several developments have substantially changed the approach to treatment and prevention of MR in the United States. Beginning in the 1960s, there has been increased emphasis on the care of persons in their homes and communities. This movement has been further stimulated by the mandate of the U.S. federal government for schools to provide appropriate education for all children with disabilities within mainstream settings when possible. The trend toward deinstitutionalization reflects various concerns about the effects of prolonged institutionalization and has led to creation of many community services. The issue of mainstreaming within education settings is the object of some debate. Many mentally retarded students are largely or entirely mainstreamed in the United States, although there are marked state-to-state variations; the benefits of mainstreaming are the focus of some debate ( [Burack et al., 1992](#)). It is clear that students with more severe disabilities are most likely to spend their school time in more restricted settings.

Another major development was the implementation, starting in the 1960s with the War on Poverty, of programs designed to prevent learning and other problems in poor, disadvantaged children. Program such as Head Start have been shown to have an important long-term impact.

One unfortunate aspect of current practice has been the often complete separation of services for those who are mentally ill from those who are mentally retarded. Although administratively useful, this approach has made provision of high-quality psychiatric care even more difficult to obtain for many persons with MR.

## PREVALENCE AND EPIDEMIOLOGY

The use of both subnormal intellectual functioning and deficits in adaptive behavior in the definition of MR has important implications for epidemiology. If only the IQ criterion is used, the expectation, based on the normal curve, would be that about 2.3% of the population should exhibit the condition. This number is significantly decreased, particularly in adulthood, if the adaptive criterion is included.

For example, in the Isle of Wight study, [Rutter and colleagues \(1976\)](#) noted that, in 9- to 11-year-old children, about 2.5 % would be classified as mentally retarded if IQ were the sole criterion but if the prevalence were based only on those receiving services, this rate would be cut almost in half (1.3%) ( [Fig. 48.2](#)). The drop in cases based on inclusion of IQ and adaptive skills is more common among those with mild MR ( [McLaren and Bryson, 1987](#); [Roelevel et al., 1997](#)); these children (and adults) may, however, need services and support at times of stress ( [Edgerton et al., 1984](#); [Granat and Granat, 1978](#)). As children, such persons are more likely to have academic and behavioral problems ( [Rutter, et al., 1976](#)).

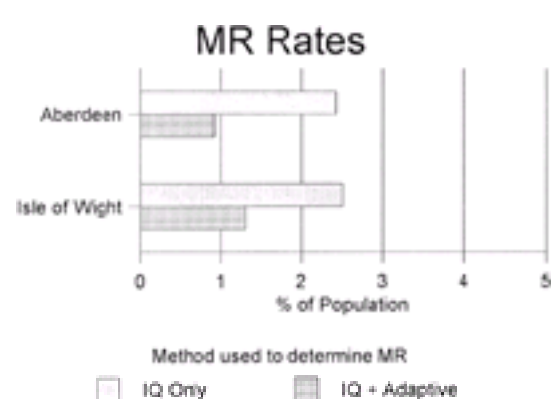

Figure 48.2. Isle of Wight Study.

## CLINICAL DESCRIPTION

### Clinical Features

Associated clinical features vary depending on several factors, most importantly the level of associated retardation. Persons with the severe and profound MR come

to diagnosis at a younger age, are more likely to exhibit related medical conditions, may exhibit dysmorphic features, and have a range of behavioral and psychiatric disturbances (Mundy et al., 1984). In contrast, persons with mild MR often come to diagnosis much later (typically when academic demands become more prominent in school), are less likely to have medical conditions that could account for the MR, and usually are of normal appearance without dysmorphic features. In this latter group, although rates of psychopathology are increased relative to nonhandicapped populations, the range and nature of problems seen are fundamentally similar to those in normative samples (Szymanski and King, 1999). Persons with moderate levels of MR are intermediate between these two extremes. It is well recognized that the nature of associated psychiatric and behavioral disorders undergoes a marked shift between the mild and more severe levels of MR (Sovner, 1986).

### Associated Psychiatric and Behavioral Problems

A growing body of work focuses on psychiatric and behavioral difficulties relative to specific genetic causes (Hodapp and Dykens, 2000). Features have been identified that are unique, or highly frequent, to specific syndromes, and in some cases to very specific genetic or biological processes, such as hyperphagia in Prader–Willi syndrome (Holm et al., 1993), attentional and social problems in fragile X syndrome (Hagerman et al., 1986), inappropriate laughter in Angelman's syndrome (Williams et al., 1996), the unusual cry in 5p- syndrome (Gersch et al., 1995), and the self-hug in Smith–Magenis syndrome (Finucane et al., 1994). In some instances, features are relatively syndrome specific, such as the unusual hand-washing stereotypies of Rett's syndrome (VanAcker, 1997). More frequently, features are shared in various conditions, such as attentional problems are frequent in fragile X, Williams', and 5p- syndromes (Baumgardner et al., 1995; Einfeld et al., 1997; Dykens and Clarke, 1997). In some instances, aspects of syndrome expression have been related to very specific aspects of genetic risk, such as the severity of MR in fragile X syndrome (Dykens et al., 1994; Tassone et al., 1999) and the severity of maladaptive behaviors in Prader–Willi syndrome (Dykens et al., 1999).

Somewhat paradoxically, for many years the diagnosis of MR tended to cause clinicians and researchers to overlook the presence of associated psychiatric and behavioral problems; that is, such difficulties were assumed to be a function of the MR when they were noted at all. In this regard, it was as if a diagnosis of MR "immunized" the individual against other diagnoses, a proposition that is on its face absurd because, presumably, the stresses of having significant intellectual and adaptive deficits should, if anything, make a person more likely to have problems. Historically, persons with MR were not routinely viewed as having comorbid psychopathology or mental illness. This "diagnostic overshadowing" (Reiss et al., 1982) remains a problem in clinical practice (White et al., 1995). Although more clinicians and researchers are being specifically trained to work with this population, the separation of MR and mental health services in most states is a further obstacle to appropriate identification and treatment of mental disorders.

Although rates vary, as many as 25% of persons with MR may have significant psychiatric problems; these rates are much higher if persons with salient behavior disorders are included (Jacobson, 1999). Rates of psychopathology vary considerably, depending on methods used to ascertain subjects. Problems are invariably seen in children who present clinically (Phillips and Williams, 1975), whereas rates are lower, from 10% to 15%, in more population-based studies, including two large-scale medical record surveys of all clients served in New York and California (Borthwick–Duffy and Eyman, 1990; Jacobson, 1982). Rates that fall between these two extremes, from 30% to 40%, are found in other studies based on informant checklists of behavior problems of children or adults in nonreferred samples (Einfeld and Tonge, 1996; Reiss, 1990; Rutter et al., 1976).

Persons with MR experience the same range of psychiatric problems as seen in the general population (King et al., 1994), but prevalence rates for specific disorders vary widely. As previously noted, some of this variability may be associated with different methods for determining "caseness," with common approaches including record reviews, behavioral checklists, and, to a lesser extent, direct interviews. An additional concern is that although some researchers assess DSM-based or ICD-based diagnoses, others identify maladaptive features commonly seen in the general population (e.g., inattention or sadness), whereas still others focus on a narrow range of behaviors seen primarily in persons with MR (e.g., stereotypies or self-injury).

For example, rates of schizophrenia or psychosis in persons with MR range from 1% to 9% among nonreferred samples and 2.8% to 24% in referred samples. Although variable, these rates are much higher than the 0.5% to 1% of the general population with schizophrenia (American Psychiatric Association, 1994). Rates for depression vary from 1.1% to 11% across nonreferred and clinic samples of persons with MR, and rates of attention deficit hyperactivity disorder range from 7% to 15% in children with MR, a finding that contrasts with the 3% to 5% estimate among children in general (American Psychiatric Association, 1994). Patterns of psychopathology also differ across persons with or without MR. For example, relative to the general population, people with MR are more likely to show psychosis, autism, and behavior disorders and are less apt to be diagnosed with substance abuse and affective disorders. (See Moss et al., 1997a for a review of these issues and Chapter 46 for a discussion of autism and other pervasive developmental disorders.)

### ASSESSMENT OF PSYCHIATRIC DISORDERS

As researchers increasingly began to appreciate the scope of problems in persons with MR, they also developed various ways of assessing these problems. Some work has been devoted to the development of specialized rating scales and surveys; most of these measures are geared specifically for persons with MR and have well-developed psychometric properties (Aman, 1991). Among the more widely used are the Aberrant Behavior Checklist (Aman and Singh, 1994), Reiss Screen (Reiss, 1988), and Developmental Behaviour Checklist (Einfeld and Tonge, 1992). A tradeoff in using these scales is that although they are sensitive to the unique concerns of those with MR, they are not necessarily compatible with DSM or ICD psychiatric diagnoses. Further, because each scale has a different set of items and factor structures, these differences may ultimately contribute to inconsistent findings across studies (Dykens, 2000).

At the same time, other researchers have taken issue with the applicability of traditional DSM or ICD diagnoses for persons with MR (Sovner, 1986). Many of these concerns relate to the psychiatric interview itself, including acquiescence bias, and the limited abilities of many persons with MR to answer questions about the onset, duration, frequency, and severity of symptoms (Moss, 1999). In response to these challenges, several groups have adapted traditional DSM or ICD criteria for persons with developmental delay (King et al., 1994; Szymanski et al., 1998), whereas others have designed interview schedules specifically for those with MR, including the Psychiatric Assessment Schedule for Adults with Developmental Disability (Moss et al., 1997b). Direct interviews with both respondents and informants result in fewer cases of missed diagnoses (Moss et al., 1996). Still others shy away from formal diagnoses and advocate a more functional analysis of challenging behavior (Sturme, 1999).

### CAUSES OF INCREASED PSYCHOPATHOLOGY

Although the field has done well with assessment and diagnostic issues, less progress has been made in advancing theories on why persons with MR are at heightened risk of psychopathology in the first place. Many reasons have been discussed over the years and most fall within the "biopsychosocial" spectrum. Yet a comprehensive model of "dual diagnosis" is lacking, in part because researchers cannot simply apply existing risk factors for psychopathology in the general population to the unique characteristics of those with MR. In addition, the causal direction of most risk factors is unclear. Poor peer or social relations, for example, may be a precursor of psychopathology or a consequence of disruptive behavior.

Even so, some advances have been made, and heightened psychopathology in persons with MR has now been linked to specific biopsychosocial problems. Biologically, these include increased rates of seizure disorders (Bird, 1997; Caplan et al., 1998), abnormal neurologic functioning that in most cases is undetected (Peterson, 1995; Robertson and Murphy, 1999), high rates of sensory or motor impairments among persons with MR (Hodapp, 1998), biochemical or neurologic anomalies associated with unusual behaviors such as severe self-injury (King, 1993), and genetic causes that carry higher than usual risks of certain maladaptive or psychiatric vulnerabilities (Dykens, 1999a).

Psychological risk factors include the following: aberrant personality styles, including an outer-directed orientation and being too wary or disinhibited with others (Bybee and Zigler, 1998; Dykens, 1999b; Zigler and Bennett–Gates, 1999); atypical motivational styles or abnormal levels of sensitivity to basic human drives such as the need for attention or acceptance (Reiss and Havercamp, 1998); increased risk of failure experiences, which may lead to learned helplessness, low expectancies for success, and depression (Weisz, 1990; Zigler and Bennett–Gates, 1999); more global and less differentiated self-concepts that may lead to more sweeping negative evaluations of the entire self instead of not liking just one aspect of one's self (Evans, 1998); and reinforcement of negative behaviors, leading to more entrenched maladaptive behavior or interactions (Reiss and Havercamp, 1997).

Finally, specific social risk factors include the following: poor communication or assertiveness skills, which may lead to increased frustration and acting-out behavior (Nezu and Nezu, 1994); social strain or stressful social interactions, more strongly correlated with psychopathology than low levels of social support (Lunksy and Havercamp, 1999; Nezu et al., 1995); social stigma, with a subsequent negative impact on daily living, adjustment, and esteem (Edgerton and Gaston, 1991); peer rejection and ostracism and, among children, atypical patterns of friendship with nonretarded children (Siperstein et al., 1997); compromised "social intelligence," or inappropriate responses to social cues, that may exacerbate stigma and isolation from others (Greenspan and Granfield, 1992); heightened risks of exploitation and abuse, which may worsen behavioral or emotional problems (Ammerman et al., 1994); and family stress, including low levels of emotional, service, or financial support

to families (Minnes, 1998).

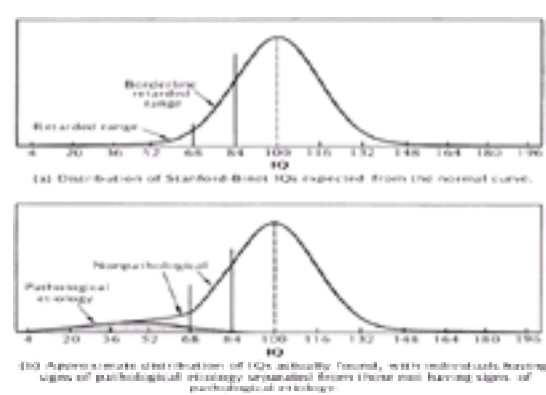

## GENETIC RISK AND PSYCHOPATHOLOGY

As previously noted, a comprehensive model has yet to be developed that identifies the relative importance of these many risk factors. To date, research aimed at doing so has generally relied on heterogeneous groups with MR. Yet each of the factors listed earlier can just as easily apply to those with a genetic diagnosis, and syndrome-specific studies may shed new light on genetic or other mechanisms associated with certain psychopathologic conditions (Dykens, 1995; Holland and Koot, 1998).

## ETIOLOGY AND PATHOGENESIS

Historically, researchers have used two broad categories to classify persons with MR (Zigler, 1967, 1969). One group has organic causes of their MR and consists of people with known prenatal, perinatal, and postnatal insults. Estimates suggest that approximately one-half of people with MR have known “organic” causes (Hodapp, 1994). The second group has no clearly identifiable organic cause of their MR and is postulated to account for most persons with mild MR. In years past, the terms “sociocultural” or “cultural-familial” retardation reflected the view that nonorganic MR stemmed from environmental deprivation. Although impoverished, chaotic environments may indeed be implicated in a few cases, this theory has generally fallen out of favor as an explanation for the population as a whole. Even so, a complicating factor is that disproportionately more persons with sociocultural MR are poor, from minority backgrounds, and of low-IQ parents (Hodapp, 1994).

With increased diagnostic precision and with the discovery of new genetic disorders, many workers speculate that more persons with nonspecific delay will receive specific genetic diagnoses in the years ahead. The complex interplay of organic and genetic (including polygenic) factors with sociocultural and environmental factors has been increasingly recognized (Rutter et al., 1996). Progress has been slower in identifying clear neurologic causes in persons with unspecified MR, because most neuroimaging research is conducted with persons with known genetic or other causes (Robertson and Murphy, 1999). However, some persons with nonorganic causes may simply represent the lower end of the normal, gaussian distribution of intelligence (Simonoff et al., 1996; Zigler, 1967). Assuming that nonorganic MR is the extreme end of the normal IQ distribution, then some persons will always belong to this group, even as progress is made in uncovering genetic or neurologic causes for other persons at the same IQ levels (Fig. 48.3).

**Figure 48.3.** A: Distribution of Stanford–Binet IQ expected from the normal curve. B: Approximate distribution of IQs actually found, with persons having signs of pathologic origin separated from those not having signs of pathologic origin. (From Achenbach T: *Developmental Psychopathology*, 2nd ed. New York, Wiley, 1974, with permission.)

In the organic group as well, many unresolved issues remain. Early researchers grouped people together who had different types of organic causes and often compared these heterogeneous groups with those with familial or nonspecific MR. Even today, mixed or heterogeneous groups, consisting of those with known and unknown causes for their delay, predominate in behavioral MR research (Dykens and Hodapp, 2000). Yet with the remarkable progress in molecular genetics, and improved diagnostic accuracy, researchers are now much better positioned to examine people with specific genetic causes. Indeed, there are now more than 750 known genetic causes of MR (Opitz, 2000), and as many as one-third of all persons with MR have already been diagnosed with a known genetic disorder (Matalainen et al., 1995). Further, although genetic and other organic causes are typically seen in persons with severe and profound delay, high-functioning persons with Down's, fragile X, Prader–Willi, Williams', and other syndromes may comprise 10% to 50% of persons with mild MR (Rutter et al., 1996).

With these advances, research on so-called behavioral phenotypes is gaining momentum, including both between-syndrome and within-syndrome designs (Dykens, 1995; Hodapp and Dykens, 1994, 2000). Between-group studies help to identify possible unique syndromic behaviors that may accelerate our understanding of gene or brain function. Specific examples of these seemingly unique behaviors include hand wringing in Rett's syndrome (Perry, 1991), hyperphagia in Prader–Willi syndrome (Holm et al., 1993), bouts of inappropriate laughter in Angelman's syndrome (Williams et al., 1995), the infantile catlike cry in 5p- syndrome (Gersch et al., 1995), and the self-hug in Smith–Magenis syndrome (Finucane et al., 1994). Further, and as shown in Table 48.2, some syndromes feature unique psychiatric vulnerabilities, including increased rates of obsessive–compulsive symptoms in Prader–Willi syndrome (Dykens et al., 1996), as well as anxiety, fears, and phobias in Williams' syndrome (Dykens, 2000). People without these syndromes can also have these conditions, but they occur much more often in these syndromes. As such, studies on these syndromes hold much promise for differentiating genetic from other pathways to these psychiatric endpoints.

Syndrome	Cognitive features	Cognitive strengths	Behavioral features
Fragile X	Language processing, auditory/visual memory	Visual/auditory attention	Social anxiety, stress, gaze aversion, inattention, hyperactivity, autism/ASD
Prader–Willi	Language processing	Visual/auditory processing	Hyperphagia, reduced daytime competence, symptoms of anxiety, autism
Williams'	Visual-spatial, visuo-motor coordination	Visual recognition, auditory/visual expressive language	Social difficulties, anxiety, fear, inattention, hyperactivity, phobias
Down'	Language processing, expressive language	Visual-spatial processing, expressive language	Autism spectrum, autism, inattention, depression and dementia in adults

**Table 48.2. Examples of Cognitive and Behavioral Profiles in Selected Mental Retardation Syndromes**

Cognitively as well, some syndromes show distinctive profiles of relative strength or weakness that are not typically seen in studies of persons with mixed or nonspecific causes of MR. As summarized in Table 48.2, persons with Williams', Prader–Willi, Down's, and other syndromes often show distinctive patterns of cognitive strength or weakness. Many people with Williams' syndrome, for example, show relative strengths in specific aspects of expressive language, along with pronounced deficits in visual–spatial functioning. Despite visual–spatial deficits, however, many persons with Williams' syndrome have a remarkable sparing of facial recognition and memory. Many, although not all, persons with Prader–Willi syndrome show remarkable skills solving jigsaw puzzles, with performances that exceed those of their chronologic agemates (Dykens, 2000).

However, most syndromic behavior appears to be “partially specific” or shared across one or more conditions (Hodapp, 1997). For example, persons with both fragile X and Prader–Willi syndromes appear to have relative weaknesses in certain short-term memory and sequential processing tasks (Dykens and Cassidy, 1999; Dykens et al., 1994), and inattention and hyperactivity are seen in Williams', fragile X, and 5p- syndromes (Baumgardner et al., 1995; Dykens and Clarke, 1997; Einfeld et al., 1997). These disorders, however, show qualitative differences in symptoms. Inattention in Williams' syndrome, for example, may be associated with heightened anxiety and social disinhibition, whereas in fragile X syndrome, these difficulties may be related to hyperarousal and anomalies in the size of the posterior

cerebellar vermis and caudate nucleus ([Mostofsky et al., 1998](#)).

Although between-group studies help to identify distinctive syndromic behaviors, within-syndrome studies help to explain individual variation in these behaviors. Researchers now need to identify the genetic, environmental, developmental, and psychosocial factors that help to explain individual behavioral differences in people with the same genetic disorder. For example, the level of cognitive delay in fragile X syndrome is associated with both age and molecular genetic status ([Dykens et al., 1994](#); [Tassone et al., 1999](#)). Similarly, in Prader–Willi syndrome, the frequency and severity of maladaptive behaviors such as skin picking appear to vary across genetic subtypes of this disorder ([Dykens et al., 1999](#)).

Whereas research on heterogeneous groups is still necessary, both between-syndrome and within-syndrome studies offer many advantages ([Dykens, 1995](#); [Hodapp and Dykens, 2000](#)). In the long term, work on behavioral phenotypes facilitates the search for gene–brain–behavior relationships, as well as contributing toward a more precise science of MR. In the short term, phenotypic data refine intervention and treatment ([Dykens and Hodapp, 1997](#); [Dykens, 2000](#)). Although many syndrome-specific recommendations for interventions have now been made, the efficacy of these approaches needs to be evaluated, including how they fare relative to more generic interventions ([Dykens et al., 2000](#)).

## DIFFERENTIAL DIAGNOSIS

The diagnosis of MR is based on the appropriate assessment of cognitive abilities and adaptive skills; clinical assessment also includes a careful developmental and family history, physical examination, and laboratory studies as appropriate. The clinician should be alert to any medical or environmental conditions that may be associated with developmental disability. For example, a strong family history or certain dysmorphic features in the child should raise the possibility of an inherited condition; a history of significant birth trauma, of exposure to environmental toxins, or exposure to marked psychosocial adversity are some of the factors that should be considered.

As noted, the age of diagnosis often varies depending on the severity of the disability, so persons with more severe MR present for clinical assessment earlier than those with mild, or borderline, MR. Careful psychological assessment of the child ([Chapter 43](#)) is obviously critical. Various other developmental difficulties, notably language and other specific developmental disorders and autism and related conditions, may be associated with some degree of mental handicap or may be confused with it. Diagnosis can be complicated because persons with MR can exhibit other developmental problems that can complicate the task of both diagnosis and assessment. For example, children with a marked expressive language disorder often do poorly on a test of intelligence test that is highly verbal. In autism and related disorders, social abilities tend to be the area of greatest weakness ([Chapter 46](#)).

## TREATMENT

The treatment of MR has undergone a marked shift in the more developed countries. More persons with MR now reside with the families and in their communities. More children now receive services within regular educational settings, and more services are available to support them and their families. At the same time, it is clear that placement in the community is not sufficient in and of itself, and the provision of adequate and appropriate support is critical. This is particularly important for the growing numbers of older persons with MR, many of whom still reside with their aging parents.

In general, treatment planning begins with a consideration of the underlying cause, if one is known, of the intellectual disability. In many instances, knowing the cause can guide both medical and psychosocial interventions; indeed, many syndrome-specific parent and professional organizations have published “best practice” guidelines across the lifespan (e.g., Prader–Willi, Williams’, and Down’s syndromes.). For rarer disorders, however, such data are lacking.

### Medical Treatment

Medically, laboratory studies should be based on the results of a careful history (including family history) and evaluation. Physical examination should include assessment of growth and developmental status as well as observation for facial features or other physical findings that could suggest a specific medical condition. It is sometimes the case that the evolution of the condition provides important clues to its cause, such as in Rett’s syndrome. Depending on the clinical circumstance, hearing or visual testing may be indicated as are, at times, specific, metabolic studies, chromosome analysis (including fragile X testing), neuroimaging or neurologic assessment, skeletal radiography, screening for organic acidurias, and so forth ([Curry et al., 1997](#); [Szymanski and King, 1999](#)).

Persons with MR may be at increased risk of certain medical conditions ([Ryan and Sunada, 1997](#)). In their review of the Aberdeen cohort of cases, Goulden and colleagues noted that at least 15% of patients developed epilepsy by adulthood; the risk was increased when associated disabilities were present or when there was a history of postnatal injury ([Goulden et al., 1991](#)). To some extent, the associated medical conditions vary depending on the cause of the MR, for example, the cardiac problems in Down’s and Williams’ syndromes and the risk of Alzheimer’s dementia in adults with Down’s syndrome.

### Cognitive and Adaptive Treatment

Regardless of the origin of MR, however, accurate assessment of each person’s intellectual and adaptive strengths and weaknesses is essential, because specific recommendations for intervention depend on the overall level and profiles of cognitive functioning. Although there are many different models of intelligence ([Sternberg and Salter, 1982](#)), investigators generally agree about many of the basic features of intelligence, such as the ability to use conceptual thinking in solving problems and in acquiring knowledge ([Sparrow and Davis, 2000](#)). Various IQ tests are now available, and they may differ in certain dimensions, such as the degree to which they emphasize language-based problem solving or short-term memory. Tests may differ in other ways; for example, some tests include timed tasks, whereas others provide the opportunity for demonstration of tasks by the examiner. As part of the standard administration of test items, the examiner is also able to collect considerable amounts of qualitative information that may be particularly important for treatment.

Some special considerations are involved in assessing persons with MR. Tests should, to the extent possible, be appropriate for the person’s chronologic age as well as her or his levels of receptive and expressive language. Cultural and other factors may need to be considered in some cases. The behavioral problems sometimes associated with MR may pose special problems; these problems can be further compounded if they tend to arise around times of change or frustration.

Assessment of adaptive functioning has the goal of providing a representative picture of the person’s typical abilities in home and school environments. In this regard, the goal is somewhat different from that of the intellectual assessment, in which the aim is to obtain optimal performance in a structured and standardized situation. Large discrepancies between intellectual level and adaptive skills suggest that the treatment should include a major focus on acquisition and generalization of adaptive skills.

Various measures of adaptive functioning have been proposed ([Chapter 43](#)). The most widely used instrument is the Vineland Adaptive Behavior Scales ([Sparrow et al., 1984](#)), which assess capacities for self-sufficiency in various domains of functioning including Communication (receptive, expressive and written language), Daily Living Skills (personal, domestic and community skills), Socialization (interpersonal relationships, play and leisure time and coping skills), and Motor Skills (gross and fine). The Vineland scales are available in three editions: a survey form to be used primarily as a diagnostic and classification tool for normal- to low-functioning children or adults, an expanded form for use in the development of individual education or rehabilitative planning, and a classroom edition to be used by teachers ([Sparrow et al., 1984](#)). Both the survey and expanded editions use a semistructured interview format administered to a parent or primary caregiver. For persons with MR, the expanded form is often particularly useful because it readily translates into goals for intervention planning.

### Psychiatric Treatment

As previously described, persons with MR are at increased risk of psychiatric problems, and these are often a major source of distress to the individual and family and may severely limit opportunities for self-sufficiency and independence ([Szymanski and King, 1999](#)). Yet these mental health problems, and medical ones for that matter, are frequently overlooked. Indeed, [Ryan and Sunada \(1997\)](#) report that up to 75% of persons with MR who are referred for psychiatric assessment have undiagnosed or undertreated medical conditions, and nearly 50% receive nonpsychotropic medications that could have behavioral side effects.

Even though associated psychiatric problems can severely limit personal and social sufficiency, there is often a tendency to neglect or overlook the mental health needs of this population ([Einfeld and Tonge, 1996](#)). Although some of the many rating scales, checklists, and other instruments for assessment of psychopathology in the general population are applicable, other instruments have been developed that are specific for persons with MR. Psychiatric assessment may entail some

modification in usual procedures, particularly for persons with more severe MR, in whom the psychiatric assessment must be comprehensive and multifocal. The presence of associated difficulties (seizures, motor impairments, sensory problems) may further complicate accurate psychiatric diagnoses.

### Other Psychosocial Treatment

General quality-of-life issues are receiving renewed attention in the MR field, with particular emphasis on improving how people with MR live, work, and play in inclusive, community-based settings. Most persons with MR benefit from employment or from structured programs that emphasize vocational, adaptive, or socialization skills, long after formal schooling. Indeed, the transition from school to work is a vulnerable point for many persons and their families. Unlike the school years, when special education and related services (e.g., occupational, physical, and speech and language therapies) are typically provided under one roof at school, services for adults risk being more fragmented. These young adults may particularly benefit from *case coordination*, to avoid becoming isolated or lost between various cracks in services.

### OUTCOME AND FOLLOW-UP DATA

As expected, the course and outcome of MR vary considerably, depending on various factors. These include the level of severity of the MR, associated biological or other vulnerabilities, and aspects of the individual's psychological functioning, family support, and other factors ( [Szymanski and King, 1999](#)). Levels of ability to cope with the demands of daily life (i.e., adaptive skills) are critical in determining adult outcome. It is also clear that the expectations of caregivers and the provision of intervention services and environmental supports are also important. For persons with known medical causes of MR, certain risks may be present, such as the risk of early development of Alzheimer's dementia in persons with Down's syndrome ( [Aylward et al., 1997](#)). Conversely, even when the specific biomedical cause is known, there may be a wide range in ultimate outcome. To simplify the discussion of outcome, we focus the discussion on levels of MR but again emphasize that the outcome in a given individual patient varies considerably, depending on a host of factors.

In mild MR, many children with the condition go on, as adolescents and adults, to make major gains in adaptive functioning and thus may "lose" the diagnosis as they become older. Such persons may be self-supporting, may marry, and may raise families. At the same time, such persons are not without difficulties, because several studies ( [Granat and Granat, 1978](#); [Rutter et al., 1976](#)) show that persons with intellectual deficits who have not required special services in school have higher rates of educational and behavioral problems. In their follow-up study of the Aberdeen cohort of children first seen at 9 to 11 years of age and then followed up at the age of 22 years, [Richardson and Koller \(1992\)](#) report that more than 75% no longer require services as adults, although only about 25% of the entire group are judged to be functioning adequately in all areas. Mild MR is likely to be diagnosed only at the time of school entry, that is, when academic demands increase. As discussed previously, persons from backgrounds of social disadvantage or adversity and from certain minority groups are more likely to be represented in these cases.

As adults, persons with moderate levels of MR (IQ 40 to 55) typically have more serious impairment. It is common for such persons to need services as adults. Moderate MR is often identified in the preschool years. At this, and lower, levels of cognitive functioning, specific medical causes are more likely to be identified, and minority group membership and psychosocial adversity in the family are less frequent. The prognosis for adult self-sufficiency is more guarded, although many persons can live semiindependently or with partial support ( [Ross et al., 1985](#)).

For persons with severe or profound retardation, case identification may occur in infancy or early childhood. Generally, high levels of supervision and support are required during the person's life. Goals for these patients include facilitating self-care and other skills as far as possible. Associated medical problems and behavioral difficulties are frequent. Communication skills may be impaired and are a further source of handicap.

Legislation, legal decisions, and some important social policy changes have markedly changed the provision of remedial programs. The provision of early diagnosis and intervention and the availability of community-based resources and educational interventions within public schools have dramatically improved the care of persons with MR as well as overall outcome.

### PREVENTION

Estimates of recurrence risk vary depending on the situation, such as from instances in which a clear genetic origin can be identified, as in fragile X syndrome, to those in which the difficulties appear to be of nongenetic origin, as in congenital rubella. When no specific cause is identified, estimates of recurrence risk vary considerable, such as between 3.5% and 14% for the siblings of a boy with MR ( [Crow and Tolmie, 1998](#)). For some disorders, such as autism, there has been a growing appreciation of genetic factors, and it now appears that, for parents who have one child with autism, the risk of having a second child with autism is between 2% and 10% ( [Fombonne et al., 1997](#)). Siblings of children with MR who are not themselves affected may be at increased risk of other difficulties, given higher levels of family and personal stress ( [Hannah and Midlarsky, 1999](#)). Support for them, and for their parents, is an important element of treatment planning ( [Crow and Tolmie, 1998](#); [Szymanski and King, 1999](#)).

### RESEARCH DIRECTIONS

Several issues will likely dominate the research agenda for the coming decade. They include the interplay between genetic and environmental (including psychosocial) risk factors in the origin of MR as well as the study of basic neural mechanisms ( [Simonoff et al., 1996](#)). Understanding of basic processes that underlie phenotypic expression, including various forms of psychopathology, offers the opportunity to advance knowledge more generally about mechanisms of disorder. Although many advances in the care and treatment of mentally retarded persons have been made, studies of treatment methods remain an important priority.

Language, a unique and characteristic capacity of the human mind, is also one of its most vulnerable faculties. Virtually any disruption in cognitive function, particularly during early development, can affect language acquisition. For this reason, disorders of language development typically accompany a variety of other conditions. This chapter first outlines briefly the most common syndromes in which disorders of communication may play a part. Specific disorders of speech and language development, which are not accompanied by deficits in other areas of mental function, are then discussed.

## SYNDROMES INVOLVING COMMUNICATION DISORDERS

### Mental Retardation

Limitation in communicative skill is often one of the first signs of mental retardation. Children with retardation are often first recognized because of their failure to begin talking at the normal time. The sequence of language acquisition in children with retardation follows, in general, the sequence of normal acquisition, although some differences can be identified. Many children with mental retardation (MR) show communicative skills that are commensurate with their developmental level, but more than half have language skills that are less than what would be expected for mental age (Miller et al., 1999). Productive deficits are common, with some children with MR showing deficits relative to mental age in this area only. Others have both receptive and expressive limitations relative to mental age. Phonologic errors are prevalent in children with MR. These children make similar errors to those seen in normal development, but errors are more frequent ( [Shriberg and Widder, 1990](#)). Pragmatic skills are usually similar to those seen in children at similar developmental levels ( [Lahey, 1988](#)). The two most prevalent syndromes of MR, Down's syndrome and fragile X syndrome, are both very frequently associated with various problems in language development ( [Dykens et al., 1994](#); Miller et al., 1999).

### Hearing Impairment

Children with impaired hearing are vulnerable to language disorders because of their lack of access to the linguistic information in the auditory signal. Still, children with hearing impairments vary greatly in their oral language ability, and as [Boothroyd \(1982\)](#) pointed out, an unaided audiogram is not a child's fate. With amplification via hearing aids, children can be moved from greater to lesser levels of severity of hearing loss. Cochlear implants and tactile aids are also used to provide auditory information to children who would otherwise be considered deaf ( [Roeser, 1988](#)). Language acquisition in children with hearing impairment (HI) follows the same general sequence as it does in children with normal hearing, although it is greatly delayed, and the delays affect all modalities: articulation, receptive and expressive communication, and oral and written language ( [Paul and Quigley, 1994](#)). Children who receive cochlear implants, however, appear to show significant benefits in terms of spoken language ( [Tomblin et al., 1999](#)). [Lahey \(1988\)](#) concluded, however, that use of language for communication is not a major problem area for children with HI but that most of their difficulties lie in acquiring the conventional verbal forms of communication. Reading and writing present particular problems, primarily because of the language basis necessary for acquiring these skills. Average reading comprehension level for adolescents with HI is third to fourth grade ( [King and Quigley, 1985](#); [Paul and Quigley, 1994](#); [Trybus and Karchmer, 1977](#)).

Many children can be taught to bypass the auditory channel through the use of manual sign language. Using this method, children can develop fluency and eloquence in sign that would never be available to them through the modality of speech. There is great controversy within the community of the hearing impaired as to the role of sign language versus oral language instruction for children with severe hearing losses. In general, children taught sign develop higher-level language skills than those taught speech, although their communication may be limited to those in the deaf community who use sign as their mode of communication. The decision whether to use an oral or signed mode of communication with a child who has severe HI must be made carefully in consultation with the child's family. Deaf parents of deaf children may feel it is more important for their child to be fluent in sign and comfortable in deaf culture than to achieve the maximum possible reading level. For these families, instruction in sign may make more sense. Deaf children of hearing parents may have families that feel communication with the general population is among their highest goals. For children in these families, oral instruction may work better. Each family must be presented with all available options in order to make the most informed decision for their child ( [Brackett, 1997](#)).

### Psychiatric Disorders

There is a very high coincidence of sociobehavioral and communicative disorders ( [Giddan and Milling, 1999](#)). [Prizant and Meyer \(1993\)](#) reported that over half of children diagnosed with communication disorders have socioemotional and behavioral problems. Conversely, [Prizant and associates \(1990\)](#) found that two-thirds of children referred to a psychiatric inpatient hospital failed speech and language screening. [Giddan and Milling \(1999\)](#) showed that 65% of children in psychiatric outpatient clinics were similarly impaired. They also reported that a third of children referred for conduct disorders had concomitant speech and language difficulties, and more than two-thirds of children with some form of attention deficit disorder have language disabilities as well. Additionally, as [Prizant and colleagues \(1990\)](#) showed, some children with anxiety and affective disorders fail language screenings. It may be impossible to know the source of this connection. Some writers ( [Redmond and Rice, 1998](#)) hold that a communication problem leads to frustration, creating behavioral or emotional disorders. It may, alternatively, be the case that a behavioral/socioemotional problem leads to decreased motivation to communicate or an inability to "tune in" to learn the rules of communication or use language for self- and other-regulation ( [Paul et al., 1999](#)); or, perhaps some other underlying factor affects both aspects of development. Whatever the answer to these questions, children with language problems are vulnerable to socioemotional difficulties, and children with psychiatric diagnoses show a higher than normal prevalence of language disorders.

The psychiatric disorder most consistently associated with communication deficits is autism, or pervasive developmental disorder (PDD). Communication problems—including severe delays in language, inability to communicate nonverbally, inability to sustain conversation, stereotyped and repetitive use of idiosyncratic language, and abnormal ability to use language for social communication—are included in the diagnostic criteria for autism/PDD ( [APA, 2000](#)). Virtually all children with autism have some form of communication disorder that presents as part of their syndrome. What differentiates autism from a more circumscribed language disorder is the global nature of the child's communication problem. Not only is language affected, but also the ability and motivation to send messages by any means, either verbal or nonverbal, is severely impaired. Although sign and other alternative forms of communication are often tried with autistic patients, it is their underlying deficit in communicative skill and motivation that impedes their use of language; therefore, providing an alternate channel does not usually result in dramatic improvement ( [Lord and Paul, 1997](#); [Tager-Flusberg, 1995](#)).

### Acquired Disorders of Communicative Function

Language disorders can be acquired during the developmental period through four types of neurologic insults: focal lesions; damage associated with seizure disorders; damage resulting from tumors, infection, or radiation; and traumatic brain injury. Focal lesions affect language in children primarily if they are unilateral on the left side. These kinds of lesions are relatively rare in children, and children younger than 10 years tend to recover from the aphasias that follow these insults

nearly completely, although some subtle effects on language and learning abilities can persist ( [Bishop, 1992](#); [Blosser and DePompei, 1994](#)).

[Landau and Kleffner \(1957\)](#) identified a syndrome of expressive and receptive language deficits accompanied by seizures that usually has its onset between 4 and 7 years of age after a period of otherwise normal development. The Landau-Kleffner syndrome has no known cause and, fortunately, is quite rare. Unlike aphasia associated with focal lesions, Landau-Kleffner syndrome usually ends in a permanent aphasia. Cognitive functioning is usually impaired as well. Anticonvulsant medication can help to control the seizures, but does not improve communication. Some behavioral and educational intervention is almost always warranted.

Brain radiation treatment used to treat acute lymphocytic leukemia (ALL) in children has greatly reduced the mortality rate of this disease, but this “cure” sometimes has the unfortunate consequence of causing language and learning problems, loss of developmental skills previously acquired, or seizures ( [Riddle et al., 1991](#) ). Brain tumors can also affect communicative functioning. In addition, brain damage that can affect language development may also result from infectious diseases, such as meningitis. The long-term sequelae of these kinds of insults can be subtle and variable, depending on timing, location, size, and area of the brain affected by the damage. Children with these injuries may retain a great deal of language function but have deficits that surface only during complex tasks, like those required for school. They may have expressive skills that are relatively intact, but poor comprehension. This can result in adults' being fooled into thinking comprehension is on par with production and being frustrated when the child “refuses” to follow instructions. The range of severity of these effects can extend from almost nonexistent to severe enough to result in a diagnosis of mental retardation.

Traumatic brain injuries (TBIs) can be focal in nature, usually involving open head injuries such as bullet wounds. Closed head injuries, such as those resulting from blows or collisions, tend to involve diffuse damage, affecting larger areas of the brain. Like children with acquired aphasia associated with focal lesions, children with TBIs of both types show a great deal of spontaneous recovery. [Russell \(1993\)](#) reported that outcome is generally predicted by the degree of coma, the length of time a child spends in an impaired state of consciousness following the injury, and the length of the posttraumatic amnesia (PTA) period. PTA lasting longer than 24 hours is considered a sign of severe injury. Age at injury does not appear to affect prognosis, and the onset of deficits may be delayed for long periods of time after the injury has taken place. Although some children retain physical disabilities from TBIs, many do not show obvious physiologic damage. However, a substantial minority of these children suffers long-term deficits in cognitive and language function ( [Plante and Beeson, 1999](#) ). [Gerring and Carney \(1992\)](#) reported that, during the acute recovery process, children tend to be mute at first. They may comprehend only simple commands. First language productions often reflect the confused state the child is in and are often dysarthric or dysfluent. Speech may be slow, and prosody may be affected so the speech sounds monotonic and “flat.” Swallowing disorders are also common during this phase of recovery.

### Disorders with Environmental Components

Communication disorders can be associated with prenatal exposure to substances such as drugs and alcohol or with parental behavior disorders such as abuse and neglect. Language disorders are frequently part of the picture seen in fetal alcohol syndrome (FAS) or fetal alcohol effects (FAEs) ( [Shprintzen, 1997](#) ). They include delayed development, poor receptive vocabulary and comprehension, and pragmatic difficulties. The communication disabilities children with FAS and FAE display are related to the level of intellectual impairment. Perseveration and echolalia are often present in children with more severe impairments ( [Sparks, 2001](#) ).

Children with a history of prenatal exposure to cocaine or other street drugs are also described as showing deficits in language development, among other symptoms ( [Sparks, 1993](#) ). However, it is important to remember that many women who abuse street drugs during pregnancy take more than one drug and may mix abuse of both drugs and alcohol. Also, the effects of the mother's drug abuse on her care taking ability are just as important as any biological effects the abuse may have caused before birth. As far as biological effects are concerned, [Sparks \(2001\)](#) pointed out that less than half of children exposed to drugs prenatally experience low birth weight, prematurity, intrauterine growth retardation, or small head circumference. Further, the developmental problems these children exhibit are not much different from those of other children who live in chaotic homes but who did not have prenatal drug exposure. In terms of communicative development, prenatal drug exposure should be considered a *risk* for communication disorder, rather than a cause of it.

Children with communicative and other developmental disorders are, as [Knutson and Sullivan \(1993\)](#) pointed out, more likely than normally developing children to experience maltreatment. [Fox and colleagues \(1988\)](#) suggested that a child with a communication disorder might be less satisfying for a parent to care for and provide less rewarding interactions. These difficulties might predispose a child to abuse.

Maltreatment itself also constitutes a risk for language disorder. [Culp and associates \(1991\)](#) argued that language development is particularly vulnerable in the maltreatment situation because of the disruption in social interaction it entails. [Coster and coworkers \(1989\)](#) showed that maltreated toddlers had more limited expressive language during play with their mothers than peers from nonabusing homes. [Allen and Oliver \(1982\)](#) found that maltreated 4-year-olds had significantly lower language scores than peers of similar socioeconomic level. [Lynch and Roberts \(1982\)](#) showed that children with a history of maltreatment scored significantly lower on verbal IQ relative to nonverbal scores. [Fox and associates \(1988\)](#) found that maltreated children had receptive language deficits, with neglected children suffering greater lags than those shown by children who were abused. In general, severe neglect seems to be a greater risk factor for communicative handicap than does abuse ( [Allen and Oliver, 1982](#); [Culp et al., 1991](#) ). [Coster and Cicchetti \(1993\)](#) point out, however, that it is not entirely clear that the language problems seen in these children are greater than what would be expected on the basis of the generally depressed cognitive levels associated with their maltreatment.

## SPECIFIC SPEECH AND LANGUAGE DISORDERS

Communication disorders can, as we have seen, be associated with a variety of conditions. They can also occur in relative isolation. These more specific disorders of speech and language development can still have broad effects on a child's ability to succeed in social and academic pursuits because communication is so central to human interaction. We examine the two types of specific speech disorders discussed in the DSM-IV-R ( [APA, 2000](#) ), stuttering and phonologic disorders, and the two types of language disorders addressed there, that is, specific language disorders and selective mutism.

### Specific Speech Disorders

#### STUTTERING

Stuttering, according to [Cooper and Cooper \(1995\)](#), is a clinical syndrome involving abnormal and persistent dysfluencies that result in the speaker's perception of a loss of control over speech, which is often accompanied by affective and behavioral reactions. Several types of speech dysfluencies also may be involved, including blocking of sounds, hesitations, and tense pauses (Perkins, 1980). Stuttering usually begins somewhere between 2 and 7 years of age, with a peak between 3 and 4 years. Although normal children often go through periods of dysfluency during the developmental period, these “normal dysfluencies” tend to occur in the larger linguistic units (word, phrases, and sentences). For children who tend to persist in stuttering over time, dysfluencies are more likely to occur in repetitions of syllables (“vi-vi-vi-vi-video”) and sounds (“g-g-g-g-ot”). Other “red flags” for persistent stuttering include sound prolongations (“WWWWWait!”), silent blocks in which the child attempts to speak but no sound comes out, and visible struggle behaviors during speech, such as blinks or grimaces ( [Plante and Beeson, 1999](#) ). If dysfluencies continue to be relatively effortless, there is a good chance of recovery. In addition, [Yairi and associates \(1996\)](#) reported that children who recover from stuttering begin to show reductions in their number of dysfluencies within the first year, whereas those who persist in stuttering are relatively stable in their rate of dysfluency.

When recovery occurs, it usually does so by adolescence, often around the time of puberty. About 1 in 30 children goes through a period of stuttering, but by adolescence, the prevalence drops to 0.8% ( [NIDCD, 1992](#) ). The disorder is much more common in boys than in girls, and the male:female ratio increases with age, suggesting that girls show higher rates of recovery than boys ( [Yairi et al., 1996](#) ).

For individuals with chronic stuttering, the severity of the disturbance varies from situation to situation and is more severe when there is pressure to communicate. Stress or anxiety have been shown to exacerbate stuttering, but are not thought to play a role in the etiology. Reducing stress during speaking can reduce stuttering episodes ( [Van Riper, 1973](#) ), but general treatments for anxiety, including the use of tranquilizing medication, have not been found to be effective treatments ( [Ham, 1990](#) ). In general, speech therapy is used both to shape fluent speech and help the client to stutter with less tension, avoidance, and interruption of the flow of communication ( [Gregory, 1995](#) ). Psychotherapy alone has not been shown to be an effective treatment for stuttering, but counseling is often helpful for overcoming the secondary effects of stuttering on self-concept, thoughts, and feelings ( [Cooper and Cooper, 1995](#) ).

Although stuttering has, at times, been thought to be a learned behavior, most researchers today consider stuttering to have a biological component. People who stutter have been found to show laryngeal behavior different from that in normal speakers, even when their speech is apparently fluent ( [Conture et al., 1985](#) ). Elements of both the central and peripheral nervous system may be involved in stuttering behaviors ( [Plante and Beeson, 1999](#) ). There also appears to be a familial component in stuttering ( [Kidd, 1977](#); [Yairi et al., 1996](#) ). The risk of stuttering among first-degree relatives is more than three times the population risk ( [APA, 2000](#) ).

Stuttering is believed by most researchers today to have a complex multiplicity of causes that include biological vulnerability, environmental demands and expectations, and temperamental characteristics of the speaker ([Adams, 1990](#)).

## PHONOLOGIC DISORDERS

Phonologic or articulation disorders are characterized by impaired production of developmentally expected speech sounds. To diagnose a specific phonologic disorder, it is necessary to ascertain that the problem is not attributable to deficits or abnormalities in intelligence, hearing, or the structure and physiology of the speech mechanism. So a phonologic disorder is one in which, although there is no organic reason for the disability, the child's speech is marked by misarticulations, including distortions of sounds (e.g., /s/ is produced with a lisp), omissions of sounds (e.g., *up* is pronounced "uh," *play* is pronounced "pay"), and incorrect substitutions of one sound for another (e.g., *cat* is pronounced "dat"). Many of these misarticulations represent processes that are typical in the speech of young normal children (e.g., deletions of final consonants, simplifications of consonant clusters), but in phonologic disorders more of them are used, they are used more often, and their use persists beyond the normal developmental period. There may also be idiosyncratic preferences for and/or avoidances of certain sounds or sound simplification processes ([Dunn and Davis, 1983](#); [Ingram, 1976](#); [Weiner, 1981](#)), and/or reversals or misordering of sounds in words ([Trantham and Pedersen, 1976](#)). The age of recognition/onset of the disorder is related to severity. Typically, the disorder becomes apparent around the age of 4 years, when normal children become fully intelligible and eliminate almost all of their normal developmental sound change patterns ([Bernthal and Bankson, 1998](#)). Children as young as 3 years can be diagnosed with this disorder, even if their speech is unintelligible to family members. Milder cases may not be identified until the child is in school.

Phonologic disorders are the most prevalent type of communication problem. [Edwards \(1984\)](#) reported that 80% of speech clinic referrals were for articulation disorder. Six percent of school-age children have phonologic disorders. The prevalence is higher for preschoolers, with estimates ranging from 10% to 15% ([Office of Scientific and Health Reports, 1988](#)).

The characteristics of the misarticulated speech are related to the child's age and severity of the disorder. Younger and/or more severely impaired children may have difficulties involving a wide range of speech sounds, including those like /b/, /p/, and /m/ that are acquired early in the developmental sequence. A variety of sound changes may occur, including dropping syllables ("nana" for *banana*), dropping final sounds (/da/ for *doll*), or leaving sounds out of consonant blends ("bu" for *blue*). These changes, cumulatively, can render the child's speech moderately to severely difficult for others to understand. Older children and/or children who are less severely affected may make only a few kinds of errors, usually substitutions or deletions. Errors in older or more mildly impaired children will occur only on sounds that are acquired later in the developmental sequence (e.g., /s/, /r/, /l/, th). Misarticulations of vowel sounds are rare in this disorder.

Phonologic disorders can, of course, occur with many of the syndromes discussed in the preceding. They can also occur in isolation, but are commonly associated with specific language disorders. [Shriberg and Kwiatkowski \(1994\)](#) found that over 50% of children with phonologic disorders have delays in expressive language, and 10% to 40% have delays in language comprehension. [Shriberg and Kwiatkowski \(1988\)](#) reported that a significant minority of these children, with either speech-only or speech/language delays as preschoolers, required continuing special services throughout their elementary school years. They emphasize the importance of careful assessment and follow-up of both speech-only and speech/language delayed children. Although most of these children do "outgrow" their unintelligible speech, some continue to require services for other aspects of language and academic development.

## Specific Language Disorders

### SPECIFIC LANGUAGE IMPAIRMENT

Some kinds of language disorders have no known concomitants. These disorders have been traditionally defined by exclusion, that is, by the absence of the other factors—mental retardation, sensory disorders, neurologic damage, emotional problems, or environmental deprivation. The terms *childhood aphasia* or *congenital aphasia* were used in the past to describe these disorders. The use of these terms grew out of the conviction of the early neurologists that difficulties in children's learning language were analogous to the loss of language seen in adults who suffered acquired aphasias. This notion evolved from observations that "aphasic" children often appeared bright in other ways and were clearly not retarded. They seemed also to have normal affective bonds to the people around them and were not emotionally disturbed. Their inability to acquire language normally was attributed to some sort of neurologic dysfunction, thought to be comparable to localized brain lesions that resulted in aphasia in adults.

A multitude of studies that attempted to identify these neurologic lesions in children with language deficits ([Paul, 1996a](#)) were unsuccessful in finding brain structure or function differences that were either common to all the children studied or specific to children with language disorders, although there are some indications of reduced hemispheric asymmetry in children with language disorders and their immediate family members ([Jackson and Plante, 1997](#); [Plante et al., 1991](#)). New diagnostic techniques, such as functional magnetic resonance imaging (fMRI) and positron-emission tomography (PET) scanning may be more successful in identifying more specific neurologic markers. However, because language disorders in children do not seem to have the same root in localized brain lesions as do adult aphasias and because no specific, reliable brain differences have been identified to date, the terms *aphasia* or *dysphasia* seem too weighted toward neurologic explanations of dubious value. More descriptive terms are now used to label these disorders. DSM-IV uses *specific language disorder*. *Specific language impairment*, often abbreviated SLI, is also commonly used to label this diagnostic category ([Paul, 2000](#); [Watkins and Rice, 1994](#)).

### Language Development in Specific Language Impairment

Children with SLI are late to begin talking. They may not say their first word until well into their second year. When they do begin to talk, they add new words slowly. They may continue to use single word or telegraphic utterances into their third year. Although expressive vocabularies tend to reach normal size by age 3 in children with mild to moderate handicaps, problems in various areas of syntax, such as verb endings and pronoun usage, persist throughout the preschool period ([Paul, 1993b](#)). Grammatical usage may be characterized by omissions of words (e.g., prepositions, indefinite pronouns, or verbal auxiliaries: "He sitting," "Where we going?") or morphemes (e.g., "Dad wear white shoe," "She sleep"), use of a limited selection of grammatical structures (e.g., only the present tense of verbs), incorrect word ordering (e.g., "Car Mummy have"), or the use of inappropriate combinations of words or morphemes ("They was reading," "two foots"). Phonologic problems very frequently coexist with slow expressive language development during the preschool years. Many of these problems resolve by the early school years in children with mild to moderate disorders. Comprehension of language may appear age-appropriate or mildly delayed during the preschool period. For preschoolers with language problems that appear to be specific to the expressive modality, risk for long-term deficits is about 20% at kindergarten age ([Paul, 1996b](#)). Other positive prognostic indicators include a milder degree of the impairment, few perinatal problems, higher nonverbal IQ, and willingness on the child's part to participate in groups ([Nelson, 1998](#)). Certain measures have been shown to be good predictors of school-age outcome in preschoolers with mild to moderate SLI. These include measures of narrative skills, nonverbal cognition ([Bishop and Edmundson, 1987](#)), and parents' socioeconomic status ([Paul and Fountain, 1999](#)).

There has been a long-running debate in the literature about whether children with language disorders show "deviant" acquisition patterns—patterns unlike those seen in younger normal children—or whether they exhibit a slowed-down version of normal development. Early studies ([Menyuk, 1964](#)) reported that there were qualitative differences in the linguistic systems of normal and disordered children. But recent research, summarized by [Leonard \(1997\)](#), suggests that children with language disorders do resemble younger normal speakers in the general nature of their linguistic systems and in most aspects of the order of acquisition. Although this pattern holds true when we look at one specific feature of development at a time, Leonard pointed out that children may be 1 year below age level in one set of features, 1.5 years below in another, 6 months below in a third, and so on. The result will be that the overall profile of language skills in a child with SLI may not resemble that of a normal child at any point in development. This does not mean that language development is deviant, but rather that it is asynchronous in some ways.

For children with chronic mild to moderate language disorders, problems in the school years tend to narrow in their focus and to be concentrated in subtle difficulties of language organization and efficiency, rather than frank errors ([Nelson, 1998](#)). Word retrieval or "word finding" difficulties, are common. Instead of using correct words (e.g., "chair"), a child with SLI may substitute an incorrect word of related meaning (e.g., "table"); or use functional descriptors (e.g., "thing to sit on"), vague or general terms (e.g., "thing"), or his or her own made-up jargon. Storytelling and discourse problems often persist and affect both oral and written modes of expression ([Paul et al., 1996](#)). These children may lack the ability to elaborate and/or self-correct when needed for clarity in conversation ([Graham et al., 1983](#); [Trantham and Pedersen, 1976](#)). There may be tangential or inappropriate responses to questions, a limited range of communicative functions (e.g., requests, imperatives, questions) expressed, difficulty maintaining and/or changing topics, and difficulty initiating interactions ([Kuder, 1997](#)). Many of these pragmatic problems are caused by a lack of flexibility in language ([Lucas, 1980](#); [Zirkelbach and Blakesley, 1985](#)). These children may sound abrupt, rude, or impolite simply because they do not have access to the full and diverse range of linguistic forms used in normal conversation to encode pragmatic nuance and make language sound appropriate to the social context. In addition, some mild social deficits may also be seen ([Bishop, 1997](#)). Academic problems tend to involve primarily reading and writing. Despite their

persistent problems, however, most of these children do finish high school, some go on to college, and most live independent lives ( [Hall and Tomblin, 1978](#)).

Prognosis is more guarded for children with severe SLI. [Paul and Cohen \(1984\)](#) studied long-term outcomes in children diagnosed as SLI as preschoolers who were not speaking in full sentences by the time they were 6. By the time they were adolescents, these subjects with severe impairments were likely to score in the retarded range on IQ tests, even if they had scored in the normal range at the preschool level. Given intensive intervention, all made steady progress in language skills throughout their school years. Still 90% of these subjects were significantly below the normal range in both areas by adolescence, and all required intensive special education, with most in special classrooms, schools, or residential facilities.

### *Prevalence*

Accurate estimates of prevalence of specific language disorders are difficult to come by, because of methodologic differences across studies (e.g., in the subclassifications and definitions; in the cutoffs and inclusionary criteria; and in the age, sex, and other characteristics of the children sampled). Estimates during the preschool period generally range from 10% to 15% ([Rescorla and Lee, 2001](#)), although some children in this group overlap with those identified with phonologic disorders. Language disorders are the most common type of developmental disability seen during the preschool period.

At school age, the prevalence of primary language disorders is thought to be about 4%, although again there is overlap with related disorders, because some preschoolers with language disorders “grow into” school-age learning disabilities and dyslexia ( [Plante and Beeson, 1999](#)), as discussed in the preceding. Specific language disorders and learning disabilities combined are the most prevalent disorders of school-age children ( [Pore and Reed, 1999](#)). Although disorders of language expression are thought to be more common than those involving comprehension, [Bishop \(1997\)](#) has argued that almost all children with language impairments do have receptive difficulties, although they may be subtle in some cases. It also appears that language disorders are more prevalent in males than in females ([Satz and Zaide, 1983](#)).

### *Etiology*

Although specific biological markers of SLI have not been identified, neurobiological factors are clearly implicated. There is evidence of genetic factors in SLI including higher concordance in monozygotic than dizygotic twins ( [Bishop et al., 1995](#)) and higher than normal risk in family members for language and learning problems if a child has SLI ([Tallal et al., 1989](#); [Tomblin, 1989](#)). The role of environmental factors in these disorders has long been at issue. Although aberrant parental linguistic input has often been suspected as a cause, numerous researchers (e.g., [Conti-Ramsden, 1990](#); [Leonard, 1989](#); [Paul and Elwood, 1991](#); [Whitehurst et al., 1988](#)) have concluded that linguistic input to children with language disorders is adequately matched to the children's language level. Some environmental factors appear to be associated with risk for language delay, however. These include lower socioeconomic status, larger family size, recurrent otitis media, neglectful home environment, and later birth order ([Nelson, 1998](#)). It appears that the operative mechanism behind these factors is deprivation of enriching linguistic input ( [Bishop, 1987](#)), occurring at a critical stage in language development.

How specific are specific language disorders? Children with SLI are at greatly increased risk for attention and activity problems ( [Damico et al., 1999](#)). Other “soft” neurologic signs are also frequently present in children with SLI ( [Benton, 1964](#); [Eisenson, 1972](#)). The involvement of a variety of nonverbal cognitive skills in SLI also has been indicated (Johnston, 1994). These findings have led to the hypothesis that children with SLI may have not just a language problem, but also a general representational deficit, affecting a variety of kinds of symbolic functioning. [Tallal \(1988\)](#) cautioned, however, that in each of these studies there were children with SLI who could perform the nonverbal cognitive tasks adequately, and that sometimes the differences between groups were not qualitative, but a matter of speed of response. [Leonard \(1997\)](#) pointed out that, although some children with SLI fall below age mates on such tasks, they still do better than younger children with comparable language skills.

[Leonard \(1991, 1994\)](#) provided an alternative explanation for SLI. He contended that children who score low on language tests, relative to their scores on other areas of cognition, may no more have a “disorder” than children who cannot learn to play the violin. He argued that some children are just “limited” in their ability to learn language, falling (as someone must) at the low end of the normal distribution of language ability. If this were the case, in his view, it would not be surprising that such children would also be limited in other abilities that related to symbolic function. He referred to [Gardner's \(1983\)](#) notion of “multiple intelligences,” which proposes that there are a variety of somewhat independent spheres of intellectual functioning and that some people have greater abilities in some than others. The tendency to call a language limitation a “handicap” stems, in Leonard's view, from the importance of linguistic skills for academic and vocational success in our society, not from any significant neurologic or neuropsychological pathology in people limited in this way. The fact that language problems tend to aggregate in families ( [Tallal et al., 1989](#); [Tomblin, 1989](#)) could be taken to support the view that some people just have fewer optimal “language genes,” and therefore less talent in language areas, than others.

Many would contest this view, however. They would hold that the frequent co-occurrence of SLI with attention and activity problems and other “soft” neurologic signs raises questions about its relation to normal development. [Aram \(1991\)](#) argued that children with nearly age-appropriate comprehension but expression limited to single words could not be seen as functioning simply at the low end of the normal range, nor could a 3-year-old who can read but can not produce spontaneous speech ([Aram and Healy, 1988](#)). Clearly, some children with SLI do have pathologic factors involved. The question for researchers and theoreticians is whether these children are the exception or the rule.

An alternative explanation has been offered by [Bishop \(1997\)](#) and [Tallal and associates \(1996\)](#). These writers discuss the possibility that SLI is related to deficits in the processing of auditory information, particularly the rapid, short-lived information contained in speech. Tallal and associates have developed an intervention program, known as Fast ForWord, based on this theory. The program trains children to discriminate auditory stimuli on the basis of increasingly brief acoustic cues. Although they have claimed dramatic success in their program, controversy still surrounds these claims at the present writing ( [Gillam, 1999](#)).

### *Subtyping*

We have already mentioned another controversy in the field of SLI; that concerning subtypes of the disorder. Several schemes have been proposed ( [Aram and Nation, 1975](#); [Fey, 1986](#); [Naremore, 1980](#); [Rapin and Allen, 1983](#)). The most common subtyping systems concern the division between disorders restricted to expressive language and those that involve both reception and expression. This is the categorization method used in DSM-IV-R ( [APA, 2000](#)). Still this scheme is not universally accepted. [Curtiss and Tallal \(1985\)](#), for example, reported that patterns of performance on language testing over time in a longitudinal study were the same for children with SLI regardless of the subgroup in which they had been placed. [Bishop \(1997\)](#), too, has argued that virtually all children with SLI have some difficulties in language comprehension. Currently, most clinicians describe children as SLI without a specific subtype given.

### **Selective Mutism**

Selective mutism is a failure to speak in one or more particular definable communicative environments. Historically, stuttering, phonologic disorders, and language disorders have been considered the domain of speech pathology and psycholinguistics, whereas selective mutism has been considered the domain of psychiatry and psychology. This division remains, to some extent, today, as exemplified by the placement of selective mutism outside the communication disorders section in DSM-IV-R. Still selective mutism does involve a form of communication disorder and is important in the differential diagnosis of other forms of communication impairment. Because this is the case, a brief discussion of this disorder is presented here.

As with other communication disorders, accurate estimates of the prevalence of selective mutism are difficult to find, although the condition is known to be rare. DSM-IV-R ([APA, 2000](#)) estimates the prevalence at less than 1% of children seen in mental health settings, a very small proportion of the population in general. Unlike all the other communication disorders discussed here, selective mutism is thought to be somewhat more common in females than males. Selective mutism is associated with the other speech/language disorders at greater than chance rates.

The major variations in symptomatology are unclear because the disorder is so rare. It appears, however, that the most common manifestation is a refusal to speak in school and to adults outside the home despite speaking normally within the home to siblings and at least one parent ( [APA, 2000](#); [Browne et al., 1963](#); [Kratowill, 1981](#)).

The child's silence seems to represent a refusal to talk rather than an inability to talk, although, as noted, language disorders are associated with this syndrome more often than would be expected by chance alone. Although these other speech/language impairments are sometimes present ( [Cantwell and Baker, 1985](#); [Kolvin and Fundudis, 1981](#)), they are not sufficiently severe to account for a lack of speech. Intellectual functioning generally is found to be average or above ( [Browne et al.,](#)

1963; [Hayden, 1980](#); [Hesselman, 1983](#)), although one study found slightly lower performance intelligence levels ([Kolvin and Fundudis, 1981](#)).

Despite their “refusal to talk,” selectively mute children usually appear interested in communication and, in the situations where they will not talk, they may attempt to communicate by using gestures, pantomimes, drawings, nods or shakes of the head, whispers, or monosyllabic utterances ([APA, 2000](#); [Cantwell and Baker, 1985](#); [Harris, 1996](#)). In those settings where they are not mute, these children may be quite talkative ([Hesselman, 1983](#)).

The disorder usually has its onset between 3 and 8 years, although the most frequent point of onset is school entry; however, some cases have been reported with onset after 12 years of age ([Kaplan and Escoll, 1973](#)). The majority of patients with selective mutism recover from their symptoms within months or years ([APA, 2000](#); [Harris, 1996](#); [Kolvin and Fundudis, 1981](#)). Improvements usually occur before the age of 10 years ([Kolvin and Fundudis, 1981](#)); the prognosis is poorer for children older than 12 years ([Hayden, 1980](#); [Kaplan and Escoll, 1973](#)).

Biological factors are usually not thought to play a significant role in the etiology of selective mutism. Still it has been found that children with selective mutism are at a somewhat increased risk for other developmental disorders (including speech/language disorders, enuresis, and encopresis) and electroencephalogram (EEG) immaturity. This suggests that a biologically based maturational disorder may play some role in the etiology of selective mutism ([Kolvin and Fundudis, 1981](#)).

Family and interpersonal dynamics have long been suspected to play a major role in the etiology of selective mutism. Some studies have found that selectively mute children have increased rates of psychiatrically ill parents and/or abnormal family dynamics ([Browne et al., 1963](#); [Hayden, 1980](#); [Hesselman, 1983](#); [Kaplan and Escoll, 1973](#); [Kolvin and Fundudis, 1981](#)). Anecdotal reports mention isolated family situations; at least one very shy or uncommunicative parent; broken families; hospitalization ([Browne et al., 1963](#)); significant separations from family ([Kolvin and Fundudis, 1981](#)); physical traumas ([Hayden, 1980](#)) such as child abuse, rape, or mouth injuries; and an overly strong attachment to the mother. Still, careful controlled research on this disorder is scarce, and larger studies with appropriate contrast groups are needed before definitive conclusions on the role of family dynamics can be drawn.

## DIFFERENTIAL DIAGNOSIS

When seeing children suspected of specific speech and language disorders, the main diagnostic task is to rule out other syndromes with which speech and language problems are frequently associated. These syndromes include the ones discussed in the first section of this chapter, that is, deafness or significant hearing loss, mental retardation, pervasive developmental disorder, autism, psychiatric disorder, and organically based communication disorders (e.g., cleft palate, apraxia, cerebral palsy, or childhood-acquired aphasia).

The absence of significant hearing impairment or deafness must be established by audiometric testing by a certified audiologist. Because subtle deficits in hearing can affect language acquisition, it is important to get complete and accurate results in order to assure that hearing deficits do not play a role in the disorder. Although chronic middle ear pathology is sometimes associated with speech and language problems, recent research ([Roberts et al., 1997](#)) suggests that chronic otitis media alone does not significantly increase the risk of language disorder in otherwise normal children. If parents report chronic otitis in a child who presents with a communication disorder, attributing the problem entirely to the middle ear problem is not justified, and treatment for the otitis will not necessarily alleviate the language disorder.

Mental retardation must be diagnosed by means of an individually administered, standardized test of intelligence, as well as by a standardized measure of adaptive behavior. For children suspected of language disorders, it is necessary to use nonverbal intelligence tests to assess intellectual ability, so as not to penalize the child for the language deficit and to get an estimate of intelligence unbiased by language performance. [Table 49.1](#) provides a sample of nonverbal intelligence assessments that can be used in the determination of cognitive level in children with communication disorders. A child must score significantly higher on the nonverbal intelligence assessment than on the language measure to be diagnosed with a specific speech or language disorder.

Instrument	Age Range	Key Feature	Comments
WISC-III Nonverbal Reasoning & Block Design Subtests (Wechsler, 1974)	6:0-17:0	Comprehension, perceptual	Best for screening language comprehension; also assesses spatial, auditory, and motor development
Cognitive Assessment Battery for Young Children (CAYC) (Fisher et al., 1989)	18-36 mos	Figure-objects	Used for children with motor impairments
Cognitive Behavior Scale (Carroll, 1975)	18-36 mos	Concept development	Used for establishing cognitive skill level
Developmental Scales Screening Inventory (DSI) (Peters and Longley, 1988)	18:0-3:0	Memory, auditory, sequencing, and problem-solving	Used to screen children with hearing impairment
Bayley Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Concept formation	Used for determining whether child is functioning at language level
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Classification, memory	Used for determining whether child is functioning above 2;0 and 3;0
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Spatial behavior	Used for determining level of representational thought
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Nonverbal skills	Used for determining level of representational thought
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Developmental delay or mental retardation	Used to determine if child is functioning at language level
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Developmental delay or mental retardation	Used to determine if child is functioning at language level
Bayley Infant Scales of Infant Development (BSID) (Bayley, 1973)	1:0-18:0	Developmental delay or mental retardation	Used to determine if child is functioning at language level

**Table 49.1. Instruments for Assessing Nonverbal Cognition**

Organic disorders that can affect the speech mechanism, such as dyspraxia, dysarthria, and motor deficits associated with cerebral palsy, can be ruled out by physical and functional assessment of the speech mechanism (oral peripheral examination). A speech-language pathologist typically examines the morphology, symmetry, and alignment of the facial features. The functional integrity of the larynx, lips, tongue, and velopharyngeal structures, as well as the respiratory support for speech are also assessed. The quality of oral volitional movements also may be examined if an apraxia is suspected. If physical limitations to speech production are identified in this examination, an alternative system of communication—such as a picture board or electronic communicative device—may be indicated ([Glennen and DeCoste, 1997](#)).

Psychiatric/behavioral assessment can rule out pervasive developmental disorder, autism, and other psychiatric disorders. Features associated with autism/PDD include lack of (nonverbal) social interactions, absence of imaginative activity, stereotypic behaviors, self-injurious behaviors, odd responses to sensory input, and mood abnormalities. Language features that characterize these disorders include abnormal use of imitation (echolalia); idiosyncratic use of words or phrases for “private” meaning; pronoun reversals (saying “you” when the speaker means “I”); persistent, obsessive preoccupation with one topic of conversation (such as bus schedules reiterated, elaborated on, and questioned about incessantly); and repetitive, inappropriate use of questions. Forty to fifty percent of children with autism are mute. What distinguishes these children from those with motor or intellectual limitations that lead to lack of speech is a dearth of nonverbal communication. That is, mute children with autism not only do not speak, but also do not use other means, such as pointing, gesturing, or shifting gaze, to convey their thoughts ([Lord and Paul, 1997](#)).

The differential diagnosis among stuttering, phonologic disorder, expressive language disorder, mixed receptive-expressive language disorder, and selective mutism requires detailed speech/language testing. Some examples of the most commonly used language tests are given in [Table 49.2](#). To diagnose stuttering, a clinician should ascertain, by means of standardized testing, that phonologic, receptive, and expressive language skills are age-appropriate. Many children go through periods of developmental dysfluency, and children with language disorders may persist in developmental dysfluency longer than normal because their developmental period is longer than normal. If dysfluency coexists with other speech and language disorders, it may be appropriate to delay making a diagnosis of stuttering until some of the other problems resolve, then reevaluate to determine whether the dysfluency has persisted.

**Table 49.2. Some Frequently Used Communication Assessment Instruments**

Phonologic disorders are diagnosed by means of standardized testing of phonologic production, usually using procedures that ask children to name pictures or objects and transcribing the child's rendition of the target word for comparison with adult production standards. Because phonologic disorders typically coexist with other language disorders, it is acceptable to confer a concurrent diagnosis of phonologic disorder even if other language disorders are present. However, it is necessary to rule out hearing impairment, mental retardation, and speech mechanism limitations before diagnosing a specific speech disorder.

To diagnose a specific expressive language disorder, it is necessary to demonstrate—by means of individually administered, standardized tests—that both nonverbal intelligence and receptive language skills are significantly better than expression. Again, because phonologic disorders so frequently coexist with expressive language deficits, both conditions can be diagnosed concurrently.

To make a diagnosis of mixed receptive-expressive (R/E) language disorder, it must be shown—again using individually administered, standardized tests—that nonverbal intelligence is significantly higher than *both* expression and comprehension of language. As with expressive disorder, phonologic deficits can coexist with R/E disorders and would be diagnosed according to the criteria given earlier.

## TREATMENT OF SPEECH AND LANGUAGE DISORDERS

It is important to make a careful differential diagnosis of any communication disorder in order to decide whether the problem is specific to speech and language or is part of a larger syndrome. In the case of communication disorders associated with syndromes such as hearing impairment, mental retardation, and autism, treatment must address all aspects of the child's problem, not just those of speech and language.

Still, once a communication problem has been identified and the broad range of interventions necessary to address all the child's needs has been instigated, treatment for the communicative aspect of the disorder is quite similar, regardless of whether the problem is specific to speech and language or part of a bigger picture of developmental disorder.

The treatment of choice for all the disorders discussed here, except for selective mutism, is individual or small group therapy administered by a certified speech/language pathologist (SLP). Because associated educational and/or psychiatric problems are common with these disorders, educational tutoring, social skills training, and/or psychiatric intervention also may be indicated, even if the disorder is specific to communication.

Methods of intervention are essentially behavioral. Some clinicians use strict operant procedures, whereas others favor more child-centered approaches such as indirect language stimulation, or “whole language” intervention that involves a rich communicative environment with opportunities for incidental learning. Many SLPs take a middle ground between these extremes, using structured play opportunities and focused stimulation to provide examples of desired forms and elicit language targets. Although all these methods have been shown to be effective in small studies (Fey et al., 1995), much more research is needed on the efficacy of particular approaches to intervention and variables that can be used to best match the method to the child.

Because selective mutism is seen more as an anxiety disorder than a developmental disorder, treatment methods differ somewhat for this syndrome. Although some authors have suggested psychodynamic therapy for selective mutism, the most convincing literature pertains to behavioral modification approaches (Giddan et al., 1997). Contingency management (positive reinforcement of verbalizations and nonreinforcement for nonverbal responses), stimulus fading (gradually extending the number of people with whom and environments wherein verbalization is rewarded), shaping (rewarding gradual approximations to speech, such as mouthing and whispering), and response cost procedures (losing money or tokens for not speaking) have all been reported to be successful in eliciting and maintaining speech in selectively mute children (Labbe and Williamson, 1984).

Caution should be exerted when treatments make claims of dramatic improvement, particularly when the improvement is claimed for a broad range of disorders. In recent years, several “miracle cures” have been advanced for communication disorders. Facilitated communication (Biklen, 1990), Fast ForWord (Tallal et al., 1996), and auditory integration training (Tharpe, 1999) are just a few examples. Clinicians who work with families of children with communication disorders need to maintain a healthy skepticism regarding these programs that make extravagant claims. If something sounds too good to be true, it probably is. Any intervention, whether familiar or innovative, must be shown to meet the particular needs of the client receiving it. Communicative interventions need to be evaluated with the same kind of rigor that would be used to evaluate the efficacy of a medical or surgical treatment. Although double blind, placebo controlled trials are difficult to design for behavioral interventions, clinicians must strive to achieve some degree of objective evaluation before deciding that a treatment is appropriate for an individual.

Developmental learning disorders are listed in the *Diagnostic and Statistical Manual*, fourth edition (DSM-IV and DSM-IV-TR) under Axis II. These disorders are characterized by inadequate development of specific academic, language, speech, and motor skills and are not caused by demonstrable physical or neurologic disorders, a pervasive developmental disorder, mental retardation, or deficient educational opportunities. There are four subgroups:

1. Reading disorder
2. Mathematics disorder
3. Disorder of written expression
4. Learning disorder not otherwise specified (NOS)

## DEFINITION

The DSM-IV conforms to the international classification system; thus, the term learning disorders with skill-related subtypes. The public school systems in the United States use the term learning disability. Thus, clinicians use the term *learning disorder* when completing medical records but use the term *learning disability* when interacting with school systems. The DSM-IV definition of a learning disorder relates to the individual's ability in specific academic areas. The disorder exists if the ability in question is "substantially below the expected given the person's chronological age, measured intelligence, and age-appropriate education." No clarification is given on the extent of the disability needed to be "substantial."

The federal guidelines used in public school systems uses a definition based on a specific level of discrepancy between potential and performance. Thus, a child or adolescent might meet the medical criteria for the diagnosis of a learning disorder but not have the extent of discrepancy to meet the educational criteria for being identified ("coded") with a learning disability. This is a critical issue, because a student must be identified with a disability to receive services. Another difference is that the federal definition states that the student must be of at least average intelligence or higher. The DSM-IV definition for a learning disorder does not state such a criterion.

The public school definition of a learning disability is based on Public Law 94-142, Education for Handicapped Children. This definition persists in the revisions of this original law now called the Individuals with Disabilities Education Act (IDEA), or Public Law 101-476. This federal definition describes a learning disability as

a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations.

This public school definition notes specific exclusionary criteria.

This term does not include children who have learning problems which are primarily the result of visual, hearing, or motor handicaps, or mental retardation, or emotional disturbance, or of environmental, cultural, or economic disadvantage.

Public school systems have specific guidelines for assessing the level of discrepancy. This level varies with each school system in this country. The average is a 1.5 to 2.0 standard deviations difference between potential (usually based on an IQ test) and performance (usually based on a battery of achievement test). In addition to this discrepancy requirement, testing must document the presence of a central nervous system processing deficit. (This concept of a processing deficit is discussed afterward in this chapter.)

## HISTORICAL BACKGROUND

Prior to the 1940s in the United States, children who had academic difficulties were considered mentally retarded, emotionally disturbed, or socially and culturally disadvantaged. A fourth possibility for these difficulties was introduced between 1940 and 1949. Children might have problems with academic performance for neurologic reasons. That is, the cause of the difficulty was related to brain function. Two different research approaches explored these presumed to be neurologically

based learning disorders.

One group of researchers noted that these children had the same types of learning difficulties often found in individuals who have known brain damage. They concluded that these children also had brain damage; however, it was so subtle or minimal that it could not be confirmed clinically; therefore, the term minimal brain damage was introduced (Strauss and Lehtinen, 1947; Werner and Strauss, 1941). Other researchers explored the possibility that the learning difficulties reflected a physiologic dysfunction. The brain functioned differently because it was “wired” differently rather than damaged. The term minimal brain dysfunction was used to reflect this concept (Clements, 1966). Recent research, to be discussed later in this chapter, confirms the concept of brain dysfunction rather than brain damage.

Initially, the types of academic difficulties were described based on the primary skill disorder (Farnham-Diggory, 1978). Reading disorders were called *dyslexia*, writing disorders were called *dysgraphia*, and arithmetic disorders were called *dyscalculia*. Later, efforts shifted from focusing on the presenting problem to the underlying brain processes responsible for the reading, writing, and math difficulties. The term *learning disability* was introduced. This is now the preferred term within the fields of education.

## PREVALENCE

The true prevalence of learning disorders is not known. In the DSM-IV, reference is made to the difficulty of obtaining data on learning disorders. In this text, the suggested prevalence rate for reading disorder is 4%, mathematics disorder 1%, and disorder of written expression 4%.

The best data come from the public school systems and can range from 1% to 30% of the school population. The number of children and adolescents identified as having learning disabilities depends largely on the criteria used to determine eligibility for services. The more stringent the discrepancy criteria, the lower the prevalence rate—the more lenient the discrepancy criteria, the higher the prevalence rate.

The only non-school system prevalence data is from the Centers for Disease Control (1987). The focus of this study was on learning disability. In the absence of standardized, consistent criteria, it was estimated that between 5% and 10% of the school-aged population was a reasonable estimate of the percentage of persons affected by learning disabilities.

The public school system uses data based on the number of children who were identified as having a learning disability and who were being serviced by the school system. No data existed before Public Law 94-142 was passed in 1975. The first year the law was implemented (1977 to 1978), fewer than 800,000 children (1.8% of the enrolled school population) received services under the category of learning disabilities. The number of students meeting the criteria for having a learning disability and receiving services has increased dramatically each year. The more recent data show that 5.27%, or over 2.4 million, receive services. These figures do not take into account the many children with learning disabilities who are not identified and diagnosed or who are evaluated but do not meet specific school systems' discrepancy criteria.

This increase in numbers reflects the greater awareness within public school systems of this disability, improved procedures for identifying and assessing learning difficulties, and increased social acceptance of this problem. Another factor is the number of court decisions forcing school systems to address the needs of individuals with learning disabilities.

Studies of children with learning disabilities have consistently noted an increased prevalence in males. The ratio reported has ranged from 3:1 to 5:1 and higher (Ackerman et al., 1983; Finucci and Childs, 1981; Rutter et al., 1976). Recent studies suggest that this increased prevalence in males over females may be explained in part by referral bias. Males are more likely to be referred for evaluation because they are likely to act out their frustrations (Berry et al., 1985). Females may become anxious or depressed more than disruptive when frustrated and may not be recognized as quickly as having difficulty. Johnson and Blalock (1987) found no specific cognitive differences or patterns of problems between the sexes.

Recent studies suggest that there may be no sexual differences in the prevalence of learning disabilities (Shaywitz et al., 1990, 1992). Any differences in statistics appear to be secondary to referral bias and the possible bias of the assessment test used that appear to identify more male than female students with learning disabilities. In this study, all children in a specific grade were evaluated for a possible learning disability. These data were compared to the school system data, based on the number of children identified and serviced. The school-identified population showed a 3:1 ratio of boys to girls. The true data based on assessing all children showed a ratio of 1:1.

## ASSOCIATED DISORDERS

Individuals with a learning disorder (disability) might have emotional or behavioral problems. For many, these emotional and behavioral disorders are secondary to the frustrations and failures experienced because the disabilities either were not identified or inadequately treated (Silver, 1989). For others, these difficulties may be another reflection of a dysfunctional nervous system. Each theme is discussed. In addition, many students develop social skill and social competency problems. These, too, are discussed in this chapter.

We now better understand a continuum of neurologically based disorders that show a high comorbidity pattern. Because these new data on brain function and dysfunction are so critical to understanding children and adolescents with learning disorders, they are discussed first.

It is critical that the clinician be aware of these associated disorders. Each must be considered and, if present, diagnosed and treated. Unless all of the problems the child or adolescent faces are addressed, there will be less than optimum clinical success.

### Continuum of Neurologically Based Disorders

Comorbidity studies suggest that there is a continuum of neurologically based disorders often found together. The common theme appears to be that something impacted on the developing brain, possibly early in pregnancy, causing some of the “wiring” to be laid down differently. For some of these individuals, we find a familial pattern and suspect a genetic theme (Cardon et al., 1994; Grigovenko et al., 1997). For others, we do not yet understand the reasons for these changes. There is an increasing concern with the impact of environmental developmental and neurologic toxins on the developing brain (discussed in the following). If something impacts on the developing brain, then more than one area is usually involved.

#### Cortex

This faulty wiring might involve the cortex, areas below the cortex, or both. If the cortex is involved, this impact might be in the areas critical to language, motor, cognitive, or executive functioning.

#### Language Difficulties

If the area of the brain that is wired differently relates to language functioning, the person will have a problem with language called a *language disability*. (These disabilities are covered in Chapter 49, Communication Disorders.) The first clue often is a delay in language development. The child is not speaking by 2 years, or by 2½ or 3 years is using only a few words. Some may be no better by 4 years old. If a speech and language therapist works with this child, it might be possible to speed up the development of language. There is a sigh of relief. Then, by 4 or 5 years old another problem becomes clear. This child may have difficulty processing and understanding what is being said (called a receptive language disability) or might have difficulty organizing thoughts, finding the right words, and speaking in a fluid and clear way (called an expressive language disability). More help is needed. Another problem might become apparent as this child enters the early elementary grades. The first task in reading is language based. The child must recognize units of sound (called phonemes) and connect this sound to the correct unit of symbol (called graphemes). There are 44 phonemes in the English language. Each letter has a sound; vowels have two sounds (a short and long sound); certain combinations (sh, th, ch, etc.) have their own sounds. There are 36 graphemes in the English language (a through z and 0 through 9). To learn to read, a child must learn to “break this code” by learning what sounds go with what symbols and sounding out words. Many children with a delay in language development and later with receptive and/or expressive language problems have difficulty learning to read in first grade. Spelling is the reverse process. One must start with the language in his or her brain and connect it with the right symbol by writing on the page. Thus, many children with reading problems also have spelling problems.

### Motor Difficulties

If the area of the brain that is wired differently relates to the use of our muscles, we see what is called a *motor disability*. For some, the primary problems relate to the ability to coordinate and use teams of large muscles (gross motor skills) and have difficulty with running, jumping, or climbing. Others might have difficulty coordinating and using teams of small muscles (fine motor skills). They have difficulty learning to button, zip, tie, color within the line, use scissors, use eating utensils, and, later, using a pencil or pen to form letters and write. Still others might have a broader pattern of motor problems called *sensory integration disorder*. Now, in addition to gross and fine motor planning functions, they might have difficulty making sense out of information coming from nerve endings in the skin. They might be very sensitive to touch or misread temperature or pain. They also might have difficulty processing information from the vestibular system, information needed to know where the body is in relation to gravity. They have difficulty with movement in space or position in space. Which of these many possible motor problems are present depends on the areas of the brain involved.

### Cognitive Difficulties

We call it a *learning disability* if the area of the brain that is wired differently relates to the processing of information for learning. In some ways, this division of the cortex is artificial. If an individual has a learning disability, then more than one area of the brain is involved.

### Executive Function Difficulties

The most recent addition to the cortex is the frontal cortex. This sophisticated area of the brain acts like the chief executive officer in a company. This area carries out what is called *executive functions*. It orchestrates behaviors. This is the area that assesses a task or problem, decides how to tackle or solve the task, orchestrates the necessary activities or functions, continually makes mid-course changes or corrections, and eventually reaches a successful conclusion. If this area of the brain is involved, then we see people who have difficulty with organizational planning and carrying out tasks successfully.

### Attention Deficit Hyperactivity Disorder

If the areas of faulty wiring involve a set of interrelated systems involving the frontal cortex, limbic system, basal ganglia, and reticular activating system, the child or adolescent may have difficulties regulating motor activity, attending, and reflecting before speaking or acting. He or she might be hyperactive, inattentive, or impulsive. This cluster of clinical problems is called attention deficit hyperactivity disorder (ADHD) ([Chapter 52](#)).

Clinical studies suggest a comorbidity rate between 15% and 30% between ADHD and learning disabilities. The difference in percent is based on the definition used to establish this diagnosis. If the discrepancy required is based on 1.0 or 1.5 standard deviation, then the rate is higher than if 2.0 standard deviations are required ([Biederman et al., 1992](#); [Halperin et al., 1984](#); [Shaywitz et al., 1992](#); [Silver, 1981](#)).

### Modulating Disorders

With the dramatic new methods for studying the brain and new data on clinical comorbidity, we have a better understanding of related clinical problems. There appears to be another area of the brain that might be called the “modulation” area. This is the area that maintains a balance or equilibrium, avoiding extremes. Studies of this area show that there are many functions that need to be modulated. If any specific area is involved, there will be a problem with modulation of a specific function. Some people have problems modulating *anxiety*. These children have a history since an early age of being high strung or anxious. Over the years, the focus of the anxiety may change, but the central theme is a high anxiety level. They might be afraid to go to sleep alone at night. Later, it might be a fear of being in part of the house alone, or bees, or something else. As these children move into later childhood and adolescence, they might develop an *anxiety disorder*. Some may have so much difficulty regulating anxiety that the level gets too high and triggers off a sympathetic discharge and a panic attack, called a *panic disorder*.

Another regulating problem relates to the ability to modulate *anger*. These children may have been more irritable and angry since early childhood. They have always had tantrums. As they get older, they show a specific form of difficulty regulating anger called *intermittent explosive disorder*. When they get angry, they do not just have a tantrum or pout or slam doors. They have a “melt down.” What is characteristic of this child or adolescent (or adult) is that they have a very short fuse. Sometimes they explode so fast that it is not clear what caused it. Once they pass over their threshold, they lose their temper. They yell, scream, curse, hit, throw, and threaten. They act in an irrational way and cannot be reasoned with. Sometimes they seem paranoid, saying people are trying to hurt them. This episode lasts minutes, sometimes up to 15 or more minutes. Then, it ends almost as abruptly. Once it is over, they may be tired and want to rest or sleep. They usually do not want to discuss what happened and may seem confused about their behavior. Later, they might feel remorse about what they did.

Some may have difficulty modulating *mood*. They seem to have been unhappy or sad much of their life. They are moody or depressed some of the time or much of the time. Some will go on to develop a *depressive disorder*. A few may show difficulty modulating not just the down side (depression) but the up side (excitement, manic behavior). They might evolve into a *bipolar disorder*. Here the mood swings are rapid and include both depression/euphoria cycles and calm/anger-rage cycles.

Another pattern of behavior that seems to relate to these modulating disorders relates to the ability to regulate thoughts and behaviors. They develop *obsessive-compulsive disorder*. They might show difficulty controlling their thoughts and obsess over a thought or thought pattern. Others might have difficulty regulating behaviors. They feel they must do certain things, or they will get too anxious. They know “it is silly” but cannot stop. They might need to touch things a certain way or number of times. They might need to check and recheck things (e.g., see if the front door is locked or the stove is off). They might need to perform certain patterns or rituals.

There is another area of difficulty with modulation that relates to this pattern of comorbidity. Some children and adolescents experience motor tics. Others may develop vocal tics. These individuals have a *motor tic disorder*. If they have a chronic history of both motor and oral tics, the disorder is *Tourette's disorder*.

Thus, the continuum of neurologically based disorders with a high incidence of comorbidity includes:

1. Cortical problems: language disorder, developmental coordination disorder, learning disorder, executive function disorder
2. Attention deficit hyperactivity disorder
3. Modulating disorders: anxiety disorder (possibly panic disorder), mood disorders (possibly bipolar disorder), anger-regulation disorder (intermittent explosive disorder), obsessive-compulsive disorder, and tic disorders

Many of the studies of comorbidity relate the modulating disorders and ADHD. Few specifically refer to these disorders and learning disorders. However, given the reported relationship between ADHD and learning disabilities, it might be appropriate to infer that learning disabilities, ADHD, anxiety disorders, mood disorders, anger-control disorders, obsessive-compulsive disorders, and tic disorders have a high level of comorbidity.

An excellent review of these patterns of comorbidity can be found in a recent publication edited by [Brown \(2000\)](#). Several references for these patterns of comorbidity include:

1. Anxiety disorders ([Anderson et al., 1987](#); [Biederman et al., 1991](#); [Bird et al., 1988](#); Tannick, 2000)
2. Mood disorders ([Anderson et al., 1987](#); [Biederman et al., 1991](#); [Bird et al., 1988](#); [Spencer et al., 2000](#))
3. Obsessive-compulsive disorder ([Curry and Murphy, 1995](#); [Geller et al., 1996](#))
4. Tic disorders ([Comings et al., 1990](#))

### Emotional and Behavioral Disorders

Some children and adolescents under stress internalize this tension. They might present with a clinical picture of depression, anxiety, or somatic difficulties. Others might find the stress too unpleasant to handle and externalize the conflicts. These individuals might present with a clinical picture of oppositional defiant disorder or conduct disorder ([Chapter 53](#)).

Many of the clinical studies on comorbidity relate primarily to ADHD and oppositional defiant/conduct disorder ( [Caron and Rutter, 1991](#)); however, there are studies relating to learning disabilities. Studies of youth diagnosed as having a conduct disorder show that about one-third have unrecognized or recognized but poorly treated learning disabilities ( [Forness, 1981](#); [Hunt and Cohen, 1984](#); [Rutter et al., 1970](#)). Similar findings have been observed with adolescent boys in juvenile detention centers ( [Berman and Siegal, 1976](#); [Keilitz et al., 1979](#); [Lewis et al., 1979](#); [Lewis and Balla, 1980](#); [Mauser, 1980](#); [Robbins et al., 1983](#)).

### **Social Skills and Social Abilities Difficulties**

Some individuals with a learning disorder (disability) have social problems because the specific learning disability interferes with specific social skills ( [Silver, 1989](#)). For example, a child with a receptive and expressive language problem might have difficulty making small talk or following what peers are saying. A child with visual perception, visual-motor, and motor skills problems might have difficulty playing sports that require quick eye–hand coordination (e.g., catching, hitting, or throwing a ball).

It may be that for some children and adolescents with learning disabilities, the inability to read social cues (facial expressions, body movements, tone of voice, etc.) might reflect another type of a perception problem. Their difficulty reading social cues and mastering social skills also may be neurologically based ( [Hazel and Schumaker, 1988](#)).

## **SPECIFIC DEVELOPMENTAL LEARNING DISORDERS**

Before describing the specific developmental disorders related to reading, writing, and arithmetic, it is helpful to review the concept of specific learning disabilities. The presenting problem, difficulty with reading, written language, or math, should lead to an assessment. This evaluation process focuses on the specific processing problems resulting in learning disabilities. Knowledge of specific learning disabilities and abilities is useful in explaining problems to parents, children and adolescents, and others. Evidence of a processing disorder is necessary to have a student identified and serviced by the school system.

A psychoeducational evaluation is the assessment process used to explore the possibility of a learning disability. These studies use a processing model. Learning is evaluated based on the steps for processing information in the brain. The first task is to receive the information and record it in the brain (input). Once recorded, this information must be handled in such a way that it can be understood (integration). The third process is storage and retrieval (memory). Finally, information must be communicated from the brain (output).

Learning disabilities are defined based on this input-integration-memory-output model. Each area is described briefly.

### **Input Disabilities**

This central brain process is called perception; a person might have a visual or auditory perception disability. Visual perception disabilities might be reflected in distinguishing subtle differences in shapes (misperceiving a “d” and a “b,” or “p” and a “q,” or a “6” and a “9”). One might have difficulty with figure-ground tasks, that is, not being able to focus on the relevant stimulus in a field of vision. Judging distance or depth is another visual perceptual task. A child or adolescent might misjudge depth, bumping into things or falling off a chair.

Auditory perception disabilities might be in the area of distinguishing subtle differences in sounds (phonemes), thus leading to misunderstanding of what is being said. Many words sound similar, such as “hair” and “air” and “ball” and “bell.” Some individuals have difficulty with auditory figure-ground, confusing what sounds to listen to when there is more than one source. Some children and adolescents cannot process sound inputs quickly. They have to think about what is heard briefly longer than normal before understanding what is said. This is called an auditory processing problem or an auditory lag. They appear to be lost or confused when too much is said and may appear to be preoccupied.

### **Integration Disabilities**

At least three steps are needed to understand what is recorded in the brain. Individual incoming stimuli must be placed in the correct order (sequenced), then understood in the context used (abstractioned), and finally integrated with all other incoming stimuli plus all relevant memory tracks into a concept (organized). One can have an integrative disability in either of these areas: sequencing, abstraction, or organization. Such a disability might be more for visual or auditory inputs. Thus, one can have visual-sequencing or auditory-sequencing disabilities, visual-abstraction or auditory-abstraction disabilities, and so forth.

Sequencing disabilities can result in an individual's confusing inputs, for example, writing a “21” rather than a “12,” “dog” rather than “god,” or mixing up parts of words and mispronouncing the word. A child might try to explain something but start in the middle, then go to the beginning, and finally the end. These individuals often have difficulty using sequences. They can memorize the months of the year, for example, but be unable to say what comes after any month without starting with January and working their way up.

The inability to derive the correct meaning of a word based on how it is used can result in an abstraction disability. These individuals may have difficulty generalizing out from specific words or concepts. They might miss the meaning of jokes, puns, or idioms. They might appear to be paranoid because they interpret what others say in a more concrete or literal way than intended.

Organizational disabilities can result in difficulty pulling multiple parts of information into a full or complete concept or breaking down whole concepts into its parts. Such individuals may show this “dys-organization” in other aspects of their life. Their notebooks or desk or their room may be totally disorganized. Organizing time or making plans might be difficult. They lose things, forget things, or do their homework but forget to turn it in.

### **Memory Disabilities**

Children or adolescents with learning disabilities usually have excellent long-term memory. They can retain information once stored. They might have difficulty, however, in short-term memory—the ability to concentrate on information and store it. They might learn information well while attending to it (spelling list, math concept, etc.), yet they will not retain this information a short time later. These students need many more repetitions to process information into long-term memory than the average. They can learn, but they must work on the process over time. One might have a visual short-term memory disability or an auditory short-term memory disability.

### **Output Disabilities**

One may have difficulty getting information out of the brain through oral communication (i.e., a language disability) or muscles (i.e., a motor disability). The individual may have a disability in one or in both of these areas.

#### *Language*

Most individuals have little difficulty with spontaneous language. In this situation, the person initiates the conversation. There is the opportunity to organize thoughts and find words before speaking. Some individuals might have difficulty with demand language. If such people are asked to produce language, they must organize their thoughts and find the right words as they speak. They might speak with ease when they initiate the conversation; however, they might not be able to respond when asked a question or requested to speak. In this situation, they might struggle for thoughts and words, ramble, or say the wrong word and appear to be disorganized.

#### *Motor*

Some people with learning disabilities have trouble coordinating the use of large or small muscle groups. Gross motor disabilities result in being clumsy or having difficulty with such activities as running, climbing, or skipping. The most frequently found fine motor disability relates to writing. This skill requires the coordination of teams of small muscles. These individuals have difficulty getting their dominant hand to write in a fast and legible way. In addition to having poor handwriting, they might have difficulty with writing tasks such as spelling, grammar, spacing, or punctuation (called a written language disability). Other fine motor problems might be in

buttoning, zipping, tying, coloring, cutting, or controlling eating utensils.

### **The Learning Disability Profile**

Each individual with a learning disability has his or her own profile of learning abilities and disabilities. Each has one or more of the previously described disabilities. There is no stereotyped individual. Each must be assessed and understood individually.

These learning disabilities might result in what would be classified under the DSM-IV as a learning disorder, communication disorder, or developmental coordination disorder.

## **DEVELOPMENTAL READING DISORDER**

### **Definition**

There are three criteria for establishing this disorder in the DSM-IV: (a) Reading achievement, as measured by an individually administered standardized test of reading accuracy or comprehension, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education. (b) The disturbance in achievement significantly interferes with academic achievement or activities of daily living that require reading skills. (c) If a sensory deficit is present, the learning difficulties are in excess of those usually associated with it.

The skills required to learn to read are usually taught in first and second grade. The child first learns to connect the proper sounds (phonemes) to letters (graphemes); thus, "decoding" the word. After a child has decoded a word frequently enough, he or she recognizes the word as a whole unit, called sight-reading. Finally, recognition of words is so automatic that children can scan lines and thoughts come into their heads, that is, there is reading comprehension. These basic reading skills should be in place by third grade. The shift is to not, can you read, but what have you read? Thus, if a child has a reading disorder, he or she might struggle with reading in first and second grade but not have major difficulties until third grade when he or she can not move on to rapid, automatic reading.

### **Etiology**

Most reading disorders involve an inability to segment the written word into its underlying phonologic components ( [Shaywitz, 1996](#); [Tallal, 1985](#)). This deficit in phonologic awareness impairs decoding, preventing word identification. This basic deficit in what is essentially a lower-order linguistic function blocks access to higher-order linguistic processes and gaining meaning from text. Thus, the child has difficulty with reading fluency and text comprehension ( [Shepherd and Uhry, 1993](#)). It is not uncommon to find a spelling disability associated with a reading disorder because spelling requires the same phonologic skills as reading.

Studies of the brain using functional magnetic resonance imaging clearly shows a difference in brain function between individuals who have no reading problems and those with this language-based reading disorder (dyslexia). Brain activation patterns differ significantly between the groups of dyslexic readers, showing relative underactivation in posterior regions (Wernicke's area, the angular gyrus, and striate cortex) and relative overactivation in an anterior region (inferior frontal gyrus). These results are seen as confirming that the impairment in dyslexia is phonologic in nature, and these brain activation patterns may provide neural proof for this impairment ( [Shaywitz et al., 1998](#)).

### **Diagnosis**

First establishing a discrepancy between reading skill and intelligence and then systematically eliminating all other explanations for the discrepancy make the diagnosis.

### **Treatment**

Direct instruction in reading (and spelling and writing) is considered the essential treatment for a student with a reading disorder. A person trained to use appropriate remedial methods provides these efforts. These methods emphasize explicit instruction in letter-sound associations. Stress is placed on improving phonologic awareness. Most instructional models use a multisensory approach. Children see a letter and hear its name and sound, they trace the letter saying its name and sound, and then they write the letter repeating its name and sound. Sounds and letters are blended to form words. Reading, spelling, and writing are taught simultaneously. Instruction involves extended practice and is supplemented by speech segmentation training and study skills instructions. Parents are asked to read to their children to enhance appreciation of reading and to give their children access to knowledge normally obtained by reading. Early recognition and intervention are critical. There is a good possibility that the child will succeed in reading if a reading disorder is identified before the fourth grade and appropriate phonologically based interventions are provided. The level of success with intervention is less if the difficulties are not identified and treated until a later grade or if the reading difficulties are noted but not addressed.

The ability to read is an essential part of education. If the student does not master this skill not only will educational progress be limited, but also occupational and vocational opportunities are limited and self-esteem and self-confidence suffer. It is critical that these children be identified early and receive appropriate educational interventions.

## **DEVELOPMENTAL DISORDER OF WRITTEN EXPRESSION**

### **Definition**

There are three essential criteria for establishing this disorder in the DSM-IV: (a) Writing skills, as measured by an individually administered standardized test (or functional assessment of writing skills) are substantially below that expected given the person's chronologic age, measured intelligence, and age-appropriate education. (b) The disturbance in skills significantly interferes with academic achievement or activities of daily living that require the composition of written texts (e.g., writing grammatically correct sentences and organized paragraphs). (c) The learning difficulties are in excess of those usually associated with it if a sensory deficit is present.

It is helpful to distinguish between a fine motor problem that results in difficulty with the mechanics of writing and a language-based learning disability that results in problems with the language of writing. Individuals with a disorder of written expression might have a fine motor problem but always have a language-based disorder, resulting in difficulty with spelling, grammar, punctuation, capitalization, and/or composition.

### **Etiology**

There must be an automatization of most of the lower level mental activities for skilled writing. These lower level mental activities guide handwriting, spelling, word choice, and the construction of sentences that conform to the conventions of written language. Lower-level mental activities also guide the construction of textual connections, specifically connections between sentences. The writer's attention can focus on the content, organization, and clarity of the task if these activities are functioning. One can shift attention between levels of mental processing without losing control of the text. Difficulties with lower-level mental activities appear to be the source of the problem in expressive writing disorder ( [Uhry and Shepherd, 1993](#)).

Research focuses on the relationship between writing and reading disorders ( [Johnson, 1988](#)). They may be linked in two ways: First, the same linguistic deficits that impede learning to read (phonologic awareness) could impede learning to write and spell. Second, slow progress in learning to read might deprive the child of knowledge about writing that is gained by reading (e.g., about sentences, punctuation, and spelling).

### **Diagnosis**

First establishing a discrepancy between writing skill and intelligence and then systematically eliminating all other explanations for the discrepancy make the diagnosis.

## Treatment

Treatment for a writing disorder might involve a skills or holistic approach ( [Uhry and Shepherd, 1993](#)). Skills programs are often used with younger children and focus on letter–sound associations, focusing on reading and spelling. Children might be asked to listen carefully for the sounds in words and then to represent these sounds with written letters, saying each letter aloud as it is written.

The holistic approach to writing begins with the student's ideas. It involves a series of highly structured steps for narrowing ideas to one topic, writing a first draft, reading it aloud to an audience of peers, and then refining organization and language. The final step involves working on mechanics in preparation for “publishing” a draft for peers to read.

Most efforts combine these two approaches. Children with a writing disorder need direct, sequential instructions in letter–sound associations and spelling rules as well as sentence structure, and the connections between sentences and paragraphs that make text cohesive. Even with good remedial interventions, writing requires enormous effort because this disorder is not “cured” but compensated for and this compensation must continue into adulthood. Appropriate accommodations, such as using a computer, may be needed throughout the individual's education and career. The use of the computer is an example of using strengths to compensate for weaknesses. Writing requires detailed fine motor planning using one's dominant hand. Typing requires the use of the lower arm muscles to lower and raise the fingers and, thus, is predominantly a gross motor planning task. Individuals who write slowly and with difficulty might be able to type with great speed and accuracy.

## MATHEMATICS DISORDER

### Definition

Three criteria are used to establish this diagnosis in the DSM-IV: (a) Mathematical ability, as measured by an individually administered standardized test, is substantially below the expected given the person's chronological age, measured intelligence, and age-appropriate education. (b) The disturbances in ability significantly interfere with academic achievement or activities of daily living that require mathematical ability. (c) The learning difficulties are in excess of those usually associated with it if a sensory deficit is present.

Children and adolescents with a mathematics disorder may have a wide range of symptoms, including delays in the acquisition of basic spatial and number concepts, problems learning and using number words and number facts or writing numbers correctly (and in correct alignment when doing computations), and difficulty in applying arithmetic skills when solving everyday problems. Because math achievement is highly dependent on the quality of instruction offered students, it may be that a significant number of those students who are coded as having a learning disability by the school system do not have intrinsic math disorders but have not had appropriate instruction.

### Etiology

Research suggests that there may be four primary factors involved in mathematics achievement: language, conceptual, visual-spatial, and memory ( [Johnson, 1988](#)). In addition, knowing how to use the correct strategy is important ( [Fleishner and Garnett, 1993](#)). Information-processing capabilities research suggests that one area of difficulty might be in visual-spatial processing deficits. Another problem might relate to the ability to use the necessary pattern of strategic behaviors associated with arithmetic learning. Proficiency in mathematics requires more than computational skills. The difficulty might be in an inability to develop a systematic plan for problem solution. Memory is essential to the ability to do mathematics. One must retain basic number facts. In addition, it is necessary to remember specific equations or other steps necessary to solve a problem. Once a problem is started, students must remember where they are in the process as they proceed from step to step.

### Diagnosis

First establishing a discrepancy between arithmetic skill and intelligence and then systematically eliminating all other explanations for the discrepancy make the diagnosis.

### Treatment

Treatment involves general concerns and specific interventions ( [Fleishner and Garnett, 1993](#)). Initially, the problem of anxiety, withdrawal, defeatism, or other responses to repeated failure must be addressed. Much of the teaching of math is based on criticism of failure. The emphasis is on getting the right answer rather than problem solving. Children may develop performance anxiety or feel they are stupid in math because of this focus on getting the right answer. For some, the premature pressure for speeded answers can short-circuit reasoning and foster impulsivity, resulting in the belief that math has little to do with thinking. Students who have difficulty with math memory may be deprived of compensatory techniques, only adding to the problem. They are told that it is shameful to use their fingers, mark down intermediate calculations, or use a calculator. These are considered “cheating.” Sometimes the difficulties reflect poor teaching in math. Further, math learning is very instruction-bound. Absenteeism, missed lessons, and inconsistency of instruction can leave gaps that result in persistent confusion. Those students with learning disabilities in the areas that result in deficits in short-term memory, language, attention, or spatial perception and those with ADHD are especially susceptible to weak instruction. Appropriately focused and systematic instruction in improving math abilities may be all that is needed.

Specific interventions focus on the underlying difficulties. Some students have problems relating to acquiring the conceptual underpinnings of the subject and some have problems relating to procedural learning, recall of discrete information, and self-monitoring. These remedial efforts must take into account the student's areas of learning abilities and disabilities.

## NEUROLOGIC BASIS FOR LEARNING DISORDERS

For many years, learning disabilities were presumed to be neurologically based. Newer brain studies confirm this concept; therefore, the word presumed is no longer needed. Gross and microscopic studies of the brain as well as newer imaging techniques have focused on finding the biological substrate for the learning disorders (disabilities). In addition, familial and genetic studies and data on environmental developmental and neurologic toxins contribute to our new knowledge.

[Galaburda and associates \(1985\)](#) showed on detailed microscopic analysis of the brains of individuals known to have had dyslexia strongly support the concept of miswiring. Each case studied demonstrated the same microscopic findings: neurons in places where they are normally absent (ectopias), cortical cellular disorganizations (dysplasias), and polymicrogyria. These cortical anomalies were located predominantly in the left hemisphere and mainly around the left sylvian fissure. These findings have been interpreted as anomalies of neuronal migration that are most likely to have occurred between the 16th and 24th weeks of gestation.

As noted, imaging studies of the brain clearly show a neurologic difference between the brain of individuals without a reading disability and those with a language-based reading disability ( [Shaywitz et al., 1998](#)). Increasing research focusing on the functional differences in brain function between individuals with learning disorders and those with specific types of learning disorders will result in even more evidence of the neurologic basis for these disorders.

Recent findings suggest a possible connection between environmental toxins and the increased incidence of developmental, learning, and behavioral problems ( [Physicians for Social Responsibility, 2000](#) ). The National Academy of Science ( [2000a,2000b](#) ) has released two studies on developmental and neurologic toxins. U.S. companies reported to the federal government that in 1998 they released 1.2 billion pounds of chemicals into the nation's air and water that have the potential to affect the way a child's body and brain develops. More than half (53%) of all toxic chemical emissions reported to the Federal Toxics Release Inventory are known or suspected to be developmental or neurologic toxins. There is much to learn about the impact of these environmental toxins on the increased incidence of developmental, learning, and behavioral problems.

## DIAGNOSIS OF DEVELOPMENTAL LEARNING DISORDERS

Children and adolescents with learning disorders (disabilities) are often first referred for an evaluation because of behavioral difficulties. Thus, when a mental health professional evaluates a student with emotional, social, and/or family problems who also have academic difficulties, it is essential that one differentiate between cause and symptom ( [Silver, 1997](#) ). Are the emotional, social, and/or family problems causing the academic difficulties or are they a consequence of the academic difficulties

and the resulting frustrations and failures? The emotional, social, and/or family problems may have started from the unrecognized and untreated learning disabilities and then evolved into emotional or behavioral disorders. Each must be addressed. However, if the clinician does not address the underlying cause of emotional and behavioral problems (possibly the learning disabilities), little progress might be made.

The clinical history helps to raise the suspicion of a learning disability. The clinician should ask about school performance and ability with each academic area. A suggested "system review" would include the following ([Silver, 1993](#)):

Start with questions relating to basic skills.

### **Reading**

Is reading something you like to do or have to do? How well do you think you read? Do you ever make mistakes because you misread questions or instructions?

Do you ever find yourself skipping words or lines or reading the same lines twice?

Do you find that you can read each word but that when you finish the page or chapter you do not remember what you have read?

### **Writing**

How is your handwriting? Do you prefer to print or use cursive?

Do you find that you cannot write as fast as you are thinking?

Tell me about your spelling? grammar? punctuation? capitalization skills?

Do you have difficulty copying off of the blackboard or overhead quickly enough?

Do you have difficulty getting your thoughts onto the page?

### **Math**

Do you know your times tables?

When you do math do you make silly mistakes like write "21" when you mean to write "12," or do you mix up your columns or add when you mean to subtract?

Do you have difficulty with word problems where you have to read and understand then change the words into formulas?

Do you sometimes start a math problem but halfway through forget what you are trying to do?

Next, ask questions relating to the processing skills needed to learn.

### **Sequencing**

When you speak or write, do you sometimes have difficulty getting everything in the right order?

Ask the child to name the months of the year. Then ask what comes after May. Can he or she answer or is it necessary to go back to January and then count forward?

Do you have trouble using the dictionary and remembering the order of the alphabet?

### **Abstraction**

Do you understand jokes when your friends tell them?

Do you sometimes get confused when people seem to say something yet they tell you they meant something else?

### **Organization**

What does your notebook look like? How about your binders and papers?

Is everything in the wrong place or falling out? What about your desk? backpack? locker? bedroom?

Do you lose or forget things? Do you do your homework but, somehow, it never gets turned in?

Do you have difficulty organizing your thoughts or the facts you are learning into a whole concept so that you can learn it?

Do you have difficulty planning time so that things get done?

### **Memory**

Do you find that you can learn something at night and then go to school the next day and forget what you have learned?

Do you learn best by listening to people (such as discussion groups) or by being alone and reading or writing?

If a learning disability is suspected, a psycho-educational assessment is needed. This should be done by the student's school system but might also be done privately. These studies include three areas of assessment: First, an assessment of the level of intellectual function; second, an assessment of academic skills in reading, writing, and math; third, a comprehensive study of processing skills.

The results of these evaluations should show if there is a discrepancy between ability and performance and establish the presence or absence of a learning disability. These findings along with the psychosocial evaluation clarify if other disorders are also present.

Some of the currently used tests used in the United States include:

1. Intellectual assessments
  - a. Stanford-Binet Intelligence Scale (ages 2 to adulthood)
  - b. Wechsler Pre-School and Primary Scale of Intelligence (WPPSI) (ages 4 to 6 1/2)
  - c. Wechsler Intelligence Scale for Children (WISC) (ages 6 to 16)
  - d. Wechsler Adult Intelligence Scale (WAIS) (ages 16 and over)
2. Achievement tests

- a. Woodcock-Johnson Psycho-educational Battery
- b. Metropolitan Achievement Tests
- c. Peabody Individual Achievement Test
- d. Stanford Diagnostic Achievement Tests
- e. Wide-Range Achievement Tests
- 3. Educational/processing abilities tests
  - a. Woodcock-Johnson Psycho-educational Battery
  - b. Detroit Tests of Learning Aptitude
  - c. McCarthy Scales of Children's Abilities
  - d. Slingerland Screening Tests

## TREATMENT OF DEVELOPMENTAL LEARNING DISORDERS

The treatment of choice for developmental learning disorders (disabilities) is special education. The specific approaches to treatment were described for each disorder. In general, there are three approaches used. Remediation is an effort to teach skills by using different approaches than the traditional models. The teaching of compensatory strategies is another valuable approach. Given the student's strengths and weaknesses, what is the best way for him or her to read and retain what is read, to write in an organized way, to learn material, and so forth. The third approach is accommodations. Teachers are asked to modify the material, teaching approach, assignments, or test designs to maximize the student's ability to communicate what is known.

If emotional, social, and/or family problems are present, they must be addressed in a multimodal treatment plan. When providing individual, group, family, or behavioral therapy, it is important to be aware of the impact the learning disabilities have on the individual's life as well as the impact of these disabilities on the treatment method itself (Ostrander and Silver, 1993). There are no psycho-pharmacologic treatments for learning disabilities. If, in addition to the learning disabilities, the individual has ADHD, medication should be used to address this disorder. Many of the psychiatric disorders found in children and adolescents with learning disabilities would benefit from the use of medication as well.

## OUTCOME

For most, learning disorders (disabilities) persist throughout life. The child with learning disabilities becomes the adolescent with learning disabilities and the adult with learning disabilities. Thus, the clinical interventions change with each developmental stage, including adulthood. Services might be needed in college, graduate, and professional schools as well as vocational and job training programs. Appropriate accommodations may be needed throughout this individual's career.

Most individuals can overcome or learn to compensate for their disabilities with early recognition and appropriate special education intervention. Additional strategies might have to be learned and mastered at each stage of education, as well as for the demands of work.

The outcome can be poor without recognition or treatment. These children and adolescents experience frustration and failure, resulting in a poor self-image and low self-esteem. They are at risk for emotional and behavioral problems. Early recognition and intervention are the best preventions for these serious problems.

## GENERAL CONSIDERATIONS

Sensory impairments do not cause psychiatric illness per se but may affect symptom presentation. Misdiagnosis of psychiatric disorders, particularly mental retardation in sensory-impaired children, may occur if the diagnostician is unaware of the adaptive differences and, hence, the variability in timing and acquisition of developmental milestones owing to the sensory impairment. Troubled behavior may represent independent psychiatric conditions or consist of acquired maladaptive compensatory behaviors. Sensory impairment influences the acquisition of skills, self-concept, and interaction with environment. In response to the impairment, the child's environment can shape the sequential acquisition of skills and the developmental process. The influence of impairments on the developmental process and presentation of psychiatric signs and symptoms and the context in which the child functions are pivotal to the psychiatric evaluation of perceptually impaired children. The objectives of a psychiatric evaluation are accurate diagnosis and development of an appropriate treatment plan that address the multiple and complex problems identified ([American Academy of Child and Adolescent Psychiatry Practice Parameters, 1997](#)). Fundamental considerations for evaluation of a sensory-impaired child include the tremendous range and heterogeneity of the individual impairments, frequent occurrence of multiple impairments, complex interdependence of the impairments with the environment and caregiver response, and differing potentials among children with similar impairments. The nature and extent of impairments differ with etiology, age of onset, and other complicating factors.

High frequency of additional impairments and comorbidities result from autism, attention deficit hyperactivity disorder (ADHD), mental retardation, neuropsychological disorders of learning, central nervous system syndromes, and traumatic brain injuries. Many children and adolescents have comorbidities that do not fit neatly into a simple diagnosis, but categories are identified in a full psychiatric evaluation through multiaxial diagnoses. Those who evaluate and work with sensory-impaired children may lack exposure to profoundly impaired individuals who lead successful and constructive lives. This is important because professional attitudes and expectations subtly shape the evaluation.

Consistent language is helpful in communicating findings to patients and their families. Impairment is an identifiable defect in the basic functions of an organ system and for our purpose concerns hearing and vision. Disability refers to limitation, restriction, or disadvantage imposed on an individual's functioning. The term handicap is not currently favored. The term challenged has been used in its place, as in visually challenged, reflecting the outcome of an actual or perceived disadvantage in performing normal life functions because of personal and/or societal expectations and attitudes toward the impairment.

Legally, "learning disability" as defined by the Individuals with Disabilities Education Act ([IDEA, 1970, 1997](#)) includes students with "perceptual handicaps" resulting from visual, hearing, motor disabilities and/or mental retardation [20 USC sec. 1401(26)(B)(C)]. There is a need to be familiar with the definition of disability as provided by the IDEA:

'a child with disability' means a child (i) with mental retardation, hearing impairments (including deafness), speech or language impairments, visual impairments (including blindness), serious emotional disturbance . . . , orthopedic impairments, or specific learning disabilities; and (ii) who, by reason thereof, needs special education and related services [20 USC sec. 1401 (3)].

An infant or toddler with a 'disability' means an individual experiencing developmental delays, in areas of cognitive, physical, communication, social or emotional, and adaptive development; or has a diagnosed physical or mental condition with a high probability of developmental delay . . . [20 USC Sec. 1432 (5)].

When the IDEA, originally passed in 1970, and revised in 1997, it replaced the Education for All Handicapped Children's Act of 1975. These federal definitions have been adapted and incorporated into state and local education laws.

## THE ROLE OF A CHILD AND ADOLESCENT PSYCHIATRIST

The role of the psychiatrist as liaison to interface and interact with a multidisciplinary medical or rehabilitation team and the family, school, and community is unique. The child psychiatrist's training permits integrating biological, developmental, family/environmental, learning/education, and psychodynamic/psychiatric issues in order to develop a diagnostic formulation. In both evaluation and treatment, the consulting psychiatrist needs to establish a collegial relationship with the parents and school

staff. Frequently, the school or rehabilitation service requests a consultation in order to assess risk of suicide, psychopharmacologic management, change in level of care, or educational program. Current educational trends for sensory impaired persons include early intervention assessments and therapeutic interventions for infants and toddlers exhibiting developmental delays and integration of sensory impaired children into regular schools. These trends increase the probability that child psychiatrists lacking specialized experience may be asked to evaluate sensory-impaired youngsters. Referrals also come from schools where children are mainstreamed. In special schools, the need is for initial triage, assessment of complex biopsychosocial issues, and monitoring outside psychiatric care. Most sensory impairments are life long; hence, the initial involvement of the child psychiatrist often evolves into long-term assistance. Child and adolescent psychiatrists must accommodate comfortably to specialized settings and adapt innovative interviewing techniques in both assessment and treatment.

Learning manual sign language is very helpful but difficult to master. An interpreter for hearing-impaired children and utilization of play with a blind child are feasible alternatives. Familiarity with the use and purpose of various assistive devices can facilitate rapport with the child and family. The child psychiatrist who is best able to approach the evaluation is knowledgeable in child development; looks for adaptational, problem-solving, and functional strengths; is aware that a sensory impairment does not routinely result in psychological impairment; and seeks to identify the strengths and weaknesses within the family. The questions, "How does the impairment interface with the developmental process and/or the environment and what have been the adaptive responses?" are very helpful. The goals of the examination should include looking for the child's level of independence, cognitive abilities, functional abilities, social adjustments, and psychological adaptations. Further, the examiner would want to consider why this case has been referred at this time; who made the referral; what is happening in the home, family, or school; for example, does the child need a new school or is the child aging out of the current school; has the child grown and developed to the point where previous management techniques are no longer possible and medications are being requested; and is there an underlying purpose for the referral, such as expediting removal of the child from the home, school, or changing the level of care? Assessment of the various domains of development is indicated in infants and toddlers. Further, the examiner would want to assess the child's ability to understand cause and effect relationships to modify his or her behavior. Reviewing various records and looking for the longitudinal patterns in addition to associated impairments answers some of these questions.

It is important for the evaluating psychiatrist to ascertain the parents' expectations and from what sources they have received advice. The normal parental wish is for a happy, unimpaired child and parents may disregard or deny the reality of their child's circumstances, pursuing unrealistic treatments and goals. The authors have repeatedly seen that the level of the parental involvement and advocacy for their child are important predictors of the child's success. In many cases, the "validity" of the parental expectations can be determined only after the fact, retrospectively once the child has grown. Assessment of the environment and family of the sensory-impaired child should consider the increased demands in time and energy required of parents. The demand of caring for a sensory impaired child can drain the emotional and physical resources of families, causing strife and parental dysfunction. Family structure and alliances can become skewed, and the full dimensions of family life may be curtailed. Financial costs can further tax family resources. Mothers more frequently than fathers attend rehabilitation services, and childcare support for the sensory impaired child or other children in the home can further drain resources. A gulf can grow between parents as polarized reactions occur. Siblings may feel excluded, jealous, or cheated while conflicted with the relief that they themselves are not impaired. Many families are able to form healthy and constructive responses. The task of communicating one's findings and engaging the family and school toward recommended treatment and intervention is made more difficult if they have contributed to maladaptive behaviors and stunted development. Clinical sensitivity and expertise is required to help parents and other caregivers including school personnel recognize both their positive and negative influence on the process and outcome of treatment.

## HEARING IMPAIRMENTS

### Definition

Hearing-impaired children are divided into hard of hearing and profoundly hearing-impaired or deaf groups. Traditionally, the distinction was based on those youngsters who could utilize their diminished auditory perceptions for communication and those who could not. The development, improvement and increased use of hearing-assistive devices including cochlear implants and expanded rehabilitation services has permitted an increasing number of hearing-impaired children with significant hearing loss to effectively use their residual hearing. Hearing-impaired children are also classified by the age of onset of hearing loss. "Prelingual" refers to onset of hearing impairment before the use of spoken language, and "postlingual" to impairments occurring after spoken language has been acquired. Generally, a loss of hearing before 2 years of age is considered prelingual. The age of onset of hearing impairment is a significant factor in subsequent language outcome even in children with similar levels of hearing loss.

### Historical Note

Hearing deprivation has existed throughout history. Educators and religious figures who have taken on the task of instruction of deaf pupils have influenced Western European attitudes and practices. In some Western European cultures, the right to inherit property was dependent on the ability to confess to God; therefore, oral speech took on a special significance. Early teaching combined variations of oral and sign communication. The controversy among proponents of manual, oral, and total communication, which is a combination of both, have waxed and waned over time and are detailed graphically by [Lane and Fischer \(1993\)](#). The deaf culture movement has challenged the rights of parents to remove a child from the culture by assistive hearing devices. Further, it has questioned the obligation of larger systems and even society's role in maintaining the integrity of the deaf culture. The deaf culture movement and the promotion of American Sign Language (ASL) have influenced implementation of IDEA. With the introduction of Public Law 94-142 in 1975, deaf and hard-of-hearing students have increasingly been taught and educated in regular schools largely populated by hearing children, although the extent of academic integration varies. The IDEA revision further supported the movement of deaf and hard-of-hearing students into mainstream education where opportunities for bilingual (sign and oral language) education and an accommodation for various communication devices (language boards, computers, etc.) is an expectation. PL99-457, which established early intervention programs, has done the same for children ages 0 through 3. The recommendations of the Commission on the Education of the Deaf also represent significant steps on behalf of the deaf.

### Prevalence and Epidemiology

The survey conducted by the Gallaudet Research Institute, now in its 32nd year, represents the largest ongoing database of information on deaf and hard-of-hearing children in the United States and provides the best epidemiologic estimates of that population. The most recent completed report for the 1997 to 1998 school year with a total of 50,629 cases represents more than 12,000 schools and is estimated to cover about 60% of identified deaf and hard-of-hearing children receiving any special services. The shift in demographics of the completed survey reflected a doubling of the Hispanic constituency over the past 20 years. There has been a dramatic decline of maternal rubella cases from 21% in 1977 to 1978 to 1% in 1996 to 1997. Over the same period, the age constituency of the survey reflected the movement of the rubella bulge, which is the cohort of children impaired secondary to the rubella epidemic in 1964. The proportional representation of other common known etiologies such as heredity, prematurity, meningitis, and otitis media remain fairly constant. However, the number whose etiology is cytomegalovirus, which was first added in the survey in 1986, has climbed steadily, and now accounts for 2% of the population. Some sociocultural changes with respect to maternal drug abuse are also reflected in the survey. Reported emotional and behavioral problems, uncorrected visual problems, mental retardation, and learning disabilities accounted for additional disabilities in a third of the population, whereas the remaining 66% reported only hearing impairment. An increase in reported learning disabilities from 2% in 1977 to 1978 to 9% in 1996 to 1997 and a decrease in emotional/behavioral problems from 7% to 4% during the same period many reflect systemic changes from IDEA implementation as students were reclassified from emotional/behavioral disability to learning disability. Critics point out under reporting of children with mild hearing impairments, thereby skewing the survey.

The degree of hearing impairment traditionally has been stated in terms of volume or decibel loss over the speech frequencies (250 to 8,000 Hz). The testing procedure measures the volume threshold at which a youngster perceives a pure single tone at a particular frequency. Such testing excludes associated frequency harmonics; the capacity to distinguish subtleties of sounds when frequencies are mixed or auditory input competes with background noise. Vowel sounds group in the low- to mid-range frequencies; consonants and sibilants tend toward the higher ranges. Thus, a child with partial loss might comprehend some words but guess at others ([Northern and Downs, 1991](#)). There is broad agreement on the need for early identification and intervention with hearing-impaired children. Universal neonatal audiologic screening to detect deafness has been suggested ([Sutton, 1999](#)), and auditory brain stem response screening for at risk newborns is seen as cost effective and clinically efficient ([Van Riper, 1999](#)). Assessments that measure specific areas of functioning may provide a more accurate picture of hearing impaired children ([Karchmer, 1999](#)). Audiologic assessment of preverbal and nonverbal children requires different evaluation methods. Periodic and repeated audiologic evaluations, particularly of young children, provide information about developmental strides. The generally accepted audiologic classifications for hearing impairments are given in [Table 51.1](#).

Hearing Loss Level	Character	Major Cause	Effect on Language Development	Developmental Effects on School Achievement	Major Needs
0-20 dB	Normal range	Conductive hearing loss	All speech sounds clearly heard	None	None
20-40 dB	Mild hearing loss	Conductive hearing loss	Speech sounds heard but may be distorted	None	None
40-70 dB	Moderate hearing loss	Conductive hearing loss	Speech sounds heard but may be distorted	None	None
70-90 dB	Severe hearing loss	Conductive hearing loss	Speech sounds heard but may be distorted	None	None
90-120 dB	Profound hearing loss	Conductive hearing loss	Speech sounds not heard	None	None
0-20 dB	Normal range	Sensorineural hearing loss	All speech sounds clearly heard	None	None
20-40 dB	Mild hearing loss	Sensorineural hearing loss	Speech sounds heard but may be distorted	None	None
40-70 dB	Moderate hearing loss	Sensorineural hearing loss	Speech sounds heard but may be distorted	None	None
70-90 dB	Severe hearing loss	Sensorineural hearing loss	Speech sounds heard but may be distorted	None	None
90-120 dB	Profound hearing loss	Sensorineural hearing loss	Speech sounds not heard	None	None

**Table 51.1. Handicapping Effects of Hearing Loss in Children**

Many states set the criterion of an average 80-dB loss in the better ear for admission to a state school for the deaf. Many children with a greater than 80-dB loss can learn to utilize their residual hearing and function in a mainstream hearing school, whereas others with a loss less than 80 dB cannot. A child with intermittent middle ear conductive impairment may vary in hearing ability from day to day. Further, a loss of more than 15 dB, especially following several episodes of otitis media during critical periods of language acquisition and education, results in diminished attainment, potential, and IQ scores ( [Northern and Downs, 1991](#) ).

### Etiology

The relative etiologies of childhood hearing loss have varied historically based on the presence of epidemics, pandemic diseases, and preventive measures available, whereas genetic inheritance has persisted in stable numbers. Deafness was a frequent consequence of ear infections and systematic diseases. Congenital deafness includes intrauterine etiologies and more than 50% of cases of congenital or early onset deafness have a genetic cause. Unknown etiologies have accounted for as much as a third of the cases of hearing impairment, although genetic sources may be responsible. There are many distinct genetic forms of hearing loss interfering with normal conversation. Mutations in the GJB2 gene are the most common cause of inherited congenital deafness ( [Green et al., 1999](#) ). The effects of the impairment may range from delays in the development of speech to lifelong impairments, although the timing of the etiologic event results in differing presentations and associated complications. Viral fetal infections interfere with other organ development, and multiple impairments are found, including visual impairments (e.g., congenital cataracts), cardiac malformations, neurologic impairments, seizure disorders, and mental retardation. The increase in cytomegalovirus infections demands a combined approach for universal screening for hearing as well as screening for cytomegalovirus in order to identify sensorineural hearing loss early ( [Fowler et al., 1999](#) ). Autism has been seen in disproportionate numbers in rubella and several other viral intrauterine etiologies ( [Chess et al., 1971](#) ). Deafness associated with prematurity and other intrauterine insults is often complicated by other disorders. Temporary, fluctuating, or permanent hearing impairment may complicate postnatal ailments such as meningitis, mumps, measles, middle ear infections, and allergies. Deaf children with hearing parents comprise the majority of the pediatric deaf population.

### Pathogenesis in Development

The basic deprivation of deafness is language ( [Meadow-Orlans, 1987](#) ). Deafness and its consequences on developing language acquisition have a profound effect on other domains of development given its influence on cognition and social behaviors. During the developing preschool years, when hearing children gain sufficient mastery of spoken language to express needs, desires, and emotions, the hearing-impaired children of hearing families are confronted with tremendous obstacles. The diverse influence and interrelationship of sound and language to the developmental processes is ubiquitous. The effects of profound prelingual hearing impairment can be grouped into language development and acquisition, cognitive development and information acquisition, and social development and behavioral difficulties.

### Language Development

Language is the tool for formulating thoughts and is differentiated from speech (articulation) or communication (which is an interactive and reciprocal exchange). A deaf baby babbles at the same age as a hearing baby. The deaf baby ceases to babble when babbling becomes social and infants begin to model the sounds they produce on the sounds they hear. There are wide variations in the milestones of the onset of speech in hearing children. The deaf child's lack of response to sounds might be rationalized away. For the hearing parents, the delayed and startling diagnosis of deafness requires a dramatic reorientation of their conceptualization of their child. The parents are faced simultaneously with a major decision as to the type of language acquisition training—manual or sign language, oral language, or total communication, which encompasses both, often in the face of conflicting professional opinions. The campaign against the use of manual language was based largely on the misconceptions that oral language is necessary for abstract thought and interacting with the hearing world, and that sign language is not a true language. [Noam Chomsky's \(1998\)](#) suggestion of an innate preprogramming for the process of language has been widely supported. Spontaneous sign systems observed in children of different cultures contribute to the understanding of the innateness of language in human infants ( [Goldin-Meadow, 1998](#) ). Observations that the syntactic structures and processes of language development of deaf and hearing children are similar lend support to the expanding use of sign. [Stokoe \(1976; Stokoe et al., 1978\)](#) demonstrated sign language to be a true language through linguistic analysis of ASL and published the first dictionary of ASL that was based on linguistic principles.

The hearing child with hearing parents learns spoken language through environmental interaction. The deaf child learns communicative language by visual means. The position of oral language proponents is that the deaf child will be unable to interact with the dominant hearing population without some spoken communication. Support for early auditory amplification and training is encouraged, so that the process of vocalization and babbling can be preserved and the concept of sound for communication and shaping of the vocalizations can be facilitated. The manual argument asserts that the vast majority of deaf people ultimately enter deaf culture for social and personal needs; therefore, they should feel comfortable with and accomplished in the language of their culture. The potential psychological conflicts in this dichotomy, which confront the consulting psychiatrist, are highly emotionally charged. This controversy is not dissimilar to the debates on bilingual education and accommodations to diversity and multiculturalism. Oral training is demanding; its proponents state that signing hinders its successful mastery. There remains great heterogeneity of achievement within both the oral and total communication groups and varying degrees of success in formal language acquisition. The tragedy of this politically charged controversy is that parents are required to make a lifelong decision for their child while facing emotional upheaval. Child psychiatrists' greatest value during the child's crucial cognitive and social development period may be to help parents teach acceptable behavior, including rules, compromise, and delayed gratification. This may be particularly difficult when the parent is dependent on only a "yes" or "no" response in exclusive oral communication.

The eventual language preference among deaf young adults balances the nature of the residual hearing, quality of early training, usefulness of communication, and cultural orientation of the individual toward the hearing world or deaf culture social groups. Many adults develop bilingualism in varying degrees but the issue of language and social isolation persists with varying psychological consequences. The deaf child in a hearing family tends to be isolated irrespective of communication. Deaf adolescents trying to function within the hearing environment particularly complain about their difficulty at parties and dances, where lowering of lights and background dance music makes communication and flirting almost impossible. To conceptualize such difficulties, consider the child who encounters any number of situations where vision and hearing are used and coordinated simultaneously, such as class note taking, talking at the dinner table, or honking cars warning of danger. Many children who later prefer to use sign but whose parents do not, often view the parents' lack of communication skills as evidence that they do not love them. Sibling interactions with the hearing-impaired child also affect self-perceptions and social skills. Adolescents often try to fake hearing and discard aids with frequent negative consequence in self-concept.

### Cognitive Processes and Theories

Cognition is linked to language acquisition. Areas of exploration, including memory, visual-motor and perceptual-motor functions and problem-solving strategies are being pursued with advanced technologies, an increased knowledge in the basic neuroscience, neuropsychology, and rehabilitation therapies. Reported intelligence quotient (IQ) scores and academic achievement are concerns for the child psychiatrist but scores can be misleading. The most commonly used tests among deaf children are the Wechsler Intelligence Scale for Children, 3rd ed (WISC-III, 1991), Leiter International Performance Scale, Wechsler Adult Intelligence Scale, 3rd ed (WAIS-III), Hiskey-Nebraska, Goodenough Draw-a-Person Test, Merrill-Palmer, and Ravens Progressive Matrices. The Wechsler scales were not designed for hearing, visual, or motor impairments. As stated in the WISC-III Manual, although one may prefer to place greater weight on the performance subtests to estimate a hearing-impaired child, the WISC-III was not standardized with modifications. If sign language and other visual aids are necessary to give instructions to a deaf child,

the evaluator and presumably the clinicians who are likely to use the tests scores should recall such alterations to have an impact on scores. For infants and preschoolers, developmental measures such as the Bayley Scales of Infant Development, 2nd ed (BSID-II), Gesell Developmental Schedules, or Cattell Infant Intelligent Scales are used. The following considerations about psychometric testing of hearing-impaired children include: The instrument should be nonverbal, because a verbal instrument can reflect language rather than cognition; there is greater likelihood that the instrument will report a falsely low score than a falsely elevated score; there is increased potential error when the test is administered by an examiner not familiar with hearing impairments, unable to communicate instructions in the child's preferred mode; personality tests are difficult to interpret because subtlety of instructions might not have been communicated and responses may be limited or unintelligible; and testing of preschool children at whose age communication skills are only beginning to develop is vulnerable to error and underestimation of potential. [Slate and Fawcett \(1995\)](#) have investigated the relationship of the WISC-III Performance scale with the WISC-R Performance scale and the WRAT-R subscales. Students communicating via total communication exhibit higher performance IQ means than students communicating orally. The WISC-III performance IQ was moderately related to the WRAT-R subscales having the strongest association with the arithmetic subscale. [Braden \(1989\)](#) found little correlation of the nonverbal, WISC-R Performance Scale k(PS) IQ to academic achievement using the Stanford Achievement Test-Hearing Impaired Edition. This suggests that the criterion of academic achievement fails to be an accurate reflection of the deaf child's innate cognitive abilities. Currently, many schools for the deaf use total communication where the teacher articulates and uses sign. The educational outcome of impaired children who have been mainstreamed is still uncertain, as is the long-range achievement results for deaf children taught by total communication. However, it is most likely that the psychiatrist evaluate a child with academic delays or unevenness in achievement.

### **Social Development and Behavioral Difficulties**

Language status influences social development and subsequent behavioral difficulties. The Vineland Scale reports show a lower social quotient among deaf children. The impact of deafness on child development can be readily observed in infants' orienting behaviors. Hearing children can hear their mother coo to them and orient toward their direction. They learn that crying attracts their mother's attention even out of sight. This experience is not available to the deaf child. Teaching social rules and concepts or right and wrong cannot be done easily by explanations, and the child often perceives limit setting as capricious. The child's developing theory of mind, as an interconnected network of beliefs, desires, and feelings influencing behavior, can be helpful in understanding social emotional and cognitive development. [Peterson and Siegal \(1995\)](#) have developed a theory of mind from studies of prelingual signing deaf children. The influence of deafness on development can be understood in light of various theories of development, for example, Eriksonian developmental stages, Bowlby's attachment theories, and so on. [Vaccari and Marschack \(1997\)](#) have explored the role of effective parent-child communication in the social and emotional development of deaf children.

The prevalence of reported emotional and behavioral problems among deaf children is three times that of the general pediatric population. In summarizing various reports, [Meadow \(1980\)](#) finds deaf children to be described as hyperactive, immature, and impulsive. There is a general impression that a typical "deaf personality" exists. Personality features usually included are characteristics such as impulsivity, hyperactivity, rigidity, suspiciousness, and immaturity. Following other investigators who have challenged these suppositions, [Chess and Fernandez \(1980\)](#) used a sample of 248 children with congenital rubella followed longitudinally from age 2.5 to 14 years. They concluded that deafness does not confer "typical personality"; it is the behavioral symptomatology of those with neurologic damage that is largely responsible for such a stereotype in the rubella-deaf. Application of stress and coping models in studying adjustment indicate that social support is predictive of maternal adjustment and that maternal problem-solving skills are significant predictors of child adjustment ([Calderon, 1999](#)).

Adolescent development poses different difficulties because information comes primarily from peers and the environment outside of the home, at the mall, pizza parlor, or street. By this age, signers have a social network within the deaf community, obtaining information not accessed from hearing parents or other adults. [Charlson and associates \(1992\)](#) have reported an in-depth evaluation of successful deaf teenagers. All of their subjects reported some degree of isolation from peers or family that was associated with communication difficulties. Their sample included deaf teenagers with deaf parents, and residential schools. Most of the students had developed a strategy for coping with the isolation, further raising the impact of parent's signing skill on adolescent social development, highlighting deafness as a significant variable in the task of developing sense of autonomy and competence. In a study of hearing-impaired youths and their hearing parents, parental ratings of adolescent behavior has been linked with parental symptomatology and low family adaptability ([Watson, 1990](#)). Gathering social information is particularly difficult for oral adolescents in a mainstream program.

### **Psychiatric Evaluation of a Hearing-Impaired Child or Adolescent**

The evaluation, treatment, and management of deaf children with psychiatric disorder is intimately related to the child's communication ([Roberts and Hindley, 1999](#)). Beyond the general techniques of child psychiatry interviewing, the examiner should focus on the preferred mode of communication for the child and be prepared to function within that modality. Assessments should include the parent's ability to communicate in the child's preferred mode, the impact of the parent-child communication and alternative, nonverbal interactive strategies of parents and their deaf children ([Vernon and Alles, 1986](#)). For preverbal and nonverbal children, a behavioral analysis with detailed information from long-term caregivers helps to interpret the child's behavior. The oral child relies on lip-reading cues; hence, the examiner should provide a continuous unobstructed view. To communicate with a deaf child a gentle touch or waving the hand in the child's visual field is acceptable. The examiner should not sit with the sun or a bright light behind the back, creating shadows and eyestrain. If the child's preferred mode of communication is sign, a certified sign interpreter is required for an examiner with sign skills no greater than those of the child or adolescent. A family member is unacceptable, because the child is not free to communicate confidentially. The interpreter is best situated next to the examiner, allowing the child an unobstructed view of both examiner and interpreter.

The syntax and grammar of ASL, as with other languages, are completely different from those of English. American Sign Language is a distinct language, not a codified form of English. When ASL is translated word for word, the language form appears fragmented and disorganized, and has been confused with psychotic processes ([Evans and Elliott, 1987](#)). Formal language defects are often similar in sign language to those found among hearing populations, with changes in rate of production, echolalia, perseveration, and neologisms. The assessment of language and communication is fundamental to any psychiatric evaluation and particularly vulnerable to errors in assessing the hearing impaired. Even good speech readers understand a limited percentage of the mouth and lip formations without cues. Effective communication requires constant concentration, guesses, adequate vocabulary level, quality training, and experience. The common use of idioms and slang in verbal conversations can present problems when working with oral (speech-reading dependent) youngsters. For example, an oral deaf adolescent boy considered to have excellent speech-reading skills responded with an inappropriate response to the quotation, "when push comes to shove." After a prolonged effort to understand and explore the bizarre response, it appeared that the youngster had speech read, "put it on the shelf" and that his response was congruent to that reading. Proverbs that are used in psychiatric examination for the hearing are misleading. Many proverbs have no meaning to the deaf, such as, "The squeaky wheel gets all the grease." Many words and phrases routinely used in mental health settings adapted from physical medicine assume a mental health, context-dependent meaning. For example, "How are you feeling?" has elicited the response, "Nothing" from a crying deaf adolescent because she had no physical pain. A common vocabulary is important with children and adolescents; and a determination whether they know the sign "emotion" and its connotations is critical. The examiner might list for the child the signs of happy, sad, and the like, interspersed with some simple nouns to find if the patient can distinguish which are emotions. Deaf individuals have hallucinations, look into space, and even sign into space toward the source, but it is not helpful to pursue the question, "Are you hearing voices?" Some may report that people or sources such as loudspeakers are talking about them or commenting specifically to or about them. This must be distinguished from prevalent beliefs often true within deaf culture that hearing people talk about them behind their backs. Schneiderian first-rank symptoms can be elicited, but ideas of reference must be teased away from cultural belief systems and experience. The psychopathology of paranoia poses similar problems. Drawings can be helpful in finding psychodynamic material. The Goodenough Draw-a-Person Test can provide an estimated intelligence level. Squilly drawings or Family Kinetic Drawings are helpful in gathering projective material and exploring relationships. It is best to interpret the drawings based on a story obtained about the drawing. Questions about what is happening, what the subject of the drawing is thinking, feeling, and hopes for the future prove richer than the usual theoretical interpretive formulations of symbolic meanings. Psychometrically sound functional scales specific to this population may further clarify symptoms and adaptive functioning.

### **Differential Diagnosis**

Mental retardation needs to be ruled out in a deaf child or an adolescent with problem behavior. Pervasive developmental disorder, autism, childhood schizophrenia, attention deficit hyperactivity disorder (ADHD), depression, conduct disorder, and parent-child conflict need careful consideration. ADHD is a common school problem not fully examined in the deaf population. Delays in academics or simple knowledge about the world may present as immaturity, dependency, or educational delay. Deaf children are accustomed to routine sequences of actions because their parents and mentors find it difficult to explain changes. They themselves may later insist on sameness, leading to a misdiagnosis of childhood schizophrenia, autism, or obsessive-compulsive personality disorder. In a deaf child, alternative causes must be considered for all these diagnoses. Differential diagnosis of behavior disturbances among sensory-impaired children requires the clinician to consider unusual presentations of conditions that exist in nonimpaired children. Tinnitus that occurs among hearing-impaired children may be mistakenly diagnosed as hallucinations. The assessment of multiply disabled deaf children requires a large team of highly specialized evaluators. The position paper on recommended assessment procedures for these youngsters adopted by the Conference of Educational Administrators Serving the Deaf provides a useful and comprehensive listing of all the areas that need to be considered. They consider deafness to be the primary disability. It is not realistically possible to go beyond that position when generating

information ([Johnson, 1989](#)) because of the lack of theoretical knowledge about the interactions of the differing impairments. IDEA and PL99-457 that establishes Early Intervention for children 0 through 3 with developmental delays and handicapping conditions identify areas that need consideration. In evaluating a deaf multiply impaired child, the psychiatrist is cautioned from automatically placing sensory impairments as the most important in the hierarchy. This could inadvertently underestimate other impairing conditions such as mental retardation, psychosis, central nervous system syndromes, and so on, which might more accurately dictate functional capacity, treatment, and prognosis.

## Treatment and Management

Deaf professionals have a vital role in providing mental health services to deaf children and adolescents. Intervention strategies utilizing competency-based approaches always should be considered. Offering services to support parents, enhance their coping skills, and develop their own support system is an integral part of providing services to this population. A developmental approach in providing services requires recognizing the parents' and children's varying needs at different ages and family stages. Management of the different developmental trajectories and unevenness in various developmental domains needs a wider array of viable modalities of communication, such as sign, play, art, movement, and so on. Prioritizing treatment and subsequent management is like that for other children presenting with psychiatric disorders. Effective communication, both prelanguage and language-based, is a high priority for primary prevention of emotional-behavior disorders. The selection of total communication or oral training depends on parental ability to sustain a demanding communication therapy program (either for oral training or to learn sign language), along with the child's intelligence, temperament, and associated impairments. The authors' general recommendation is a total communication approach but decisions should be made on a case-by-case basis. It also may be necessary to accomplish this over time and in stages. As child psychiatrists, we place a high priority on social/emotional development, psychosocial group identification and support, and a sense of self-identity, which is the core of deaf culture based on sign language. Many of the referrals are orally communicating older children, where problems have already developed. Referrals of the manual communicators come from dysfunctional families, particularly those with multiply handicapped children. We tend to see unsuccessful youngsters and their families; it is unusual to be called into a case where the impairment is newly discovered. There is a tremendous heterogeneity among hearing-impaired children, and the clinician is best advised to remain flexible in recommendations. Initial oral training is important, both prior to and after surgery, for successful use of cochlear implantation. Any 2- or 3-year-old child in a purely oral program not making prompt and significant progress should be transferred to a total communication program. Delays beyond the fourth birthday leave a child ill-prepared for school; the absence of a practical communication mode may be the largest contributor to the problem, should the child be brought for treatment of a behavior problem at a later age. The Rubella Longitudinal Study found that mainstreaming with oral education is helpful, although not mandatory if postsecondary education is used as a criterion of success. In addition to addressing the long-term consequences of the impairment, unrealistic parental expectations, and a wish to deny the impairment and diminish its impact should be discussed.

Treatment focuses on the acquisition of acceptable behaviors for the developmental period, if the behavior problem is not owing to independent psychiatric conditions. Behavior modification has been successful with deaf children, as group psychotherapy has been with deaf adolescents. Group psychotherapy provides an avenue to share feelings and behavioral strategies, particularly around maturational and adjustment issues. Studies proving efficacy of individual psychotherapy in the language used by the child are limited only by the availability of therapists. Clinical reports on the value of psychotherapy tend to be single-case studies or highly selected samples. Hearing therapists are most successful if they use a transcultural model and acquaint themselves with the cultural beliefs of their clients. As in psychotherapy of the nonimpaired, the therapist is advised to convey, "Teach me what your experience is like" rather than, "I know how you feel."

Evaluating psychopharmacologic agents and monitoring their desired and adverse effects is similar to hearing children with the same symptomatology or disorder, but with a warning. Psychoactive medications, especially neuroleptics, can be used successfully with deaf children for management, but the common anticholinergic side effects of psychoactive medications must be made clear, although they are difficult to communicate in sign language. The blurry vision often experienced with these drugs is intolerable for an individual dependent on vision and limits the usefulness of such medications. Stimulant medications can be used effectively for ADHD in carefully diagnosed cases. Hyperactivity in hearing-impaired children may be confused with a reaction to poor communication or learning social cues and appropriately responding to them. The determination is complicated by reported impulsivity among deaf children. Cases referred for stimulant medications have identified overwhelmed parents lacking communication skills, having trouble setting limits, and overusing physical punishment to establish their authority. [Kelly and colleagues \(1993a\)](#) evaluated a state residential school for the deaf and obtained ratings on 238 students using the Conners Parent Rating Scale and the Attention Deficit Disorder with Hyperactivity (ADD-H) Comprehensive Teacher Rating Scale. They found that the Conners ratings statistically differed from normative numbers for hearing children. Among those youngsters who were considered positive for ADD-H, hearing loss tended to be acquired (e.g., bacterial meningitis or congenital rubella). A wide range of management interventions, including stimulant medications, also was reported ([Kelly et al., 1993b](#)). The decision to use stimulant medication should consider that the chronic nature of the deafness results in lifetime use of medications to maintain the child in the least restrictive environment. This dilemma can be addressed only on a cautious, case-by-case basis with careful monitoring and periodic assessments. Repeated failures at nonpsychopharmacologic intervention warrant a trial of medication. Treatment goals and a time frame for the medication trial, and periodic review of the medications should include a risk-benefit analysis of optimum medication dosages.

Treatment and management includes counseling and supportive measures for the family. Emotional reactions of parents to a deaf child can interfere and/or limit their capacity to respond to their child's needs. An impaired child's temperament and the concept of goodness of fit should be considered ([Chess et al., 1980](#)). Many parents reexperience painful emotional feelings and new sets of problems with each developmental transition. Successful adaptation to the complex and ever-changing challenges of parenting a deaf child can be integrated in bereavement models. [Kampfe \(1989\)](#) adapted the House Social Stress Model for transitions into her work with parents whose child has recently been diagnosed as deaf. Conditioned variables of the parents include social status, experiences, personal resources, social support, which interact with the various responses, influencing the central core of transition to adaptation and the parent's perceptions of deafness. She has found working with these perceptions a helpful supplement to the more simplistic mourning and grief structure ([Kampfe, 1989](#)). Siblings are a sadly neglected group requiring intervention and education. Family therapy with a hearing family and deaf child should use interpreters, even if the therapist can sign ([Harvey, 1982](#)). Counseling for both the parents and siblings include teaching technical information in terms that can be understood clearly. The importance of genetic counseling services for both parents of deaf children and deaf adults cannot be overlooked ([Arnos, 1992](#)).

The first experimental cochlear implants on adults were performed in the early 1960s and clinical trials began in 1973. In 1984, the Food and Drug Administration (FDA) approved the devices in adults. The first implant trial on children was initiated in 1980 at the House Ear Institute in Los Angeles, California. By 1990, over 500 children, ranging in age from 2 to 17 years, had received the device when the FDA gave approval for implantation in children. The Subcommittee on Cochlear Implants of the American Academy of Otolaryngology makes clear that pediatric candidate selection requires more than a failure to benefit from a full trial of appropriately fitted hearing aids and other devices. Medical history must be considered in addition to psychosocial factors. The psychosocial factors for successful selection include the absence of severe organic brain damage, psychosis, mental retardation, personality traits that may interfere with training, and/or unrealistic expectations. Parent-child interaction that permits follow-up rehabilitation is a requirement for long-term speech therapy training following surgery, and frequent readjustment of the device ([Kveton et al., 1991](#)). [Kampfe and associates \(1993\)](#) review the literature on the impact of parental expectations as a contributing factor to successful procedures and suggest that parents in early stages of either shock or denial in regard to their child's deafness are not in a position to manage successful cochlear implantation. Cochlear implantation requires active long-term participation for parents and children. The experience with adult recipients of the device is more extensive, whereas the experience with children is growing. The Cooperative Veterans Implant Study showed that all recipients were able to hear sound with their implants but there was a varying degree of effective meaningful auditory perceptions, although being able to hear warning sounds (e.g., horns) is considered beneficial. Of all postlingually deafened with a working knowledge of spoken language, only 61% showed improvement in "open-set" speech recognition, that is, where the listener cannot be aided by speech reading ([Cohen et al., 1993](#)).

Cochlear implants hold out the possibility of enabling profoundly prelingually deaf children to hear. The decision to use this prosthesis is neither easy nor obvious ([Crouch, 1997](#)). [Waltzman and associates \(1992\)](#) have reported success in implanting multichannel implants in prelingually deaf children. Fourteen prelingually profoundly deaf children (2.6 to 5.1 years old) were given implants following intensive screening evaluations. The children had varying means of communication, including sign, oral, and total communication, as well as no demonstrable means of communication. Follow-up data on a variety of testing instruments showed benefit in auditory reception and the acquisition of speech and language expressive skills. Children receiving only sign language training prior to implantation did not progress as rapidly as the oral youngsters, but all of the youngsters continue to require rehabilitation services. The ultimate level of open-set auditory receptive and expressive communication these youngsters will achieve is unclear at this time. Informal observations from clinicians suggest that the youngsters are also expanding their social interactive potential and the initial reports are encouraging. Cochlear implants are not a "bionic" ear or cure for profound hearing impairments. The decision to choose hearing aids, communication devices, or medical technologies for their child can be stressful for parents. Controversies on the ethics of using medical intervention through cochlear implantation on the deaf culture, and thereby altering the relationship of social conditions, adds a moral dimension to this dilemma ([Enerstvedt, 1999](#)). The concept that deafness is not a disability requiring intervention is a position held in deaf culture ([Tucker, 1997, 1998](#)). The opposition to the use of medical technologies and intervention may distract from the purpose of evaluation. The timing and trials with hearing aids and assistive devices requires thorough evaluation and training ([Chute, 1997](#)). The benefit of cochlear implants is clear in patients who had acquired speech and language before hearing loss or who had a shorter duration of deafness. The gradual and steady improvements in speech production and perception that have occurred in prelingually deaf children are promising ([Loizou, 1999](#)). In a study of 23 prelingually, profoundly deaf children with cochlear implants, there was no significant difference between the language

performance of children who use oral versus total communication ([Robbins et al., 1999](#)). Studies show that bringing up deaf children without sign language results in deficient ability to communicate, whether they have an implant or not ([Enerstvedt, 1999](#)). In this context a decision to withhold sign is tantamount to denying language.

## Outcome and Follow-up Data

The human havoc consequent to the worldwide epidemic of congenital rubella of 1964 to 1965 is important to record, not only for its contribution to sensory and other infant impairment, but also because repeated epidemics should be anticipated owing to a large pool of unvaccinated young women and children, the ease of worldwide travel, and constantly evolving new viral infections with possible teratogenic effects. Prospective studies provide the most reliable data. In 1967, Stella Chess initiated the Congenital Rubella Behavioral Study with a cohort of 243 children whose physical status was under study at Bellevue Hospital in New York City. Initially evaluated at ages 2.5 to 5.5 years, follow-up studies were done at ages 8 to 9 and 13 to 15 by [Chess and colleagues \(1971\)](#) and at age 22 by [Kasen and colleagues \(1990\)](#). The major impairments were hearing loss (177, 72%), with 61 severely to profoundly deaf. Visual loss, mainly caused by congenital cataracts, cardiac anomalies, and neurologic impairments, also were present, often as multiple events. Fifty children with congenital rubella diagnosed on the basis of successful culture of the rubella virus were free of any deficit. These mothers' infections had been in the third trimester of pregnancy, and the children became the control population of the study.

There was an inverse correlation between the number of impairments and behavioral normalcy both on initial evaluation and into adolescence. The intelligence quotients of the rubella deaf children ( $N = 177$ ) ranged from superior to mentally retarded ( $N = 30$ ). The prevalence of autism ( $N = 18$ ) was equivalent to 741 per 10,000, several hundred-fold greater than expected. This study was ongoing at a time of great and contentious argument over the legitimacy of sign language, when oral training and lip reading were dominant. By adolescence, only a minority of the severely and profoundly deaf had been profitably mainstreamed. When evaluated at young adulthood, Kasen and Cohen ( $N = 46$ ) found that although better employment status characterized the mainstreamed group ( $N = 24$ ), the majority nevertheless felt more comfortable in the deaf community. The New York Longitudinal Rubella Study covered 22 years, during which time public attitudes and awareness concerning the special needs of impaired children and their families changed dramatically. Future research in the area of language education or English as a second language might result in different conclusions on optimal educational methods for hearing-impaired children. The complexities of culture, socioeconomic status, parental education and expectations for children, educational issues, the heterogeneity of hearing capacity and associated other impairments present daunting research challenges. This complexity and heterogeneity of the population attest to the inadequacies of simplistic approaches, based on a unitary theoretical formulation, or dogmatism, as to the (correct) communication modality for hearing-impaired children.

Data are sparse on employment of deaf individuals. An important report by [Vernon and LaFalce-Landers \(1993\)](#) presents discouraging data. Forty-seven deaf and hard of hearing individuals for whom Vernon had found a gifted IQ score (130 to 150) were followed up after a period ranging from several months to 36 years. Most had attended or graduated from college or graduate schools for the deaf or were mainstreamed, receiving liberal arts or technical/vocational training, but there was only a 52% graduation rate. The dropout rate resulted in large part from the lack of sufficient deaf support services in colleges. At the time of follow-up, one-third were in professional or supervisory work, almost all within the deaf community, whereas 30% were unemployed. The rest were underemployed with respect to their training. Forty percent had received psychiatric therapy for emotional problems or mental illness and 9% had been hospitalized.

## Research Directions

Research into sign language as a true idiom has already been done. The close relationship between gesturing and speaking in the human brain has to be pursued. The efficacy of alternative therapies in the outcome of sensory impairment is a major research area. Spirituality and its contribution to resiliency and adjustment also require serious attention. The pros and cons of the use of Signed Exact English (SEE) or ASL in schools need further examination, although most deaf children learn to read and write English as a second language. Research to improve language, reading skills, and overall literacy is most urgent.

---

### CASE ILLUSTRATION

Brian, a 13-year-old hard of hearing boy, lives in a group home for deaf and hard of hearing adolescents. Diagnosed with attention deficit hyperactivity disorder (ADHD) and conduct disorder, he has never been able to communicate effectively with oral language and relies heavily on American Sign language (ASL). Brian has consistently tested in the mildly deficient range on performance tests of the Wechsler Intelligence Scale for Children, revised (WISC-R), which is generally surprising to those who know him well, because of his apparent strengths in social skills and ability to mask his deficits. His current treatment plan includes methylphenidate for his ADHD symptoms, individual therapy, and an integrated behavior modification program in the group home and school. Brian's therapist advises staff in the group home and school and works directly with Brian using cognitive and supportive techniques to help Brian better understand the consequences of his behavior and achieve appropriate social behavior. Target behaviors have included disrespect toward authority figures, lying, refusal to do schoolwork, physical aggression, inappropriate sexual touching of others, lack of remorse or empathy for others, and blaming others for some of his problems.

On one occasion, Brian presented unusual symptoms during a routine visit to his psychiatrist. The interpreter during this visit was primarily fluent in Signed Exact English (SEE) not ASL, and was not familiar with Brian's use of language. During the previous week, group home staff described Brian as more agitated and impulsive than usual. Brian tried to explain his behavior to his psychiatrist, stating that peers were picking on him, that they "preferred the devil," commenting that, "The devil is picking on me." He preferred time alone, away from his peers. Brian reported the voice of a popular singer in his head when asked about possible auditory hallucinations. He also complained of a "machine" in his stomach. Alarmed that Brian might be developing psychotic symptoms, paranoid ideation, auditory hallucinations, and somatic delusions, the psychiatrist discontinued methylphenidate and considered treatment with an antipsychotic after a period of observation. Brian was seen a week later with an interpreter who was fluent in ASL and familiar with Brian's language and the structure and activities of the home. The interpreter learned that several teenagers in the group home, including Brian, had been attending religious education classes and had begun to express bad behavior as being an influence of the devil. Brian, who particularly lacks significant abstract reasoning skills, had meant that he was misbehaving when he said the devil was picking on him. Saying that his peers preferred the devil meant that they were misbehaving. With this interpreter, Brian clarified that he had been listening to music with headphones and had heard the voice of a popular singer in his head. Finally, Brian had been complaining the previous visit of feeling "weak" in his stomach, not that there was a "machine" in his stomach. The ASL signs for weak and machine are similar. Thus, all of the suspected psychotic symptoms were the result of communication problems! In this case, the communication problems were exacerbated by Brian's cognitive and language limitations, which included idiosyncratic signs, as well as an interpreter who was not proficient in ASL, Brian's language of choice.

---

## VISUAL IMPAIRMENT

The general considerations and role of the child and adolescent psychiatrist in the beginning of the chapter applies to visual impairment as well.

### Definitions and Historical Note

Blindness was legally defined by the American Medical Association in 1934, for the purpose of determining eligibility for federal insurance programs. This definition as central vision of 20/200 or less in the better eye with corrective glasses, and a visual field subtending an angular field of no greater than 20 degrees in the better eye has endured and is used in PL94-142, 1975. There are alternative definitions that focus on functional capacities, rehabilitative potential, and the nature and quality of the residual vision on educational perspectives; however, there is no consensus about which criteria to use and how to measure them, and the legal definition varies worldwide. The term visual impairment includes both partial sight and blindness. Partial sight is defined as visual acuity above 20/200 but worse than 20/70 in the better eye with correction. Approximately 20% of legally blind children receive no visual input and are totally blind, whereas the remaining 80% have some form of visual stimulus of tremendously varying quality and usefulness. A child who is legally blind may have considerable vision, able to read large-type materials and learn by the efficient use of residual vision. There are differences in the prevalence of blindness among the developed and developing countries, where blindness secondary to infectious processes and malnutrition continue to be epidemic. The World Health Organization (WHO) defines blindness as visual acuity of less than 3/60 (0/05), corresponding to loss of walk-about vision. The WHO definition of low vision as visual acuity of less than 6/18 (0.03) overlaps with the legal definition of blindness in the United States ([Lawrence et al., 1992](#)). Worldwide, there is increased interest in low vision, generally associated with the aging process. The nature of the visual pathology and quality of vision can result in varying perceptions and is often dependent on lighting conditions. The legal definition is essentially a distance definition, and although there is usually a correlation between near and far vision, this is not consistent. Attempts at a functional definition usually involve a reading task and are most helpful for educational purposes ([Scholl, 1986](#)).

### Prevalence and Epidemiology

The collection of statistics on incidence and etiology of visual impairments is vulnerable to the definitions of blindness. Unlike some other countries, the United States does not keep a national register of blind or visually impaired people. There is no one definitive study that includes all the relevant information owing to confusion in the field about which definition and therefore which statistics to use. The National Center for Health Statistics (NCHS) stated in 1990 that there are 95,410 "severely visually impaired" children between the ages of 0 and 17 years old in the United States. The definition of severely visually impaired differs from that of legal blindness and is not based on visual acuity but perceived vision problems generally based on reading. This number does not include institutionalized individuals ([Nelson and Dimitrova, 1993](#)). The 1992 survey of the American Printing House for the Blind reported 51,813 students who were registered as visually impaired. Of that group, 27% were classified as visual readers, 9% were in residential schools, and 4% were in programs for multihandicapped individuals ([American Printing House for the Blind, 1992](#)). [Kirchner and Schneider \(1997\)](#), in a United States demographic update, pulled together items from various perspectives. The prevalence of people 15 years and over, who have a functional to severe functional limitation, defined as those who cannot see words and letters in ordinary newsprint, is 9.7 million with a prevalence rate of four per 100. By clinical measures, the estimated prevalence of the legally blind population of the United States is 1.1 million, with a prevalence rate of 4.5 per 1,000. The estimate for the prevalence of total blindness with light perception or less is 220,000, which was calculated from 20% of the legally blind. Of

that, half or 110,000 are estimated to have no light perception at all.

## Etiology

Etiologies of visual impairments have varied through time, reflecting changing medical ability to treat infections. Vision loss in childhood caused by congenital, genetic, or prenatal congenital conditions represents approximately 50% of cases. Optic atrophy is a common diagnosis among the severely mentally retarded with visual loss. Lymphocytic choriomeningitis causing chorioretinitis *in utero* is believed to be responsible for some (Mets, 1999). Other causes include optic atrophy, retinitis pigmentosa, optic nerve hypoplasia, cataracts, foveal hypoplasia, persistent hypoplastic vitreous, and microphthalmos. Uveitis potentially leading to blindness can develop in children with juvenile rheumatoid arthritis (Foster and Nguyen, 1998). The improved management of premature infants has reduced the incidence of retinopathy of prematurity (ROP), previously referred to as retrolental fibroplasia. There is a higher incidence of handicapping conditions and blindness among lower socioeconomic and very low birth weight children. Cortical visual impairment caused by a disturbance of the posterior visual pathways in the occipital lobe is most commonly caused by perinatal hypoxia, cerebral vascular accident, meningitis, and acquired hypoxia. Most children with cortical visual impairment have other associated neurologic abnormalities (Hero et al., 1999).

## Clinical Description and Developmental Approach

Visually impaired children suffer the full range of clinical psychiatric syndromes. Developmental delays and maladaptive, troublesome behavior among visually impaired children result from failure to learn adaptive skills, or to correct maladaptive behaviors reflective of gaps in the teaching of social norms and behaviors. Commonly observed behaviors in blind children, such as stereotypic rocking, passivity, and immobility, do not signify psychiatric illness, nor is late achievement of motor milestones reflective of cognitive problems. Such behaviors may be owing to the visually impaired child's reliance on caregivers for stimuli and insufficient environmental response. Substantial developmental data on visually impaired children are accumulating with the establishment of early intervention programs. Differences are emerging between children with visual impairment alone and those with multiple handicaps, in the acquisition of sequential motor milestones between the visually impaired and nonimpaired groups. Vision provides the infant and young child with stimulation and observation to permit imitation and modeling, and to encourage exploration necessary for further development. This includes all domains of motor, cognitive, social, and language skills (O'Donnell and Livingston, 1991); the blind child is at a particular disadvantage with imitative learning.

## Conceptual Approach to the Evaluation

The psychiatric evaluation of the troubled, visually impaired child is aided by the observation that blindness affects the cognitive functions of children, the range and variety of their experience, their ability to get about, and their control of their environment and self in relation to it (Lowenfeld, 1981). Developmental assessment of a blind child needs to be integrated with personality development. The effect of visual impairment in the range and variety of experiences is a major consideration and a potential psychiatric pitfall. A blind hearing child can locate a bird by its sound but not describe its shape, size, or flight. Although the tactile sense can describe concrete objects that can be held in the hand, it does not help to describe clouds, stars, or colors, nor can the child experience a very large or small object. This affects cognitive developmental processes. In comparing 40 congenitally blind and 40 sighted children for fantasy-reality distinctions between real and imagined objects and their development of certain abstract concepts, Ittyerah and Goyal (1997) found that blind children's knowledge that contents of fantasy are not real may be obtained through interpersonal relationships. Utilizing sensory information is important in forming ideas and developing concepts of space, size, weight, and object classification. Language development for the blind and the sighted infant are essentially equivalent through the babbling stages but can be stunted without visual stimuli. The visually impaired child must rely on verbal descriptions provided by the sighted. Iverson and Goldin-Meadow (1997) compared sighted and congenitally blind children and found blind children producing gestures resembling those produced by the sighted. Both groups used similar gestures in explaining particular processes, suggesting that gestures serve a communicative function for the speaker, and that the processes of gesturing and speaking are connected. However, without the experience of knowing through sight, verbalized descriptions repeated by the blind child can seem shallow or meaningless and are referred to as "verbalisms." Because development of vocabulary and the fund of general information can lag, intelligence testing results, especially the verbal portions of the WISC-III, should be interpreted cautiously. It may be more informative to look for problem-solving strategies than to compute the IQ score. Groenvelde and Jan (1992) analyzed the subtests of the WISC-R and the Wechsler Preschool and Primary Scale of Intelligence (WIPPSI) and were able to distinguish whether errors are the result of vision, understanding sequential relationships, or the interpretation of spatial relationships.

The early motor developmental milestones of the blind infant are similar to those of the sighted child until the age of 4 months (Warren, 1984). After this period, the lack of visual stimulation as motivator for the child to explore and interact with the environment can lead to delays in crawling, walking, reaching, grasping, and bilateral hand coordination. The blind child tends to lag behind the sighted in motor tasks where visual stimulation is a motivator, whereas there is little difference when the task is purely neuromuscular (e.g., sitting or standing alone). Prolonged period of immobility and limited environmental stimulation for the blind infant can result in poor development, especially in the areas of initiative and self-confidence.

Lowenfeld's observation about control over immediate environment and the self in relation to it has a subtle but profound influence on the child's development. In the sighted child, seeing overcomes distances and provides a quick way to evaluate new or changing situations or emergencies. Vision provides the means for observing the behavior of others, especially parents or peers, and learning by imitation while obtaining immediate feedback through observing facial expressions or other nonverbal cues. Early face recognition and social smile by the infant along with eye-to-eye contact are important both to the infant and caretakers in establishing and developing affective bonds. The blind infant's muted response to the caretaker's approach can discourage parental affective response and diminish reciprocity of nonverbal communication. Nonverbal social cues and body language are not available to the visually impaired child, complicating the development of peer and social relationships. The socially isolated child who is only around adults has no way to learn age-appropriate social behaviors. An interesting study of self-esteem, body size, and parental views in 9- to 11-year-old blind children discovered positive views about self-presentation. Low self-esteem was found in children who were thought too thin by their parents, but being appraised as fat or believing their parents thought of them as fat, had no effect on self-esteem (Pierce and Wardle, 1996).

Mainstreamed blind children tend to be more socially mature than visually impaired children in a residential setting, but they usually have more residual vision and thus greater potential to observe behaviors. Despite trends toward mainstreaming of children, most schools lack teachers with the necessary training to meet the children's needs. Special schools provide necessary supports for attaining skills that complement those learned in mainstream schools. The developmental tasks of adolescence are particularly vulnerable to troubled behaviors. Visually impaired adolescents cannot tailor their clothing or appearance to conform to their peer group and may worry about how acceptable they look, nor can they compare a peer's body language with verbal statements to pick up important cues. The concern among the blind that the sighted are looking at them critically may lead to self-consciousness. Blindness and serious visual impairment have considerable economic implications, leading to loss of productivity and social dependence.

## Personality Development and Psychiatric Issues

There is no typical blind personality and personality research comparing the visually impaired and the sighted have resulted in inconsistent findings (Warren, 1984). The Vancouver study of 86 visually impaired children reports that 18.6% of these children were mentally retarded, 3.5% psychotic, and 5.8% suffered organic brain syndromes (Jan et al., 1977). Although some children carried multiple diagnoses, 43% of the children were considered to be free of psychiatric diagnoses, and the remainder had a range of difficulties, including adjustment reactions and neurotic and behavior disorders. The report makes note of several significant points for personality development. The totally blind children in the study had averaged 50 days in the hospital during the first year of life, as opposed to 20 days for the partially sighted and only 2 days for the unimpaired controls. In incubator infants, breast-feeding was markedly reduced and the parents showed increased worries about their child's health status in comparison with the control group parents. Difficulties with clinging and separation problems, prolonged bottle-feeding, and chewing problems associated with delay in offering solid foods and self-feeding were noted later. Activity levels varied and there was increased use of pacifiers. Toilet training was essentially on the same time schedule as for the control children. Of the visually impaired children, 9% had a major problem with fears, but 28% were reported not appropriately fearful. A review of the literature regarding fears noted that the average number of fears among the children was high and differed in content from reports among sighted children. The blind children's most common fear was that someone they loved would be hurt, followed by fears of physical danger and harmful situations, whereas among sighted children there tends to be a higher percentage of fears about being hurt psychologically. "Severe" fears reported by the school counselors included getting a shock from electricity; getting lost; and fear of snakes, fire, and guns. The children also reported fears of falling from high places, strangers, walking alone in the night, dying, bombing attacks, and getting or losing a boyfriend or girlfriend (Wiemer and Kratochwill, 1991).

Visually impaired children are reported to have restrictive, unimaginative play patterns. Findings from the Vancouver study suggest that play might serve a different function for blind children. The inability to imitate inspired reluctance on the part of caretakers to introduce a wide variety of toys to the child, hence, social skills are hampered owing to the visually impaired child's paucity of interactive play experience. Adults' interventions to promote social contacts may focus the child's attention toward the adult and not the playmate. In adolescence, dating arranged by sighted friends or adults reduces privacy and inhibits acquisition of social skills. Despite this, many visually impaired children and adolescents are skillful at interpersonal manipulation. Lowenfeld (1981) describes four major concerns that present difficulty

to the visually impaired adolescent: sexual curiosity, dating, mobility, and concern for the future. The inability to gather sexual information from observation or magazines might compel the sexually curious adolescent to behave in a manner that would violate cultural and social taboos. Dating is an important arena in which one develops self-confidence and asserts a gender role, but ability to date is dependent on meeting another person and engaging in rituals of flirtation and personal appearance. The visually impaired must rely on introductions and arrangements that diminish flexibility and self-confidence while invading privacy. Limited mobility reduces opportunities for the separation and individuation process to occur, which further limits autonomy. Concerns for the future that involve leaving a protective family or school setting, accepting vocational challenges, ensuring economic stability, worrying about marriage, and the genetic transmission of the visual impairments pose significant hurdles.

### Psychiatric Evaluation of a Visually Impaired Child or Adolescent

As a general principle, the child and adolescent psychiatrist is cautioned against using a “deficit model,” assuming that damage is inevitable with a perceptual impairment, or at best only partially compensated, and always results in personality and/or psychiatric disorder. The examiner should be aware of myths about the blind such as innate helplessness and total dependence, blindness as a punishment for sins, etiologic association with venereal disease, and belief of hyperacuity of other senses. Prior to the interview, the examiner should have knowledge of the child’s medical history, degree of independence and cognitive level, events in the home, school adjustment, purpose of the referral, and the child’s ability to modify behavior. The age of onset of blindness is a major consideration.

The child psychiatrist evaluating a visually impaired child must be prepared to touch the child more than he or she would touch sighted children, asking for the child’s permission when appropriate. Talking softly to orient the child toward the examiner before even touching or approaching the child helps sets the tone for the evaluation. The child should be led to the examining room, and the examiner may initially remain in continuous physical contact by holding his or her hand or touching the shoulder. The interview space, its layout—including where the child sits and all of the toys available to the child—should be described, so that valid conclusions can be drawn about activity selection. The child will often ask seemingly impertinent personal questions of the examiner, including appearance and marital status, some of which a sighted child or adolescent determines by observation. Whether answered or not, a friendly tone is essential. It is important to note that with sensory impaired children, and more so with the blind and multiply handicapped, any interaction presents an opportunity to teach and engage the child.

The vast majority of legally blind children are better described as low vision, thus lighting in the examining room is important. There are no fixed rules, but the examiner must be alert to the unique nature of the child’s vision and maximize the residual capacities. Glare, background light and shadows, along with placement of objects in the visual field are considerations. A gooseneck lamp on the table enables the child to maximize vision while playing or drawing. Creating nonglare contrast can be helpful to increase visual perceptions. If drawing tasks are to be part of the evaluation, then the table surface should be free of glare. A dull light blue-gray table surface works well, contrasting both white and dark drawing paper or covering a white table with brown wrapping paper is a satisfactory solution. If white paper is used for drawings, then the standard pencil often does not provide sufficient contrast and a black felt-tipped pen or marker would provide better contrast. Some children prefer and respond better to dark drawing paper and a light-colored or white marker.

Play therapy can be used in the evaluation of blind children, but often the child must be taught how to play. The process of learning play through imitation often is not available to the blind child. The clinician can make some valuable observations about the child in the process of teaching a particular type of play. Blind children respond best to very realistic objects or toys. Play is better with utensils that the child routinely uses, such as real fork and spoons, rather than small toys, which have no meaning to the child. Similarly, dolls close to life size with molded realistic facial features and hair elicit more meaningful response as the child fingers the face than would the soft, more stylized, cloth dolls. Dollhouses with realistic figures of people and furniture can elicit helpful information about the home life of the child. The clinician might first have to teach the child how these small objects symbolize real people or furniture. In general the child plays with toys that are for a younger age group. It is best to start with real props to develop “pretend” imaginative play as part of therapy. The children pretend play verbally by telling stories as opposed to acting out behaviors. The clinician can elicit psychodynamic material and dreams in a verbal form, but the content may seem to be lacking in affect. This lack of apparent substance or affective content or “verbalism” seems more related to the language acquisition process than to the potential for affective content and the alert clinician can piece together the affective web that binds the meaning for the child. The child’s total body and other nonverbal responses including gestures as a communicative device need to be considered with the caveat that the child’s facial expression may reveal less than he or she understands.

The visually impaired child may be slower to warm up than the nonimpaired. Long silences should be avoided and the child should be notified of the examiner’s movements. Anticipated shifts of topic in the course of the evaluation should be announced so as not to confuse or contribute to disorientation. Echolalic language is relatively common and rarely pathologic. Self-stimulating behavior and stereotypic movements are frequently seen and not diagnostic of specific psychiatric conditions. The examiner should speak directly to the child and accept as an indication of relatedness that the child faces him or her with the ear and not the eyes. In an interesting protocol, [Raver-Lampman \(1990\)](#) asked 50 subjects who were informed about blindness and in contact with the blind, to evaluate videotapes of two children without gaze direction and two with gaze direction as they answered questions from examiners sitting on either side of them. The tapes were presented in a random order and opposite recording positions. The results revealed that, when a visually impaired child used gaze direction toward the questioner, the child was evaluated by the responding subjects as being more intelligent and socially competent than when the child did not use gaze direction. This serves as a caution to the examiner to be alert to his or her personal bias and unconscious judgments, especially involving the child’s body posture and direction of gaze during the evaluation.

It is helpful to indicate that several meetings with the child are normally required when accepting the referral. The clinician should initially be ready to teach the child tools necessary for a psychodynamic evaluation; for example, pretend play and drawing tasks. In effect, the assessment is a functional protocol looking at the child’s strengths, learning, and problem-solving styles, and what if any, interfering psychiatric processes are present.

### Differential Diagnosis

Differential diagnoses include mental retardation; pervasive developmental disorder; attention deficit disorder; childhood schizophrenia; and conduct and personality disorders, including immaturity, overdependency, and obsessiveness. Repetitive rocking, swaying, or eyeball pressing and other “blindisms” are also seen in other child psychiatric entities, especially mental retardation and autism. When these behaviors are found among blind children, they should be differentiated from a symptom of other conditions. There are conflicting research data as to the etiology of these behaviors among blind children. [Warren \(1984\)](#) summarized the data and concluded that currently these repetitive behaviors constitute compensatory self-stimulation for the child in the absence of visual stimulation. [Brown \(1997\)](#) compared a group of congenitally blind children with IQ over 70 to a matched group of sighted children, and found that the blind children exhibited more autistic-like features. A group of blind children with IQ below 70 and a matched group of autistic children shared many clinical features. [Brambring and Troster \(1992\)](#) looked at a stability of stereotyped behaviors in both infants and preschool blind children over 1 year using questionnaires to the parents. Children were divided into two groups, those under 24 months of age and those over. It is noted that the age of onset and frequency of the behaviors influenced the stability of the behaviors. More frequent behaviors and later age of onset increased the probability of the behaviors remaining in the child’s repertoire; however, the brief follow-up period was limited only to preschool age.

Blind youngsters may not acquire factual information or develop learning skills without educational opportunities. Early social interaction may have been muted for blind youngsters, and care should be taken in assessing diminished interpersonal affective responses as indicating clinical psychiatric conditions. Superficial symptoms suggesting autism in a blind child often abate when meaningful personal interaction is offered. For reasons of convenience and safety, many parents and caretakers tend to provide unchanging sequences of activity to their children. An insistence on sameness or a severe negative reaction to a change in patterns and activities may be a nonpathologic adaptation to visual impairment and past learning.

### Treatment

Early intervention programs with blind infants and preschoolers teach social skills and promote attainment of developmental milestones while supporting the family structure, thereby preventing psychiatric problem. Providing a means of communication and socialization is the first consideration for preventing most conflicts. The blind child learns to speak in the usual manner, but the meaning of words that the youngster cannot experience is difficult to convey and may cause frustration. Color and the contours of large objects or very small ones are most difficult to describe. Checking self-appearance for neatness and simple rules of social behavior, such as chewing with lips closed, cannot be learned by imitation and must be demonstrated. Alternate strategies of adaptation to an invisible, barely discernible or at best blurred world must be taught so as to avoid confrontation, tantrums, and shame. A psychiatrist treating a blind child or adolescent may be involved in consultation and serve as a liaison to provide advice on management to parents, family, and the school. The examiner’s familiarity with specific technologies to help the visually impaired may be useful in guiding the family and school to meet the child or adolescent’s developmental needs. Computerized magnification, Braille computer, and other literacy devices have been increasingly available to school age children. Current advances in Global Positioning System via satellites and its application to cane technology have helped increase safe mobility, autonomy, and self-esteem. These new technologies have alleviated concerns and reassured parents and facilitated skill development. Behavior modification has been useful for both deaf and blind children. Changing specific behavior in order to gain acceptance is successful for motivated children. Sharing experiences, feelings, and problems in group therapy and counseling can be very helpful. [Erin and coworkers \(1991b\)](#) have provided a

helpful review of literature regarding teaching social skills to the blind and visually impaired. They emphasize the value of social skills for a visually impaired child to be successful in mainstream programs. Studies strongly support success in teaching social skills using different approaches. There is the interesting question of whether the goal of social skills training should be to teach the blind behaviors of the sighted or rather than other skills more appropriate to the blind. Individual psychotherapy can be invaluable for a visually impaired child or adolescent. The therapist must constantly be alert to the possibility of confusion in the use of language. Although blind individuals cannot follow a description of color, they do use many vision-related idioms, such as "I see" for "I understand."

Medications can be employed with the same criteria as for nonhandicapped children and adolescents. Medications with the potential of interfering with residual vision should be avoided especially when some vision remains. Use of psychoactive medication among the visually impaired for symptom relief should be used cautiously. Stimulant medications can be used for attention deficit disorder, giving both child and caregiver an opportunity for better communication, education, and other interactions. Even more than in the nonperceptually impaired, psychopharmacologic intervention should be used judiciously as an adjunct in addition to other psychosocial interventions.

### Outcome Study

The Vancouver, British Columbia group led by Jan and Freeman studied a group of 92 legally blind children during 1973 to 1974. Freeman reevaluated the cohort in 1987 to 1988. The information from the first evaluation compared to follow-up resulted in varying outcomes, with many of the subjects defying negative predictions. On reevaluation of 75% of the original subjects 14 years later, there was deterioration of vision among 29% of the partially sighted, which created a higher rate of psychiatric disorder (68.7%) than with those with stable vision. The presence of hard neurologic signs without mental retardation was a nonpredictor of psychiatric outcome. The authors found the original narrative to be more helpful than the early IQ numbers themselves. About half of the cohort had romantic relationships, about a fifth with sighted partners. An alarming number, especially women, reported sexual molestation or abuse. Of particular note was that stereotyped mannerisms had almost disappeared. Several participants revealed that they perform the mannerisms at home and alone but understand that they are socially unacceptable and control them in public. They remembered their mainstreaming school experiences as being very difficult, with 73% being teased in a mean way. Most (73%) traveled independently and only three used dogs, but 40% reported having been hit by a car. For partially sighted persons, there was a strong tendency to avoid the negative stereotype of blindness and try to "pass." They also found deplorable levels of unemployment among the subjects who were qualified for competitive jobs ( [Freeman et al., 1991](#)).

### Research Directions

A central issue at this time is the future direction of education for blind children. The passage of Public Law (PL) 99-457 has provided educational services for impaired children, including infants, along with encouraging educational integration of blind with sighted children. An increasing number of blind children are currently mainstreamed. There has been a long-standing concern that the development of social skills among visually impaired children is delayed in a segregated school for the blind. It is believed that these skills are better developed in an integrated environment as preparation for adult roles in the sighted world. Conversely, with the push for mainstreaming, literacy in Braille has declined. There is a controversy between mainstreaming to improve social skills versus specialized schools to increase learning and literacy skills. The outcome of using the new technologies in both settings is an open question. Consulting child psychiatrists as the child and family advocate must remind school boards about the broad heterogeneity of the blind pediatric population, to forestall decisions based on monolithic assumptions about the visually impaired, which may overlook the best interest of each child. There is great need for reconciling clinical definitions and therefore statistical studies worldwide if an impact is to be made in improving outcomes.

---

#### CASE ILLUSTRATION

Lucy is a 14-year-old blind girl, who lost her vision at the age of 1 year following bilateral enucleation for retinoblastoma. She was referred for uncontrollable outbursts of crying, screaming, and striking out wildly at people. She was diagnosed with borderline personality and started on neuroleptic medications in fairly substantial doses. Both of her parents were professionals with graduate degrees.

Lucy's early developmental milestones were within normal limits, and as an infant was easy to care for. Following her surgery and numerous prolonged hospitalizations, her development was delayed and she was remembered as a very "whiny" crying child, clinging to her mother. Her family situation included several geographic moves. A sister was born when Lucy was 4 years old. Lucy had been enrolled in a special program and later in a school for the blind. She used a Braille typewriter skillfully. She did well academically, and was described as clinging to her mother, who was described by teacher reports as "too protective and enmeshed." She had no friends or social skills in school and was described as shy and slow to warm up. Several school changes, resulting from family relocations, disrupted her education and friendships. Her parents' marital strains had increased several years prior to Lucy's referral.

On psychiatric examination, Lucy had difficulty separating from her mother, but came into the consulting room alone. She sat with her head down and her right ear turned toward the examiner as she gently swayed back and forth. Her speech was clear and vocabulary age-appropriate, although she spoke loudly with a broadcasting style. Her concepts were immature, and she repeatedly wanted reassurance that her mother would take care of her and would not leave her. She then described how her father would hit her on the head when she made a mistake, bumped into something, or knocked something over, calling her "dumb." She then said, "I couldn't see him when he hit me. I never knew which way he was hitting me from. I couldn't protect myself or get out of the way."

The parents decided to separate following a trial of family therapy. Lucy entered supportive psychotherapy, and medications were reduced. A behavior management program was introduced to increase her independence.

---

## DEAF-BLINDNESS

All that has been said in the introductory sections under the heading of general considerations and role of the child and adolescent psychiatrist is even more pertinent in the case of deaf-blindness and should be referred to. In particular, the effects of a handicapped child on family dynamics are exponential in a dually impaired child or adolescent.

### Definition

Deaf-blindness is defined in PL 94-142 as

concomitant hearing and visual impairments, the combination of which causes such severe communication and other developmental and educational problems that they cannot be accommodated in a special program solely for the deaf or blind child.

The definition is educational and does not focus on specific clinical measures. It implies that the two concomitant impairments generate specialized educational needs in combination. As with auditory or visual impairments, the child might be classified as deaf-blind while still retaining some usable residual hearing and/or vision sufficient to permit education, self-sufficiency, and support or independent living in some cases. The term "deaf-blind," although professionally widely used, might not accurately convey the individual client's circumstances. The imprecision in definition highlights the very nature of the clinical work, when the clinician's cumulative experience and knowledge is called to bear on a unique child or adolescent and his or her specific circumstances and needs. As indicated earlier in the chapter, the words "deaf" and "blind" have strong connotations and the combination can be overwhelming. Familiarity with resources and supports for sensory impaired children and their families is essential.

The data from the 1990 survey of the U.S. Department of Education reported 7,297 deaf-blind children enrolled in educational programs under various assistance programs. Children receiving no services or those remaining at home or institutionalized were excluded. One difficulty in gathering accurate numbers is that many jurisdictions classify the deaf-blind as multihandicapped. The University of Arkansas Rehabilitation group's work suggests that the mean expectation is 9,805, based on statistical data. The report shows problems in definition, identification of cases, and demographic issues (Watson and Taff-Watson, 1993). Although the total numbers are relatively small, the number of dual sensory impaired children will rise with the increasing number of children born into poverty, improved neonatal intensive care unit success with very low birth weight infants, and the increasing number of high-risk pregnancies. In addition, changing social and sexual mores, increased incidences of sexually transmitted neonatal diseases, and congenital infections with the herpes simplex and cytomegalovirus are contributors to increased risks for sensory impairment.

The literature on deaf-blindness is limited. Workers in the field of deafness view the deaf-blind child as being deaf with an associated visual problem and vice versa for visual impairments ( [Warren, 1984](#) ). Few centers are equipped to provide the comprehensive assessment that a deaf-blind child requires. The psychiatric evaluation has three potential pitfalls: failure to recognize visual or auditory impairment when evaluating a child who is known to be either deaf or blind, but ascribing the behavioral difficulties to a clinical psychiatric illness, most commonly mental retardation or autism; diagnosing a child as deaf-blind when only one sensory impairment exists concurrently with a major clinical psychiatric syndrome; and diagnosing mental retardation, schizophrenia, autism, or organic brain syndrome in a deaf-blind child, based on an unusual presentation, without being fully aware of the child's potential strengths or problem-solving and adaptive abilities. Tragically, many deaf-blind children have spent years or a lifetime in custodial institutions, based on inaccurate diagnosis. The age of onset of deaf-blindness is a crucial

consideration (other factors, such as intelligence, degree of sensory loss, and associated impairments being equal).

Estimates of independent function for deaf-blind individuals vary and depend on the degree of residual vision and hearing available to the individual. Fortunately, the historical evolution in societal attitudes has changed from warehousing in large public institutions to actively seeking placements with habilitation services if they cannot be maintained at home. Home support services with respite care are a desirable option for many families ( [Gonzales and Fontana, 1998](#)). A large public investment in programs has failed to perform longitudinal follow-up of the efficacy of various programs, and thus predictions and prognoses are uncertain (Watson, 1993). [Bjorling \(1981\)](#) summarizes the findings to estimate that probably no more than 3% to 5% of deaf-blind individuals are considered to function independently, and the vast majority of this small group comes from adventitiously impaired groups. There have been strong advocates for early infant intervention programs and these have been enacted in law. The uniqueness of the dual sensory impairment requires a systematic conceptual approach in evaluating the acquisition of various skills in a developmental sequence specific to the child.

## Etiology

Etiologies, especially of adventitious onset, include trauma, infections, diabetes, tumors, and injudicious use of antibiotic medications (aminoglycosides). Congenital conditions, including maternal rubella and cytomegalovirus infection, are causes of multiple sensory impairment. Usher syndrome is congenital deafness with progressive visual impairment of varying degrees secondary to retinitis pigmentosa, the latter starting usually during adolescence. The incidence is approximately three per 10,000 in the general population but is reported to be between 3% and 6% of the congenitally deaf population ( [Hicks and Hicks, 1981](#)). The etiology of a case of deaf-blindness influences the incidence of associated handicapping conditions. Further, the degree of sensory loss is quite variable and influences outcome. Congenital rubella has a 50% to 71% reported rate of associated neurologic complications among deaf-blind children with a high incidence of mental retardation. [Stein and associates \(1982\)](#) reported a high frequency of abnormal head size (40%), neuromuscular disorders (40%), and abnormal electroencephalogram (55%). It was remarkable that in their population of 141 "deaf-blind" children referred to their statewide research institute for special evaluation, 38 (27%) proved to have normal or near-normal hearing, and one had normal vision. This high degree of misdiagnosis is alarming because the combination of dual sensory impairment results in a profoundly different environment for the child's development. Language and general information development have been reported to be significantly below expectations for 75% of these children.

## Psychopathology

Difficult as it is for a hearing parent of a deaf child to communicate, teach social skills, and impart learning, it is even more demanding with a deaf-blind child. It is not only the addition of blindness that adds to the difficulty, but also that the environmental experience of the dynamic neurologic processes are as yet not fully understood. Techniques for teaching age-appropriate rules of society and imparting knowledge to a blind child assume common conceptualizations about the environment and society between teacher and child. A formal evaluation of adaptive behaviors and functional activities and strengths is helpful in order to formulate recommendations. Psychiatric evaluation of multiply handicapped children reveals a direct correlation between the number of impairments and the incidence of clinical psychiatric syndromes, including autism and organic brain syndromes, with an increase in mental retardation associated with dual sensory loss ( [Chess et al., 1971](#)). [Smithdas \(1980\)](#) and [Yoken \(1979\)](#) have reviewed personal experiences of deaf-blind children who experienced the world as "shrinking in space" and the isolation, dependence, anger, and societal rejection. There are often reactive feelings of anxiety, even progressive isolation, mourning the loss of function and changing self-image.

## Psychiatric Evaluation of a Deaf-Blind Child or Adolescent

When a clinician is asked to evaluate a hearing or visually impaired child, one should always consider that dual impairment could mislead the examiner. Conversely, the clinician might encounter a child who is diagnosed as deaf-blind and might be deaf-autistic, blind-autistic, or sensory impaired and mentally retarded. The diagnostic process is a collaborative team effort with psychologists, educators, and habilitation and rehabilitation specialists. Techniques for eliciting information, especially physical contact, lighting, and realistic props for toys, are all similar to those described for blind children. Evaluation requires time, patience, and the use of an interpreter if a system of manual sign language has been developed. [Wheeler and Griffin \(1997\)](#) examined a movement-based approach to development of language that assists deaf-blind children learn complex concepts by emphasizing gestures.

## Differential Diagnosis

The common differential psychiatric diagnoses in deaf-blind individuals include mental retardation, childhood autism, childhood schizophrenia, organic brain syndrome, and reactive behavior disorder. One of the sensory impairments may be missed when a diagnosis of schizophrenia or autism already has been made. The converse might also occur if the clinician attributes behavior to the sensory impairments. Ritualistic acts are common in severe or profound mental retardation as well as in childhood autism, and both rigidity of behavior and perseveration may characterize deafness or blindness, as well as mental retardation or autism. Normal deaf-blind individuals easily stop the rituals if offered human contact.

## Treatment

Data on treatment of deaf-blind individuals with reactive or more serious psychopathology are woefully lacking. Behavior therapy, psychotherapy, and counseling may each be useful. The use of medication that could affect residual hearing or diminish visual perception should be avoided, but can be useful for symptomatic treatment to assist in daily living.

## Outcome and Follow-up Data

The remarkable achievement of Helen Keller is instructive and inspiring but is not a good model because she acquired a language foundation of both sight and sound prior to the onset of her impairments. Some individuals who are deaf and blind fulfill their potential and lead competent lives. Deaf-blind youngsters who are aging out of the educational system lack appropriate supportive services, including housing. There has been a shift in focus for adolescents to establish greater independence rather than an abrupt transfer to adult rehabilitation facilities when they reach 21. The Arkansas Center's Model Program is one of a number of reports in the literature and is a helpful place for the clinician to review developments in community-based approaches to service delivery (Watson and Taff-Watson, 1993).

## Research Directions

Alternative treatments, and the role of spirituality and its contribution to outcome are areas needing further studies. Recent advances in the basic neuroscience, cognition, and its applicability in understanding learning processes in the deaf-blind continue to be a frontier of research, as are relational studies, including movement-based communication. In general, there needs to be greater awareness about the burden of impairment in order to support sensory-impaired children and families in their communities.

---

### CASE ILLUSTRATION

David is a deaf-blind 18-year-old youth referred for neuroleptic medication and "sedation" by the residence where he lived. He is profoundly hearing impaired and legally blind, and he understands simplified and exaggerated sign language. He is unable to use finger spelling and has a usable vocabulary of approximately 50 formal signs. The resident staff is concerned that when upset he swings his arms and bangs chairs on the floor. The etiology of his impairments is possible congenital rubella. Early in life, he suffered physical abuse from his mother and was subsequently placed in an institution for the mentally retarded at age 4.

Mental status examination revealed David to be a very large, neatly dressed African-American male. He frequently jumps from his chair pantomiming his responses. He rapidly moves his arms in excited gestures as he expresses himself with affect-laden signs and pantomime. Yet, when his meaning is comprehended, David immediately sits down in his chair, satisfied that he has communicated. His use of language is restricted and, at times, perseverative, but his response to limit setting is appropriate. He is alert, and no hallucinations or signing into space were observed. He picks up the furniture and bangs the floor and then returns it to the same position. There are periods when he becomes agitated, goes to his room, and "bangs around" a little.

The resident staff responds to the consultant's interpretation of the communicative nature of David's behavior and how he has never crossed the line to violence while responding to firm limit setting. The staff acknowledges that he intimidates people because of the difficulty in communicating with him, as well as his size and race. They agreed to record his baseline behaviors if they initiate a full course of medications and try to correlate his behavior with precipitating events over a 3-month period. They accepted a plan to initiate medication and record what initiated his tantrum, with neuroleptics if needed. On follow-up, David was successfully maintained in his residence for 4 years without any untoward events, and only on three occasions was he given a single dose of medication.

A popular German children's book written in 1863 by Heinrich Hoffman, entitled *Strüwel Peter*, colorfully described the characteristics of attention deficit hyperactivity disorder (ADHD). In the English translation, one verse reads:

Phil stop acting like a worm  
The table is no place to squirm  
Thus speaks the father to his son  
Severely say it, not in fun.  
Mother frowns and looks around  
Although she does not make a sound.  
But Phillip will not take advice  
He'll have his way at any price.  
He turns and churns  
He wriggles and jiggles  
Here and there on the chair.  
Phil these twists I cannot bear.

Phil's antics would not describe children who have attention deficit hyperactivity disorder (ADHD) inattentive subtype. For these children the refrain might go something like this:

Jane was dreaming, looked spaced out  
Which made her teacher want to shout  
Pay attention, start right now.  
Keep your mind on task somehow.  
You knew your spelling words last night  
And yet today there are none right.  
Your attention flits to every sound.  
Homework lost and never found.  
Your books are always out of place.  
Jane, these are problems you must face.

Phil and Jane's difficulties are seen in normal children at times, but in those who have the disorder, they are more severe and enduring, more pervasive, and are not a reaction to an immediate stressful event.

This syndrome has captured the interest of researchers and clinicians for four decades. It is now the most intensively studied syndrome in child psychiatry and possibly the most controversial. For example, between 1957 and 1960, 31 articles were published on hyperactivity in children, whereas since 1996, there have been about 400 articles a year on ADHD. The increase in the rate of publication is continuing and, as a result, it is no longer possible to write a comprehensive chapter on all aspects of the syndrome. This chapter emphasizes an update of key clinical issues and recent research findings.

Children with ADHD-combined type (ADHD-C) have inappropriate restlessness, behavioral and cognitive impulsivity, and difficulty paying attention. These problems are present at home and school and cause the children significant impairment. The children have a hard time controlling their impulses and regulating their activity, attention, and social interactions to a degree consistent with relevant age and cultural norms. This leads to their being frequently in trouble with adults and unpopular with peers. They underachieve at school (or do not achieve at the level expected for their intelligence), and most have learning difficulties—owing, mostly, to poor attention and organization, and impulsive cognitive styles. In addition, some have specific learning disabilities, such as reading disorders. Children with ADHD may also have other disruptive behavior disorders, such as conduct disorder or oppositional defiant disorder, which further compound their impairment.

Children with ADHD-inattentive type (ADHD-IA) are those who meet DSM-IV diagnostic criteria for inattention but who fail to meet criteria for hyperactivity-impulsivity. The children have difficulty with many aspects of attention such as focusing, sustaining attention, and organization. In class, they have difficulty getting started on a task, sustaining attention to that task and completing the task unless their teacher supervises them. Their work is often messy and poorly organized, and assignments are not handed in. As a result, they underachieve for their intelligence. They may seem to lack motivation, perhaps because their past attempts at success have always failed.

Children who have ADHD-hyperactive impulsive type (ADHD-HI) do not meet the diagnostic threshold for symptoms of inattention. Because these children are often younger when they present (Lahey et al., 1994), it is not yet clear if this is because they are not yet being asked to function in a classroom setting. Similarly, children with ADHD-IA often present at a slightly older age, and this may be because they have simply outgrown hyperactivity from their younger years.

## HISTORICAL NOTE

### Identification of the Syndrome

One hundred years ago, the British pediatrician [George Still \(1902\)](#) described a group of 20 children who had problems very similar to those we now diagnose as having ADHD combined type along with conduct disorder. He wrote that the children had “a defect of moral control,” which he defined as the control of activity in conformity with moral consciousness. The children lacked inhibitory control and required immediate gratification without regard to others. They were described as restless and impulsive, and had attention problems, as well as intense affect. They were dishonest, destructive, broke the law, and were cruel. Many had specific learning disorders and physical anomalies. Still believed environmental as well as organic factors were causal. This was the first published paper to identify a disorder of impulse control and inattention as a syndrome or disorder in itself, not necessarily as a result of brain injury or retardation.

Still considered whether a lack of inhibitory control or attention problems was the primary difficulty of the disorder. He concluded that poor attention was primary because it did not allow children to hold onto a course of action, thus putting them at the whim of stimuli promising immediate gratification.

It is interesting to observe that the controversies first raised by Still continue to be actively debated. Still moved difficulty with “attention” and “impulsivity” from the moral and religious sphere (laziness, badness) into a medical paradigm. The public continues to question whether or not this is appropriate because they fear that normal human struggles with laziness and disobedience will be dealt with as diseases and treated with drugs rather than discipline. Still described the syndrome with great clinical acumen. However, as noted in the discussion of the subtypes, we continue to debate what symptoms belong to the disorder, what symptoms are associated features, and what symptoms truly belong to comorbid conditions such as conduct disorder (CD). Still described a broad group of children, many of whom would be considered in today's diagnostic nomenclature to be comorbid. The extent to which problems with conduct, mood, or sleep represent associated features of the disorder or comorbid conditions is an active area of research. Finally, Still asked the question as to what is “the core deficit.” This more theoretical approach to questions about the disorder has currently been the source of much heuristic discussion and psychological experimentation ( [Barkley, 1997](#)).

There was a significant historical shift in our understanding of these children during the early 1920s. At that time, the syndrome began to be viewed as organic in origin. This was owing, in part, to the influenza pandemic following World War I and the epidemic of encephalitis lethargica that occurred as a result. Children who survived frequently developed a severe behavior disorder ( [Hohman, 1922](#)), similar to that described by Still, and were described as being “organically driven” ( [Kahn and Cohen, 1934](#)). [Lewin \(1938\)](#) in Great Britain, was also influential in that he described a link between severe brain damage and restlessness in retarded children and adults, as well as a similar correlation in laboratory animal studies. Finally, in the United States, [Strauss and Lehtinen \(1947\)](#) emphasized the organic etiology hypothesis; they described retarded children who had hyperactivity, distractibility, impulsiveness, perseveration, and cognitive defects. Strauss considered these retarded children to be brain damaged even when the latter could not be demonstrated. Strauss termed these children as having “minimal brain damage syndrome.”

Some clinicians at the time recognized the circular reasoning that this implied and suggested that a child should not be labeled as brain damaged solely because of his or her behavior, unless the damage was demonstrated. In an attempt to compromise between the idea that some disorder appeared to be present in the brains of these children, and the idea that there was a purely environmental etiology, [Clements and Peters \(1962\)](#) coined the term minimal brain dysfunction (MBD). The term achieved widespread popularity and was endorsed, but with a warning, by MacKeith at the conclusion of an international conference held in Oxford in 1962. In an article entitled “Minimal Brain Damage: A Concept Discarded,” [MacKeith \(1963\)](#) warned that the new terminology of MBD, although an improvement over the older one, included a heterogeneous group of children who would have to be subclassified in the future. Nevertheless, the term MBD was held onto tenaciously in spite of criticisms of overinclusiveness.

### Development of Formal Diagnostic Criteria

Efforts to create a more scientifically valid and reliable classification began with the International Classification of Diseases-9 (ICD) ( [World Health Organization, 1965](#)) and the DSM-II ( [American Psychiatric Association, 1968](#)), when the terminology was changed to hyperkinetic syndrome of childhood. The term hyperkinetic disorder is still in use in the United Kingdom, and retarded and/or brain-damaged children are included in the diagnosis in ICD-10. However, if conduct disorder and a hyperkinetic disorder co-occur, the term hyperkinetic conduct disorder is used. Differences in diagnostic criteria between the two countries have made comparisons of research more difficult.

The work of [Douglas \(1983\)](#) was influential in distinguishing specific learning disabilities from the core problems of ADHD, which had traditionally been an integral part of the diagnosis of MBD. Furthermore, she postulated that the basic deficit of the disorder lay not in hyperactivity, but in a failure to regulate attention, arousal, and inhibitory control, deficits that she felt were more fundamental to the disorder than restlessness. The DSM-III ( [American Psychiatric Association, 1980](#)) recognized this emerging opinion and renamed the disorder attention deficit disorder with hyperactivity (ADHD) or without hyperactivity (ADD).

DSM-III ( [American Psychiatric Association, 1980](#)) represented an advance in that a task force was created consisting of a group of experts who were committed to using available research data as the basis for changes in diagnostic criteria. Three core constituents of the disorder were described, namely inattention, impulsivity, and hyperactivity. Five or six symptoms were listed under these three headings and more than two or three symptoms in each area were arbitrarily designated as the diagnostic cutoff point. ADHD required that all three constituents were present, whereas ADD required that only inattention and impulsivity were present. The requirement of impulsivity distinguished ADD from ADHD-IA type, so that these two diagnoses are not identical. Again, this makes it difficult to compare studies done on ADD without hyperactivity and ADHD-IA. In the years following the publication and use of DSM-III, interest began to be focused once more on the lack of inhibitory control as the cardinal difficulty of these children ( [Barkley, 1994](#); [Quay, 1988](#)). Factor analytic studies of parent and teacher rating scales indicated that impulsivity correlated highly with hyperactivity, and in DSM-IV these symptom clusters form a single dimension.

The distinction between the three core problems of the syndrome was short-lived, and DSM-III-R ( [American Psychiatric Association, 1987](#)) changed the terminology to attention-deficit hyperactivity disorder (once again making restlessness more primary to the disorder) ( [Porrino et al., 1983](#)) and ADD—without hyperactivity—was omitted. DSM-III-R listed 14 symptoms, of which eight were required for a diagnosis.

In DSM-IV ( [American Psychiatric Association, 1994](#)) the terminology remains the same, ADHD, and the disorder is once again described under the category of disruptive behavior disorders ( [Table 52.1](#)). In this classification, however, a patient would obtain the diagnosis of ADHD-IA type by scoring on six out of nine items related to inattention (that have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental norms), or ADHD-HI type by scoring on six out of nine items related to hyperactivity/impulsivity. A patient is said to have ADHD-C when he or she scores above the cutoff on both the inattentive and hyperactive-impulsive items.

**Table 52.1. Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder**

This new system of classification has had a profound influence on practice in the last 5 years. This change in the definition of ADHD has led to an increase in prevalence, a broadening of the disorder to include more girls, preschoolers, and adults, influencing patterns of comorbidity, impacting on educational practices and

various forms of treatment. The use of the DSM-IV diagnostic system increased the prevalence of ADHD by more than 50% (Wolraich et al., 1996), which, in turn, contributed to a large increase in the use of stimulant medication. The specifics of these changes and how they are reflected in each of the three ADHD subtypes are reviewed in greater detail in the following.

From an historic point of view, it is interesting to observe how the DSM-IV classification scheme ( [American Psychiatric Association, 1994](#)) reflects the latest chapter in those issues first raised by [Still \(1902\)](#). DSM-IV suggests that both inattention and disinhibition may be important in ADHD but reflect different subtypes. The subtypes may also represent a compromise between the trend to make the disorder quite specific, and a need to extend diagnostic criteria to include a wider number of individuals who are impaired and suffer from various of the associated features of ADHD.

The DSM-IV diagnostic criteria are also unique in the stringent methodology of the field trials ( [Frick et al., 1994](#); [Lahey et al., 1994](#)), in which 380 children from 10 sites were evaluated systematically. The field trials confirmed the hyperactive and impulsive symptoms as one factor or dimension, and that individuals who mainly suffered from inattention were nonetheless impaired. All of these changes reflected the growing concerns of the academic community of researchers from a variety of disciplines and the subsequent emphasis on measurement and more rigorous methodology that has characterized the past 5 years.

### History of Treatment Studies

In 1937, Bradley discovered that Bensedrine (*α*- and *β*-amphetamine) resulted in marked improvement in a group of children who were inpatients at the Emma Pendleton Bradley Residential Treatment Center, many of whom had behavior problems. Treatment with this stimulant resulted in reduced restlessness, and better concentration and motivation. It was 30 years later that [Conners and coworkers \(1967\)](#) used dextroamphetamine in a double-blind study to treat a group of inpatient adolescents with behavior problems. Eisenberg helped to establish the placebo-controlled, double-blind clinical trial as the gold standard to test pharmacotherapy treatment for children. With the help of newly standardized rating scales, particularly by [Conners \(1969\)](#), study after study confirmed the effectiveness of stimulant treatment. From 1965 until 1995, over 350 clinical trials were conducted with as many as 3,000 children, demonstrating unequivocally the short and intermediate term effectiveness as well as the safety of stimulant treatment for ADHD ([Spencer et al., 1996](#)).

Empiric studies of treatment have branched into three new directions since 1996.

1. Studies looking at younger, older, and comorbid populations
2. Studies of new stimulant treatments, and other types of medications
3. Studies looking at multimodal treatment versus treatment with stimulant alone. This has been the subject of the most expensive clinical trial ever conducted by the NIMH, the Multi-modal Treatment Assessment project, described more fully in the following ([Arnold et al., 1997](#); [Greenhill et al., 1996](#); [Hinshaw et al., 1997](#)).

These new research directions have resulted in the major developments in our knowledge of ADHD that are summarized in this chapter.

In summary, a chapter on ADHD in 2001 looks at an area that has become highly publicized and researched and that is the subject of controversy. The areas of debate today are not too dissimilar from those marking the inception of the disorder. ADHD is now a complaint very much in the public awareness, with an industry of books, magazines, Websites, and support groups behind it. It is a disorder that has recently been the subject of a major National Institute of Health Consensus Conference ([http://odp.od.nih.gov/consensus/cons110110\\_intro.htm](http://odp.od.nih.gov/consensus/cons110110_intro.htm)).

Practice guidelines for treatment have been developed based on current practice and research. Despite all of these efforts by the scientific community, a sizable proportion of treatment in use is still based on alternative therapies that have not been subject to empiric study or any other type of external control. In this context, the present chapter represents an attempt to place these new developments into a historic context, and to provide both a clinical and research guide to practice.

## CLINICAL DESCRIPTION OF THE DISORDER

### Attention Difficulties

Children with ADHD-inattentive type (ADHD-IA) are mainly impaired in school. Although they may have some difficulty with social and family relationships, the presenting problem typically is academic underachievement. Teachers complain about these children being chronically late, forgetful, disorganized, losing things, daydreaming, off task, unable to finish their work, and procrastinating.

Attention is a clinical construct that has been used to embrace a wide range of difficulties that may overlap. These include difficulties getting on task, staying on task, and finishing things. Attention problems may also include being “scatterbrained,” “spaced out,” or “not listening.” They may also include problems with motivation, variability in performance, and difficulties with understanding sequenced commands or following instructions.

With such a broad sweep of clinical presentations, it is not surprising that attention has not been successfully captured by any single psychological or electronic test. It is also notable to observe the difference between the meaning of “attention” as used by professionals, and the meaning of “attention” as used in common parlance. Parents may come into the clinic stating that their child “pays excellent attention; they play video games for hours.” For the clinician, a child who is stuck on attention relieving activities such as playing video games, using construction sets, or watching television may be the very child who has an attention deficit.

At the present time, attention is most often measured by obtaining a four-point rating (ranging from “never” to “very often”) of the nine DSM-IV items chosen to operationalize the concept. These nine items are *sensitive* to attention deficits, but they are by no means a comprehensive account of these deficits. Further, we do not know the extent to which the nine symptoms of inattention defined by DSM-IV are *specific* to attention disorders. The functions associated with “attention” or executive function represent some of the most sophisticated pathways in the brain, and also perhaps those most vulnerable to injury. We know that most serious psychiatric disorders are associated with problems with attention, executive function, and concentration. We know further that for many of these disorders, attention symptoms are the first to be evident and the last to return to health. Therefore, it is important to characterize what (if any) items used to define attention deficits are specific to ADHD.

### Hyperactivity

[Rutter and associates \(1982\)](#) pointed out that hyperactivity is not a unitary dimension and that the fidgety child is different from the child who is always on the go. Furthermore, the restlessness of the hyperactive child is more than excessive activity, although the latter has been demonstrated to be present during structured in-seat activity ([Barkley et al., 1999](#)), as well as in sleep ([Porrino et al., 1983a,b](#)). Rather, hyperactivity is activity off task, out of seat, and disruptive. The activity is developmentally inappropriate and is not goal directed or purposeful to the task on hand. [Klein and Young \(1979\)](#) hold the view that it is the combination of high activity with high disruptive behavior that distinguishes the ADHD child from the normal child. The difference lies in the quality, as well as in the quantity of activity.

At the first visit of a child to a physician for evaluation of possible ADHD, hyperactivity may not be observed, even when described as severe at home and school. The increase in anxiety, newness of the situation, and amount of adult attention may improve the inhibitory control over activity. However, preschool children are likely to be restless and succeed in messing up the office and appear to be driven, even at the first visit. In older children, the syndrome should not be ruled out simply because restlessness was not observed in the office.

Restlessness can be measured in different ways, such as standardized parent–teacher rating scales, direct observation, and devices that measure activity (actometers). These measures relate to different facets of activity and are unlikely to correlate. More perplexing is the poor correlation between two teachers rating one child, and between parent and teacher ratings. Hyperactivity is clearly situation-dependent varying with the type of activity, interest in the activity, amount of adult attention available, and relationship of adult and child. [Whalen and Henker \(1991\)](#) concluded that the level of hyperactivity was a product of a given child, the situation, and the observer. Furthermore, hyperactivity varies unpredictably in any one child from day to day.

In a preschool study of 3- to 5-year-old children in an experimental nursery, children with ADHD and normal children were rated on hyperactivity by direct observation in structured play and in free play situations. Differences between children with ADHD and normal preschoolers were observed in structured but not free play when all preschoolers were active. Rule-enforced activity was differentiating ([Schleifer et al., 1975](#); [Weiss et al., 1985](#)).

Hyperactivity decreases over the course of development, and frequently children change from being on the go all the time in preschool to being able to sit in a chair fidgeting in elementary school. Hyperactivity may disappear in adolescence, although the adult may "feel restless" even when this is not observed ( [Weiss and Hechtman, 1993](#)).

## Impulsivity

Impulsivity refers to the inability to delay a response despite the anticipation of negative consequences for the behavior. The difficulty in controlling impulses is rated in comparison to others of the same age and gender. The manifestation of this difficulty varies across the life span.

In the preschool years, the following complaints are common:

"He just grabs other kids' toys if he happens to want them. Kids now avoid him."

"On the playground he shoves and pushes other kids if they are in his way: He hits when he is angry."

"He darts across the street if I am not holding his hand. He could have been hit by a car the other day."

"She burned herself on the stove yesterday. I can't believe she'd do it again today but that's what happened."

There is a relative failure to learn from experience. Impulsive preschoolers are at risk for accidents in general and accidental poisoning in particular. They have to be supervised more carefully than others the same age to ensure safety because they are often unaware of danger.

Impulsivity shows itself in behavioral and academic difficulties in elementary school. In the classroom these include interrupting or blurting out answers without waiting to hear the questions and difficulties waiting in line. Impulsive ADHD children are more daring than their peers. Therefore, accidents continue to be more common. Peer relationships are marred by being a poor loser, wanting "his way or no way," having to be the boss or leaving the game, and getting into physical fights if feelings are hurt. Procrastination becomes an increasing problem because responsibility has now increased. Assignments are not completed or handed in; homework may become a daily battle and affect family functioning.

Cognitive impulsivity refers to a cognitive style characterized by short reaction time. Schoolwork is replete with errors, detail is missing, writing is messy, and the answers are written without reading the question carefully.

Many of the preceding difficulties continue in adolescence. In addition, at this age, the risk for adolescent maladaptive behaviors increases, including early drug use, drinking, smoking, and unwanted pregnancies. A higher incidence of reckless driving and car accidents has been documented in adolescents with ADHD. Adolescents are better self-reporters than younger children and complain about losing friends because of impulsive comments or acts.

Insight into the difficulties improves in adulthood. Procrastination is frequently complained about and causes daily minor or major difficulties. Failure to answer phone calls or letters or to do any boring or difficult task is common.

A marriage may be broken without careful thought or a job may be left without other work being available. Reckless or unwise spending may lead to debts. Increased car accidents ([Weiss and Hechtman, 1993](#)) may result in loss of license or injury. Parents with ADHD may lose their temper and physically punish their children when provoked. This can be serious and may result in physical abuse.

Impulsivity across the life span has been considered to be among the most serious aspects of ADHD in causing functional impairment and also among the most difficult to treat.

## Associated Features

Areas of impairment that are not part of the hyperactive, impulsive, or inattentive symptoms listed in DSM-IV and ICD-10 accompany ADHD. These associated features, nonetheless, can cause significant difficulty, or even be the main reason for referral. These associated features fall into behavioral, cognitive, affective, and social dimensions.

### BEHAVIORAL

Children with ADHD function better in one-to-one versus group situations; this causes them great difficulty in peer relations and group situations, such as extracurricular activities, camps, sports, and group play, as well as classroom proceedings. They often respond quite differently to their father and mother, being more responsive to the parent who is less familiar. They do much better in novel versus familiar situations. By the same token, they have difficulty functioning in situations in which consequences are not immediate, consistent, and salient, or situations without adequate supervision. This implies that individuals with ADHD require a great deal more supervision at school and parenting at home, even with appropriate medication. Often this presents a crisis at the beginning of high school, when it is more difficult to provide this type of supervision.

Individuals with ADHD have problems with persistence all through the life cycle. This is more than "not finishing things," and more than difficulty with remaining on task. They describe taking up new projects with much more readiness than they show for persisting with an old project, for example, taking up a new musical instrument before mastering the last. They complain of "losing interest." They also have much more difficulty with situations in which there is delayed gratification, so that they fail to pursue opportunities in which they would have to "hold out" before receiving an anticipated benefit.

Individuals with ADHD show marked variability in performance. This makes academic assessment difficult in childhood. Teachers can neither reliably judge a child's achievement by how they do at their worst (in which case they would never graduate), nor by how they do at their best (because they cannot rely on optimal functioning being consistent). Even as adults, marked variability of performance leads to difficulty in areas of employment that demand consistent output, so that many adults seek self-employment or occupations that reward peak performance. Variability of performance leads to considerable fragility in the patient's sense of self, as well as frustration. Many individuals with ADHD describe that they have friends who are "smarter" than they are and wonder if they are "smart" or "dumb." They see that their skills do not match their performance.

Individuals with ADHD often find themselves clashing with others. They may be insensitive to some of the emotional or social nuances of those around them. On the other hand, they may also be very reactive to mood or tensions around them, escalating those tensions and precipitating crises. Although fewer than half of individuals with ADHD also meet diagnostic criteria for oppositional defiant disorder, many patients with ADHD do have difficulty with rule-governed behavior. Where this may be driven by the symptoms of ADHD itself, it appears that rule resistance is sometimes a characteristic of ADHD in its own right. Finally, the lack of sensitivity to reinforcement, and the lack of awareness of consequences from the past or consequences that may ensue in the future make it difficult for patients with ADHD to engage effectively with others toward a goal.

### COGNITIVE

Psychological ([Seidman et al., 1997](#)) and electronic testing ([Conners, 1985](#)) have not been effective ways to define or measure the cognitive characteristics of ADHD. This is partly because the testing situation itself mitigates the very qualities it intends to measure. The testing situation is structured, novel, uses short and interesting tasks, is carefully supervised, and presents a challenge that serves as an intrinsic motivator. As one mother put it while listening to a sophisticated neuropsychological report on her son in which there were no remarkable findings, "But where is the test that tells me why he comes downstairs an hour late for school, with socks that don't match, and is unaware that there's a problem?"

On the other hand, we are beginning to understand some of the associated cognitive impairments of individuals with ADHD on the clinical and theoretical levels ([Barkley, 1997](#)). Barkley has shown that individuals with ADHD have a decreased sense of time ([Barkley, 1994](#)) and therefore show difficulty in tasks that are time

dependent. This not only impacts on test performance, but also on the emotional development that grows out of connecting past, present, and future. The lack of sense of time may lead these individuals to live exclusively in the present. For example, many adults with ADHD are underinsured because they find it difficult to understand the imperative to spend money now to protect against future events that are not a present reality. A poor sense of time leads to problems with planning, waiting, and playing games.

Patients with ADHD often state that they have superb long-term memory, even for eccentric details, but very poor short-term memory. What they then go on to describe in their examples are often grouped together as difficulties with "working memory." These problems include various areas of difficulty. They may include short-term registration of a list of items, inability to remember and follow instructions, difficulty holding things in their head, and doing mental manipulations of concepts or numbers ([Denckla, 1996](#)). Most interesting and also most difficult to measure is the lack of ability to access information that has been present in the past. These are children who can know something one day, but are unpredictable in their ability to access that body of knowledge at other times. This could be described as difficulty with memory activation, like a light switch with a loose connection that works intermittently.

## EMOTIONAL

Attention deficit hyperactivity disorder is often associated with dysregulation of affect, in addition to the hallmark dysregulation of activity, speech, or activities of daily living. Children with ADHD, and those who live with them even more so, complain of temper outbursts, and mood lability and reactivity. Not only do moods change dramatically and out of tune with environmental stimuli, but also moods are often explosive, intense, and infectious. They begin almost instantaneously, but may disappear as dramatically as they appear, leaving close ones in shock, whereas the impact is unprocessed by the children themselves.

## SOCIAL

Children with ADHD are unpopular with peers ([Pelham and Bender, 1982](#)) and often at odds with siblings, parents, and teachers. Enduring friendships are rare, and may result in social isolation later in life ([Weiss and Hechtman, 1993](#)). Social impairment is complex ([Whalen and Henker, 1992](#)) and can include difficulty understanding what is appropriate, and difficulty with appropriate social performance even when the skill is established ([Barkley, 1998](#)).

Parents may comment that their child is bossy, intrusive, or insensitive to the personal space needs of other people. Children with ADHD find it difficult to cooperate with other children, respect social hierarchies, and follow rules when playing games. As they experience increasing social rejection they may also emulate the negative social teasing they receive, and become verbally or physically aggressive. Children with ADHD have trouble sharing and taking direction from other children, and trouble with impulsive pushing and touching. They may overreact to situations, have trouble with transitions, and be unable to let go of an argument or stay out of trouble between other children. Parents often complain that their child is "attracted like a magnet to other children just like him." They also complain that their child holds onto a rigid sense of justice, needing to "make it fair." The most heartbreaking complaints of a child or parent may be the observation that the child has never been invited for a play date, that invitations were sent for a birthday party and no one came, or that the child spends each recess alone because he is not asked to play.

It is interesting to observe that some of these difficulties are less pronounced in other types of social situations. Children with ADHD often love and may be good with animals that provide the "unconditional love" and companionship they crave. Children with ADHD function better one to one with a calm and patient adult, who is able to minimize excessive stimulation, and tune his responses to the child's needs and level of processing. Sometimes this type of interaction is obtained during time alone with a parent, grandparent, or childcare worker. Children with ADHD also may do better playing with children either younger or older than themselves. Adolescents with ADHD often seek out Internet chat groups, where their difficulties with impulsivity, timing, and hyperactivity are not evident. The therapist may discover that the patient's so-called best friends or boyfriends are virtual relationships. It may be possible to optimize the time that a child with ADHD spends in positive social situations and minimize time spent in rejecting social situations.

The socialization difficulties we have described involve problems with doing what is right, not doing what is wrong, knowing what to do, and then doing what you know. They involve difficulties in modulating all aspects of behavior, and require that the child do so consistently, all at once, and in overstimulating situations. Given this, it is no wonder that social deficits have been described as the "most intervention resistant domain of ADHD" ([Hinshaw, 1992](#)) and have required multimodal and specialized treatment approaches ([Piffner et al., 2000](#)).

## THE ASSESSMENT

### Parental Interview

This is the core of the assessment process, because the diagnosis of ADHD is made on clinical judgment. The child's current difficulties at home, school, and in the community are explored with respect to ADHD and its associated features. The majority of children given this diagnosis have comorbid disorders; these must be investigated because they may simulate ADHD or be true comorbid conditions. A careful history is obtained of the child's physical and emotional development from birth to the present, including the age when presenting difficulties were first seen and how they developed.

Family functioning is important to assess. Have family stresses affected the child? Is there psychosocial adversity or past trauma? What punishments do the parents use? Has the child been abused? The marital relationship is evaluated, and the effect of the child on the marriage and the family is explored. Do the parents agree on parenting issues? A history of psychiatric disorders in the family is obtained particularly with respect to ADHD, conduct disorder, learning disabilities, and depression. Does one of the parents have a disorder (e.g., depression in the mother, alcoholism in the father, or ADHD in either)?

### EVALUATION OF THE CHILD IN THE OFFICE

It is often difficult to confirm the diagnosis by interviewing the child because the child generally behaves normally at the first visit. Children often do not know why they are visiting the doctor and cannot accurately report their difficulties. Certain simple pencil and paper games can often show cognitive impulsivity. The child interview is important to understand how the child views himself or herself and the world and to evaluate comorbidity. Answers to questions such as, "Do you sometimes feel sad or mad?" "What kind of things make you feel this way?" and "Do you worry about things?" may provide windows to the child's inner world. Having the child identify three magic wishes "for things money cannot buy" can elicit unexpected and revealing answers.

### DIRECT OBSERVATION OF THE CHILD IN THE SCHOOL

Parents often request an observation, believing that this is the most accurate part of the assessment. In practice, it is time-consuming and may be inaccurate because of behavior variability. Direct observation is more useful in evaluating medication changes.

### INFORMATION FROM THE SCHOOL

Is the child in an appropriate learning situation? If not, what changes are required? It is important for the child's teacher to complete a DSM-IV rating scale to evaluate ADHD symptoms in the school (where attentional difficulties are best seen) and assess comorbidity. Ideally, the treating physician will follow this up by a telephone call to the child's teacher. Previous and current report cards are helpful in determining the onset of the disorder and present difficulties. Lack of contact between the treating physician and school was noted to be a major difficulty in assessment and treatment of ADHD by the NIMH consensus meeting (<http://odp.od.nih.govconsensus>).

### PSYCHOEDUCATIONAL ASSESSMENT

Evaluation of the child's intelligence and academic achievement is indicated. Often these resources are not available or are scarce. However, a psychoeducational assessment will determine the presence of specific learning disabilities and their nature. This is particularly important for children with the inattentive subtype, who frequently have associated learning disabilities or a language disorder. Inattention can be secondary to these; it can also result from the classroom teaching level being too advanced for children with low IQ or not sufficiently interesting for bright children.

## ELECTROENCEPHALOGRAPH AND NEUROLOGIC EVALUATION

These are indicated if seizures are suspected or if there is a history of head trauma or focal neurologic symptoms or signs or if the history is suggestive of a neurologic disorder.

## MEDICAL EVALUATION

Visual and hearing deficits must be ruled out. The child requires a complete medical history and physical examination. A history of the mother's pregnancy (including smoking and drinking patterns) is important. Impaired sleep is assessed because this may result in ADHD-like symptoms.

## AUXILIARY EVALUATIONS

These are sometimes required for school-age children who come for an ADHD assessment and may include a language assessment when indicated or an occupational therapy assessment to evaluate such problems (among others) as poor fine and gross motor skills when the history suggests impairment in these areas.

## TESTS

Parents frequently ask for a "test" for ADHD and have to be told that this does not exist. Computerized tests of attention (CPT) are not useful in the diagnostic process because of their low specificity and sensitivity ( [Lovejoy and Rasmussen, 1990](#)) and poor correlation with behavior in the classroom ( [Abikoff and Klein, 1992](#)).

Commercial actometers exist that work like a watch, are simple to use, and measure the child's total amount of activity; however, they have limited value. The quantity of activity is not generally the main difficulty; rather, it is in the quality or appropriateness of the activity ( [Pinto and Tryon, 1996](#)).

## RATING SCALES

Ratings scales play an important role in clinical practice, psychoeducation, and research. In clinical practice rating scales provide the clinician with information about a wide range of different symptoms, reported by different observers, in different environments and at varying points in time. The information that is obtained helps the clinician assess the child's symptom severity against well-standardized norms. They facilitate communication of these findings with parents and teachers, and allow measurement of change with treatment.

In research, ratings scales insure common definition of the samples being studied, measurement of efficacy and safety, and permit cross study comparison. Thus, treatment of ADHD has advanced partly as a result of the development of reliable, well validated, normed, sensitive, and specific symptom measures. The use of one of the common measures has become a standard of clinical care, meant to augment (but never replace) the clinical assessment.

Two different types of scales can be employed. Broadband scales assist with the assessment of comorbid symptoms and functioning, whereas narrow band rating scales assist with measurement of symptoms and treatment response of the primary diagnosis. Two of the best-known and commonly used rating scales are the Achenbach ( [Ostrander et al., 2000](#); [Vaughn et al., 2000](#)) or Child Behavior Checklist, and the Conners Rating Scales. A revised and updated version of the Conners Rating Scales was issued in 1999, and a new version of the Achenbach in 2001. Both have recently been revised to be comparable to DSM-IV. Thus, both scales now provide separate ratings of attention and hyperactive/impulsive symptoms. This is going to permit clinicians and researchers to rate improvement on these dimensions separately, and refine the assessment of outcome for ADHD-IA. It is pointless to measure outcome on an ADHD rating scale that emphasizes primarily hyperactive/impulsive symptoms if the child is diagnosed with ADHD-IA.

[Conners and associates \(1999\)](#) developed rating scales that were normed specifically for use with children ( [Conners, 1997](#)), adolescents, and adults ( [Conners, 1994](#)). The scales include up to seven different factors that have been empirically derived and can provide information on anxiety and oppositional symptoms, as well as cognitive, social, and somatic problems. The scale provides an ADHD index, DSM-IV symptom criteria, and a dimensional score for attention, hyperactive-impulsive symptoms, or both. The scales are sensitive (> 90%) and specific (77% to 98%), with correct classification rates of 84% to 96%.

Broadband rating scales often are used in conjunction with more specific symptom rating scales because they serve a different purpose. These scales provide a way of assessing the presence of other disorders, and symptoms in other areas. Therefore, they are useful initially to aid in diagnosis. They are also useful outcome measures in that they allow the clinician to assess how ADHD and non-ADHD symptoms change with treatment, and how changes in symptoms are correlated with actual change in functioning. The Achenbach scale described in the preceding is among the best known rating scale of this type. The Achenbach is a dimensional scale, and it provides severity ratings based on population norms on a variety of empirically derived factors. The Child Symptom Inventories ( [Gadow and Sprafkin, 1980, 1997](#)) group symptoms by DSM-IV diagnostic categories, and have been validated against semistructured interviews ( [Grayson and Carlson, 1991](#)). They are designed for a clinician to obtain a diagnostic screen based on report from the patient, parents, and teachers. There are preschool, child, adolescent, and adult versions available. The outcomes can be read easily without complex scoring procedures ( [Achenbach, 1991](#); [Biederman et al., 1993](#)).

## DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

### Differential Diagnosis

The following summarizes some of the key clinical issues in differential diagnosis:

1. Physical causes of inattention, such as hearing or visual deficits, poor sleep, chronic illness, seizure disorder, and tic disorder
2. Excessive anxiety or depression may be comorbid or may be the main cause of behavioral and attentional difficulties. In the DSM-IV, four out of six listed symptoms for generalized anxiety disorder are similar to ADHD (restlessness, difficulty concentrating, irritability, sleep disturbance). Posttraumatic stress disorder can also simulate ADHD, but in such cases there is a traumatic event that precedes the onset of ADHD symptoms.
3. Specific learning disabilities: Language disorders, other learning disabilities, and borderline IQ can result in secondary attentional problems and in restlessness out of boredom because the child is not able to understand what is being taught. In ADHD-IA comorbid with the preceding problems, the cause of the attentional problems is difficult to determine.
4. Child abuse and/or a chaotic home: Although the existence of a dysfunctional environment does not rule out ADHD, and although the presence of ADHD is a risk factor for abuse because the child is so provocative, the presence of abuse or a chaotic home may result in a behavior disorder that mimics ADHD and oppositional behavior.
5. Oppositional disorder or conduct disorder: Although these may be comorbid with ADHD, they may also simulate ADHD. In teacher and parent ratings, there may be a halo effect onto ADHD symptoms.
6. Bipolar disorder or hypomania: These can be comorbid or simulate ADHD. Distinguishing features may be found in the family history, in earlier onset of ADHD, in the latter's chronic course and the absence of an elevated mood. ADHD and hypomania are both characterized by excessive activity, impulsive behavior, and poor judgment.
7. High level of activity: Some parents do not know what level of activity to expect, particularly in a boy. The toddler age is characterized by high activity and not staying long in one place; this activity may be mistaken for restlessness.

### Comorbidity

Patients are said to be 'comorbid' when they have more than one psychiatric disorder. This is true, whether or not one disorder caused the other or exists independently.

Attention deficit hyperactivity disorder is comorbid in a majority of children, both in clinics and the community ( [Biederman et al., 1991b, 1992b, 1993b, 1996c](#)). Comorbid ADHD is often more treatment resistant, and the child is less able to function than with ADHD on its own. It is also true that treatment of a child with comorbid ADHD often requires treatment of both conditions to be successful.

Comprehensive reviews are available that describe the details of the body of research that has been developed on the clinical presentation and treatment of ADHD comorbid with each of the other major disorders (Brown, 2000a; Pliszka et al., 1999). These include many disorders such as learning disability, central auditory processing, developmental coordination disorder, neurologic disorders, and medical disorders, which are less commonly included in discussions of comorbid psychiatric illness.

#### ATTENTION DEFICIT HYPERACTIVITY AND DISRUPTIVE BEHAVIOR DISORDERS

More than half of children with ADHD also meet the diagnostic criteria for another disruptive behavior disorder. The relationship among ADHD, oppositional defiant disorder (ODD), and conduct disorder (CD) has been the subject of considerable research in the last 5 years (Biederman et al., 1996e). Younger children with CD almost always have ODD and/or ADHD as well (Szatmari et al., 1989); however, only some children with ODD go on to have CD.

Children who have both ADHD and CD tend to have a lower socioeconomic status (Lahey et al., 1988b), higher prevalence of learning problems (McGee et al., 1984), and stronger family history of antisocial behavior (Faraone et al., 1997). Comorbid CD in addition to ADHD worsens the long-term prognosis, and leads to greater antisocial behavior, substance abuse, and aggression in adulthood (Mannuzza and Klein, 2000; Mannuzza et al., 1989; Weiss and Hechtman, 1993). Nonetheless, children with ADHD-CD can respond to stimulants, with a decrease in both ADHD symptoms, as well as a decrease in antisocial behaviors (Klein et al., 1997). Caution is warranted, however. In using stimulants to treat ADHD-CD, the clinician needs to insure that there is indeed comorbid ADHD, that neither the child nor others will sell or abuse the drug, and that the individual child does not suffer a worsening of aggression or CD symptoms when the medication is wearing off. It is also important to insure that parents understand that the prognosis of stimulant treatment of ADHD-CD is more guarded, especially for the CD symptoms, than the treatment of ADHD alone. This is particularly problematic when there is also substance use or abuse.

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND DEPRESSION

Attention deficit hyperactivity disorder and depression-major depressive disorder (MDD) is common, both in children presenting for ADHD and in children presenting to the clinic for depression. There is a referral bias, so that there is a higher prevalence of ADHD-MDD in clinics than in the community. In addition to referral bias, this difference may also reflect differences in diagnostic practices in community and tertiary centers. Rates of diagnosis of depression in ADHD children vary markedly depending on whether the assessment is based on interview of the child, interview of the parent, a combination of both, rating scales, semistructured interviews, or clinical impression. Clinicians may dismiss depressive symptoms as “demoralization,” insisting that the child is reacting appropriately to rejection. They may also be reluctant to identify symptoms such as insomnia, irritability, mood lability, suicidal threats uttered in anger, decreased appetite, and poor concentration as evidence of depression, because many of these symptoms also can be understood as associated features of ADHD. There continues to be a lack of agreement regarding these issues and how they should be managed. As a result MDD is said to be present in anywhere from % to 75% of children with ADHD (Biederman et al., 1991b). Using a strict DSM-IV definition of depression and very rigorous diagnostic assessment, 6% of the children in the MTA study met criteria for a major depressive disorder (Pliszka, 2000).

Despite these caveats, there are children who have longstanding ADHD and also develop depressed mood of at least several hours duration on a daily basis and for at least 2 weeks. At times when such children also suffer psychomotor retardation, they may become lethargic and quiet, so that paradoxically when the depression lifts and they “bounce back” (literally), their teacher may describe their behavior in the classroom as worse. Children with ADHD-MDD may be tired, their attention may be even worse than their baseline, and they may have “given up.” Although it is not uncommon to see the emergence of such depression during developmental transitions, they cannot be dismissed as situational. In working with ADHD children who also become depressed, one becomes impressed with just how resilient many ADHD children are despite the difficulties they face every day.

Familial studies (Biederman et al., 1992a,b) found elevated rates of depression in both the first-degree relatives of children with ADHD and the first-degree relatives of children with ADHD-MDD. This suggested that there is a common familial link between ADHD and depression. Clinicians often find themselves treating a depressed parent when treating a child with ADHD. Conversely, it is not uncommon to find ADHD among the children of depressed mothers (Beardslee et al., 1983). Failure to treat depression in a parent could contribute to comorbid depressive symptoms in the offspring.

In treating children who have a longstanding history of ADHD and who are also clinically depressed, clinicians may use a stimulant, antidepressant, or both. Some clinicians prefer to use an antidepressant with some evidence of efficacy for both depression and ADHD such as bupropion (Casat et al., 1987; Conners et al., 1996) or venlafaxine (Olvera et al., 1996). If the ADHD does not respond, these medications can still be augmented with a stimulant. Another option is to combine stimulants with serotonin reuptake inhibitors (Gammon and Brown, 1993). Opinions differ as to whether or not in such circumstances the depression or the ADHD should be treated first. Some clinicians recommend treating the depression first (Weiss et al., 1999), noting that many depressed children with decreased appetite, insomnia, headache, and irritability will not tolerate stimulants; however, a recent practice algorithm recommended treatment of the ADHD first (Pliszka et al., 2000a,b). Research in this area is quite limited, with only two studies that demonstrate that depression in children and adolescents is responsive to SSRIs (Emslie et al., 1997, 1998, 1999; Keller et al., 1998).

#### ATTENTION DEFICIT HYPERACTIVITY AND BIPOLAR DISORDERS

This is an area of heated and unresolved controversy (Biederman et al., 1996d, 1998a; Carlson, 1997, 1999). Manic illness was classically understood to be episodic, euphoric, and distinct from periods of depression. In the DSM-III-R, and even the DSM-IV, the definition of bipolar illness and bipolar II illness evolved to include states that were chronic, of early onset, primarily irritable, and with labile mood as opposed to clear mania or depression. The differential between this difficult, stormy condition and ADHD continues to cause confusion among both clinicians and patients (Steele, 1998). This is particularly true because three of the symptoms of mania are identical to their counterpart symptoms of ADHD (distractible, talkative, hyperactive); the remaining symptoms are considered by many clinicians to be associated features of ADHD, and only three symptoms are required for a diagnosis of mania.

Attention deficit hyperactivity—bipolar disorder is described in epidemiologic studies as being quite rare (Costello et al., 1996a,b), whereas some clinical studies suggest that up to 16% of children presenting for ADHD also have mania (Biederman et al., 1996d; Wozniak and Biederman, 1997; Wozniak et al., 1995). Family genetic studies of ADHD versus ADHD-BP seem to indicate that ADHD-BP cosegregates (i.e., first-degree relatives are likely to have ADHD and BP). This literature as well as studies that look at depressed children and adolescents or young adults who go on to have bipolar illness (Akiskal et al., 1995; Strober et al., 1995) seem to strongly suggest that there is a group of ADHD children and adults who have explosive outbursts, severe comorbidity, and require multiple hospitalizations. These patients are labile, irritable, aggressive, and have difficult temperaments. Further study of this population, including long-term follow-up into adulthood, would be of great benefit in terms of better understanding these children and their management. Whatever the prevalence of this disorder, it can certainly be considered demanding of treatment resources and expertise.

There is a paucity of empiric research to guide treatment of ADHD-BP. Lithium, anticonvulsants, antidepressants, stimulants, and atypical neuroleptics have all been widely used in this population of children. Whether or not the clinician prefers a diagnosis of severe ADHD or ADHD-BP, there is good agreement that these children are extremely ill, at risk, and hard to help. They often end up in the hospital. They demand aggressive treatment, but at the same time this population is at risk for overdoses and substance use. We also know very little about the long-term side effects of mood stabilizers, such as weight gain or polycystic ovarian syndrome from valproate.

In the meanwhile, clinicians often treat these patients empirically with careful, sequential, intensive, and combination therapies. Further research may provide more information as to whether stimulants exacerbate the mood cycling of these patients, or whether the disinhibiting and activating effects of serotonin reuptake blockers exacerbate their ADHD (Findling, 1996; Hoehn-Saric et al., 1990, 1991; Riddle et al., 1991; Strober et al., 1995). Guidelines for clinical management of ADHD-BP are available elsewhere (Pliszka et al., 1999; Weiss et al., 1999).

#### ATTENTION DEFICIT HYPERACTIVITY AND ANXIETY DISORDERS

The Multimodal Treatment of ADHD (MTA) study (The MTA Cooperative Group, 1999a) found that one-third of the children referred with ADHD met criteria for an anxiety disorder. Family genetic studies indicate that anxiety and ADHD are separate disorders and that they segregate independently (Biederman et al., 1991a, 1992a; Perrin and Last, 1996). Consistent with this hypothesis, children with ADHD-ANX share the social problems associated with anxiety disorders (Tannock, 1994).

Several investigators have looked at whether comorbid anxiety impacts on the effectiveness of stimulants. Clinicians have had the impression that the presence of anxiety in addition to ADHD often predicts poor stimulant response, and more side effects, and this was demonstrated in a series of clinical trials of stimulants with ADHD-ANX children ([Pliszka, 1989](#); [Taylor et al., 1987](#)). [Tannock and colleagues \(1995, 1996\)](#) found that comorbid anxiety predicted less behavioral improvement and the behavioral improvement that was seen declined over a 1-year follow-up. ADHD-ANX also showed less improvement in working memory when treated with stimulants, as compared the ADHD without anxiety. Finally, Tannock found that children with ADHD-ANX had more side effects with stimulant treatment than children with ADHD only. These results led Tannock to suggest that ADHD-ANX represented a meaningful subtype, with a different stimulant response profile to ADHD alone ([Tannock, 1994](#)).

It is interesting that neither the MTA nor a carefully designed study from Tannock's group ([Diamond et al., 1999](#)) replicated these findings. What the MTA did show was that ADHD-ANX children benefited more from medication and psychosocial treatment than medication alone. This result supports Tannock's hypothesis that ADHD-ANX represents a distinct subtype, with a different treatment response profile, and that treatment of this subtype may require both behavioral treatment of the anxiety and medication treatment of the ADHD. At the time of writing, systematic clinical trials are in process to look at the response of children with anxiety disorders. As we learn more about the treatment of anxiety disorders in children, we may also become more adept at treating child anxiety disorders when comorbid with ADHD ([Birmaher et al., 1994](#); [Fairbanks et al., 1997](#); [Geller et al., 1996](#); [Rocca et al., 1997](#)).

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND LEARNING DISABILITIES

Learning disability (LD) has been defined in various ways. For example, it has been defined as a discrepancy between learning potential (IQ) and learning achievement on formal psychoeducational testing. The disparity may be defined as greater than 1.5 or 2 standard deviations from the mean ([Semrud-Clikeman et al., 1992](#)). The more conservative the definition, the lower the prevalence of children who will qualify as having learning disability. It also needs to be said that schools and government may use these definitions to define access to special education resources.

Children can underachieve academically for many reasons, such as lack of motivation, ill health, poor teaching, inappropriate educational placement, or language barriers. If one defines LD as disparity between IQ and achievement, then children may be precluded from early intervention, which could prevent more serious LD later. Use of this definition by schools therefore runs the risk of precluding children from being eligible to receive educational resources until they are so far behind that the resource is no longer likely to be effective.

A second definition of LD assumes that the child must be both underachieving for his or her potential and also achieving poorly. This definition of LD excludes very bright children, who are underachieving relative to their own potential, from being eligible for resources. Definitions of LD also vary as to whether they refer to more global learning impairments (overall underachievement) or only specific learning impediments such as dyslexia, dyscalculia, or dysgraphia. Again, this distinction is quite important because problems with executive function in the absence of other psychiatric symptoms would be considered a learning disability by broader definition.

The prevalence of comorbid LD with ADHD varies depending on the definition used, anywhere from 10% to 90% ([Semrud-Clikeman et al., 1992](#)). Research on reading disability (RD) and ADHD indicate that these are two distinct disorders that can be inherited independently ([Faraone et al., 1993](#); [Gilger et al., 1992](#)). Both research and clinical expertise suggest that RD alone does not respond to stimulants, but that ADHD-RD responds to stimulant treatment of the ADHD combined with special education remediation of the RD. Similarly, treatment of the ADHD alone will not lead to improvement of the RD, unless the child also has the opportunity to receive appropriate educational remediation ([Kupietz et al., 1988](#); [Richardson et al., 1988](#)).

Stimulant medication has been shown to have a specific effect on some aspects of LD. There is evidence to suggest that stimulants improve working memory ([Tannock et al., 1995](#)) and handwriting ([Schain and Reynard, 1975](#)). These effects may impact on written output, math computation, examination skills, and various other aspects of academic performance.

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND MENTAL RETARDATION

ADHD exists together with mental retardation (MR) in rates higher than the general population. Research in this area is inconsistent as to whether symptoms of disruptive behavior should be measured against the child's developmental age, rather than chronological age ([Pearson and Aman, 1994](#)). Some measure of clinical judgment is required. Adults with MR are not expected to behave as young children, nor are young children with MR expected to have attention and behaviors consistent with their chronological age. Children with ADHD-MR have been shown to respond well to stimulants in double-blind trials ([Mayes et al., 1994](#)).

It is also imperative that children with a borderline IQ have the opportunity to receive both psychological testing and appropriate educational placement. Certainly, it would be inappropriate to diagnose a child as having ADHD-IA on the basis of not paying attention to material that he or she cannot understand. We have found that this differential is becoming increasingly important and common in the face of greater awareness of ADHD-IA by teachers, and in the face of limited special education resources and psychological testing ([Aman et al., 1991](#)).

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND TOURETTE'S SYNDROME

A recent study looked at over 3,500 children referred for treatment of Tourette's syndrome (TS) and found that ADHD was the most common comorbid condition ([Freeman et al., 2000](#)). ADHD accounted for much of the anger, sleep, and behavior difficulty associated with TS. It should be noted that by contrast in a study of a nonreferred community sample, only one in 12 subjects who met diagnostic criteria for TS also met diagnostic criteria for ADHD ([Apter et al., 1993](#)). The implication is that patients with TS are more likely to be referred for psychiatric assessment if they also have comorbid behavior problems, and the comorbid symptoms account for significant aspects of their impairment. A family genetic study ([Apter et al., 1993](#); [Pauls et al., 1993](#)) indicates that TS and ADHD are genetically independent; therefore, ADHD and TS cannot be considered variant phenotypes of a common gene, as was previously hypothesized ([Comings et al., 1990](#)).

Stimulant treatment of ADHD in the presence of tic disorder or TS can be beneficial in helping to ameliorate impairment from ADHD ([Freeman, 1997](#)). Recent research strongly suggests that stimulants do not worsen tics, and are not contraindicated ([Gadow et al., 1995a,b](#); [Nolan and Gadow, 1997](#)). Gadow's findings were confirmed in an independent clinical trial conducted by [Castellanos and associates \(1997\)](#). He found that although usual doses of stimulants were not statistically correlated to an increase in tics, unusually high doses were. He also noted that children who show worsening of tics on one stimulant might not show this effect with a different stimulant. It has become our clinical practice to provide patients with written summaries of this research in order to assure their informed consent, and carefully evaluate outcome of both ADHD and TS with each child. Treatment strategies may be directed at either condition alone, or both conditions in combination.

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND DEVELOPMENTAL COORDINATION DISORDER

Developmental coordination disorder (DCD) is defined in the DSM-IV as motor coordination markedly below developmental norms, which causes impairment with activities of daily living. Specific screening tests are available, such as the Test of Motor Impairment and the Movement Assessment Battery for children ([Gillberg and Kadesjo, 2000](#)). Many studies indicate that there is a strong relationship between DCD and ADHD, such that about half of the children diagnosed as having one of the disorders also meet the diagnostic criteria for the other. This association is clearly much stronger than would be expected by chance alone, suggesting that difficulty with inhibition ([Barkley, 1997](#)) may impact on motor output as well as behavior and attention. The association between DCD and ADHD has been of particular interest in the Nordic countries, where a unitary diagnostic category, Deficits in attention, motor control, and perception (DAMP) is commonly used to describe these children. Deficits in attention, motor control, and perception have been well validated and subjected to epidemiologic ([Kadesjo and Gillberg, 1998](#)) as well as clinical ([Hellgren et al., 1994](#)) follow-up studies. The clinical implication of this work is to alert clinicians to appreciate that clumsiness may be associated with severe impairment, and should be referred to an occupational therapist. Treatment should involve provision of educational and psychological support, as well as individually designed training programs and school accommodations.

#### ATTENTION DEFICIT HYPERACTIVITY AND NEUROLOGIC OR MEDICAL DISORDERS

Several conditions are either likely to be encountered in clinical settings, or are likely to be raised by families as relevant to ADHD. A brief comment and reference is included to summarize current clinical and research expertise in these areas. It should be noted that although the clinician will encounter these comorbid presentations, they do not account for the majority of ADHD cases, most of which remain constitutional in origin.

## Epilepsy

Epileptiform discharges can be found in up to 3.5% of otherwise normal children and do not by themselves indicate epilepsy ( [Pliszka et al., 2000](#)). Children with ADHD have a somewhat higher prevalence of nonspecific electroencephalogram abnormalities ( [Kuperman et al., 1996](#)), but this has not been found to be predictive of clinical correlates or outcome. Children with ADHD and a seizure disorder are as responsive to treatment with stimulants as children without a seizure disorder. Stimulants do not lower the seizure threshold, and they do not affect anticonvulsant blood levels. Nonetheless, cautious clinicians may elect to do a prestimulant and poststimulant EEG in the individual child.

## Head Injury

There is no empirical evidence that mild head injury leads to ADHD, although it would not be surprising to find that children with ADHD have more head injuries because they are more accident prone ( [Bijur et al., 1990](#)). Severe head injury is associated with ADHD at 2-year follow-up, and up to 20% of such children show cognitive and behavioral effects ( [Gerring et al., 1998](#); [Max et al., 1998a,b](#)). These children often show features of disinhibition or a frontal lobe syndrome and should be diagnosed as having a personality change secondary to a medical condition. A trial of stimulant treatment is warranted, and has been found to be helpful in many but not all cases ( [Gualtieri, 1991](#)).

## Perinatal Complications

Studies of the relationship between perinatal complications and ADHD are inconsistent, some showing an association ( [Milberger et al., 1997c](#)) and some not ( [McGee et al., 1984](#)). ADHD may be a long-term outcome of very low birth weight, with up to half of these children showing difficulty with attention deficit or hyperactivity at age 5 ( [Astbury et al., 1987](#)). Infants who are small for gestational age (SGA) may also be at risk for later ADHD ( [Schothorst and van Engeland, 1996](#)).

## Thyroid

Attention deficit hyperactivity disorder may be more prevalent in patients with generalized resistance to thyroid hormone (GRTH) ( [Hauser et al., 1993](#)), although replication of this study did not confirm the finding. The converse is not true: GRTH is exceedingly rare as a cause of ADHD ( [Elia et al., 1994](#); [Weiss et al., 1993](#)), so that general screening for thyroid problems is only recommended in the presence of symptoms of thyroid illness.

## Diet, Allergy, and Asthma

Research has not confirmed any association between diet ( [Gross et al., 1987](#)), food additives ( [Conners, 1989](#); [Conners et al., 1980](#)), sugar ( [Wolraich et al., 1994](#)), allergy ( [McGee et al., 1993](#)), or asthma ( [Pliszka et al., 1999](#)) and ADHD over that expected by chance. Patients often come in with strong convictions that these disorders are associated with worsening behavior. Unfortunately, this has had the effect of submitting children and families to expensive and onerous treatments that are not effective, and preventing access to treatments that are effective.

## Exposure to Toxins In Utero

Fetal alcohol syndrome (FAS) and fetal alcohol effects (FAE) include craniofacial abnormalities and behavior symptoms. Many children with these syndromes also meet diagnostic criteria of ADHD ( [Coles et al., 1997](#); [Oesterheld and Wilson, 1997](#); [Steinhausen et al., 1993](#)). There are no studies comparing treatment response and dose response with stimulants in this population, but stimulants are commonly used in treatment. It has also recently been demonstrated that even low doses of alcohol may also lead to later difficulties with attention and behavior ( [Olson et al., 1997](#); [Schneider et al., 1997](#)). This implies that children with FAE and/or children who do not have FAS craniofacial abnormalities but were exposed to alcohol *in utero*, could still have neuropsychiatric sequelae of alcohol exposure.

A study on outcome of children exposed to cocaine *in utero* found deficits on attention but not behavior ( [Richardson et al., 1996](#)).

There is research supporting the idea that exposure to nicotine *in utero* also contributes to risk of ADHD in offspring ( [Milberger et al., 1996](#), [1997b](#), [1998](#)).

## Lead

Lead poisoning has been associated with cognitive and behavioral disturbance in children but only accounted for 1% of the variance after the psychosocial variables were accounted ( [Fergusson et al., 1988a,b,c](#)).

## IMPLICATIONS OF COMORBIDITY

[Peter Jensen and colleagues \(1997\)](#) proposed seven criteria that would define whether ADHD in the presence of a particular comorbid condition should be considered distinct from ADHD alone. These criteria included the presence of a distinct clinical picture, demographics, psychosocial factors, biological factors, genetics, family environment, course and outcome, and response to specific treatments. Applying this definition to a complete review of the literature led them to conclude that ADHD-CD and ADHD-ANX should be considered distinct syndromes.

Study of comorbidity is expected to be of major clinical and research importance in the future. Clinically, it is apparent that clinicians need to be aware of the treatment implication of particular comorbid presentations. Families need to be aware that functional improvement for a child with ADHD and a serious comorbid condition may be limited by the impact of the comorbidity. Clinical practice needs to provide for assessment of a wide range of symptoms, both at assessment and outcome evaluation. Strategies for management of comorbid conditions need to include practice guidelines for evaluation of the impact of one change at a time, and changes in symptoms, functioning, and development. These strategies need to be based on clinical trials that are specifically designed to determine outcome for a comorbid presentation, with treatment for the first disorder, second disorder, both, and the sequence of treatment.

Research on ADHD is complicated by the presence of various comorbid conditions in a majority of ADHD children. Neuroimaging studies and genetic studies have strengthened our understanding of ADHD and comorbid conditions. As illustrated, knowledge of whether ADHD and a comorbid condition segregate independently (as in ADHD-ANX; ADHD-LD) or together (as in ADHD-BP) has significant implications for understanding etiology and treatment. Conversely, it may well be that further research on the neurobiology of ADHD is going to require identification of distinct clinical populations. For example, studies of the D4 or DAT1 gene or neuroimaging studies looking for anatomic or metabolic differences in children with ADHD versus controls may find stronger effects if they look at a "pure" ADHD population. On the other hand, a study of environmental toxins might find greater effects if they identify a group of children who do not carry any of the ADHD genetic markers and do not have a strong family history.

## THEORETICAL CONCEPTS OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

### Historical Conceptualizations of Attention Deficit Hyperactivity Disorder

Still originally argued that the children he described in 1902 had a deficit in volitional inhibition and a defect in moral control. It was almost three-quarters of a century later that Paul Wender began the work on minimal brain dysfunction that laid the foundation for contemporary work. Wender's work is a landmark that comprised major innovations, such as:

1. Describing the syndrome as a developmental disorder
2. Publishing the first easy to understand patient material
3. Recognizing that the disorder extends through the life cycle and into adulthood in some patients
4. Conducting clinical trials of various medications at a time when clinical trials in child psychiatry were in their infancy
5. Conceptualizing MBD as a neuropsychiatric syndrome in which symptoms per se would be unlikely to remit with psychotherapy
6. Recognizing the importance of developing firm age-appropriate diagnostic criteria and rating scales

## 7. Delineating the phenomenology of the core syndrome and its associated features

In this regard, Wender's historical position is of considerable interest, as is his theoretical understanding of the disorder. Wender argued that MBD comprised six dimensions of dysfunction: motor, attention and perception, learning, impulse control, interpersonal relations, and emotional dysregulation. He suggested that these children were active, extroverted, and not easily conditioned by normal consequences. Wender went on to develop diagnostic criteria for adult ADHD that included such difficulties as hot temper, emotional reactivity, and affective lability (Wender, 1995). The result was an accurate description of the *breadth* of ADHD symptoms. By contrast, DSM focuses on those symptoms, which operationalize the concepts of attention, hyperactivity, and impulsivity while carefully excluding items that overlap with mood disorders, aggressive items that overlap with conduct disorder, cognitive difficulties that overlap with a thought disorder, or aspects of interpersonal difficulty associated with personality disorders.

Douglas (1972) was among the first of the great founders who tried to design experiments to test a theory. Her experimental work led her to believe that a *dysregulation* of attention was fundamental to the difficulties of these children. It was partly as a result of her work that the disorder was then renamed attention deficit disorder. She further described difficulty with previously undescribed aspects of cognitive functioning such as problems with effort and motivation, poor modulation of arousal, and a tendency to seek immediate gratification. She grouped all of these difficulties under one basic concept: ADHD represented an impairment of self-regulation. She is one of the pioneers who then pushed interest in ADHD into the arena of neuroscientists exploring the impact of difficulties with executive function.

### Barkley's Theory of Attention Deficit Hyperactivity Disorder

Barkley (1999c) argues that the fundamental impairment of ADHD is a deficit in delayed responding. Barkley developed a schema in which he illustrated how a deficit in behavioral inhibition then leads to the other problems associated with ADHD (Fig. 52.1). Behavioral disinhibition is seen as fundamental to problems with working memory, self-regulation of affect, motivation and arousal, internalization of speech (and in turn capacity for rule governed behavior, moral reasoning, and reflection), and finally reconstitution. Reconstitution includes problems with verbal fluency, goal-directed behavior, analysis, and synthesis. These ideas represent a landmark in that they represent the first self-conscious attempt to enunciate a theory of ADHD that could be tested, and to present that theory to the public at large.

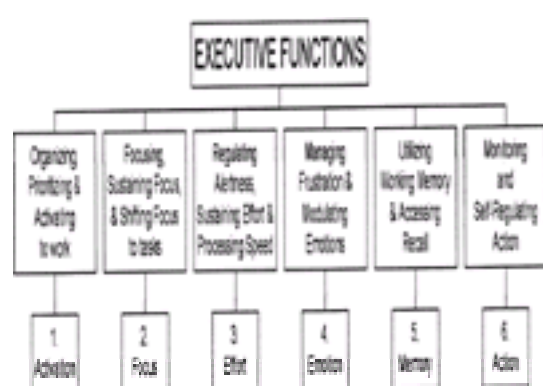

**Figure 52.1.** A model of the impairments in executive functions predicted to be associated with the deficits in behavioral inhibition that characterize ADHD. From Barkley RA: *ADHD and the Nature of Self-Control*. New York: Guilford, 1997. Copyright by Guilford Publications. Reprinted with permission.

Barkley's (1999c) theory is meant to describe children with ADHD-combined type. Barkley argues that children with ADHD-IA type who are lethargic rather than hyperactive and withdrawn rather than disinhibited may have a distinct disorder.

### Other Current Concepts of Attention Deficit Hyperactivity Disorder

Barkley's (1999c) work has also been heuristic in inspiring debate and discussion with other clinician researchers. Brown (2000a), Douglas (1999), and others (Sergeant et al., 1999) have become interested in problems with attention and difficulties with executive function as a primary source of difficulty. Brown (1996, 2001) has developed rating scales for children, adolescents, and adults that include various empirically derived dimensions of executive function. His six dimensions are illustrated in Fig. 52.2.

**Figure 52.2.** Brown's dimensions of executive function. *Brown Attention Deficit Disorder Scales, Manual*. Harcourt Brace and Company, San Antonio, TX, 1996. Permission granted by Psychological Corporation.

This work has generated new interest in adults with attention difficulties in the absence of overt hyperactivity, and raised questions about whether ADHD may lead to language and reading problems independent of learning disabilities (Purvis and Tannock, 2000).

Brown's model of ADHD differs from Barkley's in that behavioral inhibition is not considered to be primary or superordinate over other aspects or components of executive function. His model is meant to be inclusive of all the ADHD subtypes, where Barkley's model is specific to the combined type. Barkley argues that not all problems with attention are ADHD, and that it is incumbent on the clinician to demonstrate the specificity of an attention deficit in the absence of problems with delayed responding by ruling out the presence of any other learning or psychiatric disorder (Gordon and Barkley, 1999). This debate has important clinical implications. We now turn to what is known about the subtypes of ADHD.

### EPIDEMIOLOGY OF THE SUBTYPES

The change to the DSM-IV diagnostic system with the creation of the three subtypes increased the prevalence of ADHD from 3% to 5% (DSM-III-R) to about 12% (Baumgaertel et al., 1995; Wolraich et al., 1996). This is partly because of the addition of ADHD-IA, which itself has a prevalence of between 5.4% (Wolraich et al., 1996) and 9% (Baumgaertel et al., 1995). The DSM-IV subtypes permitted inclusion of more females, preschoolers, and adults who would have been excluded by previous DSM diagnostic criteria but who were found to have significant impairment.

Since the DSM-IV criteria came into use, it has become increasingly evident that further work is necessary to determine whether these two new ADHD subtypes represent changes in the presentation of ADHD at different developmental stages or unique disorders. There have been six clinic-based studies (Eiraldi et al., 1997; Faraone et al., 1998b; Lahey et al., 1994; McBurnett et al., 1995; Morgan et al., 1996; Paternite et al., 1996) and three community-based studies (Baumgaertel et al., 1995; Gaub and Carlson, 1998; Semrud-Clikeman et al., 2000). A metaanalysis of these nine studies (Carlson et al., 1999) found that there are clear differences in

the clinical correlates that characterize the various subtypes.

ADHD-HI is more common in preschoolers, and represents only about 2% of clinic ADHD populations. It is unclear at this point whether these children are simply a younger variant of the combined type (ADHD-C) who do not meet the inattentive diagnostic criteria because they have not yet encountered demands for attention in classroom settings. Children who are just hyperactive may improve with time because hyperactivity alone tends to remit with age. It is difficult to study this population because the prevalence is low.

The clinic-based studies show some consistent differences when compared with the community studies (Table 52.2). Clinic studies (Lahey et al., 1994) show a pattern in which the children with ADHD-HI are of preschool or early elementary age, children with ADHD-C are of intermediate elementary school age, and children with ADHD-IA are of late elementary or early high school age. This is not found in community studies (Gaub and Carlson, 1998). The discrepancies in age between community and clinic studies may reflect differences in when a child is referred for evaluation, rather than differences in age of onset. The age of referral may be a marker for when a particular group of symptoms presents the maximal developmental challenge. Overt hyperactivity, for example, decreases with age, but inattention does not (Lahey et al., 1988a). The mean age of a diagnostic group, therefore, may reflect referral bias based on whether the child is causing problems for others, as opposed to experiencing academic delays.

Clinical	Community
Age is older for IA	Age of IA and CB is the same
Prevalence of IA: 27%	Prevalence of IA: 50%
Gender	Gender
IA 2:1 boys/girls	IA 2:1 boys/girls
C 5:1 boys/girls	C 3:1 boys/girls
Comorbidity	Comorbidity
IA more internalizing problems than C, and more language problems	IA less internalizing problems than C

**Table 52.2. Clinical versus Community Samples**

Only in clinic populations, and only in some studies (Lahey et al., 1984), are children with ADHD-IA found to have more internalizing problems than children with ADHD-C. This suggests that children who have difficulty with attention in the absence of any other psychiatric problems are unlikely to be referred for psychiatric help or are referred later. Clinic and community studies also differ on whether depression and anxiety were identified by an interview of the child, or parent and/or teacher report on rating scales.

Clinicians may be making the assumption that because ADHD-IA children are “ADHD,” that their difficulties, prognosis and response to treatment are the same as those of children with ADHD-C; however, given the distinct clinical correlates of ADHD-IA, this should be subjected to empiric study. Children who only have attention problems or problems with hyperactive/impulsive behaviors may be quite different from children who have difficulty in all three domains. They may require different psychosocial treatments, different doses of medication, and have a different medication response profile. Further, we have never studied, and know little about, the developmental course of ADHD-IA or ADHD-HI.

The DSM-IV field trials did not attempt to determine the specificity of the ADHD-IA diagnosis, that is, whether these children might have secondary difficulties with attention as a result of other problems, such as learning disabilities, poor educational placement, language problems, depression, and so on. It may be that the diagnostic criteria of the DSM-IV are sensitive, but not specific. Clinicians may be using the inattentive-type diagnosis as a diagnosis of exclusion, that is, a diagnosis made only in the absence of other conditions that might also predict attention problems.

## TREATMENTS

### Psychosocial Treatment

#### INTRODUCTION

##### Interventions

These form a broad-based range of interventions that include all interactions between the therapist, child, and family, other than medication. The following interventions are summarized:

- Psychoeducation
- Parent training in behavioral management skills
- Classroom interventions
- Contingency management
- Cognitive behavior therapy
- Social skills training
- Individual psychotherapy of the child

Of the preceding treatment modalities, parent training, classroom interventions, contingency management, and recently social skills training have demonstrated efficacy (Pelham et al., 1998; Pfiffner et al., 2000).

Psychosocial treatments are generally combined with medication because alone, they have only a weak effect on the core symptoms of the disorder. However, medication alone cannot address parental concerns around child management issues such as the daily battles over homework, getting to bed, how to deal with critical neighbors or exasperated teachers, or how to help the child with peer rejection. Nor does medication alone address chaotic family functioning, disorders in parents affecting the family or child abuse. Medication use requires a discussion of parental fears about harm to the child and ongoing discussion about dose adjustments, side effects, and how the child feels about taking pills. Attention deficit hyperactivity disorder is a complex disorder affecting every area of functioning and requires a comprehensive treatment program.

#### PSYCHOEDUCATION

Psychoeducation is an essential component of the treatment of ADHD. It is treatment based on attention to the whole family unit and intensive support and education of the parents, over the years. All interventions are aimed at developing an ongoing therapeutic alliance between therapist, the child and his or her family, in an atmosphere that is nonjudgmental and calm.

Psychoeducation begins at the first assessment interview, when the purpose of the evaluation is made clear to the child and parents. A diagnosis of ADHD has great impact on both the child and his or her parents, usually arousing positive and negative feelings. On the positive side, there is nonjudgment and a better understanding of past difficulties in the light of the new information. On the negative side, the child is now labeled and “different.” Each family experiences the impact of the diagnosis differently, and psychoeducation provides the necessary support and information required. All uncertainties about the nature, causes, treatment, and prognosis of the disorder are discussed. The treatment plan is outlined in the context of active child and parent participation. This is an ongoing activity as treatment response is assessed and interventions are modified. The use of medication generates fears in many parents; these are aired and discussed. Accurate information of ongoing treatment studies is provided. Whether children interpret the effects of their medication as being the result of the drug, or a change they have directed (attribution) is a concern. Charlotte Johnston and colleagues (2000) have actively researched this area in recent years. It is important that the physician explains to the child and his

or her parents that the medication gives the child the potential to improve, but that the effort must still come from them.

The therapeutic alliance becomes increasingly one of mutual respect and equality as information is shared by the parents about themselves and their child, the child about his or her world, and the therapist about all aspects of the disorder. Psychoeducation forms the background for all other interventions, and for many, together with supportive interviews and ongoing information from teachers, may be the only treatment other than medication.

### SCHOOL INTERVENTION

School intervention has received considerable attention and only highlights can be discussed in this chapter. Contact with the school is a required part of the diagnosis but may be limited to the teacher completing a rating scale. Physicians may lack the time to establish adequate contact with the child's teacher. Ideally, the therapist should meet the child's teacher initially and at periods when this is helpful. These meetings have the purpose of insuring that the teacher understands the disorder, feels positive toward the child despite the behavior, understands the pros and cons of medication, and becomes an active participant in treatment. The child needs to be situated in a seat where he or she can be more intensively supervised, which is usually in the front of the classroom and some distance from other disruptive children. A psychoeducational assessment is required for some children, leading to specialized and individualized learning assistance, one-on-one tutoring, peer tutoring, or use of a computer.

Parents need help to learn how to be advocates for their children and avoid a negative feedback system with the teacher because they are disappointed with the school system. When such a conflict exists between parents and teacher, the therapist may be helpful as a mediator.

A simple to use behavioral tool is the daily report card (DRC). This is an intervention in which the teacher observes the child's academic output and behavior throughout the day. The child is rewarded; for example, after the morning and at the end of the school day by receiving tokens such as a card or star. These are brought home and exchanged for a tangible reward by the parents. An additional star can be given daily for the child accurately assessing him or herself as to work completed and behavior. This method is particularly useful because it promotes increased supervision from the teacher and positive reinforcement for the desired work habits and behavior. It also leads to more positive emotional interaction between the teacher and child. When teachers object that they do not have the time because they have so many other children in their class, they are asked to try it out because by reducing classroom disruption, it may save them time in the end. If positive reinforcement is not sufficient to produce the required results, then the parents may add negative consequences (mild punishments such as withdrawal of privileges) ([DuPaul and Stoner, 1994](#)).

Trained behavior therapists may set up a token management program of the child in the classroom with a similar program being set up at home.

The reader may refer to a recent review by [Hoffman and DuPaul \(2000\)](#) for more details on types of school interventions.

### PARENT TRAINING IN TECHNIQUES OF BEHAVIOR THERAPY

This may be carried out with groups of parents or individual parents. Parent groups are more efficient and provide group acceptance and support, but techniques learned in the group may need to be reinforced in individual parent sessions in order to be adequately implemented in the home environment.

Parent groups are usually set up with about eight sets of parents, and are held weekly for eight to 20 sessions. Parents are assigned readings and homework to practice specific skills ([Pelham and Waschbusch, 1999](#)). In our experience, the more active the parent's participation is in the group, the better the results ([Cousins and Weiss, 1993](#)). It must be remembered that for some parents didactic teaching is not useful, particularly for those parents who themselves have ADHD ([Weiss et al., 2000a](#)). These parents have a long history of "tuning out" in a classroom situation. Their difficulties with following routines, organizational skills, poor attention to detail, make the carrying out of a behavioral program difficult or impossible unless they too are treated.

Most parents are aware that their current way of handling their child is not working and are eager to learn new skills. In the group meetings parents are taught that reinforcements of desired behavior and lack of attention or negative consequences of undesired behavior can change behaviors. Positive reinforcement, for example, a later bedtime or token leading to later reward, may be used alone or together with negative consequences (mild punishments). Rewards and consequences are usually given daily. The parents are taught to "catch the child being good" and to recognize that angry, prolonged attention to the negative behavior with inconsistent consequences may actually reinforce the behavior.

Rewards and negative consequences are carefully selected with the child as an active participant. Many children choose time alone with the parent of choice, for example, 10 minutes doing an activity chosen by the child without receiving any criticism as the positive reinforcer. Access to screening activities (computer games, TV, Nintendo, etc.) has recently become a popular reinforcer. "Time out" is a common consequence that may be impossible to carry out with older children.

Behavior modification is an effective treatment ([Pelham and Waschbusch, 1999](#)), but the effects gradually dissipate when therapy stops and it has no additional effect on the core symptoms of the disorder when the child is on stimulants. For this reason, behavior therapy is usually combined with medication, and is particularly helpful for younger children. [Pelham and Fabiano \(2000\)](#) provide a recent, more comprehensive description of behavior modification.

### CONTINGENCY MANAGEMENT

Contingency management is a form of behavior therapy used in special programs such as special classroom settings, summer camps for children with ADHD, such as those run by [Bill Pelham and associates \(1997\)](#) and inpatient units. Treatment in these settings is intensive and extensive. The behavioral component is based on a token point system with reward and cost components for a range of behaviors implemented in every activity throughout the day. In these programs, contingency management is combined with medication and other psychosocial treatments such as parent training and social skill enhancement. The efficacy of these programs has been demonstrated ([Pelham and Fabiano, 2000](#)).

### COGNITIVE BEHAVIOR THERAPY (OR SELF-INSTRUCTION INTERVENTIONS)

It was hoped that teaching children how to self-regulate their behavior and modify their self-talk would lead to better rule-governed behavior. Programs were designed to teach children techniques of problem solving, dealing with anger and frustration, persistence, and social skills ([Braswell et al., 1991](#)); however, the gains made during the program were not maintained at follow-up, confirming various previous reports that little benefit remained when training was discontinued ([Abikoff, 1985](#)). The reasons for this are probably complex, and include insufficient attention being paid to the generalization of the learned skills and the immaturity of executive verbal functioning of ADHD children.

### SOCIAL SKILLS TRAINING

Impaired social functioning is one of the most debilitating aspects of children with ADHD and also the most resistant to treatment ([Whalen and Henker, 1992](#)). Social skills training (SST) programs have been refined over time and increased emphasis has been placed on the need to incorporate ways to ensure generalization of learned skills into the natural environment of the child by incorporating teachers and peers. As a result, there is now evidence of treatment efficacy ([Piffner et al., 2000](#)).

Social skills training programs have generally been carried out on small groups of school-aged children using both cognitive behavioral and behavioral interventions. These programs may include modeling, didactic instruction, symbolic play (e.g., with puppets) *in vivo* practicing, role-play, and behavioral rehearsing. Children are taught to evaluate their own behavior in the group and school yard. Prosocial behaviors are taught and practiced, and contingency management is used to increase prosocial behaviors and eliminate unwanted responses.

Linda Piffner and coworkers use six modules, related specifically to the social difficulties of ADHD children, including good sportsmanship, for example, following the rules, not leaving the game, accepting consequences gracefully, assertiveness, ignoring verbal and nonverbal provocation, problem solving, and recognizing and identifying feelings in self and others. Gains lasting 3 to 4 months after treatment stopped were recorded ([Piffner and McBurnett, 1997](#)).

## INDIVIDUAL PSYCHOTHERAPY OR PLAY THERAPY

No empiric data exist on the effectiveness of this form of treatment and it would not be expected to improve the core symptoms of the disorder. [Greenfield and colleagues \(1992\)](#) described modifications useful for treating secondary difficulties commonly seen in children with ADHD, such as intense sibling rivalry, low self-esteem, and feelings of alienation. Feeling understood and confiding in a helpful nonjudgmental adult and developing the hope of change may result in clinical improvement, although this has not been demonstrated ([Stubbe and Weiss, 2000](#)). The authors have found that brief individual psychotherapy with the child can establish the foundation of a long-term therapeutic relationship, which contributes to good long-term management of the child with ADHD and his or her family.

## Medication Treatment

### PHARMACOEPIDEMOLOGY OF MEDICATION USE

There has been a continuous and dramatic rise in the use of stimulants in North America, representing at least a doubling in the number of prescriptions every 5 years, or as many as 1.5 million children receiving medication for ADHD ([Safer et al., 1996](#)). This has raised concern in the public and the media about whether or not this increased use represents an inappropriate use of medication for behavioral control, although the prevalence statistics for use of stimulants do not extend beyond the prevalence of ADHD itself. Up to three-quarters of children with a diagnosis of ADHD are currently prescribed medication. This means that there are many children with ADHD who are not treated with stimulants, and also children without ADHD who do receive treatment ([Angold et al., 2000](#)). This is not entirely surprising because the indication for stimulants is a group of symptoms, and not necessarily the diagnosis.

The rise in the number of stimulant prescriptions can be attributed to an increase in both the population of patients treated, and the way in which medication is being prescribed. At the present time there is a significant increase in use of stimulants to treat preschoolers ([Rappley et al., 1999](#)), adolescents ([Safer and Krager, 1994](#)), and adults ([Morrow, 1997](#)). In addition, there has been a rise in the rate of stimulant treatment for patients with a diagnosis of ADHD-predominantly inattentive type from 7% (1970s) to 20% (1990) ([Safer and Zito, 2000](#)). This trend has probably continued to grow in the last decade, even though clinical trials demonstrating efficacy are still needed. There has also been a considerable increase in the use of stimulants to treat children who have diagnoses of ADHD and comorbid disorders such as bipolar disorder, anxiety and depression, autism, Tourette's syndrome, other disruptive behavior disorders, and mental retardation ([Brown, 2000b](#)).

### PRINCIPLES OF STIMULANT TREATMENT OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

Two stimulant medications commonly prescribed for the treatment of ADHD are methylphenidate (Ritalin) and dextroamphetamine (Dexedrine). Both of these stimulants are also available in a long-acting preparation. The benefits and side effects of both these medications are similar, but some patients may do better on one or the other ([Elia et al., 1991](#)). The short-term effects of stimulants are well researched. There are more than 350 double-blind placebo controlled studies (on over 3,000 children) consistently demonstrating that stimulants lead to improved impulse control, attention, academic, social, and family functioning ([Spencer et al., 1996](#)). Similar studies have been done demonstrating the same degree of improvement in adults ([Wilens et al., 1995](#)).

In practice about three-quarters of children respond to the first medication tried ([Barkley, 1999b](#)), although for children who do not respond, most (90%) respond with alterations of dose or a trial of a different medication ([Elia et al., 1991](#)). About 80% of adults respond well to methylphenidate ([Spencer et al., 1995](#)). Preschool children have a lower probability of response and a higher incidence of side effects ([Spencer et al., 1996](#)). Adolescents may benefit from particular accommodations in the way in which medication is used ([Weiss et al., 2000b](#)), but otherwise show a good response ([Spencer et al., 1996](#)).

It is recommended that medication be initiated at a low dose and increased slowly. This gives the body a chance to adapt, and minimizes nuisance side effects. There are few differences in the titration of medication for children, teens, or adults. Individuals vary widely in their sensitivity to stimulants, so that some people require higher doses, and others are very sensitive to lower doses. Doses in excess of 1 mg/kg per day or 60 mg of methylphenidate (Ritalin) or 0.5 mg/kg per day or 30 mg of dextroamphetamine (Dexedrine) should be used with caution. When titrating stimulant medication, consideration should be given to 7 day per week dosing during the titration in order to ensure that the family or significant other can observe the benefits or adverse effects. This also makes it possible to assess the effects of medication in different environments. Compliance should be assessed at each visit. Dosage is optimal when the patient has obtained significant benefit with minimal side effects.

Many patients experience difficulty when the medication is wearing off; therefore, it is very important to establish the timing of side effects, aggressive episodes, or other adverse events. It is important to know if side effects are worse during periods of peak medication, or periods in which medication is wearing off. It is important to assess whether the patient is adequately medicated during critical transition periods (e.g., recess for a child or the drive home at the end of the day for an adult). If not, it may be necessary to change the timing or frequency of medication administration, increase the dose of medication, or switch to a longer-acting formulation.

A placebo trial may be helpful if a family member, teacher, or clinician is unsure of medication response or if side effects are caused by medication ([Johnston and Fine, 1993](#)). This means that someone observes the patient and rates their symptoms, without knowing if they are on medication. There are several ways to do this. In a true double-blind placebo trial, neither the patient nor observer knows if they are receiving the active medication or the placebo with no active medication. This requires that the pharmacist encapsulate the medication because it has a strong taste. Alternatively, a single-blind trial can be done by having either a teacher or a spouse rate the patient's symptoms, without their being told if the patient is on medication or not. The observer is told that the patient will be on or off medication at different times over the month, without being told exactly when. In this way, the observer can provide blind ratings, while still being aware of the trial, so that the placebo trial can be interrupted in the event of severe deterioration.

Outcome of medication is best evaluated with a rating scale that provides separate ratings of attention, disruption, and oppositional behaviors. It is educational to the patient to compare symptom ratings before medication and after medication. It is also a useful follow-up tool that can be used by patients to determine whether the medication response should be reevaluated by the clinician. Self-ratings of ADHD symptoms often underestimate difficulty; therefore, an outside observer is critical.

### SHORT-ACTING STIMULANT MEDICATIONS

#### Methylphenidate

Methylphenidate (Ritalin) comes in 10-mg tablets. The medication starts working 30 to 45 minutes after it is taken. The maximum effect is seen 1.5 to 2.5 hours after it is taken. Then the effect decreases and is usually gone in 3 to 4 hours. It is necessary to start the medication at a low dose and increase it slowly in order for the child to obtain optimal benefit and minimal side effects. A typical titration schedule would look like this:

	Morning (mg)	Afternoon (mg)	Noon (mg)
Week 1	5	5	—
Week 2	10	5	—
Week 3	10	5	5
Week 4	10	10	5
Week 5	10	10	10

#### Stimulant Enantiomers

Methylphenidate is a complex racemic drug with two different isomers. Each enantiomer may affect different populations of ADHD individuals and has a unique side-effect profile. The  $\alpha$ -isomer (dextro-methylphenidate or  $d$ -MPH) continues to harbor the bulk of clinical efficacy of the compound. Recent research has made it possible to isolate  $d$ -MPH as a separate compound, with possible unique pharmacokinetic properties and side effects ([Quinn, 2000](#)).

#### Dextroamphetamine

Dextroamphetamine (Dexedrine) is available in 5-mg tablets. For convenience, a 5-mg tablet of dextroamphetamine is seen as roughly equivalent to a 10-mg tablet of methylphenidate. The short-acting dextroamphetamine lasts about 5 to 6 hours, and sometimes this can be an advantage over using methylphenidate. This time

difference may be quite significant in that the increased time between doses may allow for some patients to make it through critical transitions, which might otherwise have been problematic. It may also facilitate compliance. A typical titration schedule for dextroamphetamine might look like this:

	Morning (mg)	Lunch (mg)	After School (mg)
Week 1	2.5–5	—	—
Week 2	5	2.5–5	—
Week 3	5–10	5	—
Week 4	5–10	5	5

### *Adderall*

Adderall is a mixture of dextroamphetamine/amphetamine salts available in 5-, 10-, 20-, and 30-mg tablets. It contains 25% each of dextroamphetamine saccharate, amphetamine aspartate, dextroamphetamine sulfate, and amphetamine sulfate. This mixture of salts is felt to prolong the duration of action, so it will last 6 to 8 hours. Most children do well with either a morning dose, or a morning and lunch dose. Its side-effect profile and dosing is similar to that of dextroamphetamine. Adderall is not available in Canada.

### LONG-ACTING STIMULANTS

Long- and short-acting forms of a given stimulant can be combined. For example, medication with Dexedrine Spansule may cover the patient for most of the day, with a “topper” of the shorter-acting Dexedrine in the mid-afternoon to carry the patient through the evening. There is no research on combining methylphenidate with dextroamphetamine.

### *Pemoline*

Pemoline (Cylert) carries a risk for hepatotoxicity. As a result, it is now only used as a third-line medication in the United States and is unavailable in Canada and the United Kingdom. The use of pemoline requires monitoring liver enzymes.

### *Long-Acting Formulations*

Both dextroamphetamine (Dexedrine Spansule) and d,l-amphetamine (Adderall XR) are available in long acting formulations that last all day. Clinicians should be aware that long acting medications minimize rebound and provide continuity of effectiveness but may also prolong side effects such as appetite suppression and insomnia.

Ritalin SR was the first marketed longer-acting methylphenidate preparation. It is limited by difficulties with erratic release, and was somewhat less effective than methylphenidate in clinical trials. As a result its use has been superseded by other long-acting formulations. Various new release technologies have been explored, such as an osmotic pump, and others are under investigation. These modified release mechanisms have led to the development of medications with 8–12-hour duration of action. These new long-duration stimulants (LDS) have been the subject of rigorous pivotal trials that have done much to develop new methodologies to establish LDS pharmacokinetics and pharmacodynamics ([Greenhill et al., 2001a](#)). These trials differ from earlier studies on Ritalin SR in that they have a larger number of subjects, use parallel rather than crossover designs, are multisite, include open label follow-ups, and involve careful measures of multiple domains of impairment. Pharmacokinetic and dynamic information has been obtained by using simulated classrooms, of which there are now several. It is anticipated that these new medications will offer practical solutions to the stigma associated with asking children to take medication at school during the lunch hour. They are also likely to markedly increase compliance, especially in adolescents.

### ADVERSE EFFECTS

Stimulants are associated with loss of appetite, headache and stomachache, and insomnia ([Corkum et al., 1998](#); [Spencer et al., 2000](#)). Recent research suggests that growth suppression seems to be associated with a developmental delay associated with ADHD itself, rather than a direct effect of medication ([Spencer et al., 1996](#)). Caution should be exerted in children who are medicated for many years without drug holidays or used in children with short stature. Recent research (see the preceding) suggests that stimulants are not correlated with precipitating the onset of Tourette's syndrome or exacerbating tics ([Gadow et al., 1995a](#)). Careful assessment of tics prior to and following treatment as well as appropriate education of parents regarding the risks and benefits of the use of stimulants in the presence of tics is advisable. Most somatic side effects can be managed effectively ([Spencer et al., 2000](#); [Wilens and Spencer, 2000](#)).

Equally important are psychiatric side effects such as obsessive-compulsive behaviors, social withdrawal, appearing ‘zombied,’ rebound irritability, and dysphoria. Most of these psychiatric side effects are more apparent in the long than the short run ([Schachar et al., 1997](#)) and may be misinterpreted by parents as stemming from the disorder rather than its treatment. They are a significant source of distress, nonetheless, and may be associated with significant morbidity or noncompliance.

### THE BENEFITS AND LIMITATIONS OF STIMULANT TREATMENT

Stimulants are associated with a robust (effect size equal to 0.8 to 1.0) short-term effect on behavior ([Greenhill et al., 2001b](#)), and up to 62% of children who improve meet criteria for successful treatment ([Swanson et al., 2001](#)). Methylphenidate also leads to improved academic productivity and attention, although this is a less powerful effect. It is interesting that this short-term benefit has not been demonstrated to lead to a long-term improvement in academic achievement ([Schachar and Tannock, 1993](#)). It has been demonstrated that stimulants are associated with an immediate and substantial improvement in the quality of social interactions with peers, family, and teachers; however, it should be noted that not all social deficits respond. Problems with aggression, processing of social information, social withdrawal, and dysphoria may be less responsive. Most children experience improved self-esteem as their capacity to function normally improves. This may be less evident where the child has profound negative attributions around medication.

Stimulant treatment is helpful to a majority of children with ADHD; however, it offers significant palliation, not a cure. The effectiveness of stimulant medication can be limited by its duration of action, somatic and psychiatric side effects, worsening of a comorbid condition, noncompliance, lack of full normalization, periods of time off medication, tolerance, rebound, and social stigma. For all of these reasons, medication is often combined with psychosocial treatments for residual problems ([Schachar and Ickowicz, 1999](#)).

### OTHER MEDICATION TREATMENTS

Other types of medication are used as second-line treatments for ADHD ([Biederman et al., 1999](#); [Schachar and Ickowicz, 1999](#); [Wilens and Spencer, 2000](#)). There are clinical trials demonstrating an effect on ADHD for tricyclic antidepressants ([Altman et al., 1994](#); [Biederman et al., 1989](#)), bupropion ([Barrickman et al., 1995](#); [Conners et al., 1996](#); [Murphy and Barkley, 1995](#)), tomoxetine ([Spencer et al., 1998](#)), and moclobemide ([Myronuk et al., 1996](#); [Trott et al., 1991](#)). There is weak evidence of efficacy of alpha-adrenergic agonists such as clonidine ([Hunt, 1987](#); [Hunt et al., 1985](#)) and guanfacine ([Hunt et al., 1985](#)). In general, these treatments have not been found to have as robust an effect on the cognitive symptoms of ADHD but may be more effective for associated features, comorbid conditions, or where round-the-clock coverage is imperative.

### Multimodal Treatment

#### THE MULTIMODAL TREATMENT STUDY OF ATTENTION-DEFICIT HYPERACTIVITY DISORDER

The NIMH sponsored MTA (1999a,b) is the most comprehensive long-term treatment study for child psychiatric disorders, the results of which will guide clinical practice, public policy, and research in the years to come ([Boyle and Jadao, 1999](#)). Unique aspects of this study include the large number of children studied and the 14-month duration of the study, making it the first study to evaluate treatment results for a longer period. Assessment and outcome measures of the children were comprehensive and included a wide range of symptoms and areas of functioning, using rated and objective measures. All treatments used had prior established efficacy and were manualized. Titration of medication was carried out systematically according to a documented protocol. Finally, the principal investigators of all six sites from which children were recruited were experienced researchers who had made significant contributions to the field and who collaborated in the design of the study and its execution. The investigators compromised in design between the objectives of efficacy (maximum control) and effectiveness (maximum generalizability),

to enhance the feasibility and likelihood of the MTA protocol being used in clinical practice.

The aim of the study was to compare the effectiveness of medication combined with intensive and broad-based psychosocial treatment with medication management or psychosocial treatment alone, and to compare these treatment programs with treatments in the community.

The sample included 579 children 7 to 9 years old recruited from six sites, who met criteria for ADHD-C. Of these, 34% had comorbid anxiety disorders, 40% comorbid oppositional defiant disorder, and 14% had comorbid conduct disorder, 20% were girls, and 19% of the parents were on welfare. Assessments were carried out at baseline and repeated at 3 and 9 months and at the end of treatment, 14 months. These assessments spanned five domains, core ADHD symptoms, aggressive and oppositional behaviors, anxiety and depression, peer and family relations, social skills, and academic achievement. A maximum of eight emergency sessions were provided for every family.

Children in the medication management (MM) group were started on Ritalin (or alternative medication if they could not tolerate it) over a 4- to 11-day warm-up period followed by a 28-day double-blind medication placebo controlled trial. The active medication was given in different doses in the double-blind period to determine optimal benefit for a given child. Medication was adjusted on a monthly basis with monthly teacher feedback, and each family received a half hour of time each month with a pharmacotherapist. Children assigned to the MM group required a higher dose of Ritalin (mean 38.1 mg) than did children in the CT group (mean 30.1 mg). A small percentage of children (12%) did not do well on Ritalin, and half of these responded well to Dexedrine ( [Greenhill et al., 2001b](#)).

Children who received psychosocial interventions participated in an 8-week, all-day summer treatment program, STP, which utilized contingency management and included social skills training. Parents attended 27 group sessions of carefully designed training and eight individual sessions. School intervention included 10 biweekly sessions of classroom behavior management consultation with the child's teacher. The child's counselor from the STP acted as the child's classroom aide on a half-time basis for 2 months with the aim of generalizing gains made in the STP into the classroom. Seventy percent of children treated in the community control arm of the study were treated with stimulants.

Results from this comprehensive study are still being published and conclusions are being refined ( [Cunningham, 1999](#)). Findings to date are that for most ADHD symptoms, children in the combined treatment and medication management groups showed significantly greater improvement than those given intensive psychosocial treatment alone or those treated in the community. On direct comparison of ADHD core symptoms, combined treatment was not superior to medication management alone and medication management was also superior to behavioral treatment alone and treatment in the community. For non-ADHD areas of functioning, the combined treatment program offered modest advantages over single component programs ( [Jensen, 1999](#)). For some difficulties, however, such as oppositional and aggressive symptoms, internalizing symptoms, teacher-rated social skills, parent-child relations, and reading achievement, combined treatment was superior to psychosocial treatment alone and to community care.

There have been recent attempts to reanalyze the original data using different measures with the aim of clarifying small group differences in treatment outcome. [Conners and Epstein \(2001\)](#) used a "composite score" of outcome, which provided a more reliable index of change with greater statistical power, than the original analysis of multiple paired comparisons over time, which lost statistical power associated with the Bonferroni correction. This single composite score was internally consistent, reliable, and correlated with clinician global judgment. A small but significantly better outcome was found in the CT group versus the MM group using this outcome measure, whereas large differences were found between the CT group, which had the best outcome compared to the other three groups.

[Swanson and associates \(2001\)](#) also reanalyzed the data using a single composite score, the percentage of children in each group who fell into the "successful treatment" category. Sixty-eight percent in the CT group, 56% in the MM group, 34% in the BT group, and 25% in the CC group fell into this successful treatment category. Here again the outcome in the CT group was statistically significantly better than the MM group. It remains to be demonstrated if these differences are clinically significant, and if so which kinds of children with ADHD respond best to which kinds of treatment.

Recent studies utilizing the continuous performance test (CPT), have suggested that children who have ADHD only, and those with ADHD comorbid with externalizing disorders, ODD-CD or with anxiety disorder (AD) or both may be sufficiently distinct to warrant classification as subtypes. [Newcorn and colleagues \(2001\)](#) found that CPT-rated inattention, impulsivity, and dyscontrol were high in all ADHD groups; however, children with ADHD and ODD-CD were more impulsive than inattentive, whereas children with ADHD and AD were relatively more inattentive than impulsive. Girls were less impaired than boys on most CPT ratings.

[Jensen and coworkers \(2001\)](#) also found that the preceding subgroups based on comorbidity differ on baseline variables, as well as response to treatment. He suggested that these findings have clinical implications with the following rule of thumb: Children with ADHD without comorbidity and children with ADHD comorbid with ODD-CD respond best to (MTA) medication management, and behavior therapy alone is contraindicated. Those children who have ADHD and anxiety respond well to all the MTA treatments. However, combination treatment (MTA-CT) may offer significant advantage for children who have ADHD comorbid with both anxiety and ODD-CD.

It is interesting to speculate on the better outcome of the children in the medication management program compared to the children treated in the community. Perhaps entry into a prestigious study creates optimism for families. Another important point is that the doses used in the medication management program were titrated for each child to ensure maximum benefit and the average dose was higher than in those treated in the community, and even more important is the fact that dose adjustments were made monthly after feedback from the child's teacher, and the family was given half an hour with the psychopharmacologist. These monthly visits with regular teacher feedback may have been an important adjunct to the medication itself.

As pointed out by [Jensen \(1999\)](#), some erroneous conclusions have been made about the results of the MTA including the notion that behavior therapy does not work or that the treatment protocols, all of which have been well described in treatment manuals, can never be carried out in the real world. Certainly, the protocol for the medication management program is a model for medication treatment for clinicians in the community that treat children with ADHD.

The conclusion is that all four treatment programs were highly effective over the 14 months of treatment for children with ADHD. Medication management and psychosocial treatment may impact selectively on different target symptoms. The findings are optimistic given the range of problems of children with this disorder, treatment preferences of parents and variations in professional expertise and professional availability in different geographical areas.

#### *MTA FOLLOW-UP 14 TO 24 MONTHS*

Results of this 10-month follow-up (after treatment termination in the study) have been presented at the American Academy of Child and Adolescent Psychiatry Meeting in New York in 2000 but have not yet been published, and some of the findings have not yet been submitted for statistical analysis.

At the end of the 14-month treatment period, all families met with their clinician who discussed recommendations for future treatment with them based on the finding of the MTA committee. Compliance with treatment recommendations was lowest in the families who had received behavior therapy. Seventy percent of children in this group were given recommendations for initiating stimulant therapy and only 44% complied versus 88% of the children in the combined treatment and medication management groups. It was found that prior experience with a treatment was a strong predictor of compliance. Families in the medication management group sought out more child individual, family, and group therapy. Excellent responder status in the treatment period predicted compliance with recommendations.

The following results were obtained when "excellent responder" status was measured at 14 and at 24 months. Combined treatment children had 65% of excellent responders at 14 months, which fell to 44% at 24 months. Medication management children had 55% of excellent responders at 14 months, which fell to 25% at 24 months. Behavior therapy children had 25% of excellent responders at 14 months, which fell to 10% at 24 months.

The preceding pattern was obtained also by other measures of ADHD and ODD. The combined treatment group best upheld the gains made during the intensive treatment period whether or not they continued on medication. Improvement declined more steeply in the medication management group, but was better than in the community control or behavior therapy group. In general, the use of medication in the 14- to 24-month period reduced deterioration. We can conclude that the pattern of treatment response seen at 14 months was maintained at 24 months. The MTA-NIMH researchers are planning to do a 10-year follow-up with several consecutive assessments during the period. They will be able to assess individual trajectories, growth patterns, side-effects of stimulants, effects of initial and later treatments, and the possibility of the emergence of sleeper effects.

It is interesting to speculate on the possible reasons why, particularly those children in the combined treatment group but also those in the Medication Management group, maintained their gains better than the children in the behavior therapy group or those treated in the community, 10 months after their intensive treatment

ended. Although it is possible that the children in the former two treatment groups received a higher dose of stimulants in the follow-up period, this is probably not the only reason for their better outcome, even at 24 months.

## DEVELOPMENT AND OUTCOME

The adolescent, and where available, the adult outcome from four major prospective controlled follow-up studies—the Montreal, New York, Milwaukee, and Biederman Studies—are reported on. Their methodologies are summarized in the following.

### Prospective Studies

#### THE MONTREAL STUDY

Weiss and coworkers followed 91 hyperactive children 6 to 12 years old whose primary difficulties were hyperactivity, impulsivity, and attentional problems. DSM diagnoses did not exist when this study was initiated and the children were rated on a Werry Weiss Peters Scale of Hyperactivity. Children whose primary difficulties lay in conduct disorder problems were excluded, as were psychotic children, children with autism, children with an IQ below 80, and those who were not living with their family. Weiss and coworkers assessed these children at five yearly intervals at a mean age of 13, 18, and 24 years. Psychiatrists who were not blind as to the status of probands and controls assessed psychiatric status.

#### THE NEW YORK STUDY

Gittelman and colleagues conducted a 9- and 16-year follow-up on 115 cross-situationally hyperactive children 6 to 12 years old and a matched control group. The methodology of this study was similar by design to the Montreal Study but “blind” observers (versus psychiatrists) rated the groups at follow-up. A replication study of 111 ADHD children seen in the same clinic and controls were subsequently followed using the same criteria and measures as in the first study. Subjects were 18 years of age at the 9-year follow-up and 25 years of age at the 16-year follow-up. Exclusion criteria were identical to the Montreal Study.

#### THE MILWAUKEE STUDY

Barkley and colleagues studied 123 hyperactive children and 60 matched controls and compared their outcome 8 years later when their mean age was 14 years and 15 years later when their mean age was 21 years. Children were included in the study if they scored one and a half standard deviations above the mean of the control group on several well-standardized rating scales of ADHD symptoms. Unlike the Montreal and New York Studies, children who had ADHD comorbid with conduct disorder were not excluded.

#### THE BIEDERMAN STUDY

Biederman and colleagues studied 138 children with ADHD diagnosed by DSM-III criteria, their siblings, and 120 normal controls. Exclusion criteria were sensory motor handicaps, IQ below 80, psychosis or autism, and severe social adversity. The assessors were blind as to proband, sibling, or control status. The following outcome measures were used: Kiddie SADS, Gilmour Reading Test, subtests of the WISC-III, WAIS, DSM-III-R, GAF, and the Social Adjustment Inventory for children and adolescents (SAICA). The groups were assessed at baseline and 4-year follow-up, when 91% of the groups could be assessed. There were no statistical differences between the groups with respect to age and intact families at intake. Small differences in social class were corrected for statistically.

### Adolescent Outcome

Unless otherwise stated, references for adolescent outcome are as follows: Montreal Study ([Weiss et al., 1971, 1979](#)); New York Study ([Klein and Mannuzza, 1989](#)); and the Milwaukee Study ([Barkley, 1999a](#); [Barkley et al., 1990](#); [Biederman et al., 1996b](#)).

#### EDUCATIONAL ACHIEVEMENT

Poorer grades, more grades failed, and a lower level of education achieved was found in all four studies between the ages of 13 to 18 years. The adolescents previously diagnosed with ADHD (probands) performed more poorly on achievement tests of reading and arithmetic and had more learning disabilities ([Piacentini et al., 1997](#)). We can conclude that the academic difficulties, which characterized ADHD children in elementary school, are compounded in high school.

#### PSYCHIATRIC STATUS

In all four studies, probands were given more psychiatric diagnoses than controls, namely about 50% versus 20%. Probands compared to controls had an increasing number of comorbid disorders at adolescent follow-up including oppositional defiant disorder (ODD), conduct disorder (CD), major depressive disorder (MDD), psychoactive substance abuse disorder (PSUD) ([Biederman et al., 1997](#)), anxiety disorders, and learning disabilities (LD).

#### ANTISOCIAL PERSONALITY DISORDER OR CONDUCT DISORDER

A risk for the development of antisocial personality disorder (APD) or conduct disorder (CD) was found in all four studies. In the New York Study, persistence of ADHD symptomatology into adolescence (with or without hyperactivity) was highly correlated with the development of both APD and PSUD. The risk for APD varied from 23% to 40% in probands versus 1% to 8% of controls in the different studies. The risk of developing APD was greatest in those who had ODD or CD at baseline whose ADHD symptoms persisted into adolescence and for those who came from antisocial families ([Faraone et al., 1998a](#)).

#### Major Depression

In the Montreal Study at a mean age of 13 years, probands showed that they had strong feelings of discouragement or demoralization and had mood lability. DSM-II diagnoses (diagnostic nomenclature at the time) were not given.

In the Biederman study, probands were at risk for the development of MDD in midadolescence by DSM-III-R criteria. Those who had MDD at intake were most at risk for MDD at follow-up. No risk was found for the development of MDD in late adolescence in both the Montreal and New York studies. These differences may be partly explained by the inclusion of children with more comorbidity in the Biederman Study. Biederman's findings also suggested that MDD is a distinct disorder and not just demoralization secondary to ADHD.

#### CIGARETTE SMOKING

At 14 years, probands and their siblings were more likely to smoke cigarettes, and started smoking earlier ([Barkley et al., 1990](#); [Biederman et al., 1996c](#)). Cigarette smoking was associated with MDD, drug abuse, and less treatment received ([Milberger et al., 1997a](#)).

#### CAR ACCIDENTS

Probands in late adolescence had more car accidents with bodily injuries ([Barkley et al., 1993](#); [Weiss et al., 1985](#)).

#### CRIMINALITY

In the New York Study at an average age of 18 years 39% of probands versus 20% of controls had been arrested, 28% versus 11% had been convicted and 9% versus 1% jailed. Twenty-five percent versus 7% of these had been charged with a felony. An important finding was that the presence of APD almost completely accounted for the increased risk of criminality ([Mannuzza and Klein, 1999](#)). These findings were lower than the rates of criminality in Satterfield's study in California,

but higher than those in the Montreal Study ([Hechtman et al., 1984](#); [Satterfield et al., 1982](#)).

#### *FAMILY FACTORS*

In the Milwaukee and Biederman Studies, the families of probands had less stability, higher divorce rate, moved more frequently, and changed jobs more often. The fathers had a higher rate of antisocial disorders than the fathers of controls. In the Biederman Study, the families showed less cohesion and more family conflict (i.e., more evidence of family adversity) and those probands whose parents had antisocial behavior had more anxiety, MDD, antisocial behavior, and aggression at follow-up.

#### *GROWTH*

Adolescents were evaluated for possible growth deficits in the Biederman Study. Small but significant deficits in height were found in midadolescence, which usually normalized by late adolescence, and which were unrelated to the use of stimulants ([Spencer et al., 1996](#)).

#### *CONTINUED SYMPTOMS OR PRESENCE OF FULL ATTENTION DEFICIT HYPERACTIVITY DISORDER SYNDROME IN ADOLESCENCE*

In the Biederman Study, 85% of probands still met full or subthreshold evidence of the disorder, as well as evidence of impairment at a mean age of 14 years. Half of the 15%, which had remitted, did so before age 12 years (early remitters) and half after age 12 years (late remitters). It was found that early remitters and controls did not differ with respect to exposure to parental pathology and family conflict (i.e., on measures of social adversity), but family adversity was markedly elevated in late remitters. Similarly, the incidence of comorbidity and impaired psychosocial and academic functioning was higher in those adolescents whose ADHD had not remitted (Biederman et al., 1996d, [1998b](#)). In the Milwaukee Study, at a mean age of 14 years, 71% of probands versus 3% of controls still met DSM-III-R criteria for the full ADHD syndrome. In the New York study, at a mean age of 18 years, 31% of probands versus 3% of controls had the full syndrome, and 40% had two symptoms of the disorder.

In general, these results indicate that ADHD continues into early adolescence in the majority, 71% to 85%, declining somewhat to about 31% in later adolescence. The studies suggested that persistence of ADHD symptomatology was associated with more comorbidity including CD and APD.

#### **Outcome in Adulthood**

As might be predicted from the nature of the outcome in adolescence, the outcome in adulthood shows impairment in several important domains of functioning. Only three prospective controlled follow-up studies have followed children with ADHD into their twenties: the Montreal study ([Weiss and Hechtman, 1993](#)); two cohorts of the New York Study ([Mannuzza et al., 1993, 1998](#)); and the Milwaukee Study. The Milwaukee Study evaluated their subjects 15 years later at a mean age of 21 years and was able to report on 91% of their original sample. Adult outcome from these three studies are described.

#### *EDUCATIONAL ACHIEVEMENTS*

All three studies found that even in early adulthood children once diagnosed as having ADHD had completed 2 to 3 years less education than matched controls ([Mannuzza et al., 1993, 1998](#); [Weiss et al., 1979](#)). More probands dropped out of high school and less were enrolled in or had completed a graduate degree.

#### *WORK HISTORY*

All three studies had similar findings. Probands at 24 to 25 years had significantly lower occupational status than matched controls ([Mannuzza et al., 1993](#); [Weiss and Hechtman, 1993](#)). In the Montreal Study, employers rated probands significantly worse than controls on work competence, working independently, completing tasks, and getting along with supervisors; and there was a trend suggesting employers would not hire them again ([Weiss and Hechtman, 1993](#)). In the Milwaukee Study, employers rated probands as scoring worse on ADHD and ODD rating scales. The New York Study did not evaluate employer ratings. The most common occupations for both cohorts of the New York Study were skilled workers, such as plumbers, painters, machinists, and mechanics. The Montreal Study found that a greater number were fired or laid off, and they changed jobs more frequently. It is interesting that in spite of lower educational status in all three studies, there were no differences in the percentage currently working or in their annual income.

#### *SELF-ESTEEM AND SOCIAL SKILLS*

The Montreal Study found that self-esteem (Davidson and Lang checklist) and social skills (Situation Social Skills Inventory) were found to be impaired in adolescence, and social skills had deteriorated further in adulthood ([Hechtman et al., 1980](#)).

#### *PSYCHIATRIC STATUS*

##### *Personality Disorders*

All three studies, the Montreal Study, the two cohorts of the New York Study ([Mannuzza et al., 1993, 1998](#)) and the Milwaukee Study, showed that children with ADHD are at risk for the development of antisocial personality disorder (APD). In the Montreal Study, figures were 23% versus 2% ([Weiss et al., 1985](#)); in the New York Study, 12% to 18% versus 2% to 3% ([Mannuzza et al., 1993, 1998](#)); and in the Milwaukee Study, 21% versus 4%. An important question is whether conduct disorder in the childhood of ADHD accounts entirely for APD at adult follow-up. We do not have the answer to this question but both the Montreal and New York Studies excluded children at intake whose main problems lay in antisocial or aggressive behavior. However, some of the probands in the Montreal and New York Studies may have developed early onset conduct disorder after they were included into the study. In contrast, in the Milwaukee Study, the presence of conduct disorder or aggression was not an exclusion criterion for study entrance. It is possible from the overall findings that ADHD in childhood may be a risk factor for APD even in the absence of conduct disorder at baseline; however, the risk for developing APD is higher once conduct disorder develops.

It is interesting that the Milwaukee Study found that the probands also were at risk for other personality disorders, namely passive aggressive (19% versus 8%), borderline (14% versus 2%), histrionic (11% versus 0%), and narcissistic personality disorder (5% versus 0%), as measured on the semistructured interview for DSM personality disorders (SCID II).

##### *Mood Disorders*

Both the Montreal and New York Studies failed to find more major depression (MDD) in probands than in controls at age 24 to 25 years. This is in contrast to the finding in the Milwaukee Study, where 27% of probands versus 12% had MDD at follow-up. This confirmed the finding of increased MDD in the Biederman adolescent outcome study. There was a higher level of comorbidity in probands than controls in both the Montreal and Milwaukee Studies.

As mentioned in the section on adolescent outcome, the difference may be in whether or not children with conduct disorder were included in the study and used different measures of MDD outcome.

##### *Polysubstance Use Disorder*

Findings are inconsistent with respect to polysubstance use disorder (PSUD) at the time of adult reevaluation. The Montreal Study failed to find significant differences between probands and controls with respect to PSUD, but there was a trend for probands to have tried heroin and sold drugs more often. There was also a trend for more probands than controls to fall into the abuse category with respect to amount of alcohol consumed in the past 12 months ([Hechtman et al., 1984](#)).

In both cohorts of the New York Study, PSUD was significantly more prevalent in probands than controls (12% to 16% versus 4%) ([Mannuzza et al., 1993, 1998](#)). This is in agreement with the findings of the Milwaukee Study ([Milberger et al., 1997d](#)) in which probands were at increased risk for cocaine (37% versus 18%), and amphetamine use (29% versus 8%). Variations in cultural factors among sites, as well as variations in the point of time in which follow-up assessments were done, could have influenced the variations of outcome with respect to PSUD. For example, 8% of the control group in the Milwaukee Study used amphetamine; in contrast,

only a single control subject had tried amphetamines in the Montreal Study, and none had used heroin versus 3% in the Milwaukee Study.

### *Sexual Behavior*

The Milwaukee Study found that probands had intercourse at an earlier age than controls (15.4 versus 16.5 years) and had had more sexual partners (18.5% versus 16.5%). They were less likely to use birth control (76% versus 91%), and had more pregnancies (38% versus 4%). Most importantly, they had more sexually transmitted diseases (17% versus 4%) and more subjects had been tested for HIV, 21% versus 5.4%.

### *CONTINUING ATTENTION DEFICIT HYPERACTIVITY DISORDER SYMPTOMS OR ATTENTION DEFICIT HYPERACTIVITY DISORDER IN ADULTHOOD*

The Montreal and New York Studies differed significantly in their findings. The two cohorts in the New York Study ( [Mannuzza et al., 1993, 1998](#)) found that 4% to 11% of the probands met criteria for ADHD in adulthood by DSM-III criteria. The [Weiss Study \(1985\)](#) found that 66% still had disabling ADHD symptoms, but this study did not use the maintenance of the full syndrome as an outcome measure, reflecting the fact that different assessment methodologies result in different findings.

Only the probands themselves were evaluated at follow-up in the New York Study, whereas parents were included as part of the follow-up assessment in the Montreal Study. The Milwaukee Study highlighted how different ways of assessing outcome in adulthood changes the findings and also gave evidence of how parents rate probands as having a poorer outcome of the syndrome than did probands themselves. When they used the Milwaukee Young Adult Interview Self-Report, on which eight of 14 symptoms are required for diagnosis, only 3% now met diagnostic criteria. When they used 1½ standard deviations from the mean of the control group, 25% still met diagnostic criteria. However, on the parent version of this scale, parents reported that 58% still met diagnostic criteria. When DSM-IV criteria were used with parents, 42% of probands still met diagnostic criteria. The Milwaukee Study concluded that by self-report 2% met diagnostic criteria at a mean age of 21 years, or 25% if two standard deviations from the mean were used as a criterion. However, on parent reports the rate of persistence of the syndrome was 58% to 68%. This figure is quite similar to that in the Weiss Study.

The Milwaukee findings help to clarify differences between the Montreal and New York groups, because persisting symptoms were included and parents were interviewed in the former, whereas the latter relied on self-reports, did not include parent ratings, and did not count disabling continued symptoms (if they did not meet full diagnostic criteria).

The Biederman Study (unpublished) found that at 18 to 20 years, 65% had achieved full syndrome remission, 27% had achieved symptomatic remission (less than half of the symptoms required for the full disorder), and only 10% had achieved functional remission (measured as being higher than 65 on the GAF). In this study, hyperactivity had greatly improved by 9 to 11 years, and impulsivity by 12 to 14 years, but attention problems persisted.

It is clear from the preceding that how remission is measured (full syndrome, symptomatic remission, or functional remission) or 1½ to two standard deviations from the mean on a rating scale changes the findings. The figures for remission also vary according to whether adult probands report on themselves or their parents' reports are taken. No gold standard has been found to measure outcome, and it is hardly surprising that differences are found.

### **FUTURE DIRECTIONS**

The summary of research and clinical investigation reviewed in the preceding opens up questions of future research opportunities. We close by summarizing some of the developments that we anticipate may characterize the next 5 years.

The broadening of the diagnostic criteria for ADHD has made it evident that we need to learn more about the impairment suffered in preschool, adolescence, and adulthood, as well as the reliability and validity of our diagnostic criteria for these populations. We need to carry out specific treatment studies that focus on each of these developmental stages. By the same token, we also need to explore the various diagnostic subtypes. How specific are diagnoses of ADHD-HI subtype in preschool? How specific are diagnoses of ADHD-IA in adolescents and adults? Do males and females present differently?

This in turn raises the issue of how we assess attention in general, and the relationship between difficulties with attention and broad deficits in executive function. Hopefully, we will learn more about how treatments initially developed for ADHD-combined type help or do not help patients who suffer from problems with attention and executive function.

The last 5 years have witnessed an explosion of new pharmaceutical interest in medication development for ADHD, and have led to the first new treatments for ADHD in half a century. We anticipate that many issues around compliance will be addressed by better long duration stimulants, and many issues of management of rebound, tolerance, and comorbid anxiety/depression will be addressed by new and more effective designer antidepressants specifically created for round the clock coverage of ADHD. These medications need short- and intermediate-term clinical trials, but functional longer-term assessment of the impact of medication also is critical. Some of this information may come out of the 10-year follow-up of the MTA.

The majority of patients with ADHD also suffer from other conditions, and often it is the other disorder that determines outcome. Specific clinical trials on treatment of ADHD with other disorders may allow us to develop treatments specific to comorbidities, as opposed to trying to apply treatment strategies developed for simple ADHD cases to children with more complex presentations. The MTA has led to more specific knowledge of ADHD with other disorders and has opened new methodologies for exploring this further.

Finally, we conclude by noting the critical importance of extending the education of all health care specialties around this disorder because it presents at different stages of the life cycle and in different environmental contexts. Recent attempts to formalize clinical knowledge in practice parameters have already begun to lay a foundation for such educational initiatives.

Conduct disorder is a diagnostic category that is so broad and all-encompassing that it requires more deliberation to avoid the diagnosis than to make it. It is, consequently, one of the most frequently made diagnoses in child psychiatry ( [McDermott, 1996](#)). Experienced clinicians, however, know that nearly every other psychiatric diagnosis of childhood and adolescence may, under certain circumstances, be manifested by disordered, obnoxious, aggressive behaviors. Conduct disorder, as currently defined, includes such diverse behaviors as staying out late, fire setting, and sexual assault. By covering such a broad spectrum of behaviors, the diagnosis catches in its net a multitude of sins, as well as a multitude of different kinds of neuropsychiatric and psychosocial conditions and combinations thereof. Children have a limited verbal capacity as well as a limited repertoire of behaviors with which to express their discomfort, misery, and confusion. Therefore, the same kinds of maladaptive behaviors in different children can be indicators of very different kinds of problems.

Potentially treatable conditions such as attentional problems, brain damage, mood disorders, psychoses, and dissociative states frequently present with disruptive behaviors that also meet the diagnostic criteria for conduct disorder. Moreover, hidden physical, sexual, and emotional abuse play important roles in the genesis of certain kinds of aggressive behaviors and inappropriate sexual behaviors. The failure to recognize such vulnerabilities can have devastating consequences. This chapter familiarizes the clinician with some of the most common treatable conditions that underlie the antisocial, often aggressive behaviors of children and adolescents diagnosed with conduct disorder.

### HISTORICAL NOTE

Conduct disorder, listed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) under Disruptive Behavior Disorders ( [American Psychiatric Association, 1994](#)), is the latest term used to designate children whose signs, symptoms, and behaviors impinge more on others than on the child or adolescent with the condition. Although many of its childhood manifestations are very similar to the behaviors of adults diagnosed with antisocial personality disorder, conduct disorder has been separated from that adult diagnosis to acknowledge what psychiatrists believe to be a greater potential for change in the young. The diagnosis harkens back to a period in the history of psychiatry antedating the very existence of the field of child psychiatry, a time in which adult psychiatrists struggled to understand the behaviors of their recurrently antisocial but not overtly psychotic patients. Terms such as *manie sans delire* (mania without delirium) ( [Maugh, 1941](#)) and *moral insanity* ( [Prichard, 1837](#)) were used to designate patients with recurrently antisocial behaviors who were not blatantly psychotic.

In 1952, the diagnosis of “Sociopathic Personality: Antisocial Reaction” for adults was codified by the American Psychiatric Association in DSM-I ( [American Psychiatric Association, 1952](#)). Individuals so diagnosed were described with pejoratives: immature, disloyal, hedonistic, irresponsible, and unable to benefit from experience or punishment. In DSM-II ( [American Psychiatric Association, 1975](#)), under the category of Behavior Disorders of Childhood and Adolescence, the diagnosis for behaviorally maladapted children became “Unsocialized Aggressive Reaction of Childhood (or Adolescence).” The words used to delineate this syndrome were more judgmental than scientific (e.g., quarrelsomeness, vengefulness, disobedience).

In 1980, DSM-III ( [American Psychiatric Association, 1980](#)) was published, and with it came the new category, conduct disorder. Like its predecessor, conduct disorder was used to designate children with behaviors ranging from truancy and substance abuse to rape and assault. Conduct disorder was divided into four different categories: aggressive and nonaggressive, socialized and undersocialized.

In DSM-III-R ( [American Psychiatric Association, 1987](#)), the four subtypes of conduct disorder gave way to three other subtypes: (a) solitary aggressive type, (b) group type, and (c) undifferentiated type. For a child to qualify for the diagnosis of conduct disorder, he or she needed only to have manifested 3 of 13 types of undesirable behaviors.

Little in the definition of conduct disorder changed between DSM-III-R and DSM-IV. DSM-IV defines conduct disorder as “A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated as manifested by the presence of three (or more) of 15 criteria in the past 12 months, with at least one criterion present in the past 6 months.” As can be seen in [Table 53.1](#), the 15 criteria include widely diverse kinds of behaviors, grouped into four very different categories from DSM-III-R, namely: (a) aggression to people and animals, (b) destruction of property, (c) deceitfulness or theft, and (d) serious violations of rules. The changes in categorization from DSM-III to DSM-III-R to DSM-IV reflect the difficulties framers of these documents had in getting a handle on the disorder. All 13 of the original behaviors listed in DSM-III-R reappear in DSM-IV, plus two additional behaviors, bullying or intimidating and staying out late in spite of parental prohibitions. Given the diversity of behaviors listed, a child who has shoplifted, lied, and stayed out late could receive the same diagnosis as a child who has robbed banks, pistol-whipped guards, and raped toddlers.

**Table 53.1. Diagnostic Criteria for Conduct Disorder (312.8)**

The DSM-IV distinguishes two kinds of conduct disorder that are based not on behaviors, but rather on age of onset. Childhood-onset type is defined by 3 or more of the 15 listed behaviors, at least 1 of which must have occurred before age 10 years. Adolescent-onset type is defined by an absence of any of these behaviors before age 10 years. This distinction is made because of the especially poor prognosis for children whose maladaptive behaviors start early in life because they tend to have more neuropsychiatric vulnerabilities, to require more psychiatric treatment later in life, and to act more aggressively ( [Lahey et al., 1999](#) ).

As with other diagnostic categories, diagnosticians are required by DSM-IV to specify the severity of the clinical picture by ratings of mild, moderate, or severe. Because all 15 of the behaviors listed are signs, not symptoms, the definition of conduct disorder does not distinguish among assaultive children who are paranoid and retaliate in response to imagined threats, those who fight because they are frequently the butt of teasing, those with episodic manic rages, or those with organic conditions that impair impulse control. Children with the disorder are described as callous, unempathic, and without remorse, terms more reflective of an examiner's attitude than his or her clinical judgment. It is therefore up to the user of DSM-IV to keep in mind that all 15 behaviors listed under conduct disorder, and combinations thereof, occur as part of numerous other diagnoses. The clinician must refrain from using the diagnostic category of conduct disorder in cookbook fashion, ticking off behavioral ingredients and measuring the length of time they have been heating up. Making a diagnosis is different from making a lamb stew.

**EPIDEMIOLOGIC AND SOCIOLOGIC PERSPECTIVES**

Because the criteria for making the diagnosis of conduct disorder vary from time to time and place to place, it is impossible to determine its prevalence. It is, however, one of the most frequently made diagnoses in the United States ( [Quaay, 1999](#) ), undoubtedly because of its broad definition. Estimates of prevalence have ranged from 1% to 10%, depending on the city, country, and period in which studies have been conducted. On the other hand, the occurrence of juvenile violence, commonly considered synonymous with conduct disorder, is easier to measure. Within societies, violence flourishes in urban areas ( [Elliott et al., 1989](#) ) and in the lowest socioeconomic sectors of cities ( [Blau and Blau, 1982](#); [Currie, 1998](#); [Shihedeh and Ousey, 1998](#) ). The association of poverty and violence is found in other cultures, as well as in the United States ( [Farrington, 1989](#); [Merton, 1963](#) ). It is not just poverty but, rather, *extreme* poverty, with which violence is associated ( [Krivo and Peterson, 1996](#) ). Disorganization, joblessness, single-parent homes, and what [Currie \(2000\)](#) has termed *brutalization* are more prevalent in conditions of extreme socioeconomic deprivation. Study after study confirms the finding that violent youths are disproportionately those who themselves have been victimized ( [Lewis et al., 1988, 1989](#); [Smith and Thornberry, 1995](#); [Widom, 1989](#) ). Other factors associated with the development of aggressive behaviors are broken homes ( [Farrington, 1998](#); [Henry et al., 1996](#) ), large family size ( [Capaldi and Patterson, 1996](#); [Farrington, 1998](#) ), and gang membership ( [Thornberry, 1998](#) ). Of note, studies indicate that violence often precedes membership in a gang ( [Thornberry, 1998](#) ) and therefore is not necessarily a result of membership.

[Farrington and Loeber \(2000\)](#) conclude that the most important variables contributing to ongoing aggressive adaptational styles are "individual (high impulsiveness and low intelligence, possibly linked to the executive functions of the brain); family (poor supervision, harsh discipline, child physical abuse, a violent parent, large family size, poverty, a broken family); peer delinquency; gang membership; urban residence; and living in a high crime neighborhood (characterized by gangs, guns, and drugs in the United States)." We would add that, in our clinical work, we have found that severe parental psychopathology also contributes greatly to the chaos and violence in the households of aggressive children and adolescents. Parental mental illness can be crucial to understanding a family's chaotic relationships, inability to provide adequate financial support, poor disciplinary practices, and violent, abusive behaviors.

**COURSE**

An abundance of data indicates that early severe behavioral problems often are followed by a variety of subsequent adaptational difficulties. [Bauermeister and colleagues \(1994\)](#), in their elegant literature review, concluded, "Preschool behavior problems are a strong risk factor for antisocial disruptive disorders at preadolescence." Several studies reported that aggressive behavior problems at 8 years of age were predictive of serious delinquency in adolescence ( [Lefkowitz et al., 1977](#); [West and Farrington, 1973](#) ). A study of youths from four U.S. communities documented a strong association between very early behavior problems and subsequent serious, aggressive behaviors and psychiatric problems ( [Lahey et al., 1999](#) ). As a result of these kinds of findings, DSM-IV distinguishes two types of conduct disorder, one, an aggressive type, starting in early childhood; the other, a nonaggressive type, starting in preadolescence or adolescence. Almost all studies, regardless of time, place, or sample, have found conduct disturbances to be far more common in boys than in girls.

It is important to keep in mind that, despite the aforementioned findings, most behaviorally disturbed children do *not* go on to become antisocial or criminal adults ( [Robins, 1966](#); [Rutter and Giller, 1984](#) ). Even among those children and adolescents whose behaviors bring them in conflict with the law, there is evidence that only a small proportion become recidivists ( [Tracy et al., 1990](#) ). However, this recidivistic group commits a disproportionate number of adult criminal acts.

Because of the diversity of the psychopathology underlying them, conduct disorders are followed by a wide range of psychiatric and adaptational problems other than antisocial or criminal behaviors ( [Rutter and Giller, 1984](#) ), including mood disorders, anxiety disorders, somatoform disorders, substance-related disorders, and psychoses ( [American Psychiatric Association, 1994](#); [Lewis et al., 1991, 1994](#); [Robins, 1966](#) ). [Hechtman and Offord \(1994\)](#) observed that, in addition to criminality and mental illness, early childhood disorders of conduct also are predictive of "widespread social malfunction, as seen in high rates of divorce and separation, poor work history, and unsatisfactory social relationships."

**CLINICAL DESCRIPTION**

Because disordered conduct can be a manifestation of such a wide variety of different neuropsychiatric conditions or can coexist with them, a useful way of approaching a child with behavioral problems is to try to identify first his or her intrinsic vulnerabilities to maladaptation. That is, are there any potentially remediable psychiatric, neurologic, medical, or cognitive problems that underlie and contribute to the child's undesirable behaviors? Second, what are the environmental stressors that influence the disruptive ways such vulnerabilities are expressed?

**Psychiatric Vulnerabilities**

Children with maladaptive, aggressive behaviors rarely appear to have serious neuropsychiatric problems. The key word in the previous sentence is *appear*. Unfortunately, their obnoxious behaviors overshadow underlying psychopathology and tend to deter clinicians from conducting the kinds of comprehensive evaluations necessary to uncover it. This section focuses on some of the most common psychiatric conditions underlying the behaviors associated with conduct disorder.

**ATTENTION DEFICIT HYPERACTIVITY DISORDER**

The diagnosis attention deficit hyperactivity disorder (ADHD) is characterized by impulsivity, short attention span, cognitive and social disinhibition, overactivity, social inappropriateness, poor judgment, and school problems, all of which are seen in children diagnosed with conduct disorder ( [Barkley, 1997](#) ). Evidence from neuroimaging studies suggests ADHD can be associated with a variety of different structural and functional brain abnormalities ( [Baving et al., 1999](#); [Mataro et al., 1997](#); [Rubia et al. 1999](#); [Zametkin et al., 1993](#) ). ADHD is one of the most common diagnoses of both violent and nonviolent delinquents, second only to that of

conduct disorder ([Biederman et al., 1991](#); [Offord et al., 1991](#)). However, the relationship between delinquency, aggression, and ADHD is not entirely clear. ADHD alone is not strongly predictive of a delinquent outcome. For example, longitudinal studies of boys with ADHD ([Lambert et al., 1987](#); [Mannuzza et al., 1989](#); [Weiss et al., 1971](#)) have shown that only 19% to 27% of hyperactive boys became antisocial in adolescence. When ADHD is coupled with other disorders, however, a poor outcome is more likely. Children with both ADHD and early conduct problems appear to be at greatest risk for later aggression and delinquency ([Dalteg and Levander, 1998](#); [Farrington et al., 1990](#); [Foley et al., 1996](#)).

One of the most interesting if misdiagnosed causes of episodic uncontrollable tantrums which can masquerade as conduct disorder/ADHD is the acute confusional state sometimes associated with migraine auras. These auras, indicators of brain dysfunctions deep in the brain and parts of the cortex, last minutes to hours and can occur before, during, after or in between migraine headaches. Children experiencing them may periodically go on rampages, destroying objects and attacking people who get in their way. These kinds of attacks may precede by years the development of headaches and can therefore, be extremely difficult to diagnose (see [chapter 29](#)).

The clinician must be cautious when considering a diagnosis of ADHD for behaviorally disordered or aggressive youngsters because inattention, overactivity, impulsivity, and poor judgment also are characteristic of other disorders [e.g., manic and hypomanic states ([Carlson, 1996](#)), dissociative disorders ([Lewis and Yeager, 1996](#))].

## MOOD DISORDERS

Depression and suicide attempts are well recognized concomitants of adolescent aggression and delinquency ([Loeber et al., 1991](#); [Zoccolillo, 1992](#)). More recently, however, child psychiatrists have begun to appreciate the relationship of mania to delinquent behaviors. In a study of 50 incarcerated youths, 20% were found to meet diagnostic criteria for mania ([Pliszka et al., 2000](#)). Mania in behaviorally disordered children looks very much like ADHD, oppositional defiant disorder, or conduct disorder, and does not have the "classic" presentation seen in adulthood ([Carlson, 1996](#)). In adolescence, the mood swings tend to be "mixed" or rapid cycling as opposed to the clearly defined episodes seen in adults with the disorder.

Whenever the clinician is confronted with a grandiose, boastful, belligerent, delinquent youngster, a bipolar diagnosis should be considered. Unfortunately, such youngsters alienate examiners and often are dismissed as merely narcissistic and sociopathic. Mania can manifest as vandalism sprees or sporadic episodes of robbery and burglary. One of our especially violent patients, when manic, shot out the street lights in his hometown. The disorder was not diagnosed until a second manic episode occurred during which a series of burglaries and a high-speed chase led to the shooting death of two officers.

## THOUGHT DISORDERS

Few seriously conduct-disordered or aggressive juveniles appear overtly psychotic. Nonetheless, their episodically violent and bizarre behaviors sometimes are manifestations of sporadic psychotic thinking and hallucinations. When not under stress, these children usually can maintain a normal facade. [Bender \(1959\)](#) made the observation that children who were psychotic in their early years appeared to be merely antisocial during adolescence. The most common psychotic symptom of aggressive children and adolescents is paranoid thinking ([Dodge et al., 1990](#); [Lewis et al., 1979b, 1989](#); [Myers et al., 1995](#); [Ulzen and Hamilton, 1998](#)). Unfortunately, their paranoia and grandiosity often are misconstrued as bravado or simply as the result of living in a tough neighborhood. Youngsters who view the world as a hostile, threatening place are primed to attack. Their grandiosity gives the appearance of remorselessness.

Our own studies suggest that the more violent or bizarre the youngster's acts, the more likely he or she has underlying psychotic symptomatology ([Lewis et al., 1979b, 1989](#)). Many aggressive juveniles who experience episodic auditory hallucinations try to hide these symptoms for fear of being labeled "crazy." We recently examined a 15-year-old boy who had gone on a shooting spree, killing and wounding several children. Periodically, since 12 years of age, he had heard voices in his head inciting him to violence. He had told no one about them.

## DISSOCIATIVE DISORDERS

It should come as no surprise that the scientific literature on delinquency and aggression fails utterly to recognize the existence of dissociative disorders, much less their contribution toward violent behavior. Our own early work is a case in point. We never considered the possibility that dissociative disorders, especially dissociative identity disorder, might account for particularly puzzling symptoms or bizarre behaviors in the violent youths we examined. Years ago, the fact that dissociation might have explained why some of the children we saw did not recall their acts never even occurred to us. However, as we learned, during dissociative episodes children may curse, steal others' belongings, set fires, even attack others, and subsequently deny their acts because they do not remember them. Many of the symptoms usually associated with complex partial seizures (e.g., lapses, staring spells, impaired memory, dreamlike states) also are characteristic of dissociation.

Children with severe dissociative disorders often hear voices in their heads ordering them to strike out at others or to kill themselves. Sometimes they are misdiagnosed schizophrenic. In fact, it has been reported that 19% of male patients with dissociative identity disorder are actually homicidal ([Loewenstein and Putnam, 1990](#)). Severe abuse and resultant dissociative disorders often are associated with extreme violence. In one study sample of severely abused, behaviorally disturbed children in residential treatment, dissociative symptoms abounded ([Trujillo et al., 1996](#)). However, because of their distractibility and episodic aggression, all of these children carried diagnoses of conduct disorder or ADHD. We reported the objective documentation of childhood dissociative symptoms and a history of extraordinary abuse in a series of 12 adult murderers with dissociative identity disorder ([Lewis et al., 1997](#)).

Among the many behaviors characteristic of the childhood externalizing disorders that also are typical of dissociation are episodic aggression, inappropriate sexual behaviors, mood lability, denial of behaviors, wandering away from home or school for hours or days, and apparent stealing (e.g., finding something in one's possession and denying any knowledge about how it got there). When the dissociative nature of these signs and symptoms goes unrecognized, children are dismissed as liars and thieves—in other words, as having a conduct disorder.

## SUBSTANCE ABUSE

Over half of violent crimes are committed when perpetrators are under the influence of alcohol ([Pihl and Peterson, 1993](#)). U.S. regional surveys have found that between 40% and 60% of male juvenile arrestees have drugs or alcohol in their systems at the time of detainment ([ADAM, 1999](#)). Surveys of high school students in urban areas reveal that drug and alcohol use is associated with increased risk of violent behavior, especially weapon carrying and fist fights ([Dukarm et al., 1996](#)). Similarly, violent adolescents are, reportedly, more likely than their less aggressive peers to use illicit substances ([DuRant et al., 1997](#)). Estimates of the prevalence of "multiproblem" youths in our society range from 4% to 20%—that is, youths who are violent, abuse substances, and have emotional problems ([Dryfoos, 1990](#); [Ellickson et al., 1997](#); [Elliot et al., 1989](#)).

The earlier and more serious the child's aggression, the greater the risk for subsequent substance abuse ([Loeber and Keenan, 1995](#)). Unfortunately, the causes underlying these aggressive behaviors rarely are determined before the onset of substance abuse. Looking backward, after an adolescent has committed aggressive acts and has started abusing alcohol or drugs, often all the clinician can discern in the distant past is a history of poor behavior, of conduct disorder.

Although the violence-promoting effects of most drugs seem to depend greatly on the psychological and physiologic condition of the user/abuser, and on environmental influences, there are certain substances that, in and of themselves, have reportedly engendered violence. These include crack cocaine ([Honer et al., 1987](#); [Taylor, 1990](#)), phencyclidine (PCP) (Fauman and [Fauman, 1982](#)), and the amphetamines ([King and Ellenwood, 1992](#)). We have evaluated several homicidal individuals, one a teenager, whose murderous acts took place while coming down from methamphetamine. The effects of benzodiazepines and barbiturates reportedly are dose dependent; low doses tend to decrease aggression, whereas moderate to high doses may increase it ([Cherek, 1990](#); [Taylor, 1990](#)). Marijuana, the most frequently used illicit substance among teenagers in the United States, usually causes relaxation and euphoria. In some individuals, however, it creates paranoia and panicky states that can lead to violence. It also may be laced with more dangerous substances (e.g., PCP) ([Hall and Solowij, 1998](#)).

The use of body-building substances also has been associated with violence. The anabolic steroids induce irritability, hostility, anger, and outright aggression ([Bahrke et al., 1990a, b](#); [Choi et al., 1990](#); [Parrott et al., 1994](#); [Uzych, 1992](#)). Some of the nonsteroidal substances consumed by body builders also can engender violence. We evaluated an otherwise nonviolent man who became homicidal while taking a mixture of ephedrine, caffeine, and chromium picolinate.

Substance abuse is used by different juveniles for different reasons, including attempts to self-medicate for depression, anxiety, panic episodes, psychosis,

dissociation, and hyperactivity. In fact, the drug of choice may provide a clue to the underlying disorder. It is therefore important to ask how the substance in question affects the youngster.

### Neurologic Vulnerabilities

As in the case of psychiatric vulnerabilities, neurologic impairment in conduct-disordered children rarely is obvious. In the past, neurologists tended to minimize the importance of "minor" head injuries (e.g., those that did not lead to prolonged periods of unconsciousness). We now know that even minor concussions from, for example, athletic injuries can have a cumulative effect, even when bleeding is not detectable on magnetic resonance imaging (MRI) ( [Pearl, 1998](#)). The temporal and frontal poles of the brain are especially vulnerable ( [Varney, 1999](#)). Recurrently violent children and adolescents have such horrendous medical histories ( [Lewis and Shanok, 1977](#); [Lewis et al., 1979a](#)) that it often is impossible to determine exactly when injury to the brain occurred. Even mild concussions may cause cognitive impairment ( [McCrea et al., 1997](#)), and children who have sustained one concussion are reportedly at higher risk for permanent damage from a second head injury than are their noninjured peers. Although the areas of damage cannot necessarily be localized, any injury to the brain may increase emotional lability, diminish judgment, and impair impulse control. Frontal lobe damage or dysfunction, in particular, has been associated with aggression ( [Raine et al., 1994, 1997b, 1998](#)). The frontal lobes contain the "executive" parts of the brain that are responsible for judgment, foresight, impulse control, and the appreciation of interpersonal cues. Damage to them impairs social functioning even when intellect remains intact. The frontal lobes also modulate the strong feelings emanating from the limbic system. Injury to the ventromedial parts of the frontal lobes affects autonomic responsiveness (e.g., blood pressure, heart rate, skin conductance). Studies of patients with damage to these areas revealed impaired physiologic responsiveness to emotionally charged materials ( [Damasio, 1998](#)).

Unfortunately, there is a paucity of data on orbitofrontal functioning in aggressive or delinquent children. Only one study has examined the effects of very early orbitofrontal damage on personality development and psychosocial adaptation in two children ( [Anderson et al., 1999](#)). Although both children reached developmental milestones at the usual times, both began to exhibit patterns of serious social maladaptation early on, including inability to follow rules or learn from punishment, lack of empathy toward others, lack of motivation and initiative, emotional lability, inability to develop friendships, and chronic lying, stealing, and physical fighting.

Few seriously conduct-disordered children or adolescents have epilepsy. However, many, perhaps by virtue of their adverse medical histories, have equivocal or diffusely abnormal electroencephalograms (EEGs). Psychomotor seizures (complex partial seizures), although uncommon in the conduct-disordered population, have been reported to be significantly more common in very violent delinquents than in the general population ( [Lewis et al., 1982](#)). Whether violent acts can occur during a seizure remains an area of heated debate. However, individuals with seizures often are more irritable interictally than persons without the condition.

### Intellectual and Cognitive Vulnerabilities

Most conduct-disordered children are not severely retarded. On the other hand, as a group, they tend to score in the low-normal or borderline ranges of intelligence as measured by standard tests ( [Hirschi and Hindelang, 1977](#); [Schonfeld et al., 1988](#); [Wilson and Herrnstein, 1986](#)). This association of behavior problems and intelligence quotient (IQ) has been documented to exist as early as 3 years of age, and hence is thought not to be the result of school failure ( [Richman et al., 1982](#)). Cognitive problems have been found to precede behavior problems ( [Schonfeld et al., 1988](#)). [Moffitt \(1990a\)](#) reported that aggressive delinquents whose behavior problems started early scored significantly lower on IQ tests than other samples of delinquent children. Because these intellectual deficits rarely are severe, behaviorally disordered children find themselves on the border of a diagnosis.

Learning disabilities, especially verbal learning deficits, are prevalent among behaviorally disordered and delinquent juveniles ( [Robbins et al., 1983](#)). Reading disabilities in particular have been associated with specific neurodevelopmental abnormalities in the language areas of the cerebral cortex ( [Galaburda et al., 1985](#); [Hynd et al., 1998](#)). Exactly how learning disabilities relate to behavior problems is unclear. We do know that verbal deficits limit a child's ability to express feelings in words rather than deeds. Furthermore, learning-disabled children experience more peer rejection and neglect than their normal schoolmates ( [Hazel and Schumaker, 1988](#)). It may be that learning disabilities are simply the most apparent sign of more pervasive neuropsychological impairment that, as a whole, diminishes judgment and increases impulsivity. Learning-disabled children whose difficulties include visual-spatial (right hemisphere) processing deficits frequently also have seriously impaired social skills ( [Reynolds, 2000](#); [Rourke and Furest, 1991](#)). These children tend to misread social cues, associated facial expression, body language, and tone of voice and, consequently, respond inappropriately.

The frontal lobe dysfunction characteristic of many conduct-disordered children impairs memory, abstract reasoning, and concentration, all of which are vital to the learning process ( [Moffitt and Lynam, 1994](#); [Skoff and Libon, 1987](#); [Wolff et al., 1982](#)). The cognitive deficits of behaviorally disordered children often appear clinically mild and such youngsters rarely score in the severely impaired range on testing. Hence, these children do not look "brain damaged." When such deficits in executive function are overlooked and untreated, children tend to be labeled simply as conduct disordered.

## ETIOLOGY AND PATHOGENESIS

For decades, the most influential theories regarding the development of antisocial behaviors were sociologic. Most influential was Merton's assertion that socioeconomically disadvantaged youngsters, unable to succeed through legitimate avenues, would, of necessity, turn to crime ( [Merton, 1938, 1957](#)). Others hypothesized that antisocial behaviors were not aberrant but, rather, were manifestations of a subculture of violence ( [Cohen, 1955, 1956](#)). However, more recently, even sociologists agree that socioeconomic disadvantage accounts only in part for antisocial behaviors.

### Possible Physiologic and Biochemical Contributions to Conduct Disorder

Over the past quarter century, investigators have struggled to find measurable physiologic characteristics with which to identify conduct-disordered and antisocial individuals. [Mednick \(1981\)](#) and [Hare \(1970\)](#) have hypothesized antisocial individuals suffer from an inherent autonomic hyporeactivity. They theorized that, as a consequence, delinquency-prone youngsters are less likely to inhibit their antisocial behaviors in response to aversive stimuli (i.e., punishment). [Porges and colleagues \(1996\)](#) reported an association between an infant's difficulties regulating the "vagal brake" (slowing of the heart rate) and subsequent behavioral problems at 3 years of age. More recently, [Damasio and colleagues \(1998\)](#) showed a relationship between damage to ventromedial parts of the frontal lobes and impaired autonomic responsiveness. This finding suggests that if autonomic hyporesponsivity exists in behaviorally disordered individuals, it may not be an inherited but, rather, an acquired condition. [Raine and colleagues \(2000\)](#) measured a variety of autonomic nervous system functions and found significant differences between a group of antisocial, aggressive individuals and comparison groups of substance abusers and healthy control subjects, and hypothesized a "significant brain basis" to antisocial personality disorder.

Studies of animals and humans suggest that such neurotransmitters as dopamine, norepinephrine, serotonin, and vasopressin influence aggressiveness ( [Ferris et al., 1998](#)). A strong association has been found between diminished amounts of serotonin in the central nervous system (CNS) and aggressive behaviors ( [Brown et al., 1979](#); [Coccaro et al., 1989](#); [Virkkunen et al., 1989](#)). Others are studying possible links between impaired metabolism of noradrenergic substances and aggressiveness ( [Pliszka et al., 1988](#); [Rogeness, 1994](#)). (For a more detailed discussion of the neurobiology of aggression, see [Chapter 29](#), Development of the Symptom of Violence).

The reader should bear in mind that the study of the neurophysiology of violence is in its infancy and that environment strongly influences the functioning of the CNS.

### Genetic Perspectives

Reports in the 1960s and 1970s suggested an association between certain chromosomal anomalies (47,XYY anomaly) and increased sociopathic tendencies ( [Casey et al., 1966](#); [Nielson, 1968](#)). However, few prisoners have the 47,XYY complement of chromosomes ( [Baker et al., 1970](#); [Jacobs et al., 1971](#)), and the overwhelming majority of people carrying the anomaly remain outside prisons and mental hospitals ( [Gerald, 1976](#)). Certain chromosomal abnormalities may impart a greater vulnerability to a variety of different problems in adaptation that manifest themselves as aggressiveness only in certain contexts ( [Owen, 1972](#)). There are studies that indicate that dysfunctional households may determine whether an individual with a particular genetic anomaly will manifest antisocial behaviors ( [Nielson, 1968](#)).

In another approach to issues of heredity, [Hutchings and Mednick \(1974\)](#) studied the records of adopted-away offspring of criminal fathers and found that their children were more likely to become antisocial than were the adopted-away children of noncriminal fathers. The children at greatest risk for antisocial behavior were those with criminal biological fathers and criminal adoptive fathers, a finding consistent with an interplay of genetic and environmental influences. Studies like these, relying as they do on registered parental criminality, must be interpreted with caution. They do not take into consideration the likelihood that parental criminality, especially in men, may simply be the most obvious manifestation of other, underlying neuropsychiatric disorders. There is, after all, strong evidence that the children

of parents who have a variety of different psychiatric disorders are more likely than the children of healthy parents to have behavioral problems ( [Moffitt, 1987](#); [Wilson and Herrnstein, 1986](#)). As [Walker et al. \(1989\)](#) have stressed, mentally ill parents often act in aggressive and neglectful ways and thereby contribute to maladaptation.

Regardless of etiology, the adaptational problems of males are especially likely to be manifested through aggressive acts compared with those of females. Unfortunately, disruptive males are more likely than females to be dismissed simply as delinquent or criminal and to be incarcerated, regardless of the neuropsychiatric underpinnings of their behaviors.

[Alsbrook and Pauls \(2000\)](#) observed, "Studying the genetics of behavior and psychiatric disorders is a particularly difficult endeavor since they are complex traits.... Genetic variables may be independent single genes (loci) or as is more likely to be the case, multiple loci functioning within the larger context of numerous environmental influences."

Researchers are only beginning to identify those genes that influence temperament and behavior ( [Buss and Plomin, 1984](#); [Gjone and Stevenson, 1997](#)). For example, genes have been identified that control the synthesis and degradation of particular neurotransmitters. [Brunner and colleagues \(1993\)](#) described a family in the Netherlands in which several of the male members exhibited aggressive, impulsive behaviors. Each of them was discovered to have a mutation in his monoamine oxidase-A (MAO-A)-regulating gene, which resulted in a deficiency of the enzyme. Similar findings have been reported for the gene regulating the production of catechol-O-methyltransferase ([Lachman et al., 1998](#); [Straus et al., 1997](#)).

Caution must be exercised in interpreting these kinds of genetic findings. The relationships of neurophysiologic predispositions to particular behaviors are complex. The transmission of behavioral traits from generation to generation depends on the interaction of numerous different heritable and environmental factors.

### Testosterone and Aggression

Although no abnormal constellation of chromosomes associated with violence has been identified, a normal constellation, XY, is strongly associated with it. Male aggressiveness is common to most animal species. There is reason to believe that male aggression is related to the masculinization of the brain *in utero* and is not simply a sociocultural phenomenon. Some studies of girls and boys born with adrenogenital syndrome have suggested that such children may be more energetic and physically active than their normal counterparts ( [Ehrhardt, 1975](#)). Other studies have called these findings into question ( [Hines, 1982](#)).

The relationship of serum testosterone levels to aggressive behavior is a subject of debate. [Persky and colleagues \(1971\)](#), in one of the first systematic studies of male aggression and testosterone, reported a positive correlation between self-assessed aggression and plasma levels of testosterone. Others have failed to replicate these findings ( [Meyer-Bahlburg et al., 1974](#); [Monti et al., 1977](#)). [Virkkunen et al. \(1994\)](#), in their study of adults, found elevated cerebrospinal fluid testosterone in impulsive, aggressive, antisocial, alcoholic men. [Mattsson and colleagues \(1980\)](#), in one of the few hormonal studies using juvenile delinquent subjects, found that incarcerated recidivist male subjects had slightly higher testosterone levels than did normal male adolescents. On the other hand, [Constantino and colleagues \(1993\)](#) found no significant differences in serum androgen levels between aggressive and nonaggressive prepubertal boys. Thus, the jury is still out on whether endogenous androgens distinguish more aggressive from less aggressive men.

### Abuse and Behavioral Problems

When all is said and done, the most important influences on violence are environmental or experiential. Although violence does not invariably beget violence, there is abundant evidence of the association of early maltreatment with the development of aggressive coping styles ( [Lewis et al., 1987, 1989](#); [Widom, 1989](#)). One of the most important characteristics of parents of seriously delinquent, violent juveniles is physical abusiveness toward their children and violence toward each other. The histories of severely behaviorally disturbed aggressive children again and again reveal a picture of physical or sexual abuse at the hands of adults, usually parents. This abuse usually is sufficient to leave evidence in terms of scars, but only occasionally is obvious enough to elicit protection of the child by the state. When abuse is serious enough to require hospital care, parents provide other explanations for children's injuries. The abuse remains hidden and nothing is done.

There are several ways to understand how abuse begets violence. First, parental violence becomes a model of behavior; second, it often results in CNS damage that contributes to a child's adaptational difficulties; and third, the stresses of maltreatment actually alter brain anatomy and physiology ( [Bremner et al., 1997](#)). People with posttraumatic stress disorder resulting from early sexual abuse reportedly have subtle signs of brain dysfunction and a plethora of neurodevelopmental problems ([Gurvits et al., 2000](#)). Finally, abuse engenders rage that usually is displaced from the abusing parent onto other figures in the child's environment, such as teachers and peers.

Our own work ([Lewis et al., 1979b, 1988, 1989, 1991, 1994](#)) and that of [Raine and colleagues \(1996, 1997a\)](#) documents some of the ways in which early deprivation and abuse, coupled with brain dysfunction, predispose children to early and ongoing violent, maladaptive behaviors (also see [Chapter 29](#)).

A word should be said about children who witness violence. Numerous studies have documented the cognitive, developmental, and psychiatric problems of children who witness family violence. These problems include not only anxiety, depression, and slow cognitive development ( [Edelson, 1999](#)), but aggression and antisocial behavior ([Henning et al., 1996](#); [Song et al., 1998](#); [Spaccarelli et al., 1995](#)).

### Summary of Etiologies

This review of the intrinsic and extrinsic contributors to disturbances of behavior illustrates that conduct disorder is not a single diagnostic entity. It is, rather, the final common pathway of the interaction of a variety of different kinds of psychobiological vulnerabilities with a variety of different kinds of environmental stressors. It is clear that children with disorders of conduct are on the border of numerous neuropsychiatric disorders and, in child psychiatry, the border of any condition is a precarious line on which to teeter.

## DIAGNOSTIC EVALUATION

Because the criteria for diagnosing conduct disorder are so broad, and so many different kinds of psychiatric disorders present as behavior problems, it is imperative that the clinician perform a detailed, comprehensive neuropsychiatric evaluation before dismissing a child as simply having a conduct disorder. Clinicians must therefore overcome negative feelings aroused by a child's obnoxious behaviors and embark on the evaluation with curiosity and an open mind.

A plethora of rating scales has emerged over the years, designed to enable the clinician to obtain information regarding behaviors from children, parents, and teachers. Among the most widely used are the Conners' Rating Scales ([Conners, 1997](#)) and the Child Behavior Checklist ([Achenbach, 1992](#)). Unfortunately, these scales focus almost exclusively on conduct, inattention, and hyperactivity; they do not encourage parents or teachers to share other kinds of invaluable observations relevant to diagnosis and treatment. Some of the semistructured interviews, such as the National Institute of Mental Health Diagnostic Interview Schedule for Children, Revised (NIMH-DISC-R) ([Schaffer et al., 1996](#)), Diagnostic Interview for Children and Adolescents (DICA) ([Welner et al., 1987](#)), and the Schedule for Affective Disorders and Schizophrenia, Childhood Version (K-SADS) ([Ambrosini and Dixon, 1996](#)), are of potentially greater clinical usefulness because the evaluator is obliged to explore areas other than just behavioral problems. Occasionally, the clinician uncovers a distinct diagnostic entity, such as a bipolar mood disorder or paranoid schizophrenia, masquerading as conduct disorder. More often the evaluation turns into a painstaking search for combinations of biopsychosocial vulnerabilities that affect behavior. Space precludes a detailed description of the diagnostic process; however, certain parts of the evaluation are highlighted.

### The Behaviors

First, the nature of the problematic behaviors must be explored in detail, including the circumstances in which they occur, the precipitants, and the amount of control the child seems to have over them. In the case of aggressive acts, it is essential to learn whether the child can tell in advance when the behavior will occur, the extent to which he or she can discontinue it voluntarily, the aftermath of the act (e.g., does the child feel shaky or dizzy or sleepy?), and the child's memory for the act. Many paranoid youngsters say that they can tell in advance when a fight will begin by the way the other person looks or stands. Children with complex partial seizures may experience auras before emotional outbursts and may feel confused, sick, or sleepy afterwards. After aggressive acts, paranoid or delusionally grandiose children often say they feel glad and that the victim "deserved it." Children with seizure disorders or dissociative disorders have trouble recalling what happened.

## The Medical History

One of the most important aspects of the evaluation is a detailed medical history, obtained from the child as well as the parent. Questions must be asked in ways that avoid “yes” or “no” responses, and answers must be pursued to their fullest. For example, after inquiring about the most serious accidents or injuries the child has experienced, the examiner, regardless of whether a negative response was given, must ask specifically about cars, bicycles, falls from high places, blows to the head, about dizziness, headaches, and blackouts. All positive responses should be followed up with such questions as, “And what *other* bicycle accidents have you had?” “And when else did you feel dizzy?” ([Hatzitaskos et al., 1994](#); [Stein et al., 1993](#)). We also have found the medical history to be a useful device for conducting parts of the mental status examination. Tough adolescents are unlikely to admit to hallucinations or delusions if asked about them directly. They would rather be thought bad than crazy. However, if these issues are integrated into the medical history (e.g., “How are your ears? Have you ever had an ear infection? Have your ears ever played tricks on you? Have you ever had the experience of thinking someone said something bad about you or your mom, and you turn around to fight, and the person really didn't say anything?”), the wary adolescent, who has experienced episodic hallucinations or paranoid misperceptions, may reveal them for the first time.

Many conduct-disordered youngsters carry evidence of their medical and family histories all over their faces, heads, arms, legs, and bodies in the form of scars. Part of the medical history is inquiry regarding the cause of every visible scar. Examiners should ask, “Are there any scars I can't see?” These kinds of questions often bring to light forgotten injuries and previously ignored evidence of child abuse. The child's or adolescent's body must be examined carefully in an appropriate setting. We recently examined a violent teenager and discovered a scar several inches in length running down his penis, into the scrotum.

## Inquiring About Sexual Abuse

Conduct-disordered children, especially those with sexually inappropriate or provocative behaviors, often have histories of having been sexually abused. The examiner must not only develop skill inquiring about sexual abuse, but must feel comfortable with the follow-up questions, “And who else bothered you? And who else? How about outside the family?” There is an art to enabling a child to reveal the unspeakable without posing unduly leading questions. We ask, “Who taught you about sex?” and “Have you ever had sex with someone much older? Much younger?”

## THE NEUROLOGIC EXAMINATION

Few children and adolescents who come in conflict with the law as a result of aggressive behaviors have obvious signs of CNS damage or dysfunction. On the other hand, as a result of the early, multiple insults to the CNS that are characteristic of the medical histories of violent children and adolescents ([Lewis and Shanok, 1977](#); [Lewis et al., 1979a](#)), they commonly have a myriad of subtle indicators of CNS dysfunction. Whether these vulnerabilities are recognized and addressed depends on the thoroughness of the neurologic investigation.

The way in which a referral is made affects the quality of the neurologic data obtained. It is therefore insufficient simply to refer a child to a clinic or to a particular neurologist for “a neurologic evaluation.” The clinician responsible for the overall assessment of the child or adolescent should already have taken a detailed medical and neurologic history, the findings from which should be presented as part of the referral to the neurologist (e.g., the child's failure to recall behaviors, history of head trauma, findings on neuropsychological testing). Without this kind of information, the neurologist will likely perform a “routine” examination and leave out assessments of subtle brain dysfunction (e.g., frontal lobe impairment, complex partial seizures).

Children with clear evidence of organic impairment or dysfunction on neuropsychological tests may have normal EEGs and MRI scans. On the other hand, EEG and MRI sometimes bring to light otherwise questionable brain damage.

## Psychological and Neuropsychological Testing

The usual tests of intelligence [e.g., the Wechsler Intelligence Scale for Children (WISC-III)] are helpful for documenting a child's level of understanding, but they do not tap frontal lobe or “executive functions” adequately. Neuropsychological assessment aims to tie observable abnormal behaviors to neurologic dysfunction or damage by parsing complex mental processes into their elemental cognitive components ([Moffitt, 1990b](#)). Neuropsychological examination of the aggressive child or adolescent should therefore attempt to identify the kinds of deficits that put the youngster at risk for responding maladaptively. It often can identify functional brain impairment not evident either on neurologic examination or neuroimaging. There is no one set of tests used routinely to assess neuropsychological functions. Selection should be based on the nature of the clinical questions to be addressed and, of course, reliability, validity, and the adequacy of norms for the patient's chronologic age and socioeconomic status.

The most commonly used personality assessment instruments for adolescents, namely, the Minnesota Multiphasic Personality Inventory—Adolescent version (MMPI-A) ([Butcher et al., 1992](#)) and the Millon Adolescent Clinical Inventory (MACI) ([Millon et al., 1993](#)), are more assessments of immediate psychopathology and emotional distress than of stable personality traits. Unfortunately, data gleaned from these instruments often are overinterpreted for purposes of predicting future delinquency and aggression and can be misused in juvenile justice and criminal justice settings. We have found frequently that adolescents with a multiplicity of symptoms who honestly subscribe to many different items risk being dismissed as fakers.

## Psychoeducational Assessment

Scholastic underachievement and school failure are common correlates of delinquency and aggression. Clinicians must not automatically ascribe academic problems simply to the juvenile's lack of motivation or bad attitude; instead, underlying cognitive, psychiatric, emotional, and environmental causes of academic underachievement must be investigated. School is perhaps the most potent source of social and psychological reinforcement for the older child and adolescent, and the inability to perform up to the expectations of parents, teachers, and peers has potentially life-long negative effects on self-esteem, social aptitude, and occupational stability. There is no one standard educational assessment battery. Suffice it to say that whatever tests are used must have appropriate norms and a high degree of validity and reliability. Findings from educational testing should be coordinated with those from neuropsychological testing.

## DIFFERENTIAL DIAGNOSIS

The diagnosis of conduct disorder usually just tells people what they already know: the child misbehaves. The differential diagnosis, however, is almost as broad as the entire field of child and adolescent psychiatry. Learning disorders, attention deficit hyperactivity disorder, mild mental retardation, seizure disorders, schizophrenia, mood disorders, dissociative disorders, even dissociative identity disorder (multiple personality disorder), all may manifest themselves as disorders of conduct. Most often, the conduct-disordered child or adolescent is found to have a variety of different kinds of psychiatric, neurologic, cognitive, and environmental vulnerabilities that, together, contribute to maladaptation. Each must therefore be identified and addressed. When these specific vulnerabilities are addressed, the child's conduct almost invariably improves.

Conduct disorder is much like fever; it can have many different causes, and it resolves only when those causes are identified and treated specifically. Whenever possible, a diagnosis reflective of underlying psychiatric or neurologic impairment should be used, rather than conduct disorder. However, just as, occasionally, in the absence of adequate information, the clinician must make the descriptive diagnosis of fever of unknown origin, so from time to time he or she may be forced to settle for the purely descriptive designation *conduct disorder*, meaning “behavior problem of unknown origin.” Often, conduct disorder proves to be an interim diagnosis on the way to a better understanding of the child's psychopathology and to a more therapeutically useful conceptualization of the clinical picture.

## TREATMENT

Many different treatment modalities for conduct-disordered children and adolescents have been tried, including psychotherapy and community-based programs ([Kazdin, 2000](#)). The success of most of these diverse modalities, unfortunately, remains untested. According to Kazdin, at this time, only three modalities have been shown, through controlled clinical trials, replication, and follow-up evaluation, to be effective—that is, to be “evidence based.” These modalities are (a) parent management training (PMT), (b) cognitive problem-solving skills training (PSST), and (c) multisystemic therapy (MST). This does not mean that other approaches may not be equally as good or superior. It means only that the research demonstrating success has not yet been done. Hence, this section focuses on the evidence-based modalities.

## Parent Management Training

Parent management training (PMT) focuses on teaching parents methods of interacting with their children to encourage appropriate behaviors and discourage antisocial, aggressive behaviors. It is based on the theory that many of the parents of behaviorally disturbed children unwittingly, through harsh punishments for infractions and failure to acknowledge good behavior, wind up reinforcing the very behaviors they wish to suppress ( [Dishion and Andrews, 1995](#)). Therapists work with the parents to help them use positive reinforcement for desirable behaviors, to use mild punishments for misbehavior, and to develop new ways of negotiating with their children ( [Patterson, 1982](#)). A literature review has singled out PMT as the only well established modality for the treatment of conduct disorder ( [Brestan and Eyberg, 1998](#)). In several studies, treatment gains were reportedly maintained from 1 to 3 years after treatment ( [Kazdin, 2000](#)).

A major drawback to successful outcome using PMT is the responsibility it places on parents to understand the basic principles underlying the program (e.g., the counterproductiveness of coercive disciplinary methods), to observe their children's behaviors systematically, to implement different ways of interacting and, of course, to attend training sessions. Unfortunately, the children and families in greatest need usually also are the most impaired and the least likely to follow through with a PMT program.

## Cognitive Problem-Solving Skills Training

Problem-solving skills training is a treatment modality that focuses on the child or adolescent ( [Spivak and Shure, 1974, 1978](#)). Based on the theory that conduct-disordered youngsters do not make proper use of their potential cognitive abilities, this modality tries to help children identify problems, recognize causation, appreciate consequences, consider alternative ways of handling difficult situations, and improve reality testing by cognitive means ( [Dodge and Frame, 1982](#); [Dodge and Tomlin, 1983](#); [Dodge et al., 1990](#)). Others have used PSST to enhance children's abilities to handle anger ( [Kendall and Braswell, 1982](#); [Lochman et al., 1991](#)). PSST attempts to help children think ahead, generate alternative solutions to problems previously dealt with impulsively, and to anticipate the potential consequences of behaviors. These are particularly difficult tasks for children with frontal lobe dysfunction. Older children seem to respond better than younger children to these kinds of modalities ( [Durlak et al., 1991](#)). It is not surprising that children with identified comorbid problems and those from chaotic homes respond less well to cognitive interventions than do more intact children from more stable households ( [Kazdin, 1995, 1997](#)).

## Multisystemic Therapy

Multisystemic therapy (MST) is based on the theory that a multiplicity of systems influence a child's adaptation, including family, peers, schools, and communities. Treatment focuses on the nature of these systems and how the child interacts with them. Treatment varies, depending on the child's and family's needs. It may therefore include PMT, PSST, marital counseling, or whatever other modalities are considered appropriate to identified problems. It is not surprising to learn that MST has been shown to be effective in several outcome studies, given that it recognizes the individual and environmental vulnerabilities of severely delinquent children and adolescents and attempts to address all of them. It is the antithesis of the "one size fits all" approach to treating conduct disorders. As such, it has been found superior to the usual services provided obstreperous or aggressive adolescents (e.g., probation, individual counseling) ( [Henggeler et al., 1998](#)). As [Kazdin \(2000\)](#) observes, MST poses replication difficulties because the precise techniques to use to address particular problem areas are not clearly specified. Nevertheless, he observes, "It may be the case that this model of treatment delivery is precisely what is needed for clinical problems that are multiply determined, protracted and recalcitrant to more abbreviated interventions" ( [Kazdin, 2000](#)).

## Pharmacotherapy

Because conduct disorder is not really a single entity, it is not surprising that no single medication or type of medication is especially useful. Such medications as stimulants, tricyclic antidepressants, lithium carbonate, MAO inhibitors, clonidine, antiepileptics, sedatives, and even beta blockers have been tried. Results, except in cases of the use of stimulants for clearly defined attentional problems, have been equivocal at best ( [Karper and Krystal, 1997](#); [Werry, 1994](#)). That is not to say that medication cannot be of enormous help. The choice of which medication or medications to use, however, must rest on the underlying symptoms to be addressed, and medication alone is rarely, if ever, sufficient. Used judiciously and on the basis of the specific clinical findings in each individual case, appropriate medication enhances the success of other treatment modalities.

The vulnerabilities of conduct-disordered children usually are chronic. Therefore, a successful treatment program must incorporate a plan for ongoing treatment and support systems. Medical, emotional, educational, and social supports often are required well beyond 16 years of age if severely behaviorally disordered children and adolescents are to adapt appropriately as adults.

## RESEARCH DIRECTIONS

It certainly is possible that neurochemical or physiologic factors related to conduct disorder will be discovered. However, the fact that so many different kinds of biopsychosocial problems are associated with behavior problems makes it unlikely that the search for a single biological or genetic factor peculiar to conduct disorder or its adult counterpart, antisocial personality, will be especially fruitful. It is likely, however, the development of laboratory tests for other kinds of psychiatric disorders such as schizophrenia, depression, and bipolar disorders will eventually help identify children whose antisocial behaviors obfuscate underlying, potentially more easily treatable mental illnesses. As neuroimaging studies of behaviorally disturbed children become safer and more feasible, it is possible that the diagnosis of particular frontal lobe syndromes will take the place of the diagnosis conduct disorder in many cases.

Recognition of the biopsychosocial interactions that contribute to deviant behavior raises important ethical and legal questions. Therefore, ethical issues regarding individual responsibility and the appropriate societal response to violent, antisocial behaviors deserve to be studied. The effect of incarceration on aggressiveness is a vital research question. Furthermore, the negative attitudes of clinicians toward behaviorally disordered, aggressive patients, and the ways these attitudes affect the diagnostic process, must become a focus of research. Aggressive patients, children and adults alike, rarely receive as careful, unbiased assessments as do patients with less frightening symptomatology. As we understand more and more about the psychobiological vulnerabilities of behaviorally disordered children, the global diagnosis conduct disorder will resolve into more discrete and treatable entities. It may even disappear.

[Chapter References](#)

Although eating disorders are frequently assumed to be synonymous with adolescent-onset anorexia and bulimia nervosa, a panoply of eating and growth disorders occurs earlier in life. This clinical myopia is reflected in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association, 1994](#)), which recognizes only three eating disorders of early childhood: pica, rumination, and feeding disorder of infancy or early childhood. The lack of official diagnostic recognition of many eating disorders reflects their extraordinary complexity and resulting problems in nosologic definition. Eating and growth disorders are unique in medicine and psychiatry in their position at the dynamic interface of the somatopsychic boundary of developmental neuropsychiatric disorders, emotional/behavioral disturbances, and physical changes, which all interact in a complex fashion over time. Unfortunately, this complex interaction has not been recognized. For example, the two most common eating and growth disorders of infancy and childhood, failure to thrive (FTT) syndrome and obesity, are both currently categorized as medical conditions in DSM-IV and the 10th edition of the *International Classification of Diseases* ([World Health Organization, 1990](#)). The rationale for this approach is that both syndromes are defined by caloric nutritional status regardless of etiology. Therefore, some infants and children may have FTT or obesity but not actually have an eating disorder.

Until recently, understanding, and even categorization, of such disorders has been hampered by a reductionistic approach relying on deterministic, linear causality ([Woolston, 1988](#)) in which each disorder or developmental disturbance was viewed as having a single cause. This approach gradually has been replaced by the concept of a multifactorial, transactional model of development ([Sameroff and Chandler, 1975](#); [Sameroff and Fiese, 1989](#); [Woolston, 1989](#)). Despite this more sophisticated theoretical approach of developmental psychopathology, advancement in the understanding of early growth disorders has been hampered by a variety of controversies that actually arise from the complexity of the phenomena. Two such controversies are in phenomenology and etiology. The phenomenology of eating disorders has been plagued by a paucity of data and by persistent diagnostic confusion. For example, FTT and psychosocial dwarfism (PSD) frequently are used synonymously (e.g., [Green et al., 1984](#)); the distinctions among rumination, gastroesophageal reflux (GER), and psychophysiological vomiting rarely are delineated; and subtypes of such disorders as FTT ([Egan et al., 1980](#); [Woolston, 1983](#)), obesity ([Woolston, 1987](#)), and rumination ([Mayes et al., 1988](#)) have proliferated. Furthermore, controversy about etiology frequently has focused on a rigid dichotomy between an intrinsic, organic cause ("sick baby") versus an external, environmental disturbance ("bad mother") ([Woolston, 1991](#)). The counterproductive effect of such a dichotomous approach has been best demonstrated by the research in FTT syndrome, in which the organic/nonorganic differentiation has not held up to scrutiny ([Bell and Woolston, 1985](#); [Polan et al., 1991a](#)).

A fundamental obstacle to progress in the understanding and treatment of eating and growth disorders is lack of understanding of the basic mechanisms of hunger and satiety. The first major advance in this field occurred with the identification and coding of the ob gene, as well as its protein product, leptin ([Considine et al., 1995](#); [Green et al., 1995](#); [Zhang et al., 1994](#)). Experimental evidence suggests that leptin, produced in adipocytes, acts a hormonal feedback signal to regulate fat cell size

through hypothalamic mechanisms controlling food intake and metabolic rate ([Considine et al., 1996](#); [Lonnqvist et al., 1995](#); [Woods and Stock, 1996](#)). Leptin levels are highly correlated with body mass index in normal children, but not in children with eating disorders, resulting in a significantly elevated or reduced body mass index ([Argente et al., 1997](#)). These findings provide the first steps in elucidating the physiologic mechanisms of hunger and satiety.

## PICA

### Definition and Clinical Description

Pica would appear to be without the nosologic problems that beset other eating and growth disorders of infants and children. In fact, DSM-IV, which lists pica as the first feeding/eating disorder, defines it as the persistent eating of nonnutritive substances for at least 1 month in such a fashion that such eating is inappropriate to developmental level and is not part of culturally sanctioned practice. The two dependent clauses in this definition disqualify the two largest populations described in the extensive literature about pica: toddlers who ingest paint chips and young pregnant women who eat starch and clay ([Lacey, 1993](#)). This artificial clarity in definition attempts to solve the confusion that bedevils all aspects of the understanding of this disorder. Rather than being a narrowly homogeneous phenomenon, pica represents an eating disorder of enormously varied populations, including normally developing toddlers mouthing lead paint chips, rural pregnant women eating clay or starch, severely retarded adults eating feces, and normally developed adults chewing pencil erasers, fingernails, ice, and burnt matches. As if to create an aura of scientific understanding, pica as defined in literature before DSM-IV was subtyped according to the substance ingested. These terms include geophagia (eating clay), pagophagia (eating ice), plumbophagia (eating lead), amylophagia (eating starch), coprophagia (eating feces), cautoxyreophagia (eating burnt matches), trichophagia (eating hair), lithophagia (eating stones), and geomelophagia (eating raw potatoes). Aside from a review of Latin root words, such subtyping is most useful at documenting the extraordinary range of substances that people may ingest.

In many ways, the heterogeneity of pica precludes a coherent statement about age of onset, developmental outcome, etiology, or treatment. Because the pediatric literature has paid great attention to the phenomenology of lead poisoning, pica has become synonymous with children eating paint chips. For these children, pica has been reported to be more common in situations of relative environmental deprivation ([Madden et al., 1980](#)) or parental psychopathology. In this population, pica begins in the second and third year of life and may continue into childhood. In a second population, young pregnant women, the onset of pica begins with the first pregnancy in late adolescence or early adulthood and may continue intermittently for several decades. Pica in mentally retarded people begins in childhood and may diminish after middle age ([McAlpine and Singh, 1986](#)). In this population, the risk of pica appears to be related to the degree of retardation, so that the most severely retarded are most likely to have the disorder ([Danforth and Huber, 1982](#)). Pica in chronically anxious children or adults has never been studied or described in the literature. In this last group, a possible relationship between pica, trichotillomania, and other compulsive behavior disorders has never been investigated.

### Prevalence and Epidemiology

Incidence and prevalence figures for such a heterogeneous disorder are difficult to interpret. However, among specific at-risk populations, pica has been reported to be quite common. [Halstead \(1968\)](#) summarized findings from research studies that indicated that pica occurred in 25% to 33% of young children and 40% to 50% of poor, pregnant black women. The incidence of pica among institutionalized retarded adults has been reported to range from 9% ([McAlpine and Singh, 1986](#)) to 25% ([Danforth and Huber, 1982](#)).

Numerous studies have documented that the eating of specific substances such as clay and starch is strongly influenced by cultural and family factors ([Lacey, 1990](#)) because various social groups, especially poor and rural people, regard the eating of certain nonnutritive substances as acceptable. In addition, toddlers who are poorly supervised and understimulated are at high risk for ingesting inappropriate materials like paint chips.

### Biology and Pathogenesis

Except as mediated by mental retardation, there are no known genetic factors in the etiology of pica. Boredom, anxiety, and depression may exacerbate pica, but little has been reported about such associated psychopathology. Iron deficiency sometimes is associated with pica, but the direction of the causal association is unclear ([Vyas and Chandra, 1984](#)).

### Laboratory Studies and Differential Diagnosis

Although the extraordinary diversity of this disorder makes any useful classification schema unlikely, the remarkable prevalence and seriousness of its medical complications require a thoughtful, vigorous approach. These medical complications include heavy metal poisoning, mineral/vitamin deficiency, parasite ingestion, and intestinal obstruction. For toddlers and young children with a history of pica, a careful evaluation of the home environment and family functioning is required. In addition, these children should be evaluated for cognitive and psychiatric impairments. Pregnant women with pica presumably have more voluntary control over their eating. A careful assessment of their cultural and nutritional beliefs is essential, so that nutritional counseling can be helpful. Severely retarded people presenting with pica should be assessed for access to noxious materials and provided with sufficient supervision to prevent pica.

### Treatment, Natural History, and Outcome

Because of the extreme heterogeneity of the disorder, few comments are germane to the treatment and natural history for the wide spectrum of people who meet the criteria for pica. For toddlers and young children, as well as older mentally retarded individuals, proper supervision is the most important intervention. In addition, careful scrutiny of the environment to remove toxic substances is crucial. Older adolescents and young adults should be provided with psychoeducation and counseling about the medical risks associated with ingestion of nonnutritive substances.

## RUMINATION DISORDER

### Definition

Similar to pica, rumination disorder has the superficial appearance of a homogenous, unitary disorder. DSM-IV defines rumination as (a) repeated regurgitation and rechewing of food (in the absence of associated gastrointestinal illness) for a period of at least 1 month after a period of normal functioning and (b) not due to an associated gastrointestinal or other general medical condition (e.g., esophageal reflux).

### Prevalence and Epidemiology

Very little is known about the incidence and prevalence of rumination, although the most severely affected cases, which are the ones that have been reported, are rare. The sex ratio of the disorder also is unclear, although one case series ([Mayes et al., 1988](#)) reported a male predominance.

### Clinical Description

Rumination appears to require three factors: an impaired ability of the infant or retarded person to regulate his or her internal state of satisfaction, a physical propensity to regurgitate food, and a learned association that regurgitation helps relieve the internal state of dissatisfaction. The assessment of the child must include an evaluation of each of these factors, as well as the medical sequelae of rumination such as malnutrition and aspiration. Obviously, these medical sequelae will influence the vigor of the intervention, as well as serving as a baseline by which to measure the child's response to treatment.

### Biology and Pathogenesis

Unfortunately, the clinical reality of this phenomenon is more complex than portrayed by DSM-IV. Some infants and retarded adults may vomit the stomach contents rather than rechewing and reswallowing them. Although this phenomenon is called *psychophysiological* ([Ferholt and Provence, 1976](#)) or *operant* ([Johnston, 1993](#)) vomiting, its differentiation from rumination is problematic. Furthermore, the requirement that rumination not be associated with gastrointestinal disorders such as GER is overly restrictive because it implies that rumination has no underlying physiologic contributions. Indeed, the relationship, if any, between GER, rumination, and operant vomiting has not been investigated.

Because rumination is apparently a relatively rare disorder, virtually all of the information about the phenomenology must be derived from single case reports or small case series (e.g., [Mayes et al., 1988](#); [Sauvage et al., 1985](#); [Winton and Singh, 1983](#)) without comparison groups. In otherwise normally developing infants, the age of onset is in the first year of life, whereas in mentally retarded people, the age of onset can extend into adulthood ([Mayes et al., 1988](#)). Rumination has been reported to occur in nonretarded adults, many of whom have an additional comorbid eating disorder ([Eckern et al., 1999](#)). In some unknown proportion of cases, the disorder remits spontaneously, whereas in others, the course may be malignant, marked by aspiration, severe malnutrition, growth failure, developmental delay, and death. Some authors ([Mayes et al., 1988](#)) have proposed two diagnostic subgroups, psychogenic and self-stimulatory, to capture the difference in the course of retarded and nonretarded individuals. However, the relatively small sample size appears to make diagnostic subtyping premature.

Several authors have proposed that an adverse psychosocial environment is central to the development of rumination in otherwise normal infants (e.g., [Hollowell and Gardner, 1965](#); [Mayes et al., 1988](#); [Richmond et al., 1958](#)). The most common environmental factor cited in the genesis of rumination is an unsatisfactory mother–infant relationship that causes the infant to seek an internal source of gratification. This turning inward by the infant has been proposed to occur because the environment is more stimulating than the infant can tolerate or because the environment is not gratifying enough ([Richmond et al., 1958](#)), or because the environment is too stimulating with negative effects ([Ferholt and Provence, 1976](#); [Hollowell and Gardner, 1965](#)). Aside from these proposed contradictory environmental factors, no information has been reported about more general sociodemographic features. Similarly, the role of genetic factors is unknown.

Learning theorists have explained rumination in terms of the reinforcing response that it elicits ([Johnston, 1993](#)). These proposed feedback mechanisms include positive reinforcement when a desired event such as pleasure or attention follows rumination and negative reinforcement when an undesired event such as anxiety is reduced or removed. A more sophisticated theory involves combining the concept of positive and negative reinforcement by proposing a change in the valence of the behavioral consequences. For example, consequences that normally are behavior suppressing may acquire behavior-reinforcing characteristics if other, more usually positive, consequences are lacking ([Winton and Singh, 1983](#)). These concepts of the operant conditioning psychogenic factors in rumination are useful as the theoretical underpinnings of certain behavioral treatments of rumination.

The role of organic factors in rumination remains obscure, but some authors have argued that rumination is totally the result of physical disorders, including hiatal hernia and other esophageal abnormalities ([Herbst et al., 1971](#)). The relationship between the syndromes of rumination and GER is unknown, although high rates of association have been reported ([Shepherd et al., 1987](#)). GER, or chaliasia, is the syndrome of regurgitation of the stomach contents into the mouth and esophagus, apparently as a result of hypomotility of the gastric fundus and delayed gastric emptying rather than a weakened esophageal sphincter ([Papaila et al., 1989](#)). A possible but untested hypothesis is that GER is the physiologic substrate on which various psychosocial disruptions or deviant operant conditioning act so that rumination develops.

The assessment of the infant's capacity to regulate his or her internal state must include a general developmental assessment to evaluate for serious developmental delay, as well as hyperirritability states. In addition, the mother–infant relationship must be carefully examined for clues to stimuli that are noxious or disruptive to the infant.

### Laboratory Studies

The child's propensity to regurgitate can best be evaluated by procedures developed for GER, including esophageal pH monitoring, scintigraphic GER scan, endoscopy, and gastric emptying studies. In addition, various radiologic procedures that evaluate esophageal abnormalities should be considered.

### Treatment and Natural History

Similar to other eating disorders of early childhood, the extraordinary heterogeneity precludes specific treatments for all persons with this disorder. The learned aspect of rumination, especially in retarded people, may be crucial to modify. After careful evaluation of this factor, various behavioral interventions must be considered, especially if there are serious medical complications. These interventions include aversive techniques, in which a noxious stimulus is paired with rumination ([Glasscock et al., 1986](#)), and nonaversive techniques such as differential reinforcement of other incompatible responses.

## FAILURE TO THRIVE

### Definition

Failure to thrive is a disorder of infancy and early childhood characterized by a marked deceleration of weight gain and a slowing or disruption of acquisition of emotional and social developmental milestones. Deceleration of linear growth and head circumference growth are associated but not primary phenomena.

### Historical Note

The DSM-III ([American Psychiatric Association, 1980](#)) focused on the developmental delays presumably caused by psychosocial deprivation and virtually ignored the disordered growth and feeding. For this reason, DSM-III described FTT as reactive attachment disorder. DSM-IV ([American Psychiatric Association, 1994](#)) sought to redress this lack of recognition of the feeding disorder by new diagnosis of feeding disorder of infancy and early childhood. Although creating a new diagnostic category has the advantage of freeing it from a long history of misconception and controversy, it has the disadvantage of losing a long, rich history of research.

Despite a 45-year history of study, the understanding of FTT has been marked by confusion and controversy about such basic issues as the definition and the name of the disorder. The plethora of syndromic names provides a glimpse into the confused literature: hospitalism, anaclitic depression, institutionalism, environmental retardation, maternal deprivation syndrome, psychosocial deprivation dwarfism, deprivational dwarfism, deprivation syndrome, FTT, environmental FTT, and nonorganic FTT syndrome. This blizzard of interchangeable but nonsynonymous terms, which frequently represented the mistaken or oversimplified underlying conceptions of the investigators, has created a major obstacle to the course of research. These misconceptions arose out of the multifaceted nature of the syndrome. At different times, the three components of FTT, weight gain deceleration, linear growth delay, and developmental delays, were considered separately so that each was perceived as the central aspect, to the exclusion of the other parts. In fact, depending on the focus of the definition, FTT has been reported as consisting of only one component rather than a triad. For example, when the diagnosis of FTT is made on the basis of primary weight gain deceleration, developmental deficits are less evident ([Field, 1984](#)), and indeed, in one study using age-matched control subjects, there were no differences in development test scores between infants with FTT and normally growing infants ([Mitchell et al., 1980](#)). A second aspect of this confusion in the understanding of FTT has been the controversy over the relative contributions of emotional deprivation and of malnutrition. From the earliest observers to contemporary clinicians, the correlation between emotional misery and growth problems has been obvious. Perhaps too simplistically, some investigators argued that such disorders were directly caused by misery, mediated by some effect on the mind acting directly on the body, without requiring such external factors as altered caloric intake.

The starkest presentation of the argument has been the theoretical debate over the importance of love versus food in the etiology of FTT ([Widdowson, 1951](#)). Early clinical experience indicated that some infants with FTT who were given a normal caloric intake did not gain weight at their expected rate. These observations were used to bolster the argument that calories alone were not sufficient for weight gain. However, studies of malnourished children have demonstrated that they have supracaloric requirements before catch-up growth is possible ([Casey and Arnold, 1985](#)). In addition, [Whitten et al. \(1969\)](#) reported that even grossly understimulated infants with FTT gained weight rapidly if given enough food.

### Prevalence and Epidemiology

Failure to thrive is a common disorder, occurring at a rate of 1% to 5% of pediatric hospital admissions ([Berwick, 1980](#)). Surveys of low-income children in primary care suggest that nearly 10% show weight or length below the fifth percentile for age ([Koumjian and Marks, 1985](#)). Approximately 5% to 10% of all children 2 to 5 years of age in the United States exhibit poor growth that is unrelated to a medical disorder ([Drotar and Sturm, 1998](#)). This common condition is of great concern because FTT is associated with increased risk for lasting deficits in growth, cognition, and socioeconomic functioning (e.g., [Oates et al., 1985](#)). Despite the clinical importance of FTT in pediatric populations, the heterogeneity of etiology and phenomenology has impeded research efforts ([Benoit, 1993](#)).

### Clinical Description, Etiology, and Pathogenesis

The persistence of the debate over love versus food has several origins. First, FTT is a syndrome with physical (weight gain and growth deceleration) and behavioral/emotional (developmental delays) components. The overwhelming evidence indicates that inadequate caloric intake is the primary cause of growth deceleration, whereas emotional and socioeconomic deprivation is the primary cause of the developmental delays ( [Casey et al., 1984](#)). However, the depression-like symptoms associated with FTT probably reduce the infant's interest in feeding, rendering the infant harder to feed. Similarly, the significant malnutrition associated with FTT can produce a state of apathetic withdrawal. To complicate matters further, a small group of severely deprived and abused young children have a disruption of pituitary function even in the presence of adequate nutrition. Although these children represent a clearly defined and distinct diagnostic syndrome of PSD ( [Powell et al., 1967](#)), their condition is persistently confused with FTT.

Failure to thrive is a disorder with an onset in the first 3 years of life. Typically, infants who have onset of FTT before the end of 1 year of life are more likely to have been actively deprived of food or to have primary physiologic disorders that interfere with caloric intake. When the initial onset of FTT occurs in older infants and toddlers, there is more likely to be active interactional difficulties between the child and primary caregiver, which manifest as an eating disorder. Frequently, a young infant who presents with FTT responds rapidly to adequate feeding. However, the same social/familial conditions that are associated with such acute malnutrition also may be associated with chronic emotional and physical deprivation and poor infant-caregiver relationships. Therefore, in infants whose initial episode of FTT is rapidly ameliorated by refeeding, a second episode of FTT may develop that is characterized by a more chronic and internalized eating disorder. These toddlers and young children resist ingestion of adequate caloric intake and show secondary stunting of linear growth and head circumference as a result of chronic malnutrition.

The developmental outcome of children with FTT is remarkably heterogeneous, perhaps because of the heterogeneity of the syndrome. Significant variables that influence outcome include general factors such as socioeconomic status, maternal education, parental mental illness, and family social functioning. Because these factors are risk factors for both FTT and poor developmental outcome, they probably mediate their influence somewhat independently of FTT *per se*. Risk factors that are more directly linked to FTT include degree and chronicity of malnutrition, degree and chronicity of developmental delay, severity and duration of the dysfunction in infant-caretaker relationship, and severity of major medical disorder. Problems associated with FTT such as physical abuse, medical neglect, educational neglect, and social isolation interact with the general and specific risk factors to influence developmental outcome.

As indicated in the introduction, FTT is a common disorder, with an incidence ranging from 1% to 3% of inpatient pediatric admissions to 10% to 15% of some outpatient populations. Few data exist on historical trends for shifting prevalence of FTT. Sex ratio is reported to be approximately equal, although studies of older infants indicate a slight preponderance of boys.

Although FTT occurs in children of all social strata, it is more common in families where functioning is compromised by poverty, unemployment, social dislocation and isolation, and parental mental illness ( [Kessler and Dawson, 1999](#); [Fischaff et al., 1971](#)). As with any complex, multifactorial disorder, most infants develop relatively normally in conditions characterized by many of these risk factors, whereas a minority develop an eating/growth disorder such as FTT. On the other hand, FTT develops in some infants despite the apparent absence of any of these risk factors. Thus, social and family risk factors are just that: risk factors rather than specific etiologic agents.

Virtually nothing is known about what, if any, genetic factors exist in various forms of FTT. Obviously, there are important genetic contributions to various mental disorders that can influence caretaker adequacy.

Because the etiology of FTT is a multifactorial process, virtually any temperament or psychological factor that interferes with somatic homeostasis or attunement between infant and caretaker may well disrupt feeding and cause inadequate caloric intake ( [Wilson et al., 1986](#)). In young infants, the two most common such difficulties are marked irritability and apathy. Both of these states are themselves the result of multiple underlying factors, including basic psychophysiologic temperament, nutritional state, physical health, and affective interaction with the primary caregiver. This last factor has been the focus of considerable research as the major etiologic factor in the development of FTT. Investigators have postulated that any emotional or behavioral disturbance in the primary caretaker that causes her or him to be physically or emotionally absent will result in the state of apathetic depression in the infant. Alternatively, emotional disturbance in the caregiver that results in the infant's experiencing constant anger, rejection, irritability, or hatred will cause the infant to be irritable, difficult to soothe, or withdrawn.

### Laboratory Studies

Clinicians in the past sometimes have overemphasized the importance of the search for occult organic factors, as has been demonstrated by the low yield from exhaustive testing ( [Berwick et al., 1982](#); [Sills, 1978](#)). A major impetus for this excessive use of laboratory testing has been the misconception of the organic/nonorganic dichotomy. To be sure, the number of primary medical illnesses that can be associated with FTT is extensive. However, a thorough pediatric history, physical examination, and minimal screening laboratory tests usually identify physical illnesses that are contributing to FTT. These screening tests include complete blood count, lead level and free erythrocyte protoporphyrin, tuberculosis skin test (purified protein derivative), urinalysis and urine culture, and a sweat test in populations predisposed to cystic fibrosis ( [Frank and Zeisel, 1988](#)).

Some organic factors may be caused by the malnutrition associated with FTT as well as aggravating its course. Malnutrition suppresses immune functions so that children with FTT are at risk for chronic respiratory and gastrointestinal infections. The illnesses that these infections produce interfere with the infant's ability to ingest adequate calories, which exacerbates the infant's state of malnutrition. Similarly, infants with FTT are at risk for vitamin and mineral deficiencies, especially of calcium, iron, and zinc. These deficiencies result in blood dyscrasias and metabolic disturbances, which worsen the infant's clinical state. In addition, the mineral deficiencies and malnutrition increase the risk of lead toxicity because lead absorption is significantly increased in these deficiency states. Perhaps most important in evaluation of organic factors is the concept that illnesses that coexist with FTT belong in a continuum, from those that actually cause malnutrition (e.g., malabsorption) at one end to those that are caused by malnutrition (e.g., immunosuppression) ( [Woolston, 1985](#)) at the other.

### Treatment

As with other eating disorders that have associated malnutrition, ensuring adequate caloric intake is the most important intervention. Obviously, the clinician must identify the major reason for such inadequate caloric intake and remediate it. For infants who primarily are severely neglected, this simply means providing enough appropriate food. For older infants, toddlers, and children who have developed a more active pattern of food refusal, a more careful assessment of the triggers for food refusal must be performed to guide the intervention.

### Natural History and Outcome

The crucial axes on which to evaluate an infant with FTT include age of onset and duration of FTT, degree of malnutrition, degree of linear growth and head circumference stunting, presence of other physical illness, developmental delay, and level of family functioning.

Age of onset is important both in understanding the genesis of the FTT as well as in its prognosis. FTT with onset in the first 12 months of life in the absence of any concurrent medical illness is almost always a feeding disturbance resulting from either the infant's being deprived of adequate caloric intake or being so fussy and irritable that feeding is nearly impossible. In the former situation, the infant rapidly gains weight when offered enough food. Thus, if the factors that contributed to the inadequate caloric intake can be ameliorated, infants with this pattern of FTT have an excellent prognosis. Similarly, most infants who have severe problems with establishment of basic physiologic homeostasis develop more effective state regulation by the second and third year of life. However, the presence of other risk factors on the multiaxial approach to FTT puts such infants at high risk for poor developmental outcome. Some authors have been very specific in the linkage between developmental stage and etiology. For example, [Chatoor and colleagues \(1985\)](#) have proposed three distinct forms of FTT based on developmental stage of onset: (a) feeding disorder of homeostasis, in the newborn period; (b) feeding disorder of attachment, between 2 and 8 months of age, usually associated with maternal deprivation; and (c) feeding disorder of separation, between 6 months and 3 years of age, during the transition to self-feeding.

Calculation of degree of malnutrition is crucial in all aspects of the clinical management of FTT, including diagnosis, prognosis, and treatment. Frequently, the severity of the malnutrition is associated with the severity of the other risk factors that are influencing FTT. The degree of malnutrition affects the severity of medical complications associated with FTT, ranging from acute immunosuppression to permanent interference with brain growth. Calculation of degree of malnutrition is essential for the correct nutritional treatment required for compensatory catch-up growth.

The degree of height and head circumference growth stunting provides important data about the chronicity and severity of malnutrition ( [McLaren and Reed, 1972](#)). Such stunting usually is associated with a poorer growth prognosis because such growth arrest is both difficult to overcome, as well as strongly associated with

long-standing psychosocial deprivation. Stunting of head circumference growth is especially ominous because it reflects structural alterations in brain size. If nutritional interventions are delayed or inadequate, deficits in head circumference may be lifelong, even if weight and length deficits may be largely restored.

An important caveat in the calculation of growth stunting is the consideration of intrauterine growth retardation (IUGR) and prematurity. IUGR is defined as both weight and height less than the 10th percentile for gestational age (Frank and Zeisel, 1981). The growth prognosis for children with a history of IUGR varies with the nature of the prenatal insult. Infants with IUGR who are underweight compared with their length or head circumference have the best prognosis for later growth. Presumably such infants have been poorly nourished during the end of gestation and can regain adequate weight for height by appropriate caloric intake. In contrast, infants with IUGR whose weight and length are equally delayed frequently remain small despite intervention. These infants often have suffered a variety of systemic intrauterine pathologic events, including exposure to teratogens, infections, and chromosomal abnormalities ( [Frank and Zeisel, 1988](#)).

Infants who were born prematurely may appear to be growth delayed simply because they are being evaluated by chronologic age of birth rather than by gestational age. The age used to evaluate height and weight should be calculated by subtracting the number of weeks since birth ( [Frank and Zeisel, 1988](#)). Such corrections should be made for head circumference until 18 months after birth, for weight until 24 months, and for height until 40 months. Obviously, FTT may develop in children with IUGR and prematurity in addition to their preexisting conditions. In fact, because both conditions commonly are associated with such risk factors for FTT as maternal substance and alcohol abuse, family dysfunction, and maternal mental illness or poor competence, infants with prematurity or IUGR are at higher risk for development of FTT than are full-term, normally developed neonates. Thus, although the diagnosis of either of these conditions by no means precludes the diagnosis of FTT, prematurity and IUGR must be taken into account when assessing the infant's degree of growth delay.

The presence of other medical disorders associated with FTT is a complex phenomenon that covers the continuum from illnesses like malabsorption, which directly cause malnutrition, to recurring infections secondary to malnutrition-induced immunosuppression ( [Frank and Zeisel, 1988](#)). At one time, researchers and clinicians alike attempted rigidly to dichotomize children who were "only" malnourished (so-called nonorganic FTT) and children who had a presumably etiologic medical illness (organic FTT). This rigid dichotomy served to obscure both evaluation and treatment ( [Frank and Zeisel, 1988](#)). Rather than focusing only on a disorder that causes the malnutrition, the clinician must evaluate a child with FTT as being at high risk for chronic infectious illnesses, elevated blood levels of heavy metals, and mineral deficiencies.

As with the other factors in the multiaxial approach to diagnosis and assessment of FTT, developmental delay is an important, multiply determined, and transactional risk factor. Both malnutrition and emotional deprivation are independently associated with developmental delay ( [Frank and Zeisel, 1988](#)). Obviously, when they are combined, they are potent risk factors. In addition, developmental delays themselves may contribute to the infant's feeding problems.

Level of family functioning is a crucial variable in assessment and treatment of FTT. The clinician must come to understand which of a myriad of family dysfunctions is contributing to the infant's failure to ingest adequate caloric intake. Earlier researchers had wondered about a specific type of family and especially maternal problem. No such specific dysfunctions have been found for children with FTT as a group. However, many reports have described specific family-related problems that appear to be directly related to specific infants with FTT. Thus, the absence of a prototypical family dysfunction that is related to most cases of FTT should not discourage the clinician from the search for sources of family problems for a specific child with FTT. Such an exploration is crucial because the ongoing nutritional supplementation and emotional stimulation must be done in the context of the child's family. Frequently, the family problems that contributed to the infant's FTT serve as roadblocks to effective treatment.

## FEEDING DISORDER OF INFANCY OR EARLY CHILDHOOD

### Definition

The fourth edition of DSM addressed the complex and controversial issues associated with FTT syndrome by creating a new diagnostic category, feeding disorder in infancy or early childhood. DSM-IV defined this disorder as (a) a feeding disturbance as manifested by persistent failure to eat adequately with a significant failure to gain weight or significant loss of weight over at least 1 month; (b) not due to an associated gastrointestinal or other general medical condition (e.g., esophageal reflux); (c) not better accounted for by another mental disorder or lack of available food; and (d) having onset before age 6 years. Although this new diagnostic category has provided a rational basis for the development of a nosology for eating and growth disorders in early childhood, there are a number of problems with the current definition. First, DSM-IV did not quantify "significant" failure to gain weight. It is hoped that future iterations of DSM will provide some quantification of this in terms of percentage of ideal body weight or shift in percentile on weight and length growth curves. Second, DSM-IV ignored the proven lack of validity of the organic/nonorganic dichotomy implied by the criteria of the absence of a general medical condition ( [Bell and Woolston, 1985](#); [Polan et al., 1991a, b](#)). Perhaps most important, this new diagnostic category makes no provision for subtyping. The likelihood that a single general diagnosis will cover two developmental epochs is very small. As described in the section on FTT, [Chatoor and colleagues \(1998a, b\)](#) have proposed three distinct feeding disorders of infancy and early childhood that are well defined and have preliminary empirical support as valid and separate disorders within the broad diagnostic category.

## FUNCTIONAL DYSPHAGIA

### Definition

Functional dysphagia is an eating disorder characterized by a subjective experience of difficulty or discomfort associated with the act of swallowing that is not primarily due to an organic medical condition.

### Clinical Description

The two most commonly described variations are conversion dysphagia and posttraumatic dysphagia. ( [Culbert et al., 1996](#)). Functional dysphagia and its variants have a variety of alternate names, including *posttraumatic feeding disorder* ( [Chatoor et al., 1988](#)); *food aversion* ( [Siegel, 1982](#)); *food phobia* ( [Singer et al., 1992](#)); *feeding resistance* ( [Geerstma et al., 1985](#)); *food refusal* ( [Linscheid et al., 1987](#); [Ramsay and Zelazo, 1988](#)); *phagophobia* ( [Culbert et al., 1996](#)); and *globus hystericus* ( [Koon, 1983](#)). Although functional dysphagia can occur throughout the life cycle, its onset is most commonly in preschool- and school-aged children ( [Culbert et al., 1996](#)). Problems associated with functional dysphagia include total or partial food refusal, food selectivity, adipsia or polydipsia, rumination or vomiting, failure to gain weight or weight loss, and dehydration. Functional dysphagia frequently has a variety of initiators and maintainers. These include organic factors such as esophageal irritation or hyperactive gag reflex; psychosocial factors such as abuse related to feeding, dysfunctional family meal time culture, and social reinforcement; and emotional and behavioral factors such as actual or vicarious choking event, anxious/intense temperament, anxiety disorders, and distorted body image ( [Culbert et al., 1996](#)). Developmental outcome of functional dysphagia is completely unreported in the literature.

### Treatment

Treatment of functional dysphagia has included cognitive-behavioral therapy ( [Koon, 1983](#)), hypnotherapeutic therapy ( [Culbert et al., 1996](#)) as well a multimodal approach that integrates cognitive-behavioral, individual, family, and pharmacologic therapies ( [Atkins et al., 1994](#)).

## PSYCHOSOCIAL DWARFISM

### Definition

Psychosocial dwarfism (PSD), also called *derivational dwarfism* or *hyperphagic short stature*, is a syndrome of deceleration of linear growth combined with characteristic behavior disturbances (sleep disorder and bizarre eating habits), both of which are reversible by a change in the psychosocial environment ( [Gilmore and Skuse, 1999](#); [Green et al., 1984](#); [Powell et al., 1967](#); [Skuse et al., 1996](#)).

### Prevalence and Epidemiology

PSD apparently is a rare disorder, so virtually, all of the available literature consists of case reports or small case series. Incidence, prevalence, sex ratio, and sociodemographic features are unknown.

## Clinical Description

The deceleration of linear growth is remarkable in that it occurs in the absence of weight gain deceleration. In this way, PSD is quite distinct from growth stunting secondary to malnutrition (FTT), but rather resembles primary hypopituitarism (Blizzard, 1973; Powell et al., 1967). The most common, characteristic abnormal eating behaviors include polyphagia, gorging, vomiting, stealing and hoarding food, and eating from garbage pails and animal food dishes. Other behaviors reported include polydipsia, including drinking stagnant water, toilet bowl water, and dishwater. Various sleep disorders have been described, such as initial-onset insomnia and night wandering. These sleep disturbances may be related to growth delay because they interfere with the major nocturnal pulsatile release of growth hormone. Children with PSD may exhibit a variety of unusual patterns of relatedness and problems with behavior, including aggressiveness and impulsivity. Both specific language delays and delays in general intellectual development have been reported (Drash et al., 1986).

The age of onset is unclear but reportedly occurs between 18 and 48 months. Blizzard (1973) argued that the onset must occur after 24 months to distinguish it reliably from FTT.

## Etiology and Pathogenesis

The literature is virtually unanimous in describing parental psychopathology that results in maltreatment of the child (e.g., Powell et al., 1967), including overt abuse or neglect (Drash et al., 1968). Several reports have indicated that both the parental psychopathology and maltreatment of the child may be obscured in initial interviews. The parents have been reported to withhold clinical information and be uncooperative with treatment. The frequent association of parental psychopathology and the reversal of the associated features with change in environment appear to be quite convincing. However, because no studies have been reported that control for such basic variables as socioeconomic class, the validity of these findings should be viewed as preliminary.

## Laboratory Studies

Much of the research on PSD has focused on neuroendocrine abnormalities found in the syndrome in an attempt to unravel the relationship between growth rate and neuroendocrine changes. Unfortunately, these investigations have led to the discovery of no pathognomonic or consistently abnormal findings, with the possible exception of depressed somatomedin levels (Green et al., 1984). The abnormalities in hormonal levels and hypothalamic functioning have been found to normalize partially or completely after the subject's removal from the inimical environment. This normalization may occur in several weeks or require as long as 2 years, depending on the specific endocrine disturbance and the type of specific medical, hormonal, or psychiatric treatment (Green et al., 1984). In addition to this great variability in the normalization of endocrine abnormalities, none of the abnormal hormonal findings correlates specifically with growth failure. Growth failure has occurred with normal endocrine values, and catch-up growth has occurred with subnormal values (Green et al., 1984). The mechanisms causing the growth failure in PSD therefore are as yet unknown.

## Natural History and Outcome

Developmental outcome appears to be highly variable, although limited outcome data are available. Outcome appears to be highly contingent on the adequacy of the child's psychosocial environment. Hospitalization or removal to a less noxious home environment is presumed to be ameliorative because it is associated with reversal of some of the neuroendocrine, growth, and behavioral concomitants of the disorder (Powell et al., 1967). If the child is returned to the noxious home environment, the various gains that have been achieved may be arrested or reversed. Behavioral disturbance, developmental delays, and short stature are possible long-term sequelae. In addition, delayed puberty may occur (Howse et al., 1977).

The explanation for the rarity of PSD, even among children exposed to severe maltreatment, is a mystery. Possible factors may include genetic vulnerability to a disruption in the rate or rhythm of growth hormone production or some specific type of psychosocial deprivation that causes such neuroendocrine dysfunction. However, the unraveling of these mysteries awaits better designed studies that have larger sample sizes and matched control subjects.

## Treatment

The treatment and evaluation of PSD must include the three cardinal factors associated with the disorder: a reversible neuroendocrine and growth dysfunction, behavioral disturbances and developmental delays, and presumably a noxious psychosocial environment. The evaluation of the neuroendocrine and growth dysfunction is important in the differential diagnosis of other disorders that are associated with short stature as well as in monitoring the response to treatment. These other disorders involving short stature include primordial dwarfism, IUGR with persistent small size, hypopituitarism from a variety of etiologies, constitutional delayed growth, Turner's syndrome (XO chromosomal pattern), osteochondrodystrophies, and growth stunting secondary to chronic malnutrition with or without chronic disease. PSD is virtually unique in being reversible with a change in living situations and in the absence of any signs of physical illness except growth delay.

The behavioral disturbances and developmental delays found in PSD serve as important factors to help monitor response to treatment as well as to represent serious aspects of the disorder that must be addressed. A careful psychiatric evaluation of the child is required that assesses for the presence of bizarre and disruptive behaviors, as well as for problems in normal social relatedness. A developmental assessment must evaluate for both specific delays, especially in language, and general developmental delays. In older children, psychoeducational testing is helpful to assess specific intellectual, academic, and adaptive functioning. Psychotherapeutic and educational interventions should be guided by these findings.

The evaluation and intervention to ameliorate the psychosocial adversity is both the most important as well as most difficult task. According to all reports, caretakers of a child with PSD may be actively uncooperative in the assessment and treatment phases. Ideally, the caretakers can be engaged in the appropriate individual and family psychotherapies. In addition, they can use various social supports such as home aides and support groups. In the event of active treatment refusal, which may result in permanent damage to the child, the treaters must consider removal of the child from the home.

## CHILDHOOD OBESITY

### Definition

Obesity is defined as a state of excess adiposity, so that the body weight is greater than 120% of expected for age and height.

### Historical Note

Considerable attention in the literature has been focused on the eating disorders of early childhood that result in growth failure, such as FTT, PSD, and rumination. In contrast, the eating disorders that result in excessive weight gain have been virtually ignored. DSM-IV has reinforced this prejudice by refusing to classify any form of obesity as an eating disorder (American Psychiatric Association, 1994). Instead, it relegates obesity to Axis III as a physical disorder. In conjunction with this lack of interest in obesity in the psychiatric literature, there are many widely held misconceptions about its etiology, course, and even heterogeneity of subtypes. This state of clinical indifference about the fundamentals of obesity in general, and childhood obesity in particular, makes a scientific strategy for intervention difficult.

### Prevalence and Epidemiology

The incidence and prevalence of obesity in childhood is not nearly as well studied as obesity in adulthood. The few studies indicate that the prevalence rate of obesity is 5% to 10% of preschool-age children (Maloney and Klykylo, 1983). Occasionally, "epidemics" of infantile obesity have been reported with prevalence rates of 16.7% of infants younger than 12 months of age (Shukla et al., 1972). These epidemics appear to be caused by culturally determined misinformation or fads about infant feeding practices (Shukla et al., 1972).

Female obesity is nine times more common in working class families than in middle and upper social class families (Stunkard et al., 1972). The prevalence of obesity is linked to the socioeconomic status of the parents almost as strongly as it is to the subject's own social class (Goldblatt et al., 1965). This finding argues that socioeconomic status is linked to obesity in a causal rather than a simple associative manner, perhaps mediated through culturally determined eating habits and dietary misconceptions. A family-line analysis of obesity indicates that there is a strong correlation between the fatness of parents and their children. For example, by

17 years of age, the children of obese parents have three times the chance of being obese as the children of lean parents. If one sibling is fat, there is a 40% chance that a second sibling will be fat ([Garn and Clark, 1976](#)). If two siblings are fat, there is an 80% chance that the third sibling will be fat. Although these data seem to support a genetic basis for obesity, other nongenetic, but family-related, factors must be kept in mind. The same study that reported the sibling data indicates that if one spouse is fat, there is a 30% chance that the other spouse also will be fat ([Garn and Clark, 1976](#)). Obviously, this finding cannot be explained by genetic factors. Indeed, Birch and colleagues (e.g., [Birch and Fisher, 1998](#); [Johnson and Birch, 1994](#)) have demonstrated a significant psychosocially transmitted influence from parents to their children related to eating behaviors and obesity. However, well designed genetic studies involving monozygotic/dizygotic concordance ([Stunkard et al., 1986a](#)) and adoption samples ([Stunkard et al., 1986b](#)) support a strong genetic contribution to all forms of body habitus ranging from fatness to thinness.

Studies of overt psychopathology in obese adults have been as contradictory as studies of other aspects of obesity. [Silverstone \(1969\)](#) attempted to reconcile these discrepant reports by differentiating between late-onset adult obesity secondary to a gradual accumulation of fat and early-onset adult obesity characterized by a sudden increase in fatness that was the result of anxiety-driven overeating. Indeed, psychogenic obesity of infancy and early childhood has been reported to occur only in the context of a disorganized family in which the child's needs are poorly perceived and even more poorly differentiated ([Kahn, 1973](#); [Woolston, 1987](#); [Woolston and Forsyth, 1989](#)).

### Clinical Description

The first step in the elucidation of any new field of study is an operational definition that is phenomenologically reliable and valid. In the study of obesity, there needs to be an easy, accurate, reliable method of defining the clinical condition. Because obesity denotes being excessively fat, the operational definition must differentiate the condition of having excessive adipose tissue for chronologic age from simply being heavy for chronologic age as a result of large muscle mass or skeletal frame. Triceps skinfold thickness ([Garn and Clark, 1976](#)) and an obesity index using weight gain, suprailiac skin fold, and waist circumference ([Crawford et al., 1974](#)) are two well standardized measurements that appear to satisfy the requirements for a useful, operational definition of obesity. A simpler, if slightly less valid, measure of obesity is defined by exceeding 120% of ideal body weight for height for a given age and sex. Specifically, ideal body weight is calculated by dividing actual weight by the expected weight for a given age and sex and height percentile.

One of the most obvious explanations for the contradictory results of various studies in regard to developmental course and etiology is that obesity in childhood is a heterogeneous syndrome. Many authors (e.g., [Maloney and Klyklo, 1983](#); [Stunkard, 1980](#)) have identified multiple factors that contribute to the development of obesity, including emotional, socioeconomic, genetic, developmental, and neurologic.

Although preliminary attempts have been made to subdivide forms of juvenile-onset obesity into phenomenologically homogeneous groupings ([Woolston, 1988](#); [Woolston and Forsyth, 1989](#)), such attempts probably are premature. Many of the same issues related to diagnostic classification of FTT apply to obesity. Fundamentally, all forms of obesity have the same organic basis: caloric intake that exceeds caloric expenditure. Like FTT, there are a multitude of primary medical illnesses that are associated with obesity. However, because it is the excess caloric intake that actually mediates the obesity, there frequently are psychosocial/emotional factors that complicate all forms of obesity, including those associated with developmental syndromes. The database of obesity of early childhood is too small to permit construction of clinically useful categorization. Instead, like FTT, a multiaxial list of major risk factors is more helpful. These should include age of onset and duration, degree of obesity, family history of obesity, presence of a medical illness or syndrome associated with obesity, and type of family functioning.

In a similar fashion to FTT, obesity that is associated with an acute onset in the first 12 months has an excellent prognosis because the treatment is simply a matter of reducing the infant's caloric intake to the recommended level for height and age. However, this benign condition can become much more problematic if there are other risk factors such as severe family dysfunction, a strong family history for obesity, or a medical syndrome associated with obesity. The longer the obesity persists beyond infancy and the later is its onset in childhood, the more persistent it is likely to be.

Obesity in infancy and childhood is a heterogeneous syndrome that has been relatively neglected in the eating disorder literature. The development of obesity is influenced by the interplay of social, familial, emotional, and physical factors. Analogous to FTT, obesity has been subtyped according to the presence or absence of physical disorders that are associated with obesity. Much less attention has been given to the different roles of genetics, cultural eating habits, and psychogenic factors.

### Natural History and Course

The study of the natural history of obesity in infancy and childhood is in its beginning stages. Data about the typical course of this disorder are contradictory. The most widely held belief is that obesity of early onset is a chronic and steadily progressive disorder with very few remissions ([Charney et al., 1976](#); [Eid, 1970](#)). However, more recent works ([Poskitt, 1980](#); [Shapiro et al., 1984](#)) have reported that obesity in infancy is a poorer predictor of later childhood obesity than was believed previously.

This rather poor correlation between obesity in infancy and obesity in later childhood calls into question the notion of relentlessly progressive obesity that is triggered by fat cell proliferation in infancy. Rather than there being a critical phase in infancy for fat cell proliferation, it is more likely that the degree and duration of obesity are the major determinants of total adipose cell number in humans.

### Laboratory Studies and Differential Diagnosis

In the differential diagnosis of infantile or childhood-onset obesity, clinicians frequently search for the discovery of discrete genetic, endocrinologic, or neurologic syndromes associated with obesity, including Prader-Willi, Klinefelter, Fröhlich, Laurence-Moon-Biedl, Kleine-Levin, and Mauriac syndromes.

Although these syndromes associated with obesity frequently are searched for as an etiology for obesity in childhood, they are quite rare. In addition, a clinical rule of thumb distinguishes between obesity associated with a developmental syndrome and that associated with otherwise normal development. Children with a developmental syndrome usually are below the 25th percentile in height and have delayed bone age, whereas children with normal development are above the 50th percentile in height and have an advanced bone age.

### Natural History and Outcome

The degree of obesity, expressed either as a percentile of ideal body weight for height and age or as a Z score, predicts prognosis in that the degree of obesity may reflect the seriousness of the underlying risk factors. More important, the degree of obesity helps guide the clinician regarding the likelihood of serious medical sequelae of obesity such as slipped femoral head epiphysis, sleep apnea, pickwickian syndrome, hypercholesterolemia, and diabetes mellitus. In addition, the degree of obesity must guide the nutritional intervention. Caloric restriction below the recommended amounts for height, age, and sex rarely is indicated. Instead, the primary goal is to arrest continued weight gain until the child's height and weight are proportional.

### Treatment

Preliminary data indicate that children with a positive family history for being overweight as their only risk factor may have a relatively good response to brief, family-based behavioral intervention. Using a prospective, randomized, controlled experimental design, [Epstein et al. \(1990\)](#) reported that an 8-week behavioral intervention program for both the obese child and his or her parents significantly reduced the obesity in the child at the end of the 10-year follow-up. Unfortunately, this study has not been replicated in the absence of other risk factors. Children with this pattern of obesity rarely become morbidly obese, and so rarely develop the major medical complications of severe obesity. As indicated earlier, children with obesity as part of a primary developmental syndrome usually are below the 25th percentile in height and frequently are cognitively impaired.

Level of family functioning may be crucial in both the genesis of obesity as well as its treatment. Severely dysfunctional families provide the child with an environment of emotional neglect, a sense of abandonment, and no limit setting around the use of food. A small number of children who grow up in such environments acquire a pattern of enormous caloric intake and a rapid onset of severe obesity, usually beginning between 3 and 5 years of age. These children are at high risk for poor developmental outcome because the constellation of risk factors conspire to produce a powerfully negative synergistic spiral. These children usually have low self-esteem, which is exacerbated by their obesity. They are likely to suffer the most serious medical complication of obesity. Most important, they are at high risk because the only effective intervention for treatment of obesity is mediated through the family system. This intervention includes the orchestration of appropriate

medical and mental health services, effective limit setting, and the development of more positive self-esteem and emotional security. Unfortunately, the very risk factor that contributed so heavily to the genesis of the disorder, family dysfunction, makes intervention difficult ( [Woolston and Forsyth, 1989](#)).

## **BENIGN NUTRITIONAL DWARFING**

### **Definition**

Benign nutritional dwarfing (BND) is a disorder of school-age children and young adolescents in which maladaptive eating patterns unaccompanied by psychiatric or medical disorders result in a marked slowing of weight gain for at least 1 year, followed by a deceleration of linear growth.

### **Prevalence and Epidemiology**

Because of the relatively recent reporting of BND, satisfactory data on its incidence and prevalence do not exist. In most reports of BND, there is a slight predominance of boys over girls.

### **Clinical Description**

Delayed puberty may be associated with this disorder. Because the subnormal weight gain in such children is accompanied by a proportionate decline in growth velocity, body weight-for-height deficits frequently are not evident. Therefore, children with BND do not present with emaciation, as is commonly observed in cases of severe malnutrition. Although dwarfing secondary to chronic malnutrition in childhood is as old as humankind, BND is a relatively newly described disorder ( [Apley et al., 1971](#); [Davis et al., 1978](#); [Lifshitz et al., 1971](#); [Pugliese et al., 1983](#); [Sanberg et al., 1991](#)). Although various authors report various different motivations for the inadequate caloric intake, all reports have been consistent in describing an absence of weight loss (as opposed to a slowing of weight gain) and an absence of body image distortion. One well controlled study found virtually no differences in various measures of psychological functioning between children with BND and matched children with constitutional growth delay or familial short stature ( [Sanberg et al., 1991](#)).

Typically, the age of onset of BND is middle childhood to early adolescence (8 to 14 years), although some authors have included children as young as 2 years ( [Davis et al., 1978](#)) and as old as 15 years of age ( [Lifshitz et al., 1971](#)). Although the consequences of chronic insufficient caloric intake can include delayed puberty and permanent short stature, children with BND frequently respond to relatively straightforward nutritional counseling with an increase in caloric intake sufficient to reinstate normal growth. There are no reports of associated development or psychiatric disorders either during the course of BND or as its sequelae.

### **Etiology and Pathogenesis**

Benign nutritional dwarfing is characterized by the absence of social or familial dysfunction that typifies other eating and growth disorders. There are no reports that indicate any particular parental psychopathology or genetic factors. Some reports have described special nutritional concerns ( [Pugliese et al., 1983](#)) and chronic nonspecific feeding disturbances ( [Davis et al., 1978](#)).

The only psychogenic factors reported to be related to BND are inaccurate nutritional beliefs about weight gain or special dietary needs.

As indicated earlier, inadequate caloric intake to maintain normal weight gain is the only known organic factor. Various mineral and vitamin deficiencies may complicate the inadequate caloric intake ( [Lifshitz et al., 1971](#)).

### **Differential Diagnosis and Treatment**

Benign nutritional dwarfing is characterized by chronic inadequate caloric intake as a result of mistaken nutritional beliefs. Although a variety of medical and psychiatric disorders may result in chronic malnutrition, children with BND have a normal physical and psychiatric examination except for a history of weight velocity deceleration, followed by growth velocity deceleration. A careful history of growth and of dietary beliefs and eating habits is crucial to establish the diagnosis and guide the intervention. The treatment of BND should focus on nutritional counseling of the child and parents. Follow-up visits should be scheduled to ascertain weight gain.

## **PREPUBERTAL ANOREXIA NERVOSA**

### **Definition**

Prepubertal anorexia nervosa has all of the essential features of typical adolescent-onset anorexia, including intense fear of becoming fat, disturbance of body image, significant and defined weight loss, and a refusal to maintain a minimum normal body weight. The only modifications of the standard diagnostic criteria are those required by the physical characteristics of prepubertal children. Obviously, because these children are prepubertal, amenorrhea is not a meaningful criterion.

### **Historical Note**

Although prepubertal anorexia nervosa was reported in the same year ( [Collins, 1894](#)) that adolescent-onset anorexia nervosa was first described, substantial case reports were not recorded until nearly 70 years later. Indeed, full recognition of the special characteristics of prepubertal anorexia nervosa awaited reports in the 1980s to establish this as a relatively rare but bona fide form of anorexia nervosa ( [Bostic et al., 1997](#); [Growers et al., 1991](#); [Irwin, 1984](#); [Jacobs and Isaacs, 1986](#); [Lask and Bryant-Waugh, 1992](#); [Russell, 1985](#)).

### **Prevalence and Epidemiology**

Although anorexia nervosa is a relatively rare disorder, prepubertal anorexia is considerably rarer. The sex ratio and sociodemographics appear to be similar to those in the more typical anorexia nervosa. Current published reports indicate that the same types of social and family factors are implicated in the genesis of prepubertal anorexia nervosa as with more typical anorexia nervosa. These factors include middle or upper middle class and an enmeshed, intrusive family communication style. Like social and family factors, genetic factors may play an important role in anorexia nervosa regardless of the age of onset ( [Garfinkel and Garner, 1982](#); [Morgan and Russell, 1975](#)).

### **Clinical Description**

Because prepubertal children have a smaller percentage of body fat than adolescents, a smaller percentage of weight loss has a greater physiologic impact. This relatively greater deleterious effect of weight loss sometimes is compounded by the fact that prepubertal children are more concrete in their thinking, so that they more frequently generalize their pathologic eating to include their fluid intake ( [Irwin, 1984](#)).

### **Etiology and Pathogenesis**

Although numerous theories exist about various psychogenic factors related to anorexia nervosa, all remain relatively speculative. Children with prepubertal-onset anorexia express fewer concerns about sexual maturity ( [Jacobs and Isaacs, 1986](#)) than those with later-onset anorexia. In addition, prepubertal children with anorexia nervosa have less cognitive ability to understand various concepts of nutritional counseling. Some of the emotional and social goals in the treatment of adolescent anorexia related to differentiation from the family may be inappropriate for a prepubertal child.

As with other forms of anorexia nervosa, there are no known organic factors related to etiology. Acute malnutrition has a variety of important consequences for neuroendocrine functioning and growth.

## Natural History

Because relatively few cases of prepubertal anorexia nervosa have been reported, conclusions about any aspect of natural history remain tentative. However, existing reports support the notion that prepubertal anorexia carries all of the possible negative sequelae of adolescent anorexia nervosa. In addition, the experience of an episode of acute malnutrition severe enough to cause significant weight loss in a prepubertal child will likely have a deleterious effect on growth ( [Russell, 1985](#)).

## Treatment

The prepubertal age of onset in this typically adolescent and adult disorder is the main stumbling block to accurate diagnosis and treatment. In general, clinicians who typically treat anorexia nervosa have little knowledge about the special cognitive, emotional, or physical needs of prepubertal children. Analogously, clinicians who treat prepubertal children have little experience in the diagnosis or treatment of anorexia nervosa. Once these obstacles have been overcome, the diagnosis and treatment are at once as straightforward and as difficult as in more typical anorexia.

---

### CASE ILLUSTRATION CHRONIC FAILURE TO THRIVE WITH SECONDARY DWARFING

George M. was a 5-year, 8-month-old child who was admitted to a children's psychiatric inpatient service because of his protective service case worker's "concern about his not picking up weight" and because of evidence of depression as indicated by statements such as "I want to be nothing. If I don't eat, I will be nothing."

George had been diagnosed as having failure to thrive (FTT) at age 3 years, 2 months when he was admitted to a pediatric unit of a community hospital for evaluation of his poor weight gain and linear growth. The workup for an organic etiology of his FTT was negative except that he was noted to consume inadequate calories. His mother was charged with medical neglect, and he was committed to the state, which placed him in a series of foster homes with continued visitation with his mother. Finally, at age 4 years, he was placed in a permanent foster home, which allowed ongoing visitation with his mother. His growth failure continued, so that he was evaluated on an outpatient basis at a children's hospital. Again, the pediatric workup was negative for an organic etiology except for his inadequate caloric intake. The evaluators were concerned by the unresponsive and apathetic styles of interaction with his biological mother and recommended termination of parental rights. However, George's biological mother appeared to improve her parenting style after she was informed of the intention to terminate her parental rights. Because of his apparent improvement, the protective service agency dropped the termination petition.

In the several months before admission, the protective service agency had attempted to reunite George with both his biological mother and father. However, this proved difficult, especially because George's parents had separated as a result of his father's alcohol abuse and violent temper. George was observed to have a picky and poor appetite in general but especially during and after visits with his parents. At these times, he ate very little and vomited what he did eat.

On admission, George presented as a small, thin, 5-year, 8-month-old boy with a flat affect and a depressed mood. He engaged easily with the interviewer and occasionally his affect brightened somewhat. He was unable to describe any wishes because he felt wishes were pointless and they would never come true. He had a realistic assessment of his body image, stating he was too skinny and needed to gain weight. George was quite articulate about his concerns about his future placement because he knew that his mother and his foster parents were vying for his custody.

George's developmental history was characterized by a full-term gestation, normal vaginal delivery, and normal early developmental milestones. By age 4 years, he was noted to have mild delays in language and in fine, gross, and visual motor skills.

His admission physical examination was remarkable only for his small stature, with a weight of 13.7 kg and height of 102.9 cm. These measurements represent a height age of 3 years, 2 months, a weight age of 2 years, 8 months, and a percentage of ideal body weight of 85%. His admission laboratory evaluations, including complete blood count, sedimentation rate, electrolytes, thyroid functions, urinalysis, somatomedin-C, head computed tomography scan, and bone age, were all within normal limits.

During the course of his 3-month hospitalization, George went through three phases in his process of developing greater trust and reliance in close attachments: first was avoidance and rejection of caregivers, second was testing the stability of these relationships, and third was his realization that he was indeed cared for. Despite ongoing visitation by George's biological mother, she continued her highly ambivalent and highly volatile relationship with George. Although she was sometimes warm and affectionate, at other times she was harsh and overtly rejecting. She persistently maintained that, "George needed to learn that you can't always be the center of attention." She interpreted his slow and picky eating as a personal attack on her parenting skills. Her overall personality structure was so fragile that the stress of a difficult visit with George and her taxi not arriving led her to experience a transient episode of a gross thought process disorder.

The treatment team and protective service agency decided that George could not return to live with his mother. Before discharge, a legal risk adoptive mother was identified and introduced to George. By the time of discharge, he had gained only 1 kg but had progressed considerably in his self-esteem and ability to verbalize his feelings. For the next 1½ years, George continued to improve emotionally and developmentally but remained a picky eater. However, within several months of termination of his mother's parental rights and finalization of his adoption, he began to eat with gusto. His rate of weight gain increased, so that he moved from below the 5th percentile to above the 25th. Several months later, his linear growth followed suit.

## DEFINITION

Anorexia nervosa and bulimia nervosa are the two major eating disorders. They are complex syndromes with considerable psychiatric and medical comorbidities. Current diagnostic criteria for anorexia nervosa and bulimia nervosa from the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association, 1994) are shown in [Table 55.1](#) and [Table 55.2](#). For those patients who have serious problems with eating behavior but who do not fall into the diagnostic categories of anorexia nervosa or bulimia nervosa, the DSM-IV has designated a category of Eating Disorder Not Otherwise Specified (EDNOS). Most cases of eating disorders have an onset during adolescence.

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- B. Intense fear of gaining weight or becoming fat, even though underweight.
- C. Disturbance in the way in which one's body weight or shape is experienced; undue influence of body weight or shape on self-evaluation; or denial of the seriousness of the current low body weight.
- D. In postmenarcheal females, amenorrhea (i.e., the absence of at least three consecutive menstrual cycles).

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC: American Psychiatric Association, 1994.

**Table 55.1. Diagnostic Criteria for Anorexia Nervosa**

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
  2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC: American Psychiatric Association, 1994.

**Table 55.2. Diagnostic Criteria for Bulimia Nervosa**

There are four major criteria that define anorexia nervosa. The first criterion is a guideline for defining weight loss because there is no specific amount of weight loss associated with the other symptoms that constitute anorexia nervosa. Therefore, an adult is considered "underweight" if he or she weighs less than 85% of a weight that is considered normal for that person's age and height. For children up to the age of 18 years, pediatric growth charts should be used. Some children may not have weight loss but still weigh less than the expected weight because they have failed to make weight gains during a growth in height. The second criterion, intense fear of gaining weight, is present even during emaciated states. Anorectic patients often deny this fear because they are resistant to treatment, and hence, their fear of gaining weight often must be inferred from reports of their behavior that reveal rigorous attempts to prevent weight gain, such as severe food restriction and exercising. The third criterion, pertaining to body image disturbance, has evolved into a more complex concept. The significance of body weight and shape are greatly distorted in these individuals. Some feel globally overweight, and others realize they are thin but feel certain parts of their body, especially the abdomen and thighs, are too fat. The distorted significance of body weight and shape is related to a feeling of being very ineffective. Losing weight and being thin is one area in which these individuals can be effective and in control. The latter undoubtedly influences their denial of the serious medical complications of their malnourished state.

The fourth criterion for diagnosis of anorexia nervosa in the DSM-IV is amenorrhea. In some adolescents who have never menstruated, the amenorrhea is primary and menarche is delayed by the anorexia nervosa. Amenorrhea can appear before noticeable weight loss has occurred ([Halmi and Falk, 1981](#)). Because it is difficult to obtain an accurate history of menses and because of the great variation associated with weight loss in menses, some academicians are advocating abolishing this criterion.

There are two subtypes of anorexia nervosa: the restricting type and the binge-purge type. Studies have consistently demonstrated that impulsive behaviors, including stealing, drug abuse, suicide attempts, self-mutilations, and promiscuity, are more prevalent in anorectic-bulimics compared with anorectic restrictors. The anorectic-binge-purge type also has a higher prevalence of premorbid obesity, familial obesity, debilitating personality traits, and specific medical complications compared with the anorectic restrictors ([Eckert et al., 1987](#); [Halmi and Falk, 1982](#); [Strober et al., 1982](#)).

The criteria for bulimia nervosa are more arbitrary and less specific than the criteria for anorexia nervosa. There is no consensus on what constitutes a binge and how frequently bingeing must occur to warrant a diagnosis of this disorder. In the first criterion for bulimia nervosa in DSM-IV, binge eating is defined as eating more food than most people eat in similar circumstances and in a similar period. The sense of losing control is a significant subjective aspect that needs to be present. The second criterion, which is the recurrent use of inappropriate compensatory behaviors to avoid weight gain, usually means self-induced vomiting. However, bulimic patients often use cathartics for weight control and have an eating pattern of alternate binges and long fasting periods. The third criterion designed to address

chronicity and frequency is not based on specific research but rather clinicians' consensus about obvious impairment of function. The fourth criterion acknowledges that patients with bulimia nervosa also are concerned about their body shape and weight and tend to place excessive estimation of their worth in terms of appearance. The fifth criterion for bulimia nervosa differentiates the latter from the binge-purge subtype of anorexia nervosa. The diagnosis of bulimia nervosa also is subtyped into a purging type for those who regularly engage in self-induced vomiting or use of laxatives or diuretics and a nonpurging type for those who use strict dieting, fasting, or rigorous exercise but do not engage in purging behaviors. Patients with bulimia nervosa who do not purge tend to have less body image disturbance and less anxiety concerning eating compared with those who purge ([Davis et al., 1997](#)).

Binge eating disorder is listed in the EDNOS category of the DSM-IV for eating disorders. People with this disorder lack the compensatory weight control behaviors and the exaggerated concern with weight and shape ([Devlin et al., 1992](#)). Field trials are being conducted to provide evidence as to whether binge eating disorder should be a specific diagnostic category.

An EDNOS diagnosis also is given to persons who vomit after eating small amounts of food but who maintain a weight within a normal range and menstruate.

## HISTORICAL CONTEXT

Disturbances of eating behavior are described in the Middle Ages. Well documented case reports of anorexia nervosa are found in the literature describing early Christian saints. The severe starving behavior and bingeing episodes of Saint Catherine of Sienna are recorded in monastery documents, along with the kind of reed she used to induce vomiting and the herbal cathartics she used for purging ([Bell, 1985](#)). Another example of this irreversible self-starvation in a fasting female saint is Princess Margaret of Hungary, who lived from 1240 to 1271 ([Halmi, 1994](#)). She was the daughter of a king and was raised in a Dominican convent, where she excelled in all of her studies and in the undesirable chores of the monastery. It is likely that the biological vulnerability factors are similar in those dieting for sainthood during the Middle Ages and those dieting for thinness (attractiveness) in the 20th century. In the 17th century, both [John Reynolds \(1669\)](#) and [Richard Morton \(1689\)](#) described cases of typical anorexia nervosa symptomatology and distinguished them from consumption. In the 19th century, [Marcé \(1860\)](#), [Gull \(1888\)](#), and [Laséque \(1873\)](#) described additional cases of anorexia nervosa and recommended treatment. In the 20th century, the first major publication on anorexia nervosa was a book by [Bliss and Branch \(1960\)](#) that presented endocrine studies as well as psychological descriptions of the disorder. A decade later, [Hilda Bruch \(1973\)](#) further articulated the psychology of anorexia nervosa in her phrases "the relentless pursuit of thinness" and "the paralyzing sense of ineffectiveness, which pervades all thinking and activities." In 1979, Russell identified bulimia nervosa as a separate entity from anorexia nervosa. Subsequently it became apparent that there were young women who had the full syndrome of bulimia nervosa without a history of anorexia nervosa.

## EPIDEMIOLOGY AND DEMOGRAPHIC CHARACTERISTICS

Most studies of the incidence and prevalence of eating disorders have been conducted on restricted populations in very restricted areas of their countries. Thus, our knowledge about the incidence and prevalence of anorexia nervosa and bulimia nervosa in various countries is most likely inaccurate. Some figures, however, may be a close approximation to reality. An incidence study conducted in northeastern Scotland showed that between 1965 and 1991, there was almost a sixfold increase in the incidence of anorexia nervosa, from three cases per 100,000 population to 17 per 100,000 ([Hoek, 1993](#)). In a large representative sample of the Dutch population in Holland, [Hoek \(1991\)](#) reported the incidence of bulimia nervosa as 9.9 per 100,000 per year during the period 1985 to 1986 and 11.4 per 100,000 during the period 1986 to 1989. In Rochester, Minnesota, a study covering a 50-year span found an overall adjusted incidence for women of 14.6 per 100,000 per year; for men, the corresponding figure was 1.8 per 100,000 ([Lucas et al., 1991](#)). This study showed no change in the rates for women 20 years of age and older. Among 10- through 19-year-old girls, the incidence rates increased substantially from 1950 to 1984. In summary, when estimates are based on the population at large, the incidence rate of anorexia nervosa in industrialized countries is estimated at 8.1 per 100,000 per year.

[Soundy et al. \(1995\)](#) found that the community-based incidences of bulimia nervosa rose sharply from 1980 to 1983 and then remained relatively constant through 1990. The incidence rates in Rochester, Minnesota, during that decade were 26.5 per 100,000 population for women and girls and 0.8 per 100,000 for men and boys. The mean age for women is 23 years. Among 15- through 24-year-old adolescent girls and young women, it had become at least twice as common as anorexia nervosa.

Prevalence studies of eating disorders are more numerous and easier to conduct. The average prevalence of anorexia nervosa in England, Sweden, and Scotland using strict diagnostic criteria was 0.28% of young women ([Hoek, 1993](#)).

Over 50 prevalence studies of bulimia nervosa conducted between 1981 and 1989 gave a fairly consistent prevalence rate of 1% for bulimia nervosa in adolescent and young adult women ([Fairburn and Beglin, 1990](#)).

The male-to-female ratio for eating disorders in clinical samples lies consistently between 1:10 and 1:20 ([Hoek, 1991](#)). The onset of anorexia nervosa usually is between the ages of 10 and 30 years, with 85% of all anorectic patients developing the illness between the ages of 13 and 20 years ([Halmi, 1974](#)). In one large sample study, a bimodal distribution of age onset was found, with peaks at 14.5 and 18 years ([Halmi et al., 1979](#)). The stress of dieting may be greater at these times, during mid-puberty and at 18 years of age, when adolescents are preparing to leave home for a job or attend college. Because attractiveness is equated with better acceptance, young women may be more concerned about their appearance when they are preparing to leave the safe and dependent home environment.

## CLINICAL DESCRIPTION

Two hallmark characteristics of patients with anorexia nervosa are denial of the seriousness of their illness and resistance to treatment, both of which make obtaining an accurate history and producing an effective treatment result a challenge. Anorectic people demonstrate their intense fear of gaining weight by their intense preoccupation with thoughts of food and irrational worries about fatness. They frequently look in mirrors to make sure they are thin and incessantly express concern about their appearance. They take a great deal of time cutting up food into small pieces and rearranging food on their plates in order to eat less. An overwhelming feeling of inadequacy and ineffectiveness is a core symptom of all anorectic patients. Their success at losing weight is an impressive accomplishment and boosts their self-confidence. Obsessive-compulsive behaviors often develop or become worse as their anorexia nervosa becomes more severe. Obsessions with cleanliness and an increase in cleaning activities and compulsive studying commonly are observed. Perfectionist traits are common in the patient with the restricting type of anorexia nervosa.

Many adolescent anorectic patients have delayed psychosocial development, and adults often have a markedly decreased interest in sex with the onset of anorexia nervosa.

There are important physiologic differences between the two subtypes of anorectic patients. Most of the physiologic and metabolic changes in anorexia nervosa are secondary to the starvation state or purging behavior. These changes revert to normal with nutritional rehabilitation and the cessation of purging behavior.

In the patients with anorexia nervosa who engage in self-induced vomiting or abuse laxatives and diuretics, hypokalemic alkalosis may develop ([Table 55.3](#)). This electrolyte disturbance is associated with physical symptoms of weakness, lethargy, and, at times, cardiac arrhythmias. The latter condition may result in sudden cardiac arrest, a cause of death in patients who purge. Mild elevation of serum liver enzymes may occur both in the emaciated anorectic phase and during refeeding. This reflects some fatty degeneration of the liver. Elevated serum cholesterol levels tend to occur more frequently in younger patients and return to normal with weight gain. Other common laboratory findings in emaciated patients with anorexia nervosa are listed in [Table 55.4](#).

- 
1. Dental enamel erosion and caries
  2. Perioral dermatitis
  3. Periodontitis
  4. Subconjunctival hemorrhage
  5. Esophageal or gastric rupture
  6. Metabolic alkalosis with hypokalemia
  7. Cardiac arrhythmias
  8. Cardiomyopathy and cardiac failure secondary to ipecac abuse
  9. Renal failure
  10. Seizures

---

1. Hematologic
Anemia
Leukopenia with relative lymphocytosis
2. Serum and plasma
Hypercarotemia
Hypoproteinemia
Hypercholesterolemia
3. Endocrine
Decreased estrogens
Decreased testosterone (in males)
Immature secretion pattern of luteinizing hormone
Decreased or blunted luteinizing hormone-releasing hormone
Decreased thyrotropin
Increased corticotropin-releasing hormone
Increased fasting and impaired growth hormone secretion responses
Blunted diurnal cortisol levels
Uncoupled vasopressin secretion from osmotic challenge
Low basal metabolic rate
Reduced bone density

---

**Table 55.4. Common Laboratory Findings in Emaciated Anorexia Nervosa**

Laboratory findings present with binging and purging behavior are listed in [Table 55.5](#).

---

Hypokalemia
Hypochloremic alkalosis
Elevated serum amylase
Electrocardiogram—QT interval and T-wave changes
Photon absorptiometry—reduced bone density

**Table 55.5. Common Laboratory Findings with Binging and Purging Behavior**

Patients with bulimia nervosa should not be below 15% of the normal weight range. If they are, in most circumstances the correct diagnosis will be anorexia nervosa, binge-purge subtype. Patients with bulimia nervosa can be overweight. The sense of losing control of eating is a significant subjective aspect that occurs during binge eating. Abdominal pain or discomfort, self-induced vomiting, sleep, or social interruption usually terminate the bulimic episode, which is followed by feelings of guilt, depression, or self-disgust. Bulimic patients have a fear of not being able to stop eating voluntarily. Thus, ironically, they may fast for long periods, lose control because of severe hunger, and then binge eat. Hence, they completely forego a normal eating pattern and establish a routine of alternate binges and fasts. The food consumed during a binge usually has a high caloric content and a texture that facilitates rapid eating. Frequent weight fluctuations occur in bulimia nervosa but without the severity of weight loss present in anorexia nervosa. Most bulimic patients have difficulty feeling satiety at the end of a normal meal. They usually prefer to eat alone and at their homes. Approximately one-fourth to one-third of these patients have had a previous history of anorexia nervosa.

Most patients with bulimia nervosa have depressive signs and symptoms. They have problems with interpersonal relationships, self-concept, and impulsive behaviors and also show high levels of anxiety and compulsivity. Alcohol abuse and other drug dependencies are not uncommon in this disorder. Bulimic patients abuse amphetamines to reduce their appetite and lose weight. As is present in the patient with the binge-purge type of anorexia, patients with bulimia nervosa can have severe erosion of the enamel of their teeth, pathologic pulp exposures, loss of integrity of dental arches, diminished masticatory ability, and an obvious unaesthetic appearance of their teeth.

Parotid gland enlargement is associated with elevated serum amylase in bulimic patients who binge and vomit. Other complications of binging and purging behavior are listed in [Table 55.3](#). Severe abdominal pain in bulimic patients should alert the physician to a diagnosis of gastric dilatation and a need for nasal gastric suction, radiography, and surgical consultation.

Cardiac failure may be caused by a cardiomyopathy from ipecac abuse. This is a medical emergency that usually results in death. Symptoms of pericardial pain, dyspnea, and generalized muscle weakness associated with hypotension, tachycardia, and electrocardiographic abnormalities should alert the clinician to possible ipecac intoxication.

## ETIOLOGY AND PATHOGENESIS

The development of anorexia nervosa and bulimia nervosa is best conceptualized within the framework of a multidimensional model, which states that these disorders begin with dieting behavior. Antecedent conditions such as sociocultural influences, family environment, and psychological or personality characteristics and biological vulnerabilities affect the dieting behavior to produce the full-blown disorders of anorexia nervosa and bulimia nervosa. As fasting behavior, weight loss, and binge-purge behaviors continue, significant psychological and physiologic changes occur. Some of these changes are strong secondary reinforcers that allow the process of fasting, weight loss, and binge-purge behavior to continue.

Secondary psychological reinforcement occurs when the young women initially receive compliments for their weight loss and later realize this is one area of their life in which they can be extremely effective and in control. Patients who binge soon achieve a relief of anxiety during their binge eating even though this is followed by unpleasant feelings of guilt and depression. The physiologic reinforcements are less precisely defined. For example, with a period of only 8 hours of fasting, there is an increased secretion of corticotropin-releasing hormone (CRH), which is a potent anorectic agent. This may be effective in assisting some anorectic patients to continue their decreased calorie intake. Exercising causes a release of norepinephrine and endogenous opioids, which may also reinforce a feeling of exhilaration.

### Social and Cultural Influences

Anorexia nervosa and bulimia nervosa seem to be predominantly a “Western” disorder in that they are largely associated with the effects of industrialization and the resulting affluence. The Japanese health care system has been facing increasing numbers of patients with anorexia nervosa since World War II and the greater influence of Western values ([Suematsu et al., 1985](#)). Transcultural studies show that anorexia nervosa is rare in non-Western, poorly industrialized countries ([Lee et al., 1989](#)). When non-Western people are exposed to Western ideals of thinness, they are significantly affected by the exposure. For example, [Fichter et al. \(1988\)](#) found the prevalence of anorexia nervosa in Greek girls living in Germany and exposed to Western ideals of thinness was twice that of Greek girls who remained in Greece and were not exposed to Western values of body image. There have been suggestions that cultural differences in dietary habits, patterns of parent-child interactions, value orientation, and family structure may reveal more about the societal impact on the development of eating disorders ([Pate et al., 1992](#)).

Feminist theories emphasize that women are indoctrinated into a belief system that overvalues feminine beauty and thinness in particular. Women cannot achieve satisfactory self-esteem without attaining ideals that are impossible to fulfill. Eating disorders then become the adaptive response to the stress of demands that

women conform to an impossible and oppressive social expectation.

## Stressful Life Events

Studies investigating the role of sexual abuse as a risk factor in the initiation of an eating disorder have produced contradictory results ( [Connors and Morce, 1993](#)). Overall, approximately 30% of eating-disordered patients have been sexually abused in childhood, and this figure is comparable with rates found in the normal population. Studies have shown that abuse in multiple forms increases the likelihood of lifetime comorbid Axis I disorders and personality pathology among bulimic patients ( [Rorty et al., 1994](#)). It probably is most reasonable to suggest that for some patients there may be a direct link between sexual trauma and eating disorders but that, in general, sexual abuse may best be considered a risk factor for development of a wide range of psychological and psychiatric problems.

In the pre-morbidly vulnerable individual, normative developmental events such as the onset of puberty, leaving home, beginning school, and the start of new relationship have been precipitating events for the onset of an eating disorder ( [Cooper, 1995](#)). Adverse life events such as the death of a close relative, the breakup of a relationship, or an illness also have been related as precipitating eating disorders.

## Biological Factors

### *Genetic Factors*

Genetic vulnerability may be direct through inheritance of genes that are directly associated with the development of anorexia nervosa or bulimia nervosa. An indirect genetic predisposition, on the other hand, could become manifest under adverse conditions such as inappropriate dieting or emotional stress. These predispositions could manifest as a particular personality type, a susceptibility to psychiatric instability (especially affective or anxiety disorders), or a hypothalamic dysfunction. Six controlled studies have found a familial aggregation of anorexia nervosa and bulimia nervosa in the first-degree relatives of anorexia nervosa and bulimia nervosa probands ( [Kaye et al., 2000](#)). In a series of 67 twin probands, [Treasure and Holland \(1989\)](#) found that the concordance for a restricting anorexia nervosa was markedly higher for monozygotic (66%) than for dizygotic twins (0%). In a large, population-based twin registry study, [Kendler et al. \(1991\)](#) showed that concordance for bulimia nervosa was significantly higher in monozygotic than in dizygotic twin pairs. In the first large, uncontrolled study of siblings of anorectic patients, [Theander \(1970\)](#) found that in a sample of 94 anorectic patients, there was a 6.6% risk for female siblings to be diagnosed with anorexia nervosa.

### *Neuroendocrine Factors*

Under stresses such as severe dieting, vulnerability to destabilization of some of the endocrine and metabolic mechanisms affecting eating behavior may influence the development of a full-blown eating disorder. Most of the neuroendocrine changes in the eating disorders are directly related to dieting behaviors, weight loss, and reduced caloric intake. These changes revert to normal with resumption of normal eating behavior and nutritional rehabilitation. For example, increased CRH secretion occurs in underweight anorectic patients and in normal-weight, dieting individuals, but returns to normal with weight restoration. However, CRH is a potent anorectic hormone and may have a role in maintaining anorectic behaviors and initiating a relapse.

It is well established that pituitary cells producing luteinizing hormone are understimulated in patients with anorexia nervosa because of hyposecretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus. A dysfunction may be present in the neurotransmitter systems that influence GnRH release and secretion. The considerable difference in patterns of severe dieting and fasting in patients with bulimia nervosa probably explains the variability in the function of the hypothalamic-pituitary-ovarian axis as measured in various studies of bulimic patients. Some anorectic women remain amenorrheic for a long time (several years) after weight restoration. Studies have shown these women to be more psychologically disturbed compared with those who have a rapid resumption of menses ( [Halmi and Falk, 1983](#)).

The neurotransmitter serotonin is inhibitory to feeding, exploratory, and sexual behaviors, all of which are inhibited in anorexia nervosa. Studies of serotonin receptor polymorphisms have been contradictory. Both serotonin agonists and antagonists have been found useful as adjunct treatments of anorexia nervosa. Cyproheptadine, a serotonin antagonist, was shown to facilitate weight gain in anorectic restrictor patients. This drug most likely acts on hypothalamic appetite centers to decrease satiety and, hence, increase food intake. Clomipramine and fluoxetine (selective serotonin reuptake inhibitors) have been useful in preventing weight relapse in anorexia nervosa and may specifically target the characteristic obsessive-compulsive behaviors associated with food and weight control. Decreased serotonergic turnover in the cerebrospinal fluid (CSF) has been associated with impulsive, suicidal, and aggressive behavior. Animal studies have shown that impaired serotonergic function leads to overeating and obesity. The bingeing and purging behaviors of patients with bulimia nervosa are suggestive of impulse control and satiety regulation problems. Several studies have reported impaired serotonergic function in bulimic patients. Patients with bulimia nervosa have lower CSF 5-hydroxyindoleacetic acid levels compared with control subjects, and blunted prolactin responses to pharmacologic challenge with meta-chlorophenylpiperazine (m-CPP), and to the serotonin agonist fenfluramine ( [Jimmerson et al., 1997](#); [Levitan et al., 1997](#)).

The abnormal pleasure-reward response to food seen in both anorectic and bulimic patients could be related to a dysfunction of the dopaminergic system and its role in self-stimulating or addictive behaviors. This area needs further study. The neurotransmitters norepinephrine, dopamine, and serotonin all interact and affect secretions of neuropeptides that in turn can have appetite-stimulating or satiety-producing effects. At present, there is no definitive evidence that any of the neuropeptides actually cause the initiation of an eating disorder ( [Halmi, 1995](#)).

Serum levels of leptin, the product of an obesity gene, were shown to correlate significantly with body mass index and the amount of adipose tissue in patients with anorexia nervosa. Thus, emaciated anorectic patients have extremely low levels of leptin, which increase as the patients gain weight ( [Eckert et al., 1998](#)). It is unlikely that leptin is a causal agent for producing eating disorders. [Crisp \(1984\)](#) espoused the theory that anorexia nervosa reflects an attempt to cope with maturational problems through the mechanism of avoidance of biological maturity. He found that girls who have an early menarche and who are mildly overweight are at greater risk for development of eating disorders.

## Psychological Factors

Assessing psychological factors as risk factors in the development of eating disorders is problematic because any such study must be retrospective. In a study of recovered patients with anorexia nervosa, [Casper \(1990\)](#) and [Strober \(1980\)](#) found that compared with control subjects and with their sisters, anorectic patients with long-term recovery had greater obsessive-compulsive personality disorder traits. More recently, a multinational collaborative study showed perfectionism and obsessive-compulsive characteristics to be robust traits in patients with anorexia nervosa ( [Halmi, 1999](#)). Restricting anorectic patients tend to receive Cluster C (anxious-fearful) diagnoses such as avoidant or dependent personality disorder. By contrast, anorectic bulimic patients have an equal likelihood of receiving a Cluster B (dramatic-erratic personality diagnoses such as borderline personality disorder) or Cluster C diagnosis. There appears to be no fundamental personality trait that serves as the major risk factor for the development of bulimia nervosa.

## Family Factors

Because family interactions are studied during or after the development of an eating disorder, it is impossible to determine specific interactions as risk factors. There also is the problem of designing valid instruments with which to assess family interactions. In bulimic families, studies have uncovered deficits such as lack of parental affection, negative, hostile and disengaged interactions in the family, parental impulsivity, and family alcoholism and obesity ( [Strober and Humphrey, 1987](#)). Patients with anorexia nervosa perceive their families as stable, nonconflictive, cohesive, and adequately nurturing ( [Vandereycken et al., 1989](#)). In contrast, bulimic patients rate their families as conflictive, badly organized, noncohesive, and lacking in nurturance ( [Wonderlich et al., 1990](#)). Undoubtedly, family factors have a role in the development, maintenance, and relapse of eating disorders, but what percentage of the "variance" can be attributed to family factors is unknown.

## DIFFERENTIAL DIAGNOSIS

In making a diagnosis of anorexia nervosa, it is important to be certain the patient has no medical illness that can account for weight loss. Occasionally, a patient may have both anorexia nervosa and a medical illness contributing to weight loss. In this situation, the diagnosis of anorexia nervosa is made by the positive criteria for the disorder, and both the underlying medical condition and the anorexia nervosa are diagnosed and treated as such. Weight loss frequently occurs in depressive disorders. However, in the latter, the patient usually has a decreased appetite, whereas an anorectic patient denies the existence of an appetite. The hyperactivity seen in anorexia nervosa differs from the agitated activity seen in depressive disorders in that the anorectic's activity is planned and ritualistic, such as exercising programs of jogging and cycling. The preoccupation with the calorie content of food, collecting recipes, and preparing meals for others is typical of the anorectic

patient but not present in those with a depressive disorder. The latter do not have a fear of becoming fat or disturbance in their body image, as is characteristic in anorexia nervosa.

Delusions about food in schizophrenia rarely are concerned with the calorie content of food. A fear of becoming obese and hyperactivity also is uncommon in the schizophrenic but is typical of the anorectic patient.

Chronic medical illnesses frequently associated with weight loss are Crohn disease, hyperthyroidism, Addison disease, and diabetes mellitus. Overeating episodes may occur in the Klüver-Bucy syndrome, which consist of visual agnosia, compulsive licking and biting, inability to ignore any stimulus, and hypersexuality. Another uncommon syndrome associated with hyperphagia is the Kleine-Levin syndrome, which is characterized by periodic hypersomnia lasting for several weeks.

## TREATMENT

### Anorexia Nervosa

There are fewer than 10 randomized, controlled treatment studies in anorexia nervosa. This is most likely because these patients are resistant to and uninterested in treatment, as well as being prone to the development of serious medical complications, which requires withdrawal from research treatment protocols. Open studies have indicated that a multidimensional treatment approach that includes medical management, psychoeducation, and individual therapy using both cognitive and behavioral principles is the most effective treatment. Controlled studies have shown that children younger than 18 years of age do better if they have family therapy or counseling. Nutritional counseling and pharmacologic intervention also can be useful components in the treatment plan.

The severity of illness determines the intensity of treatment required for patients with anorexia nervosa. Treatment levels can range from a medical intensive care unit, to a specialized eating disorder inpatient unit, to a general psychiatric hospital unit, to a day program, to outpatient care. Outpatient therapy as an initial approach has the best chance of success in anorectic patients who have had the illness for less than 6 months, are not bingeing and vomiting, and have parents who are likely to cooperate and effectively participate in family therapy.

Cognitive and behavior therapy principles can be applied in both inpatient and outpatient settings. Although there have been controlled inpatient studies of the effectiveness of behavior therapy for inducing weight gain ([Wullemier et al., 1995](#)), there have been no satisfactory controlled studies of any other type of individual psychotherapy in the treatment of anorexia nervosa. An in-depth discussion of cognitive-behavioral therapy (CBT) for anorexia nervosa can be found in articles by [Garner and Bemis \(1982\)](#) and [Kleifield et al. \(1996\)](#). Alliance building with the patient is essential because patients with anorexia nervosa find it extremely difficult to participate honestly in any therapeutic relationship. At best, they are ambivalent about any treatment attempt or therapeutic relationship that may change their behavior. It is important to foster the patient's cooperation in the treatment program, and this can be done by conveying respect for the patient's dependence on anorexia as a means of coping. Weight restoration and nutritional rehabilitation are extremely important because the state of being underweight is associated with depression, difficulty concentrating, irritability, and preoccupation with food. Also, cognitive impairment is present during this state of calorie restriction. To accomplish necessary changes with psychotherapy, the patient must be in a condition in which she can actually concentrate on the issues of psychotherapy. Monitoring is an important part of CBT. In an outpatient setting, the patient is taught to record not only her food intake but stressful circumstances during the day and her emotional responses to them. Cognitive restructuring is a method in which patients are taught to identify their disturbing cognitions and challenge their core beliefs. In this process, they become aware of specific negative thoughts and present arguments and evidence both to support and to cast doubt on their validity. From this, they try to form a reasoned conclusion based on the evidence. Problem solving is another method whereby patients learn to reason through difficult food-related or interpersonal situations. Adolescents from age 12 years on are fully capable of participating in this type of therapy.

A family analysis should be done on all anorectic patients who are living with their families. From this analysis, a clinical judgment should be made as to what type of family therapy or counseling is clinically advisable. There will be some cases in which family therapy is not possible, and in those instances family relationships can be addressed in individual therapy. In other situations, brief counseling sessions with the immediate family members may be the best way of dealing with family issues. A controlled family therapy study ([Russell et al., 1987](#)) has shown that anorectic patients younger than 18 years of age benefited from this, whereas patients older than age 18 years did worse in family therapy compared with the control therapy. There are no controlled studies of the combination of individual and family therapy. In actual practice, many clinicians provide individual therapy and some sort of family counseling in managing anorexia nervosa.

Medications can be useful adjuncts in the treatment of anorexia nervosa. There have been many large-sample, open studies in Europe concerning the use of chlorpromazine in the treatment of anorexia nervosa. Unfortunately, there are no controlled, double-blind studies to prove definitely the efficacy of this drug for inducing weight gain. However, this medication on an observational basis is especially effective in severely obsessive-compulsive and overwhelmed anorectic patients in that it helps reduce their preoccupations and makes them more amenable to therapy. It may be necessary to start at a low dose of 3 mg three times a day and gradually increase the dosage. There have been several double-blind studies to show that cyproheptadine, especially in high doses up to 24 mg/day, is effective in facilitating weight gain and reducing depressive symptomatology. This drug has the advantage of very few side effects, which makes it attractive for use in emaciated anorectic patients. Unlike the tricyclic antidepressants, it does not reduce blood pressure and increase heart rate. There is some indication that fluoxetine may be effective in preventing relapse in weight-restored patients with anorexia nervosa ([Kaye et al., 1991](#)).

Anorexia nervosa is a complex disorder that responds best to a multifaceted treatment approach that includes medical rehabilitation with weight restoration, individual cognitive psychotherapy, and family therapy or counseling for patients younger than 18 years of age. At times, specific medication such as chlorpromazine, fluoxetine, or cyproheptadine can be useful as adjuncts in the treatment of anorexia nervosa.

### Bulimia Nervosa

Cognitive-behavioral therapy (CBT) is the first-line treatment for bulimia nervosa. It has been found to be the most effective treatment in over 35 controlled studies. In these studies, the treatment program usually lasted 16 to 20 weeks, after which 40% to 50% of the patients were abstinent from both bingeing and purging. A reduction of bingeing and purging occurred in 70% to 95% of patients. Another 30% of those who did not show improvement immediately after treatment did show improvement to full recovery 1 year after treatment. In bulimia nervosa, CBT interrupts the self-maintaining cycle of bingeing and purging and alters the person's dysfunctional cognitions and beliefs about food, weight, body image, and overall self-concept. For therapists to be effective in using CBT for the treatment of bulimia nervosa, they need to be trained from the specific manuals available for this purpose. [Wilson and Fairburn \(1993\)](#) have written an excellent review of these studies.

Although there are no family studies of bulimia nervosa, it is common practice for most clinicians to include the family either in counseling sessions or a form of family therapy in the program of those patients younger than 18 years of age.

Over a dozen double-blind, placebo-controlled trials of antidepressants, including desipramine, imipramine, amitriptyline, nortriptyline, phenelzine, and fluoxetine, have been conducted in normal-weight outpatients with bulimia nervosa. The dosage of antidepressant medication used was similar to that used for the treatment of depression. In all trials, antidepressants were significantly more effective than placebo in reducing binge eating. These medications also improved mood and reduced eating disorder symptoms such as preoccupation with shape and weight. However, the abstinence rate from bingeing and purging was only 22% on the average. [Mitchell and DeZwaan \(1993\)](#) provide an excellent review of these studies. There is some indication that combining antidepressant medication with CBT is helpful in some individuals ([Agras et al., 1992](#)).

Although group therapy has not been studied in a controlled manner, in practice, many clinicians are conducting group CBT for patients with bulimia nervosa. This seems to be especially effective and popular with college students and young adults. Furthermore, it is a cost-effective treatment modality for both patients and therapist.

Adolescents from age 12 years on are fully capable in participating in CBT therapy for bulimia. This treatment has been widely investigated and consistently shown effective in reducing binge eating and purging, improving mood and self-esteem, improving interpersonal functioning, and reducing concerns about shape and weight. These results usually are well maintained. Interpersonal psychotherapy also shows promise as an alternative treatment but requires further investigation. When CBT is not available or possible, most clinicians opt to use a serotonin reuptake inhibitor in treating bulimic patients because this class of drugs has fewer side effects than the tricyclic depressants.

## OUTCOME AND COURSE OF ILLNESS

Long-term outcome studies have been conducted only on patients who have presented for treatment, and therefore, a generalization cannot be made about the course of all patients with eating disorder. Long-term follow-up research (10 years or longer for all patients) indicates that most patients with anorexia nervosa have ongoing problems with the illness (Eckert et al., 1995; Hsu and Crisp, 1979; Theander, 1985). Approximately one-fourth recover, one-fourth stay chronically ill with no improvement, and one-half have partial improvement. Mortality rates at 10 years after presentation for treatment are 6.6%, and at 30 years, 18% to 20%. Most follow-up studies for bulimia nervosa have had a 6-month to 2-year posttreatment follow-up. A review of 88 articles on the course and treatment follow-up studies on bulimic patients (Keel and Mitchell, 1997) summarize mortality rates between 0% and 3%. For those patients who were followed for between 5 and 10 years, approximately 50% fully recovered, whereas 20% continued to meet criteria for bulimia nervosa. Relapse poses a serious threat for bulimics, with approximately one-third of recovered bulimics relapsing within 4 years after treatment. Approximately 20% of bulimic patients seem to sustain an unremitting bulimic illness.

For anorexia nervosa, predictors of outcome have varied from study to study. Most studies, however, have shown that age of onset between 12 and 18 years portends a better outcome than onset before age 12 and after 18 years. Repeated hospitalizations, purging behavior, long duration of illness, and very low weight at presentation for treatment also are predictors of worse outcome in most studies (Eckert et al., 1995). For bulimia nervosa, larger patient samples and longer-term follow-ups are needed to obtain more accurate predictors of outcome in this disorder. A review of research studies on bulimia nervosa (Keel and Mitchell, 1997) concluded that personality disorders marked by problems with impulse control were associated with a worse prognosis in these patients.

## RESEARCH DIRECTIONS

Since the advent of new and efficient techniques in genetic research, the search for the genetic underpinnings of eating disorders has undergone rapid development. Several multinational collaborative studies are under way using a variety of methodologies. The search is on for identification of genetic markers, clusters of genes associated with anorexia and bulimia nervosa, and receptor polymorphisms of specific neurotransmitters in these disorders. Although it will be many years before any clinically meaningful application can be derived from these studies, such research nonetheless is an important and essential undertaking in the next decade.

Improving treatment strategies is another extremely important area for further research. Strategies for motivating eating-disordered patients are necessary to keep them in treatment. Treatment studies conducted over the course of 1 year invariably show high dropout rates, with less than half of the patients achieving a complete cure. Thus, more immediately effective treatment strategies need to be developed, as well as effective means of giving those patients who need more time to deal with a greater number of complex problems the motivation to stay in treatment. Valid assessments for evaluating family interaction need to be developed to ascertain better the family's effect on the course of eating disorders. Cost efficacy studies are necessary to present evidence for adequate insurance coverage for the treatment of eating disorders.

---

### CASE ILLUSTRATION

Alice is a 17-year-old, single Caucasian girl who has just completed 4 months in an eating disorder specialty unit for the treatment of anorexia nervosa and obsessive-compulsive disorder (OCD). She arrived weighing 30 kg (66 lbs.) and was 162 cm (5ft4in) tall. She met DSM-IV criteria for anorexia nervosa and OCD, as well as meeting criteria for an Axis II obsessive-compulsive personality disorder.

Her parents describe Alice at 4 years of age as having to do everything perfectly and having rituals around cleaning things thoroughly and putting her toys in their proper places. These behaviors continued throughout grade school. She was always extremely competitive and obtained straight A's. When she was 12 years of age and in sixth grade, she began engaging in peculiar food handling, such as eating food slowly and reducing her total calorie intake. The following summer, she was hospitalized because of weight loss and was given the diagnosis of anorexia nervosa. Her obsessions and compulsions became more severe as her anorexia nervosa progressed. She developed rituals around cleaning, straightening and arranging objects, counting, and exercising. She felt and continues to feel that she must constantly be moving and accomplishing things because she fears becoming "lazy." Alice often was unable to leave her room in the morning for hours because she had to touch objects and perform a number of rituals. This caused her frequently to be late for school. The following year, her weight dropped to 50 lbs. and she was again hospitalized. This was beginning of a series of repeated hospitalizations and weight losses up to the time of the current hospitalization.

Alice denies any bingeing, purging, or drug or alcohol use. She also denies using cigarettes or caffeine. She only restricts her intake and exercises vigorously. She is very distressed about her obsessions and compulsions, but not about her eating behavior. She has primary amenorrhea and has never shown signs of depression. In her past hospitalizations, she was placed on both fluphenazine and clomipramine, but she discontinued medication shortly after she was placed in an outpatient program.

Alice began gymnastics when she was 8 years of age and continued until the onset of her anorexia nervosa. She has never dated or had a boyfriend, and has never been sexually active. She has a very antagonistic and angry relationship with her father, from whom she has always wanted attention and approval and claims she has never received it. She is the youngest of three children. Her two older sisters have done well academically and professionally.

Alice was placed on a liquid diet when she was admitted to a specialized eating disorder program. She had great difficulty adhering to unit rules and procedures and would drink her formula only out of fear of receiving a nasogastric tube if she did not gain weight. She was constantly in motion and became very upset and angry when confronted by staff. Although she was exceedingly harsh, critical, and self-punishing, she was on the other hand very sensitive to criticism about herself. During her fourth month of hospitalization, she was able successfully to maintain her weight within a normal range. Her confidence was greatly improved with her ability to eat three meals and maintain her weight. She actually enjoyed eating because she was allowed to be a vegetarian. She was more sociable, interacting with peers and vocal in community meetings and groups. Her rituals had greatly decreased and she actually was able to get through most of the day without any rituals. However, evenings were still difficult for her because at this time she had preoccupations about "being lazy."

During her fourth month of hospitalization, when she had reached her target weight, Alice was placed on clomipramine 225 mg/day. This medication was helpful in reducing her obsessions and compulsions. Throughout her hospitalization, Alice was treated with CBT and family counseling. She was discharged to a specialized eating disorder outpatient program with cognitive psychotherapy, family counseling, and group therapy.

### Comment

Alice had perfectionistic traits, a feature of obsessive-compulsive personality disorder, as a young child. There is growing evidence that a perfectionistic personality trait is a risk factor for development of anorexia nervosa. Alice was obsessed by her counting and checking obsessions and compulsions, but she was not distressed by her eating disorder rituals and preoccupations. This is a distinguishing factor between the egodystonic obsessions and compulsions of the obsessive-compulsive patient and the egosyntonic preoccupations and rituals associated with an eating disorder. Both of these phenomena had specific expressions in Alice's life, as well as an interaction. Alice's obsessions and compulsions became worse as her anorexia nervosa became more severe. She was managed effectively with cognitive-behavioral therapy techniques, a unit milieu program in a specialized eating disorder unit, and family counseling. The nutritional rehabilitation and medical management was part of the unit milieu program. When Alice reached a normal weight range and still showed bothersome obsessions and compulsions, she was then treated with clomipramine. Alice was able to complete her high school education and graduated as valedictorian.

## ENURESIS

### Definition and Historical Note

Enuresis is subclassified into two subtypes, primary and secondary. *Primary enuresis* encompasses children who have never achieved continence, whereas the term *secondary enuresis* refers to those children who maintain continence for at least 1 year, only to lose it at some point after that. The term itself is derived from the Greek *enourein*, “to void urine” and has come to imply nocturnal events, although that connotation is not inherent in the derivation of the word itself.

There is a rich literature concerning enuresis and its treatment over the centuries. In retrospect, many of these treatment approaches now appear to have been quite sadistic. This history has been summarized in an excellent review by [Glicklich \(1951\)](#), which covers material dating back to the Papyrus Ebers of 1550 B.C.

There has been substantial progress in the treatment of enuresis. This therapeutic progress has contributed to a greater understanding of the fundamental pathophysiologic processes that contribute to enuresis. These advances are reviewed in this chapter.

### Prevalence and Epidemiology

Statistics concerning the prevalence of enuresis also must take into account the severity of the disorder. For example, in the Isle of Wight Study, Rutter and colleagues found that 15.2% of boys were wet less often than once a week, whereas only 6.7% wet at least once a week. The corresponding figures for girls were 12.2% and 3.3%. By age 14 years, only 1.9% of boys were wet less often than once a week, and 1.1% were wetting at least once a week, with the corresponding figures for girls being 1.2% and 0.5% ([Rutter et al., 1973](#)). Longitudinal data from the Isle of Wight Study have illustrated that wetting develops in many children between the ages of 5 and 7 years. Enuresis also was found in greater frequency in children who were undergoing psychosocial stress and in those living in socially disadvantaged circumstances ([Rutter, 1989](#)).

A Scandinavian study of 3,206 7-year-old children found an overall prevalence of 9.8%; 6.4% of this group was accounted for by children with night wetting, 1.8% by day wetters, and 1.6% by those with mixed day and night wetting. This study also showed a strong genetic influence in that the risk of a child's having enuresis was 7.1 times greater if the father manifested enuresis after 4 years of age and 5.2 times greater if the mother did ([Jarvelin et al., 1988](#)).

An 8-year longitudinal study in New Zealand found a prevalence of 7.4% for nocturnal enuresis in 8 year olds. This figure was accounted for by 3.3% with primary enuresis and 4.1% with secondary enuresis ([Fergusson et al., 1986](#)).

More recent studies have found remarkably similar results. In a group of 392 7-year-old children from the west coast of Sweden, [Wille \(1994c\)](#) reported a prevalence of 7.3% for monosymptomatic primary enuresis. A questionnaire study involving a large cohort of Australian children in the 5- to 12-year-old range reported an overall incidence of 5.1% for nocturnal enuresis of least weekly frequency and 1.4% for daytime wetting of similar frequency ([Bower et al., 1996](#)).

### Clinical Description

As noted, the term *enuresis* itself denotes only the voiding of urine. Over the years, the term has acquired both a pathologic and a nocturnal connotation. Daytime wetting is correctly referred to as *diurnal enuresis*, whereas nighttime wetting is referred to as *nocturnal enuresis*.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association, 1994](#)) defines functional enuresis as “repeated voiding of urine during the day or at night into bed or clothes.” DSM-IV goes on to note that “to qualify for a diagnosis of enuresis, the voiding of urine must occur at least twice per week for at least three months or else must cause clinically significant distress or impairment in social, academic (occupational) or other important areas of functioning.” The child must also have reached an age at which continence could definitively be expected. DSM-IV uses a chronologic age of 5 years as a cutoff or a mental age of 5 years for those children with developmental delays. DSM-IV also stipulates that the wetting not be the result of “the direct physiological effects of a substance (e.g., diuretics) or a general medical condition (e.g., diabetes, spina bifida, a seizure disorder).” Three subtypes of enuresis are defined: nocturnal only (nighttime wetting), diurnal only (daytime wetting), and nocturnal and diurnal (mixed day and night wetting). A distinction also is made between “primary” and “secondary” enuresis. Primary enuresis refers to those children who have never achieved urinary continence, whereas secondary enuresis refers to those children who have achieved continence and then lost it. The period of continence necessary to differentiate between primary and secondary enuresis had variously been thought to be 6 months to 1 year. DSM-IV does not put forward a precise period of time for the distinction, but instead makes reference to “a secondary type in which the disturbance develops after a period of established urinary continence.” A child is not considered to have primary functional enuresis until 5 years of age. Secondary enuresis can begin at any time, once the criterion of initial continence has been fulfilled, but the usual onset is between 5 and 7 years of age ([Rutter, 1989](#)).

### Etiology and Pathogenesis

The physiologic manifestations of this disorder have led to a wide range of etiologic theories. A primary focus of these studies has naturally been the anatomy of the bladder and urinary tract. [Shaffer et al. \(1984\)](#) elegantly combined an investigation of bladder anatomy and physiology with the covariable of behavioral disturbance. It might intuitively be expected that children with dysfunctional or abnormal bladders would be those without a concomitant behavioral disorder to explain their enuresis and that those whose enuresis could be explained on the basis of psychopathology would have normal bladders. The results were counterintuitive in that those children who were behaviorally disturbed also had significantly lower functional bladder volumes and more developmental delays. Thus, although not providing a

parsimonious explanation to differentiate the etiology of enuretic events between psychiatrically disturbed and nondisturbed children with enuresis, the study did lend further support to a theory of general developmental delay, which would explain both the enuresis and the high frequency of behavioral disturbance. In a more recent study, which investigated bladder capacity in children with primary nocturnal enuresis, former enuretic patients, and control subjects, also failed to find any significant difference in bladder capacity between the groups ([Wille, 1994a](#)). It also has been demonstrated that fluid loading can produce enuretic events in children who do not have a history of enuresis ([Kirk et al., 1996](#); [Rasmussen et al., 1997](#)). Children with enuresis were found to have developmental delays twice as often as those without in a large longitudinal population study ([Essen and Peckham, 1976](#)). A study that compared 35 otherwise healthy children with enuresis with a control group found that the bone age of the children with enuresis displayed a significant lag behind chronologic age, leading the authors to speculate about delayed maturation of central nervous system regulatory functions ([Mimouni et al., 1985](#)).

There is an obvious relationship between enuresis and bladder infection ([Hansson, 1992](#)); thus, an infection of the urogenital tract should be ruled out before a diagnosis of functional enuresis is made. This is especially important for girls, who are more prone to urinary tract infections ([Hjalmas, 1992](#)). The possibility of urinary tract obstruction as a widespread cause of enuresis has been reported ([Mahony, 1971](#)) but has been criticized because such a hypothesis can lead to unnecessary surgery ([Smith, 1969](#)). After extensively reviewing the literature on this subject, [Shaffer \(1985\)](#) concluded, "There is no evidence that urethral dilatation or bladder neck repair are effective treatment for enuresis." The only exception to this would be if there were very specific pathophysiologic findings.

More recent investigations into the role of urodynamic abnormalities in the pathogenesis of primary nocturnal urinalysis support Schaffer's conclusion ([McDermott and Merrick, 1994](#)). In a large study, [Kawauchi et al. \(1996a\)](#) found an incidence of urologic abnormalities of 1.8% on intravenous pyelography (n = 940), 7.1% on voiding cystourethrography (n = 695), 11.5% on cystometry (n = 487); and no abnormalities on renal ultrasonography (n = 58). Of those who did manifest reflux on voiding cystourethrography, the degree of reflux was assessed as mild in 92.1%.

The nature of the enuretic phenomenon has naturally led to speculation concerning a psychodynamic etiology. These hypotheses have in general evolved from case reports or have been derived from theoretical considerations. There has been one rigorous attempt to define the generalizations derived from the literature regarding enuresis and encopresis and then to determine with what frequency these generalizations were borne out by an analysis of the clinical material. This elegant study by [Achenbach and Lewis \(1971\)](#) revealed "only two of the twenty-four generalizations derived from the literature regarding encopresis and enuresis received support at the conventional level (probability = 0.05) of statistical significance."

Epidemiologic studies have, however, shown a correlation between psychological disturbance and enuresis, which is more pronounced in older children ([Rutter, 1989](#)). This observation then raises the question of the nature of the relationship: Is it a causal, incidental, or secondary relationship? The aforementioned link between enuresis and developmental delays, which also are linked to psychopathology, would suggest that there is a common underlying maturational factor that predisposes vulnerable children to manifest both behavioral disturbances and enuresis. In further support of this hypothesis are the observations that the nature of the behavioral disturbance in children with enuresis is nonspecific ([Mikkelsen et al., 1980](#)) and that no physiologic marker can be found that reliably differentiates psychologically disturbed from nondisturbed children with enuresis ([Mikkelsen and Rapoport, 1980](#); [Shaffer et al., 1984](#)). When children with enuresis have been compared with other children attending a child psychiatric clinic, the only discernible differences were an increased frequency of developmental delays and a lesser frequency of eating disorders and specific neurotic patterns ([Steinhausen and Gobel, 1989](#)). [Biederman et al. \(1995\)](#) have evaluated the possible linkage between enuresis and attention deficit hyperactivity disorder (ADHD). Their findings indicated that enuresis did not increase the risk for psychopathology in children with or without ADHD but was associated with increased risk for learning disability in normal control children, but not in those with ADHD. The association with behavioral disturbance has been reported as being greater for secondary enuresis ([Feehan et al., 1990](#); [McGee et al., 1984](#); [von Gontard et al., 1999b](#)) and with enuresis persisting into adolescence ([Fergusson and Horwood, 1994](#)). One study that specifically evaluated risk factors for development of secondary enuresis found that delayed attainment of initial nocturnal continence and exposure to four or more stressful life events in a year were significantly related to the development of secondary enuresis ([Fergusson et al., 1990](#)). Similar results with regard to the relationship between psychosocial stress and secondary enuresis have been reported by [von Gontard et al. \(1997\)](#). However, at least one large study in the Netherlands found no difference in psychopathology between children with primary and secondary enuresis ([Hirasing et al., 1997](#)).

The occurrence of the enuretic episodes during sleep naturally led to a series of studies investigating the relationship between sleep states and the occurrence of enuretic events. The earliest of these studies suggested that the enuretic events occurred in "deep sleep" and led to a theory that enuretic events were dream equivalents ([Pierce et al., 1961](#)). This theory was subsequently supplanted by Broughton's ([Broughton, 1968](#); [Gastaut and Broughton, 1964](#)) view that enuresis was a disorder of arousal. This research suggested that enuretic episodes were preceded by arousal signals and originated in delta sleep. A further elaboration of this theory held that psychiatrically disturbed children with enuresis received normal arousal signals but did not respond to them, whereas those without psychiatric disturbance did not generate arousal signals ([Ritvo et al., 1969](#)). The largest and most convincing sleep studies indicate that enuretic episodes occur in each sleep stage in proportion to the time spent in that stage, when time of night also is considered ([Kales et al., 1977](#); [Mikkelsen et al., 1980](#); [Robert et al., 1993](#)). There have been three studies that suggested that children with primary enuresis may be more difficult to arouse from sleep than control subjects, although the methodology is somewhat subjective with regard to defining arousability ([Neveus et al., 1999a](#); [Wille, 1994c](#); [Wolfish, 1999](#)). Recent research in this area has focused on combining sleep studies with cystometry ([Norgaard et al., 1989](#)). This work may lead to the identification of subtypes of children with enuresis ([Imada et al., 1998](#); [Watanabe and Azuma, 1989](#); [Watanabe et al., 1994](#)).

The development of desmopressin acetate (DDAVP) as a treatment for enuresis (see later) has led to the observation that some children with enuresis do not have the ability to concentrate the urine they produce during the night and reduce urine volume ([Miller et al., 1992](#)). In a further investigation of this hypothesis, [Rittig et al. \(1991\)](#) compared the circadian variation of plasma atrial natriuretic peptide (ANP) with the clearance of creatinine and the excretion of sodium and potassium. Subjects in the study consisted of 15 children with nocturnal enuresis and 11 control subjects matched for age, sex, and weight. The children with enuresis did not differ from control subjects with regard to ANP, but during the first hours of sleep, they did manifest significantly more polyuria, natriuresis, and kaliuresis despite normal levels of ANP. The authors concluded that children with enuresis display abnormal diurnal rhythmicity in the urinary excretion of potassium and sodium that is not correlated with plasma levels of ANP. They speculated that the abnormalities in sodium and potassium may be related to abnormal tubular handling. This hypothesis has been further supported by subsequent research ([Natochin and Kuznetsova, 1999](#); [Vurgun et al., 1997](#)). [Steffens et al. \(1993\)](#) used a radioimmunoassay to evaluate the circadian rhythmicity of plasma arginine vasopressin (AVP) in 55 children with enuresis and 15 control subjects. The AVP levels were measured under conditions of controlled water intake three times per day for 72 hours. Only 14 of the 55 children with enuresis had a significant decrease in AVP compared with control subjects. Nine of these 14 AVP-deficient children subsequently were found to be totally dry with DDAVP treatment.

The circadian rhythmicity of AVP has continued to be a focus of investigation because it theoretically could explain both the pathophysiology of enuresis and its response to DDAVP. Accordingly, researchers have been particularly interested in any differences that could be detected between DDAVP responders and nonresponders. One study has reported significant differences in morning values of AVP between normal control subjects (n = 7) and children whose enuresis responded to DDAVP (n = 6), as well as between the responders (n = 6) and nonresponders to DDAVP (n = 5). Thus, the morning AVP levels were able to differentiate the children with enuresis from the control subjects, and the responders from the nonresponders ([Medel et al., 1998](#)). However, further complicating this line of research has been the finding that AVP is secreted in a "pulsatile pattern," which dictates frequent sampling of plasma levels to be meaningful ([Wood et al., 1994](#)). Studies using frequent measurements of AVP have produced mixed results. Two studies that used more frequent AVP measurements ([Lackgren et al., 1997](#); [Wood et al., 1994](#)) found no differences between responders and nonresponders to DDAVP. [Aikawa et al. \(1998, 1999\)](#) addressed this question in a series of studies that measured AVP secretion on an hourly basis for 24 hours. The first set of these studies looked at AVP secretion profiles in children with enuresis (n = 9) and control subjects (n = 8). The results did establish that the plasma AVP level was significantly lower in the children with enuresis in the 11 P.M. to 4 A.M. time period. They then looked at the secretion dynamics in two phenomenologic subgroups of children with enuresis: those with low urinary osmotic pressure and large nocturnal urine output, as opposed to a group with normal urinary osmotic pressure and small nocturnal urine output. The results showed that the mean nocturnal AVP levels were significantly lower in the first (large nocturnal output) group and that treatment with DDAVP did produce a significant increase in AVP for this group as a whole, but not for each child.

Another area of research has been the role of urine osmolality in the production of nocturnal enuresis. Three separate studies that looked at first morning urinary specific gravity in preschool children have suggested that children who wet the bed tend to have lower mean urinary specific gravity than those who do not, but the findings do not reach statistical significance ([Kawauchi, 1996b](#); [Mevorach et al., 1995](#); [Salita et al., 1998](#)).

The effect of fluid restriction on AVP levels and urine osmolality also has been investigated. These studies indicate that AVP levels are increased in both control subjects and in children with enuresis in response to fluid restriction, and that the degree of AVP secretion is related to plasma osmolality ([Eggert et al., 1999](#)). When DDAVP responders and nonresponders are compared with control subjects, all three groups manifest an increase in AVP, but the DDAVP responders showed a lower increase than the other groups ([Hunsballe et al., 1999](#)). Studies involving adolescents and adults with refractory enuresis also have suggested that the primary pathophysiologic mechanism may be an abnormal tubular processing of sodium related to a relative insensitivity to AVP ([Hunsballe et al., 1998](#); [Robertson et al., 1999](#)) that is corrected to some degree by DDAVP. Similar research in children led [Eggert and Kuhn \(1995\)](#) to hypothesize that the primary difference between

children with enuresis and control subjects may be at the receptor level.

Although this line of research has primarily involved DDAVP, it also has led to a reexamination of the therapeutic effect exerted by imipramine. [Hunsballe et al. \(1997\)](#) reported a decrease in urine output and reduced osmolal clearance induced by imipramine that, in part, was contributed to by a lower excretion of sodium and potassium.

One of the newest areas of research has been the exploration of genetic linkages. It has long been known that enuresis tends to run in families and that a positive family history can be related to positive treatment outcome ([Hogg and Husman, 1993](#)). In general, the new genetic studies involve large numbers of families with multigenerational transmission of primary nocturnal enuresis. The chromosomes that have been identified to date include 13q, 12q, 8, and 22 ([Arnell et al., 1997](#); [Eiberg et al., 1995](#); [von Gontard et al., 1999a](#)). In some families, an autosomal dominant mode of transmission with penetrance above 90% has been identified.

### Laboratory Studies

The fact that urinary tract infections can precipitate enuretic events in children means that a urinalysis should be performed to rule out this readily treatable cause of enuresis.

The use of more invasive and painful studies remains controversial. Although it is certainly possible that altered bladder physiology may lead to primary enuresis, the yield from these studies does not appear to be of sufficient magnitude to warrant subjecting all children with enuresis to them. A thorough review of this subject has been performed by [Cohen \(1975\)](#), who found the incidence of obstructive lesions in children with enuresis to be 3.7% in a primary care pediatric setting. Accordingly, he suggested that “contrast studies are indicated only when there is significant evidence of anatomical or functional pathology by history or exam.” Subsequent studies have supported this general position ([Blickman and Schimmelpenninck-Scheiffers, 1984](#); [Kawauchi et al., 1996a](#); [McDermott and Merrick, 1994](#)), while suggesting that those children with daytime wetting and overt symptoms of voiding disturbance are more apt to have urinary tract abnormalities than those who wet solely at night ([Jarvelin et al., 1990](#)).

### Differential Diagnosis

The differential diagnosis includes the possibility of urinary tract infection and altered bladder physiology. There are scattered case reports of enuresis being secondary to other primary medical problems, such as hyperthyroidism ([Stoffer, 1988](#)), constipation ([Oregon et al., 1986](#)), and central hormonal abnormalities ([Kikuchi et al., 1989](#)). Although such reports are infrequent, the clinician should do a thorough physical examination and consider the possibility of underlying organic illness. Psychological testing in conjunction with structured interviews may provide further insight into the coexistence of psychopathology. However, the studies reviewed previously suggest that any coexisting psychological disorder should be viewed as an accompanying finding rather than as a causal effect.

The distinction between primary and secondary enuresis can be made by history.

### Treatment

Although psychotherapy may be helpful for managing the behavioral disorders that accompany enuresis, it appears to have little effect on primary enuresis itself, with studies showing a success rate of 20%, which may largely be accounted for by spontaneous remission ([Cohen, 1975](#)). Psychotherapy may be more useful for those children with secondary enuresis, especially those whose episodes begin after a traumatic event or parental divorce.

It has been shown that having nocturnal enuresis has a negative impact on self-esteem, which can be normalized by effective treatment ([Hagglof et al., 1998](#); [Moffatt et al., 1987](#)).

The two primary means of treating children with enuresis fall into the categories of behavioral methods and psychopharmacologic methods.

Behavioral treatment should be attempted first because it usually is more innocuous than pharmacologic intervention. The underlying assumption of the behavioral strategy is that it is helping children with enuresis and their families master an affliction rather than tacitly implying that the children are either consciously or unconsciously causing the wetting themselves. One unfortunate consequence of various reward–punishment strategies is that they can subtly imply to children and their families that the disorder is quasi-volitional. The bell and pad method of conditioning is a reasonable first approach. A review of this treatment modality indicated that it was first reported in 1904 and has been in routine use since the 1930s ([Rappaport, 1997](#)). In reviewing the results of several studies involving over 1,000 children, [Werry \(1966\)](#) found a success rate of 75%. Recent studies are consistent with this ([Berg et al., 1982](#); [Devlin and O’Cathain, 1990](#)). There appear to be two subgroups of responders: those who sleep through the night after treatment without wetting, and those who wake up spontaneously to go to the bathroom ([Bonde et al., 1994](#)). Psychiatric disorder in the child and family stress appear to be negative prognostic factors when predicating outcome with this modality ([Devlin and O’Cathain, 1990](#)). An investigation into the effectiveness of a simple bell and pad method as opposed to two variations that had more behavioral embellishments found no statistical difference between the modalities. However, one variation that included reward contingencies tended to have a slightly lower rate of relapse than the bell and pad alone ([Kaplan et al., 1989](#)). As noted, whenever reward–punishment contingencies are considered, it is extremely important to ensure that one is not communicating to the parents and child that the disorder is quasi-volitional. Although their frequency has decreased with improved bell and pad technology, reports of “buzzer ulcers” do continue to appear, and parents should be alerted to this ([Diez and Berger, 1988](#)).

An attempt has been made to investigate the relationship between bladder capacity and response to behavioral treatment. A study involving 50 children who were wet at least 2 nights a week found that children with small pretreatment maximal functional bladder capacities did better with the bell and pad method in conjunction with retention–control training, whereas the children with larger bladder capacities responded to the bell and pad method alone. However, this was a qualitative difference in response, because 92.5% of the 40 children who completed the study met the outcome criteria of 14 consecutive dry nights, regardless of which group they were in ([Geffken et al., 1986](#)). A similar study that examined the impact of bladder capacity on response to the bell and pad system found no association with outcome ([Berg et al., 1982](#)). Both of these investigations indicated that behavioral disturbance was related to failure to respond to conditioning techniques ([Berg et al., 1982](#); [Geffken et al., 1986](#)).

Bladder capacity also has been investigated with regard to changes occurring during treatment. [Oredsson and Jorgensen \(1998\)](#) measured bladder capacity in 18 children with severe nocturnal enuresis before beginning a 6-week period of treatment with the bell and pad and again after treatment. Ten of the 18 children ceased wetting, but overall there was a significant increase in bladder capacity for the entire group that did not correlate with outcome.

Behavioral treatment continues to evolve. In a study involving 125 children, an attempt was made to replace the bell and pad mechanism with a simple alarm clock that was either set to go off at a time when the bladder might be expected to be reaching maximal capacity (group I) or after 2 to 3 hours of sleep (group II). The results were comparable with previously published figures for the bell and pad, with success noted in 77.1% of group I and 61.8% of group II, and respective 6-month relapse rates of 24.1% and 14.7% ([El-Anany et al., 1999](#)).

Another innovation involves replacing the pad that signals the enuretic event with a small ultrasonic monitor mounted to an elastic abdominal belt that signals the alarm when bladder capacity is reaching a predetermined threshold ([Petrican and Sawan, 1998](#)). Results of a clinical trial of this methodology were comparable with those obtained with the traditional bell and pad technique, and increases in nighttime bladder capacity also were noted ([Pretlow, 1999](#)).

An approach using bladder biofeedback has been developed for children with enuresis who are refractory to other forms of treatment, have small bladder capacities, and have evidence of an unstable detrusor. Specifically, the authors noted that of 24 children who fit these criteria, 17 experienced complete remission (two of these later relapsed), six experienced a decrease, and in one, there was no change ([Hoekx et al., 1998](#)).

As noted earlier, the presence of behavioral or family functioning problems can have a negative impact on the outcome of behavioral treatment. A successful intervention in refractory children with severe wetting who have these issues is to combine traditional alarm therapy with treatment with DDAVP ([Bradbury, 1997](#); [Bradbury and Meadow, 1995](#)).

The Australian psychiatrist, [MacLean \(1960\)](#), first described the efficacy of imipramine for nocturnal enuresis in 1960. Since then, there have been over 40 double-blind studies confirming the efficacy of imipramine for nocturnal enuresis, whereas results with other classes of psychotropic agents have been in general equivocal or negative ([Blackwell and Currah, 1973](#)). Lack of response to imipramine often can be traced to the reluctance of primary care physicians to exceed

dosages of 25 to 50 mg. Nevertheless, it is reasonable to begin at a dose of 25 mg and to titrate up slowly because some children respond to the lower dosages. Allowing 4 to 7 days between dosage increments makes it possible to detect these low-dose responders. Most children respond in the 75- to 125-mg range. The upper range of dosage is determined by the child's weight, with the standard upper limit being 5 mg/kg. A baseline electrocardiogram should be obtained before instituting treatment with imipramine, and monitoring is advised above 3.5 mg/kg ( [Mikkelsen and Rapoport, 1980](#)). A case of sudden death has been reported in a girl receiving 14.7 mg/kg for school phobia ( [Robertson and Barker, 1976](#)).

The relatively high rate of spontaneous remission in enuresis militates against keeping children on medication for long periods. A practical approach is to taper slowly and discontinue the imipramine every 3 months. If wetting resumes as the dosage is tapered or after it is discontinued, then the dosage can simply be titrated back up to the effective dose for another 3-month period. It has been the author's impression that more children do not experience a reactivation of the enuresis after a 3-month period of imipramine treatment than can be accounted for by spontaneous remission alone, but this has not been statistically proven.

There have been tragic reports of children who reasoned that if three pills would stop the wetting for a night, then taking the whole bottle should stop it permanently. Thus, it is important to warn parents about the magical thinking of children in this regard and the importance of controlling the medication. Younger siblings also are at risk of overdosing with the medication if it is not controlled. In cases of mild to moderate overdose, supportive measures, including the symptomatic management of seizures and cardiac arrhythmias, may be sufficient. Physostigmine also may be useful in more severe overdoses ( [Greene, 1981](#)).

There have been five studies investigating the relationship between blood level of imipramine and clinical response. One study found no correlation between improvement in enuresis and the blood level of imipramine either alone or in conjunction with its metabolites ( [Devane et al., 1984](#)). However, three studies have now demonstrated a significant correlation between the diminution of enuretic events and the steady-state concentrations of imipramine plus its metabolite desipramine ( [de Gatta et al., 1984, 1990](#); [Jorgensen et al., 1980](#); [Rapoport et al., 1980](#)). One of these studies found an optimal effect when the combined steady-state imipramine plus desipramine concentrations were above 60 mg/L ( [Jorgensen et al., 1980](#)), and another reported favorable outcomes when steady-state combined levels were greater than 80 ng/mL ( [de Gatta et al., 1984](#)). The most recent study in this line of investigation ( [Fritz et al., 1994](#)) evaluated the blood level–efficacy equation in 18 children who, after baseline and placebo, received increasing dosages of imipramine at 2-week intervals. The specific dosages used were 1, 1.5, 2, and 2.5 mg/kg. They found that efficacy was “moderately but significantly” related to increasing dose. However, there was tremendous (700%) variation in serum levels between the individual children at every dosage level. There is a good correlation between side effects and blood level, especially dry mouth ( [Rapoport et al., 1980](#)). This may prove clinically useful in monitoring children who are extremely phobic about having their blood drawn.

As might be expected, the advent of treatment with DDAVP has led to a marked decline in new research concerning imipramine.

One multicenter, randomized, double-blind, placebo-controlled study did compare imipramine with the tetracyclic antidepressant mianserin, which does not have significant anticholinergic effects ( [Smellie et al., 1996](#)). The authors reported that imipramine was statistically significantly superior to both mianserin and placebo, leading them to conclude that imipramine's efficacy was not related to its antidepressant effect. As noted previously, one study has suggested that imipramine may exert a nocturnal antidiuretic effect mediated by effects at the renal tubular level ( [Hunsballe et al., 1997](#)).

Despite the efficacy of behavioral interventions, survey studies tend to indicate that in clinical practice medication is more apt to be used than behavioral interventions ( [Devlin, 1991](#)). A large population-based study found that only 38% of children with enuresis had seen a physician. Over one-third of this physician-treated group had been prescribed some form of pharmacotherapy, and only 3% had been advised to use the bell and pad conditioning technique. This study also revealed that over half of the children were psychologically distressed by the enuresis, and two-thirds of the parents expressed concern ( [Foxman et al., 1986](#)). This may be changing, because a more recent study reported 80% of physicians recommended the bell and pad ( [Vogel et al., 1996](#)). Throughout the literature there also are reports of novel treatment approaches such as acupuncture ( [Capozza et al., 1991](#); [Minni et al., 1990](#); [Roje-Starcevic, 1990](#)), a prostaglandin synthesis inhibitor ( [Metin and Aykol, 1992](#)), an anticholinergic calcium antagonist ( [Elmer et al., 1991](#)), the oral synthetic androgen mesterolone ( [el-Sadr et al., 1990](#)), and hypnosis ( [Banerjee et al., 1993](#)). Oxybutynin hydrochloride has been reported as effective for children who are refractory to imipramine and also have inadequate bladder storage function ( [Kosar et al., 1999](#)). Although many of these studies are controlled, the use of these approaches in enuresis still should be considered experimental.

The newest research into pharmacotherapy for enuresis involves the use of DDAVP. [Moffatt et al. \(1993\)](#) reviewed all of the then-existing controlled studies concerning the use of DDAVP for enuresis. In the process, they located 18 randomized, controlled trials (11 crossover and seven parallel), which included a total of 689 subjects, most of whom had been refractory to prior treatment. The decreased frequency of enuretic events in the study ranged from 10% to 91%. In general, wetting resumes once the medication is discontinued. Those studies that reported long-term follow-up indicated that 5.7% remained dry after stopping the medication. The most common side effects were nasal stuffiness, headache, epistaxis, and mild abdominal pain. Positive prognostic factors appear to be fewer initial (pretreatment) wet nights and age greater than 9 years. [Hogg and Husmann \(1993\)](#) and [Terho \(1991\)](#) particularly looked at the efficacy of DDAVP for children who had been refractory to conditioning treatment and imipramine, using a randomized, double-blind, placebo-controlled crossover study. Of the 52 children studied (age range, 5 to 13 years), 53% had a complete cessation of wetting, 19% were partial responders, and 28% had no or minimal response. The dosages used ranged from 20 to 40 µg (intranasal) and response did not persist after termination of treatment. In a 5-year retrospective review of 59 children, [Key et al. \(1992\)](#) suggested that lower doses may be just as effective. In their series, 5 µg at bedtime was the initial starting dose, and 81% improved on less than 10 µg. A single-blind study did reveal a dose–response phenomenon ( [Fjellestad-Paulsen et al., 1987](#)).

A study investigating the differential response of children with enuresis to DDAVP and the bell and pad method of conditioning found that 70% improved with the DDAVP and 86% improved with the alarm method, yielding no significant differences ( [Wille, 1986](#)). A similar experiment that compared the therapeutic benefits of DDAVP in combination with the bell and pad to placebo found that the combination of DDAVP and the alarm resulted in significantly more dry nights ( [Sukhai et al., 1989](#)). A follow-up study of children receiving treatment for an average of 13 months with DDAVP revealed no hormonal or hematologic side effects, and it was concluded that treatment of this duration was safe ( [Rew and Rundle, 1989](#)). However, there have been reports of hyponatremia ( [Kallio et al., 1993](#)) and hyponatremic seizures ( [Beach et al., 1992](#); [Schwab et al., 1996](#); [Yaouyanc et al., 1992](#)) with intranasal use of DDAVP. A case report and literature review documented 14 cases in the English language literature with symptomatic hyponatremia involving seizures or mental status changes ( [Bernstein and Williford, 1997](#)). A similar review noted that excess fluid intake was identified in 6 of 11 case reports, leading the authors to recommend that patients receiving DDAVP for nocturnal enuresis should not ingest more than 8 ounces of fluid on the nights when DDAVP is administered ( [Robson et al., 1996](#)).

Sufficient time has now elapsed since the institution of the widespread use of DDAVP to permit more follow-up studies. A large, multicenter Swedish study used a 4-week observation phase, a 6-week dose titration period (20 to 40 µg DDAVP), and a 1-year long-term treatment period into which a treatment-free week was introduced every 3 months to assess for remission. Subjects were 399 children with primary nocturnal enuresis aged 6 to 12 years. Sixty-one percent (245) experienced a 50% or greater reduction in wet nights during the dose titration phase and then entered the long-term phase. The average number of wet nights decreased from 5.3 during the observation phase to 0.8 during the last 3-month interval. Within 6 months of treatment initiation, 77 children became dry. There were significantly more responders in the older age groups. Overall, long-term treatment at these dosages was found to be safe ( [Hjalmas et al., 1998](#); [Tullus et al., 1999](#)).

Another strategy has been rapidly to titrate the dosage of DDAVP (maximum, 50 µg) until dryness is achieved, maintain this dosage for at least 4 to 6 weeks, then decrease the daily dosage by 10 µg every 4 dry weeks. This strategy resulted in 71% achieving complete dryness with no relapses. A further 7% achieved dryness after relapses, 7% showed partial improvement, and 15% showed little or no response. The mean dose was 20 µg, the mean duration of treatment was 28 weeks, and median follow-up was 18 months ( [Riccabona et al., 1998](#)).

The formulation of oral DDAVP has made it significantly easier to administer. In an early open 6-week trial involving 33 children with primary nocturnal enuresis, five children responded to 200 µg/day and 17 to 400 µg/day, whereas seven showed no response, and four dropped out. A subsequent 2-week treatment with 40 µg of the nasal spray showed similar efficacy and was able to increase the number of dry nights in two of the nonresponders ( [Matthiesen et al., 1994](#)). A multicenter, randomized study compared 200- and 400-µg doses of the oral preparation, as well as a 20-µg dose of the spray. No significant differences were found between any of the treatment conditions. However, there tended to be fewer wet nights when the children who initially received 200 µg of the oral preparation were increased to 400 µg ( [Janknegt et al., 1997](#)).

The dose response of oral DDAVP was explored in a randomized, placebo-controlled study that used 200-, 400-, and 600-µg daily doses. The 400- and 600-µg doses were significantly more effective than placebo, and there also was a significant linear trend for decreases in wet nights with increasing dosage ( [Skoog et al., 1997](#)).

An early oral DDAVP study with adolescents ( [Stenberg and Lackgren, 1994](#)) also has produced long-term follow-up results ( [Lackgren et al., 1998](#)). The initial study included two 12-week treatment periods with most of the patients receiving 400 µg/day. The initial studies showed that oral DDAVP was significantly more effective than placebo. The long-term, 7-year follow-up indicated that the “cure rate” at both the 2-year and 7-year follow-ups was greater than would be expected by data on

the rate of spontaneous remission.

As indicated earlier, in the section on Pathophysiology, the success of treatment with DDAVP has led to an increase in research regarding the etiology of enuresis. Related to this are studies that try to elucidate factors related to successful treatment with DDAVP. A consistent finding in this regard is older age, larger bladder capacity, and fewer pretreatment numbers of wet nights ([Butler et al., 1998](#); [Eller et al., 1997, 1998](#); [Folwell et al., 1997](#); [Neveus et al., 1999b](#); [Rushton et al., 1996](#)).

Urine osmolality parameters also have been extensively investigated as potential predictors of response to DDAVP. [Rushton et al. \(1995\)](#) found that DDAVP treatment is associated with a significant increase in nocturnal urine osmolality, as well as nocturnal diurnal osmolality ratios. Although responders tended to have higher urine osmolality than nonresponders, the differences did not reach statistical significance and the authors concluded that it therefore was not a reliable predictor of response. Similar results have been reported by other investigators ([Eller et al., 1997](#); [Folwell et al., 1997](#); [Neveus et al., 1999b](#)).

### Outcome and Follow-up

The natural history of primary enuresis must be taken into account in any treatment plan, whether it is primarily behavioral or pharmacologic. There is a high rate of spontaneous remission between the ages of 5 and 7 and again after age 12 years. Accordingly, the clinician might want to wait until after age 7 years before instituting pharmacologic treatment, unless other factors indicate otherwise. Similarly, the strong possibility of spontaneous remission should be considered in any positive treatment response after 10 or 11 years of age.

Pharmacologic studies have indicated that treatment with imipramine can result in three subtypes of response. There are true responders who have a sustained response, and there are also true nonresponders. There also is a surprisingly large group of transient responders. These children have an initial response to imipramine and then lose it over 2 to 3 weeks. When the dosage is increased by another 25 mg, they again respond for another 2 to 3 weeks. Eventually, the dosage required to maintain a response becomes prohibitive. Although long-term treatment with imipramine is not an option for these children, imipramine still can be used for brief, socially important periods, such as camp, because the initial response can be recaptured after a medication-free period ([Rapoport et al., 1980](#)).

There has been one large follow-up study that compared observation, imipramine, DDAVP, and the alarm system. Patients were weaned from therapy after 6 months. Continence was assessed at the 3-, 6-, 9-, and 12-month points of the protocol, so that the 12-month assessment would be 6 months after treatment ceased. Among the observation group (n = 50), only 6% were continent at 6 months and 16% at 12 months. Of the imipramine group (n = 44), 36% were continent at 6 months while still on medication, but this decreased to 16% at the 12-month assessment. The corresponding figures for DDAVP (n = 88) were 68% continent at 6 months, but only 10% at 12 months. The alarm system showed the best long-term effects, with 63% continent at 6 months, and 56% at 12 months ([Monda and Husman, 1995](#)).

### Areas for Future Research

As indicated by the new research reviewed previously, there has been a dramatic increase in research into the etiology and treatment of enuresis. Much of this has been stimulated by the recognition that DDAVP is an effective treatment for the disorder. Despite this new research, a definitive explanation that would link DDAVP efficacy with the pathophysiology of the disorder has not yet been proven, and there is no consistently reliable way to differentiate DDAVP responders from nonresponders, either retrospectively or prospectively.

This and other findings related to bladder physiology and anatomy suggest that we might ultimately be able to differentiate distinct phenomenologic subgroups that relate to treatment outcome.

The long-standing observation that enuresis has a hereditary basis has been advanced by the elucidation of genetic linkages in some large, multigenerational pedigrees. This research will likely continue to advance and may ultimately provide important information on clinical subtypes.

---

#### CASE ILLUSTRATION

John is an 8-year-old boy with primary enuresis. He wets the bed an average of 3 to 4 nights per week. At age 5 years, his pediatrician found no psychological explanation for the enuresis. The family elected to wait on treatment for a few years to see if John would spontaneously remit. The family handled the wetting in a matter-of-fact manner, with John changing the bed each morning. However, the wetting was now beginning to become a social problem for John because it interfered with his plans to sleep overnight with friends and was an embarrassment at summer camp. Accordingly, the family sought treatment, and their pediatrician recommended the bell and pad method of conditioning. John did not rapidly respond to the bell and pad, and it was quite disruptive for the family because they lived in a small house and John shared a room with his younger brother. At this point, the pediatrician decided that medication might be warranted, and he referred the family to a child psychiatrist with whom he was familiar. After receiving medical clearance from the pediatrician and discussing side effects with the family, the child psychiatrist prescribed oral DDAVP 200 µg/day. John did not respond to this dosage but did respond rapidly at a dosage of 400 µg/day. The child psychiatrist would taper and discontinue the DDAVP every 3 months. During the first such tapering process, John developed breakthrough wetting at 200 µg, and the dosage was returned to 400 µg with good results. Three months later, the DDAVP was again tapered. On this occasion, there was no resumption of wetting as the DDAVP was decreased, and it appeared that John's enuresis had now spontaneously resolved.

#### Comment

*Was John's remission spontaneous or due to the DDAVP treatment?* There is no firm indication that a period of treatment with DDAVP leads to cessation of enuresis after the medication is removed, and relapse usually occurs on removal. Thus, John most likely had a spontaneous remission. However, there is one study that suggests that the remission rate after discontinuation of successful treatment with DDAVP is greater than could be anticipated from the spontaneous remission rate.

*If John had not responded to DDAVP, what would have been the next step?* The family could have been asked to try the bell and pad method for a longer time. Alternatively, the child psychiatrist could discuss with the pediatrician a possible trial of imipramine, which has success rates comparable with those of DDAVP.

---

## ENCOPRESIS

### Definition

Encopresis is defined by DSM-IV ([American Psychiatric Association, 1994](#)) as the "repeated passage of feces into inappropriate places." The manual goes on to note that the soiling must occur at least once a month for at least 3 months and that the mental or chronological age of the child must be at least 4 years. Physical disorders must, of course, be ruled out. If there has been a period of fecal continence preceding the recurrence of soiling, it is classified as secondary encopresis.

The DSM-IV also denotes two subtypes of encopresis, which it labels as "with constipation and overflow incontinence" and "without constipation and overflow incontinence." The former category roughly corresponds to what has been referred to in the literature as *retentive encopresis*, whereas the latter corresponds to what has been known as *nonretentive encopresis*.

### Prevalence and Epidemiology

A study involving 8,863 children found a frequency of 1.5% among children between 7 and 8 years of age, with a male:female ratio of over 3:1 ([Bellman, 1966](#)). In the Isle of Wight Study, Rutter and colleagues found that 1.3% of boys between the ages of 10 to 12 years soiled at least once a month, with the corresponding figure for girls being 0.3%. That study also found a significant relationship between enuresis and encopresis ([Rutter et al., 1981](#)).

### Clinical Description

Encopresis has been classified in different ways. As noted, DSM-IV makes a distinction between primary and secondary encopresis and has added subtypes that denote the distinction between retentive and nonretentive encopresis. Retentive encopresis is characterized by a cycle of several days of retention, a painful expulsion, and another period of retention. While the fecal mass is growing, there may be leakage around the mass. The category of nonretentive encopresis applies to those children who simply do not control the expulsion of feces on either a psychological, physiologic, or combined basis.

[Hersov \(1985\)](#) has proposed three categories: (a) children who have adequate bowel control and volitionally deposit feces in inappropriate places; (b) children who either are unaware that they are soiling or are aware but unable to control the process; and (c) situations where the soiling is due to excessive fluid, which may be caused by diarrhea, anxiety, or the retentive overflow process described previously. The last mechanism is responsible for approximately 75% of this category.

## Etiology and Pathogenesis

There have been extensive investigations into the physiologic basis for encopresis. [Loening-Baucke \(1987\)](#) found that 56% of children with retentive encopresis were unable to defecate rectal balloons, and most of these children had abnormal contractions of the external anal sphincter. This study also had prognostic significance in that only 14% of those who were unable to defecate the rectal balloons had responded to treatment after 1 year, whereas 64% of those who could defecate the balloons recovered after 1 year. Similarly, only 13% of patients who were unable to relax the anal sphincter at initial evaluation were improved 1 year later, whereas the corresponding figure for those who could relax the sphincter was 70%. Interestingly, none of the patients who presented with an abdominal fecal mass at the time of the initial evaluation showed improvement 1 year later, regardless of ability to defecate the rectal balloons. Constipated children subsequently were compared with control subjects on a wide range of physiologic measures during the act of bearing down ([Loening-Baucke and Cruikshank, 1986](#)). These studies revealed that the act of bearing down led to decreased anal sphincter activity in 100% of control children, 58% of constipated children who were able to defecate a rectal balloon, and 7% of those constipated children who were unable to defecate the balloon. The latter group was significantly less likely to respond to conventional laxative treatment, and the authors concluded that the increased external sphincter activity could relate to their chronic fecal retention and encopresis. A companion study ([Loening-Baucke et al., 1987](#)) investigated the social competence and behavioral profiles of 38 children with encopresis and correlated these variables with the physiologic variables of anorectal manometric and electromyographic evaluations as they related to treatment outcome. The study found that social competence and behavioral rating scores were not significantly different between those boys who were or were not able to defecate the balloons. The behavioral problem ratings also were similar in both physiologic subgroups of girls. The social competence score of the girls who could not defecate the balloons was lower than that of those who could. The follow-up data indicated that the behavioral and social competence scores did not correlate with successful outcome at 6-month and 1-year follow-ups, but there was a significant negative correlation between positive outcome in the inability to defecate the balloon and the inability to relax the sphincter. Thus, the physiologic variables were predictive of outcome, and the psychological variables were not. A subsequent study by the same group with a similar design continued to demonstrate some predictive value of the balloon test, in that children with functional constipation and encopresis who were able to defecate the balloon were twice as likely to have recovered at 12-month follow-up. However, the author concluded that even though these results were statistically significant, the calculation of predictive value indicated that the defecation test could not, in and of itself, reliably predict recovery ([Loening-Baucke, 1996](#)).

A similar study at a different center concluded that a significant number of boys with encopresis have abnormalities of anorectal expulsion dynamics, but the researchers could not find abnormalities of anorectal sensory or motor function ([Wald et al., 1986](#)). [Sentovich et al. \(1998\)](#) specifically investigated pudendal nerve terminal motor latency in 23 children with encopresis, compared with 23 control subjects, and could find no significant difference. However, anal electromyography did indicate nonrelaxation of the external anal sphincter in 75% of the encopretic children, as opposed to 13% of the control subjects ( $p < 0.001$ ), as well as lower pressures at rest and with squeezing ( $p < 0.01$ ). Complementary abnormalities of anal sphincter function have been reported by others ([Catto-Smith et al., 1998](#); [Sutphen et al., 1997](#)).

Another approach has been to investigate potential involvement of hormones that affect gastrointestinal motility. [Stern et al. \(1995\)](#) measured plasma levels of gastrin, pancreatic polypeptide, cholecystokinin, motilin, thyroxin, estrogen, and insulin at several intervals after the administration of a standardized meal to 10 children with encopresis and the same number of matched control subjects. The authors reported significant differences for postprandial levels of pancreatic polypeptide, which peaked earlier and remained higher in children with encopresis, as well as a lower motilin response. However, the authors could not entirely rule out that their findings were not the result of chronic constipation, rather than the cause ([Stern et al., 1995](#)).

The dramatic nature of the soiling incident has naturally led to psychodynamic speculation. [Bemporad and Hallowell \(1987\)](#) have identified a "small number" of children with intractable encopresis for which they have proposed the term *chronic neurotic encopresis*. The characteristics of these children were (a) history of neurologic delay, (b) early or harsh bowel training, and (c) a distant father and a neurotic mother.

Environmental factors have been noted for some time and include the observations of [Freud and Burlingham \(1943\)](#), who noted a high frequency of soiling and wetting in children separated from their parents during World War II.

At least two studies revealed no correlation between social class and soiling ([Rutter et al., 1981](#); [Stein and Susser, 1967](#)). [Foreman and Thambirajah \(1996\)](#) specifically looked at associated psychopathology in boys with primary encopresis, compared with those with secondary encopresis. They found that the children with primary encopresis were more likely to have experienced developmental delays and to have associated enuresis, whereas those with secondary encopresis had experienced more psychosocial stressors and had higher rates of associated conduct disorder.

## Laboratory Studies

The physiologic studies described previously must be considered research investigations and not the representation of a usual and customary workup. However, they do suggest that a more detailed physiologic investigation than usually is done may be warranted. Usually, once the more obvious physiologic problems, such as Hirschsprung's disease, are ruled out, the problem is considered to be psychogenic.

The plain abdominal roentgenogram reveals evidence of fecal retention. In general, a positive rectal examination is sufficient to determine fecal retention, but a negative rectal examination does not rule it out, and in those cases, the abdominal roentgenogram can be helpful in establishing the diagnosis ([Rockney et al., 1995](#)).

One of the most important investigations may well be a thorough history that documents the frequency, nature, and circumstances of the soiling events in great detail. This history should be elicited both from the parents and from the child.

Psychological testing and evaluation are important in providing a thorough picture of the child, but it remains difficult to know if concomitant psychological problems are associated, causal, or secondary.

## Differential Diagnosis

The differential diagnosis of encopresis must take into account that the soiling can be either a symptom of another problem or the primary problem itself. For example, historically encopresis and enuresis have been reported to occur under stress in normal children and to remit when the stressor is removed. Similarly, in children who are retarded or significantly developmentally delayed, the encopresis may be only one expression of the primary problem. Children who are impulsive and hyperactive may have occasional episodes of encopresis simply because they do not attend to the stimuli until it is too late. Thus, the symptom of encopresis must be viewed in the context of the child's larger psychological and environmental profile. Strictly medical causes, such as Hirschsprung disease, stenosis of the rectum or anus, smooth muscle disease, and endocrine abnormalities, also should be ruled out.

## Treatment

The most widely accepted first line of treatment is one that encompasses educational, psychological, and behavioral approaches. As outlined by [Levine \(1982\)](#), this approach entails an initial meeting that is designed to educate both the parents and child about bowel function and to diffuse the psychological tension that may have developed in the family around the encopresis. This educational and psychological intervention is then followed by an initial bowel catharsis, after which the child receives daily doses of laxatives or mineral oil. There also is a behavioral component to the treatment, which consists of daily timed intervals on the toilet with rewards for success. A 78% success rate has been reported for this approach, without symptom substitution ([Levine and Bakow, 1976](#); [Levine et al., 1980](#)).

[Stark et al. \(1997\)](#) have replicated earlier work reporting the efficacy of group treatment with an educational and behavioral focus in conjunction with medical management for children who had not responded to medical management alone.

The adjunctive use of oral laxatives and conditional rectal cathartics also has been investigated ([Sprague-McRae et al., 1993](#)). Specifically, the authors compared the results obtained with children who were all treated with a high-fiber diet, initial bowel evacuation, behavior modification program, and random assignment to either oral laxatives ( $n = 24$ ) or conditioning rectal cathartics ( $n = 37$ ). Only 61 of 136 patients evaluated completed treatment, and thus there was a high dropout rate. No significant outcome difference was found between the two groups, and 87% continued in remission at 6- to 12-month follow-up. [Nolan et al. \(1991\)](#) used a random allocation design to compare combined treatment with laxatives and behavior modification ( $n = 83$ ) to behavior modification alone ( $n = 86$ ). At 12-month follow-up, 51% of the combined therapy group had at least one 4-week period without an encopretic episode, compared with 36% of the behavior modification group. After the authors excluded children with poor compliance, there was no statistical difference between groups, although the authors maintained that from a clinical perspective,

use of laxatives combined with behavior modification was superior to behavior modification alone.

[Loening-Baucke \(1990\)](#) has expanded on the pathophysiologic studies described earlier by exploring the utility of biofeedback training in children with abnormal defecation dynamics. Specifically, patients (ages 5 to 16 years) were randomly assigned to traditional medical treatment alone (n = 19) or conventional treatment plus up to six biofeedback sessions. Eighty-six percent of the biofeedback group had learned normal defecation dynamics at the conclusion of biofeedback treatment. At 7-month follow-up, 77% of the biofeedback group had normal defecation dynamics, as opposed to only 13% of the conventionally treated ( $p < 0.01$ ). The improvement in defecation dynamics was correlated with clinical improvement at 12 months (16% with conventional treatment and 50% with biofeedback;  $p < 0.05$ ). Similar successful results were reported in a European study ([Benninga et al., 1993](#)).

A longer follow-up study ( $4.1 \pm 1.5$  years) compared the long-term outcome in 129 children with constipation and encopresis, as well as abnormal defecation dynamics, who were treated with conventional treatment, with 63 children who received additional biofeedback training that was directed toward normalizing the defecation dynamics. The results indicated that both groups showed similar rates of improvement (86% of the conventionally treated and 87% of the biofeedback group). At long-term follow-up, complete recovery was documented in 62% of the conventionally treated, 50% of those who had achieved success with the biofeedback treatment, and 23% of those who had not responded to biofeedback treatment. Length of time at follow-up was significantly related to recovery for the group as a whole ( $p < 0.01$ ), suggesting that the natural history of the disorder is to move toward continence. The author concluded that biofeedback treatment cannot be demonstrated to be statistically superior to conventional treatment ([Loening-Baucke, 1995](#)).

A subsequent study by another group with a somewhat similar design reached the same conclusion ([Nolan et al., 1998](#)). However, research into biofeedback treatment continues using a newly developed portable apparatus ([Griffiths et al., 1999](#)), and as an adjunctive treatment in combination with other behavioral strategies and laxative therapy ([Cox et al., 1998](#)).

More intensive psychotherapeutic intervention may be required for those children with intractable encopresis who appear to fit the psychological profile described by [Bemporad and Hallowell \(1987\)](#), where it seems clear that interpersonal–psychodynamic factors are perpetuating the problem.

Pharmacologic treatment with imipramine also has been reported as useful for encopresis. There have been 15 reported cases of children with encopresis responding to imipramine, which have been described in six papers ([Abrahams, 1963](#); [Connell, 1972](#); [Gavanski, 1971](#); [Geormaneanu and Voiculescu, 1980](#); [Siomopoulos, 1976](#); [White, 1977](#)). All but three of the reported subjects are male. In general, the therapeutic effect occurred within a few days to 2 weeks. The doses of imipramine reported are relatively low, in the 25- to 75-mg range. There also is a similar positive case report involving amitriptyline treatment of a 6-year-old ([Dosssetor et al., 1998](#)). There is one double-blind study demonstrating the effectiveness of the prokinetic agent cisapride (Propulsid) for encopresis related to constipation (Nurko et al., 2000). However, this agent has been removed from the market in the U.S. by the F.D.A., due to serious side effects.

### Outcome and Follow-up Data

The 78% success rate described by Levine suggests that most children will respond to a relatively innocuous approach that involves educational, behavioral, and physiologic components, as do the follow-up data of [Loening-Baucke \(1995\)](#). In general, the longer-term follow-up studies consistently indicate that the passage of time is an important contributor to remission of the disorder ([Loening-Baucke, 1995](#); [Rockney et al., 1996](#)). The epidemiologic data also indicate that the effects of maturation will provide a significant number of spontaneous remissions from year to year. The evaluation of any long-term intervention such as psychotherapy should take this factor into account. All but a few children will have either responded to treatment or spontaneously remitted by age 16 years, and persistence beyond that age is quite unusual ([Rex et al., 1992](#)).

### Areas for Future Research

This review suggests that encopresis is an excellent paradigm for assessing the relative impacts of biological, psychological, and social factors. For example, do the physiologic findings described previously represent a constitutional vulnerability, or are they the result of the effects of chronic constipation on the bowel? The symptom of encopresis in its various presentations can be a fruitful area of research for those interested in elucidating the interrelation between mind, body, and culture in children.

---

#### CASE ILLUSTRATION

Peter is a 10-year-old boy with a 2-year history of encopresis occurring at a frequency of once to twice per week. The feces are formed, and the episodes usually occur at home after school. Frequently he hides the soiled underclothes, only to have his parents find them around the house a few days later.

Peter's biological parents divorced 3 years ago. His father was awarded custody of Peter and his younger brother and sister. His father remarried 2 years ago. Peter and his stepmother have been at odds since she moved in.

Treatment with the conventional catharsis and bowel-training regimen was not successful. The family sought treatment with a child psychiatrist. It was apparent that there was considerable tension between Peter's father and stepmother. His father tended to be removed and distant, which greatly angered his stepmother. The couple tended to blame all of their problems on Peter's encopresis. Peter was treated with once-weekly individual and family psychotherapy. As an adjunctive measure, imipramine was prescribed for the encopresis because it was thought that removing the symptom would help to clarify the other significant family issues. Baseline data on the frequency of encopresis were collected for 1 month. After this, imipramine was begun at a dose of 25 mg and titrated up to a dose of 75 mg. Imipramine was effective, and the frequency of encopresis declined from five times per week to two times per week. However, approximately 6 weeks later, the frequency of soiling began to escalate back to its pretreatment levels. In the family sessions, it emerged that Peter's stepmother had become very inconsistent in giving him the imipramine. An attempt was made to have his father administer the medication, but he refused.

Even though the encopresis did recur, the response to medication coupled with the parents' apparent sabotaging of the treatment led to a fuller clarification of the family dynamics. The stepmother became more forceful in expressing her hatred of Peter and eventually took the position that either Peter would leave or she would. The father capitulated on this demand, and Peter went to live with his paternal uncle's family. One month after the move, the encopresis completely remitted. Because the family lived nearby, Peter was able to maintain close contact with his father and siblings.

#### Comment

Given the relatively high success rate with the bowel training approach, why did Peter not respond? The literature clearly shows that children who have more psychological disturbance or are from more troubled families are less apt to respond to this intervention.

What can be inferred from Peter's positive response to imipramine? This would suggest that imipramine's efficacy in encopresis could be a nonpsychotropic effect. Alternatively, it could be argued that Peter was concomitantly depressed and that the therapeutic effect on the encopresis was secondary to an antidepressant effect. It also is quite likely that the response was a placebo effect because there have not been large, placebo-controlled, double-blind studies of imipramine's efficacy for encopresis.

Firesetting behavior in youngsters is the result of a complex interaction of individual, social, and environmental factors. There is a range of firesetting activities representing increasingly severe levels of psychopathology. Although current epidemiologic information is somewhat thin, there are studies suggesting that youngsters 18 years of age and younger represent a significant proportion of individuals involved in firesetting and arson-related behaviors. Several theoretical perspectives present hypotheses regarding the causative factors of firesetting. Research supporting these theories suggests that there is a common group of clinical features describing pathologic firesetting. Swift diagnosis of firesetting behavior can result in successful intervention and remediation. There are many clinical reports suggesting the availability of a wide variety of therapeutic methods that are effective in abating pathologic firesetting behavior in youngsters.

### DEFINITION OF TERMS

The development of fire behavior in youngsters can be viewed as following a naturally occurring sequence of psychosocial phases ( [Gaynor and Hatcher, 1987](#); [Grolnick et al., 1990](#); [Kafry et al., 1980](#)). There are at least three sequential phases of fire behavior: fire interest, firestarting, and firesetting. These categories of fire behavior represent increasing levels of involvement with fire. By experiencing each of these sequential phases, most children learn age-appropriate, fire-safe behaviors. However, for a percentage of youngsters, the influence of risk factors, such as deficits in emotional functioning, difficulties in the family environment, or frequent stressful life events, affect their development and produce such behaviors as unsupervised firestarting, repeated, intentional firesetting, and arson.

Fire interest is experienced by most children 3 to 5 years of age ( [Gaynor and Hatcher, 1987](#); [Hanson et al., 1995](#); [Jackson et al., 1987](#)). There are several ways in which youngsters express their interest in fire. For example, they may ask questions such as, "How hot is fire?" and "What makes fire burn?" Or they may incorporate fire into their play by wearing fire hats, playing with toy fire trucks, and cooking food on their toy stoves. Fire interest represents one of the many curiosities youngsters have about the physical properties of their natural environment.

Firestarting occurs when children experiment with matches or other ignition sources. This type of behavior emerges in children between the ages of 5 and 9 years, and it is observed predominantly in young boys ( [Gaynor and Hatcher, 1987](#); [Showers and Pickrell, 1987](#)). When this experimentation takes place under controlled and supervised conditions, the result is the development of competent, fire-safe behaviors. For example, if youngsters request and are given permission to light the candles on their birthday cake, they are learning the conditions under which it is safe to strike a match and light candles. Children can be given the appropriate responsibility for fire at specific ages, although this responsibility should not be given prematurely ( [Grolnick et al., 1990](#)). Teaching children the importance of fire in their environment and helping them to gain mastery and control over it are benefits of participating in supervised fire-related activities.

Unfortunately, a greater majority of youngsters participate in unsupervised firestarting activities. Studies estimate that over 60% of children interested in fire engage in at least one unsupervised firestarting incident ( [Cole et al., 1986](#); [Gaynor and Hatcher, 1987](#)). In addition, many youngsters will not admit to having participated in these firestarting activities unless specifically questioned about them ( [Kafry et al., 1980](#)). Most unsupervised firestarting is a single-episode event primarily motivated by curiosity. The resulting fires are either accidental or unintentional, and if a fire becomes out of control, youngsters make serious attempts either to extinguish the fire themselves or go for help ( [Cole et al., 1986](#); [Gaynor and Hatcher, 1987](#); [Kafry et al., 1980](#)). Although unsupervised firestarting incidents are unplanned and occur only once or twice for most youngsters, it is estimated that although the probability is fairly low that first-time firestarts will result in a significant fire, this probability increases significantly for subsequent firestarting activities ( [Lewis and Yarnell, 1951](#)). Hence, although unsupervised firestarts can be the result of innocent curiosity or accidental behavior, the risks of starting a significant fire and the resulting consequences exceed the benefits of the learning that may result from the youngster's experimentation.

By 10 years of age, most children have learned the rules of fire safety and prevention and are capable of engaging in age-appropriate firesetting activities such as helping to light the family barbecue or building a campfire ( [Cole et al., 1986](#); [Gaynor and Hatcher, 1987](#)). If adequate fire-related experiential and educational efforts have occurred at home and in school, youngsters will have achieved a sense of competence and mastery over a powerful and fascinating aspect of their physical environment. However, for a number of children, what begins as one or two unsupervised firestarting incidents leads to repeated, intentional firesetting behavior. Hypothesized explanations for the development of pathologic firesetting follow in a subsequent section. [Table 57.1](#) presents a description of the factors distinguishing unsupervised firestarting from pathologic firesetting.

Factor	Firestarting	Firesetting
History	Single episode	Recurrent
Method	Unplanned	Planned
Motiv	Accidental	Intentional
Ignition	Available	Acquired
Target	Nonspecific	Specific
Behavior	Extinguish fire	Run away

**Table 57.1. Factors Distinguishing Firestarting and Pathologic Firesetting**

Pathologic firesetting is characterized by a history of multiple ignitions that take place over at least a 6-month period ( [Gaynor and Hatcher, 1987](#)). The nature and extent of these ignitions may vary, ranging from parents finding burned candles concealed in their youngsters' rooms to fires requiring fire department suppression. The ignitions usually are planned as opposed to being a spur-of-the-moment, impulsive activity ( [Gaynor and Hatcher, 1987](#); [Icove and Estep, 1987](#)). Ignition sources, such as matches and lighters, often are searched for, acquired, and concealed until they are needed ( [Benians, 1981](#); [Gaynor and Hatcher, 1987](#); [Icove and Estep, 1987](#); [Kolko and Kazdin, 1986](#)). The firesetting activity usually takes place in a concealed or isolated area in or near the home, where there is little possibility of immediate detection by an adult or authority figure ( [Icove and Estep, 1987](#)). When a fire is set, there often is an attempt to gather flammable and combustible materials, such as old newspapers and rags, or chemicals, such as paints and alcohol, to use as aids in spreading the fire ( [Gaynor and Hatcher, 1987](#); [Icove and Estep, 1987](#)). These fires can be motivated by a variety of reasons, including revenge and anger, attention, malicious mischief, watching the fire burn, and, in a small number of adolescent cases, profit ( [Benians, 1981](#); [Gaynor and Hatcher, 1987](#)). The target of the firestart often has significant meaning for the firesetter because of the emotional importance of the fire ( [Canter and Fritzon, 1998](#); [Gaynor and Hatcher, 1987](#)). For example, if a youngster has set fire to the cushions of his mother's favorite chair, then it is likely that one of the primary motivations for the firesetting lies in the nature of the relationship between the mother and her child. After the fire, youngsters usually do not voluntarily admit to their involvement in the ignition ( [Gaynor and Hatcher, 1987](#)). If the fire is out of control, rather than calling for help, they

are likely to run away to a safe spot, sometimes to watch the fire burn and await for the arrival of the fire department ( [Gaynor and Hatcher, 1987](#); [Icove and Estep, 1987](#)). Although individual case reports reveal variations in ignition patterns, these are the predominant characteristics that represent pathologic firesetting behavior.

## EPIDEMIOLOGY

Information on the prevalence of firesetting behavior in youngsters is derived from four general areas of study. The first is the annual fire cause and origin rates in the United States. There are two primary resources for this annual data—the U.S. Fire Administration's National Incidence Reporting System and the National Fire Protection Association's United States Arson Trends and Patterns. In 1997, children started 65,060 fires, causing 284 deaths, 2,158 injuries, and \$283.3 million in direct property damage ( [Hall, 2000](#)). Children 5 years of age and younger were responsible for three-fourths of the deaths caused by child-set fires ( [Hall, 2000](#)). Most often these victims were the younger siblings or playmates of the children who started the fires. Although firesetting is the second leading cause of death (second to automobile accidents) for children and adolescents ages 6 to 14 years, it is the number one cause of death (accounting for 33% of the total) for preschoolers ( [Hall, 2000](#)). Hence, very young children are not only most likely to start fires, but they also are most likely to be their victims.

The second source of information relates to the prevalence of unsupervised firestarting and firesetting in populations of school-age children. One study interviewing kindergarten, second, and fourth grade children and their parents (n = 139) from three randomly selected schools reveals that 60% of the children admitted to engaging in unsupervised firestarting and that 77% of them reported to be present when their friends participated in the same behavior ( [Gaynor and Hatcher, 1987](#)). Of the unsupervised firestarting group (n = 83), 37% of the children admitted to one incident, 40% said they started fires two times, and 23% disclosed they had participated in unsupervised firestarting more than twice ( [Gaynor and Hatcher, 1987](#)). Of the group reporting to firestart more than once (n = 52), 55% of the children admitted to burning purposely items such as grass, leaves, rugs, clothes, and paper products ( [Gaynor and Hatcher, 1987](#)). Of these children, 23 were boys, and 15 were girls; boys were more likely to burn items and to set fires outside the home, whereas girls were more likely to do it indoors. None of these fires required firefighting suppression ( [Gaynor and Hatcher, 1987](#)). In addition, 47% of the parents reported that they had engaged in unsupervised firestarting during their childhood ( [Gaynor and Hatcher, 1987](#)). Another study surveying school-age youngsters in grades one through eight (n = 77) indicated that 75% of their sample reported knowing someone who had firestarted with matches or lighters, 58% of the youngsters had actually witnessed unsupervised firestarting, and 38% admitted to engaging in at least one unsupervised firestart ( [Cole et al., 1986](#)). Of this sample, 3% of the firestarting incidents resulted in fires requiring fire department intervention. Hence, these studies offer preliminary findings suggesting that most school children may be exposed to or participate in unsupervised firestarting activities, with fortunately few of these incidents resulting in major fires.

The third type of epidemiologic data examines the prevalence of firesetting behavior among psychiatric populations. An early study indicated that 2% of the evaluations in an outpatient child psychiatry clinic of a large voluntary hospital presented with firesetting as the primary complaint, and 3% of the evaluations conducted in a suburban private practice were firesetting cases ( [Vandersall and Weiner, 1970](#)). Two studies confirm these estimates. One study reports that between 1973 and 1981, 2.45% of their outpatient clinic population (104 of 4,242 children) presented with definite or marked firesetting behavior ( [Jacobson, 1985a](#)). This study also characterized firesetting as a subgroup of the conduct disorder diagnosis. Firesetters differed significantly from a matched group of youngsters with conduct disorder in that they demonstrated more antisocial, aggressive, and destructive behaviors. A second study shows that 2.1% of 100 consecutive referrals to an adolescent forensic mental health service presented with significant firesetting behavior ( [Jasper et al., 1998](#)). When fire behavior in psychiatric populations is examined, a slightly different picture emerges. [Kolko and Kazdin \(1988\)](#) delineated five categories of fire behavior—match play, participation in at least one unsupervised firestart, setting fire more than twice, setting a fire causing serious damage, and setting a fire requiring firefighter suppression—occurring in psychiatric outpatient and inpatient populations. Their results indicate that the prevalence rates for match play and participation in at least one unsupervised firestart were 24% and 19%, respectively, for outpatients and 52% and 35%, respectively, for inpatients ( [Kolko and Kazdin, 1988](#)). Although these outpatient rates are somewhat lower than previously cited rates in a sample of school children (60% for match play and 37% for firestarting) ( [Kafry et al., 1980](#)), the rates for inpatients are more closely aligned ( [Kafry et al., 1980](#); [Kolko and Kazdin, 1988](#)). However, a further comparison of the fire involvement rates from these two studies indicates that more youngsters in the outpatient and inpatient groups were involved in recurrent firesetting (outpatients, 11/21; inpatients, 18/25) than those children sampled from the school population (19/83) ( [Kafry et al., 1980](#); [Kolko and Kazdin, 1988](#)). In addition, whereas none of the firestarts in the school sample resulted in significant fires, 13 of 22 fires started by outpatients resulted in serious damage, and 9 of 24 fires started by inpatients resulted in serious damage ( [Kafry et al., 1980](#); [Kolko and Kazdin, 1988](#)). Therefore, these studies suggest that although the proportion of psychiatric cases presenting with the primary complaint of firesetting remains in range of 2% to 3%, the frequencies with which outpatient and inpatient populations engage in recurrent fire behaviors, some of which lead to serious and damaging fires, may be remarkably higher.

The final type of epidemiologic information on firesetting comes from the arson arrest records of juveniles. Youngsters starting fires that warrant firefighting suppression and that result in significant property damage, loss, or personal injury are at risk for being investigated by law enforcement for the crime of arson. If probable cause can be demonstrated, that is, if existing evidence indicates that firestarting is the result of a malicious and willful intent to destroy by fire, and youngsters have reached the age of accountability, then they can be arrested for arson. During the last two decades, juveniles have accounted for 38% to 56% of all arson arrestees ( [Federal Bureau of Investigation, 1979–1999](#)). In 1998, arson had the highest juvenile arrest rate (52%) of all violent and property crimes indexed by the [Federal Bureau of Investigation \(1999\)](#). Demographic information indicates that most (85%) of these arrested juveniles are white and male ( [Federal Bureau of Investigation, 1979–1999](#)). In addition, most of these youngsters are between the ages of 15 and 18 years (in 1995, 63% were older than 15 years of age) ( [Federal Bureau of Investigation, 1979–1999](#); [Hall, 2000](#)). Hence, youngsters involved in firesetting not only pose significant problems for the mental health community, they represent a major burden for the law enforcement and juvenile justice systems.

## CLINICAL DESCRIPTION

Information on the clinical features of firesetting youngsters primarily comes from descriptive studies, with a smaller proportion of data emerging from empirical investigations that meet rigorous scientific standards of acceptability. Therefore, the essential clinical features reportedly associated with firesetting must be viewed as representing trends rather than empirically verified patterns of behavior.

There is a growing amount of clinical speculation suggesting motivational subtypes to describe firesetting behavior ( [Canter and Fritzon, 1998](#); [Gaynor, 2000](#); [Grolnick et al., 1990](#); [Kocsis et al., 1998](#)). Although these motivational subtypes are intuitively useful, they offer a relatively singular explanation of the development of firesetting behavior in children and they lack empirical investigation and support. They are mentioned because they provide a useful starting point to understanding firesetting behavior. The four motivational subtypes are curiosity—fires set as a result of experimentation or accident; troubled—fires set as an expression of psychological distress; delinquent—intentionally set fires for the purpose of control, destruction, or harm; and pathologic—fires set because of severe mental disorder. Although these subtypes present a conceptual framework for describing four general motives for firesetting behavior, these motives have not yet been empirically validated, nor have they been linked to the clinical features that describe different types of children and adolescents who are firesetters.

It has been proposed that the clinical features of firesetting can be organized into three major categories: individual characteristics, social circumstances, and environmental conditions ( [Fineman, 1980, 1995](#); [Gaynor, 2000](#); [Gaynor and Hatcher, 1987](#)). Each of these categories comprises specific risk factors that predict the essential features of firesetting youngsters. In addition, there is a body of research supporting the notion that firesetting youngsters can be divided into two major age groups, younger children averaging 8 years and adolescents 13 years of age and older ( [Jacobson, 1985a, 1985b](#)). It is hypothesized that the bimodal nature of this age distribution distinguishes two different classes of firesetters, a younger group whose clinical features and motives for firesetting differ significantly from those of the older group ( [Jacobson, 1985a, 1985b](#); [Kolko, 1988](#)). Given these general assumptions, [Table 57.2](#) and [Table 57.3](#) outline the essential clinical features describing these two age groups of firesetting youngsters.

Feature	Description
<b>Individual characteristics</b>	
Demographic	Residence in young (age range 10 to 15) or older (age range 16 to 18) areas; living in a high-risk area; low socioeconomic background
Intelligence	Normal to above average intelligence; high IQ; high IQ; high IQ
Spontaneity	A greater number of reported fires; more frequent and varied types of fires; more frequent and varied types of fires
Proximity	Overwhelming feelings of anger and aggression; contact with or proximity to highly flammable materials
Motivation	General interest in fire; curiosity; desire to test limits; desire to cause damage; desire to cause damage; desire to cause damage
<b>Social circumstances</b>	
Family	Engagement in fire with or without other children; living in a high-risk area; living in a high-risk area; living in a high-risk area
Peer	Socially isolated; contact with or proximity to highly flammable materials; contact with or proximity to highly flammable materials
School	Peer pressure; performance; evidence of learning disabilities; academic achievement; academic achievement
<b>Environmental conditions</b>	
Availability of materials	Specific materials used for fire; availability of materials
Accompanying behavior	The act of firesetting represents the emotional release of anger, rage, and aggression
Consequences	Reactivity to both immediate positive reinforcing properties of attention and effect with the parents; negative outcomes if property is lost and punishment

**Table 57.2. Clinical Features of Pathologic Firesetters, Children 12 Years of Age and Younger**

Feature	Description
<b>Individual characteristics</b>	
Demographics	The majority are white boys. They all seem of average intelligence from middle socioeconomic backgrounds.
Intelligence	Normal levels of intelligence, but long histories of academic failure.
Appearance	A higher than average number of accidents starting in plastic models, higher levels of animal abuse, repetitive enuresis, general conduct and conduct problems.
Enuresis	There is a lack of emotional depth and restricted capacity of expression. Firesetting appears to be a coping strategy and aggressive behavior of defiance and defiance of the fire with a common aim: to seek a difficult separating episode of full fire burning.
Behavior	Violent, impulsive, and defiant are typical behaviors coupled with higher than average levels of fire setting. A specific strategy of early withdrawal of contact observed from the moment of fire ignition and dependence on others to extinguish the fire.
<b>Social environment</b>	
Home	Single-parent homes where the father is absent or the mother is over-protective. There is a high degree of marital discord, severe discipline and superior, poor communication, parental alcoholism and maternal depression. There is a history of the water patterns of early firesetting (see text).
Peer	Isolation and withdrawal from the company of other children and non-firesetting peers.
School	Characterized by poor academic achievement, failure to advance in school grades and conduct and behavioral problems with frequent absences and suspensions.
<b>Developmental conditions</b>	
Attachment issues	The same group supports and encourages firesetting, which often is the result of enuresis or incontinence before setting, with the encouragement of others to set a fire.
Accompanying behaviors	Other antisocial and disruptive behaviors such as alcohol consumption, self-harm, and violence towards others at the same time as or before firesetting in the company of other children or in the home.
Consequences	The immediate, reinforcing properties of firesetting include the resulting attention from family, friends, and the fire department. There is a tendency for a continuation of a cycle of the negative outcomes of property loss and destruction.

**Table 57.3. Clinical Features of Pathologic Firesetters, Adolescents 13 Years of Age and Older**

### Firesetting Children

Demographic information indicates that young firesetting children averaging 8 years of age are predominantly boys coming from a mixed socioeconomic background (Kolko et al., 1985; Showers and Pickrell, 1987). Most studies suggest that these youngsters are of average intelligence (Kolko et al., 1985; Ritvo et al., 1982). However, there are widespread reports indicating that firesetting children typically do not perform well in elementary school, and this finding may be related to a handful of studies suggesting that these youngsters have a higher-than-average incidence of learning disabilities (Kuhnley et al., 1982; Vandersall and Weiner, 1970).

There are scattered studies in the literature pointing to certain types of experiences that occur in the lives of these children that may have a relationship to their firesetting behavior. For example, one study suggests that firesetting children between the ages of 6 and 10 years have a greater number of chronic physical illnesses, including allergies and respiratory problems, than their nonfiresetting counterparts (Siegelman and Folkman, 1971). No attempts have been made to replicate these findings, although there is a hypothesized relationship between chronic illness and the development of violent behavior in children (Group for the Advancement of Psychiatry, 1999). There is a continuing controversy regarding the relationship between enuresis, firesetting, and delinquent behavior, with some studies suggesting that childhood enuresis and firesetting predict later arson arrests and convictions (Lewis and Yarnell, 1951; Repo et al., 1997), whereas other studies indicate no such relationship (Heller et al., 1984; Jacobson, 1985a; Showers and Pickrell, 1987). Also, some studies show a significant relationship between abuse, neglect, and firesetting behavior in children (Jasper et al., 1998; Wooden and Berkey, 1984; Yeo, 1998). The specific nature of the relationship between experienced abuse, neglect, and firesetting behavior remains to be explained both clinically as well as empirically, although one hypothesis suggests that firesetting is an inappropriate strategy for coping with an adverse environment or a method for sending a "smoke signal" to indicate psychological distress (Gaynor and Hatcher, 1987; Yeo, 1998).

The emotional style of these children has been described by clinical studies as one in which there appears to be marked difficulty in modulating feelings of anger and revenge (Bumpass et al., 1983, 1985; Sakheim and Osborn, 1999; Sakheim et al., 1991). It has been suggested that not only are these children unable to recognize or understand these types of feelings when they occur, but they do not have the experience nor skill to express them in socially acceptable ways (Bumpass et al., 1983, 1985). Consequently, they engage in firesetting as a means of expressing accumulated feelings of displaced anger, revenge, and aggression (Bumpass et al., 1983, 1985). This is partially substantiated by clinical work suggesting that the targets of young children's firestarts often are the objects and possessions of those to whom their anger is directed (Gaynor and Hatcher, 1987). For example, there have been clinical reports of youngsters who admit to setting their mother's bed on fire because they were angry with her (Minuchin, 1974). The primary justification of this emotional style comes only from clinical observations, however, and further empirical work needs to be pursued to verify these findings.

The behavior pattern of firesetting children has been characterized as overactive, impulsive, and mischievous (Babinski et al., 1999; Jacobson, 1985a; Sakheim and Osborn, 1999; Sakheim et al., 1991). Although the early documentation of the interrelationship of the behavioral triad of enuresis, cruelty to animals, and firesetting has failed to hold up under more recent scrutiny (Fine and Louie, 1979; Heller et al., 1984; Jacobson, 1985a; Showers and Pickrell, 1987), other recent work suggests there may be a relationship between animal abuse and property offenses, including firesetting (Arluke et al., 1999; Sakheim et al., 1991). Clinical reports indicate young firesetters have difficulty controlling their tempers and have histories of destroying their toys and other personal objects in fits of anger and rage (Gaynor and Hatcher, 1987). This behavioral pattern is fairly consistent with the previously described emotional style of accumulated anger and aggression typically being discharged in a socially inappropriate and unacceptable manner. Clearly, there remains a great deal of work to be done at arriving at a detailed description of the linkages between the emotional and behavioral styles of firesetting children.

There is a growing amount of literature indicating that young firesetting children come either from single-parent homes or from families where one of the two parents, typically the father, is absent for long periods (Fine and Louie, 1979; Gruber et al., 1981; Stewart and Culver, 1982; Vandersall and Weiner, 1970). Studies suggest that, when the family is intact, there appears to be a higher-than-average amount of marital discord (Kazdin and Kolko, 1986; Kolko and Kazdin, 1990). Patterns of family interaction for firesetting children have been characterized by a greater use of overly harsh methods of discipline, including corporal punishment, and an unaffectionate, distant, negative, and conflicted environment (Jacobson, 1985a; Siegelman and Folkman, 1971; Vandersall and Weiner, 1970; Yeo, 1998). In addition, there have been reports that families of firesetting children tend to exhibit more verbally and physically aggressive patterns of family interaction than families of nonfiresetting children (Patterson, 1975; Patterson et al., 1998). Finally, there are a number of studies suggesting that parents of firesetting children have significant psychiatric histories, including one or more family members carrying a diagnosis of antisocial personality, alcoholism, or depression (Group for the Advancement of Psychiatry, 1999; Gruber et al., 1981; Kazdin and Kolko, 1986; Stewart and Culver, 1982). Although much of this information on family patterns comes from clinical impressions, it represents a strong starting point for further empirical work.

There is somewhat limited information on the behavior of firesetting children in social situations. Preliminary work suggests that these children have a great deal of trouble establishing and sustaining meaningful interpersonal relationships (Heath et al., 1985; Vandersall and Weiner, 1970). In addition, studies have shown that when firesetting youngsters find themselves in social situations, they exhibit poor judgment and are unable to plan and anticipate outcomes (Bullis et al., 1998; Sakheim and Osborn, 1994; Sakheim and Osborn, 1999; Sakheim et al., 1991). The degree to which these youngsters feel detached, alone, and isolated may have an effect on their need to gain attention and recognition through firesetting. This is somewhat verified by the findings that young children typically firestart alone rather than in the company of friends (Benians, 1981). If youngsters gain recognition from their peers as a result of their firesetting, then their involvement with their peer group not only reinforces their firesetting behavior, but increases the likelihood that it will recur (Fineman, 1995; Patterson et al., 1998). These observations regarding their behavior in social relationships are speculative, and until more systematic work is undertaken, they are presented only as possible clues for further investigation.

There is evidence indicating that elementary school children with histories of firesetting experience significant academic and behavior problems in school (Bullis et al., 1998; Gruber et al., 1981; Kuhnley et al., 1982; Showers and Pickrell, 1987; Vandersall and Weiner, 1970). The higher proportion of learning disabilities experienced by firesetting children may account partially for this poor academic showing (Showers and Pickrell, 1987). In addition, because some firesetting children carry a diagnosis of hyperactivity, which sometimes is accompanied by the feature of shortened attention spans, they may have difficulty concentrating on and completing their assigned work (Gruber et al., 1981; Loeber et al., 1998). As a result of their academic failures, these children may feel frustrated and angry and they may act out their feelings, thereby becoming conduct and behavior problems in school. Hence, these studies suggest that, for a variety of reasons, firesetting children are not likely to have successful and rewarding experiences in school.

It has been hypothesized that there are immediate environmental conditions that set the stage for firesetting behavior in young children and reinforce the behavior once it has occurred. It has been suggested that there are antecedent stressors that take place in the lives of these youngsters and that trigger particular emotional reactions (Fineman, 1980, 1995; Gaynor and Hatcher, 1987). Specifically, these antecedent stressors trigger accumulated feelings of anger and revenge experienced by these children. The act of firesetting is motivated by the emotional release of displaced anger and aggression or by feelings of revenge. Firesetting holds both the

positively reinforcing properties of attention and effect, as well as the negative outcomes of property loss, injury, and punishment. Although intuitively interesting, these assumptions have yet to be examined in any systematic fashion, either through clinical observation or empirical investigation.

The following case example is presented for the purpose of illustrating the clinical features of children exhibiting pathologic firesetting behavior.

---

#### CASE ILLUSTRATION

Frank is a 10-year-old who lives with his mother and his 11-year-old sister in a lower-middle income urban area. Frank's mother and father have been divorced for 8 years. Frank's mother had been living with a man who, she says, was very generous to her family. He liked to spend time with her children, but he could be extremely rigid and overly punitive, particularly when Frank did something that displeased him. Recently, the mother separated from him because he physically abused her. Frank had witnessed this abuse several times and also may have been a victim. However, when asked, both mother and Frank deny that any of the physical abuse was directed at Frank.

During the time of the separation, Frank's mother began to notice some behavior problems in her son. His ability to concentrate dramatically decreased, and reports came from school that he was involved in fights with his peers. At home, Frank had frequent temper outbursts during which he would become so angry that he would destroy his toys. Also, Frank was verbally aggressive and belligerent toward his sister. He was being generally disruptive both at school and at home. His mother reported that this was unusual behavior for Frank and that she was very concerned for his well-being.

Frank's mother noted that he had been curious about fire since the age of 3 years, when she found him playing with matches in their kitchen. At that time, she taught him how to strike a match correctly. Together they would practice striking matches, blowing them out, and throwing them in the fireplace. Frank was told never to play with matches. He also was encouraged to come to his mother if he ever felt the urge to strike a match, and they would do it together. Despite these rules about firestarting, during the past few weeks, Frank's mother found some scrapes of burned newspaper in their fireplace. One afternoon she arrived home early from work in time to see Frank rolling up pages of newspaper, lighting them, and throwing them into the fireplace. She became angry, describing the possible consequences of what could happen if the flaming newspaper accidentally caught the house on fire.

Frank's most recent fire episode involved igniting his model airplane on the kitchen stove and running with it to the living room fireplace. Unfortunately, he did not reach the fireplace in time, and the burning airplane fell on the carpet, starting a small fire. Frightened and confused, Frank ran out of the house screaming for help. Luckily, his mother was nearby and heard his screams. She and Frank ran back to the house and together they were able to extinguish the fire.

#### Comment

Frank's firesetting episodes are typical of this age group in that his unsupervised firestarts occur alone and in his home. Despite his mother's attempts to be firm and constructive in teaching him fire safety rules, he continues to engage in repeated and intentional firesetting behavior. The question becomes, Why has the frequency of his firestarting increased and intensified at this time? There may be several reasons for Frank's apparent preoccupation with firesetting. First, there could be a relationship between his fire behavior and the discord and separation in his family. Children with family histories of divorce, neglect, or physical or sexual abuse may firestart to express their distress. Frank's firestarting may be his way of expressing his inner turmoil about his family situation. Second, he could be testing the limits of his mother's authority. Third, firesetting may be Frank's way of asking for more attention from his mother. Finally, Frank's fire behavior may represent a "cry for help." Frank may be experiencing general psychological distress, and he may not have the capability of understanding or expressing his pain and conflict. Firesetting becomes his method for calling attention to his emotional difficulties and his way of asking for help.

---

### Firesetting Adolescents

There are far fewer systematic studies focused on describing the clinical characteristics of firesetting adolescents than there are studies describing firesetting children. Demographic information indicates that it is 10 times more common for adolescent boys than girls to firestart ([Heath et al., 1985](#)). Most of these young boys are white and typically fall into the age range of 15 to 18 years ([Federal Bureau of Investigation, 1979–1999](#); [Hall, 2000](#)). There is some work indicating that these youngsters are of average intelligence; however, they have long histories of academic and behavior difficulties in school ([Bullis et al., 1998](#); [Kolko et al., 1985](#); [Kuhnley et al., 1982](#); [Ritvo et al., 1982](#)).

There are some preliminary studies suggesting that firesetting adolescents are more likely to have certain types of experiences and conflicts than their nonfiresetting counterparts. For example, one study suggests that adolescents with histories of firesetting have a higher than average number of accidents resulting in physical injuries ([Jackson et al., 1987](#)). A plausible explanation of this finding is that adolescent firesetters are greater risk takers and that risk-taking behavior more frequently results in accidents. Also, a series of studies shows that firesetting adolescents may experience a higher level of sexual arousal and fantasy excitement than nonfiresetters ([Freud, 1932](#); [Lewis and Yarnell, 1951](#); [Sakheim and Osborn, 1994](#); [Sakheim et al., 1991](#); [Yarnell, 1940](#)). There also is some work reporting that firesetting adolescents experienced more sexual conflicts and gender conflicts ([Bumpass et al., 1985](#); [Sakheim and Osborn, 1986](#); [Sakheim and Osborn, 1994](#); [Sakheim and Osborn, 1999](#); [Sakheim et al., 1985](#); [Sakheim et al., 1991](#)). One study indicates that adolescent firesetters are more frequently involved in sexual misbehavior ([Jacobson, 1985a](#)). This information, however, emerges from a limited number of investigations that rely heavily on clinical impressions rather than on controlled empirical observation.

There is very little work examining the emotional style of adolescent firesetters. Clinical studies characterize them as angry, aggressive youngsters who have little regard for social rules and norms ([Gaynor and Hatcher, 1987](#)). They may feel excitement and defiance before the actual firestart. Once the fire is set, they often do not feel guilt or remorse for their actions ([Gaynor and Karchmer, 1988](#)). These youngsters are unable to experience a depth of emotional feeling and their resulting behavior reflects a restricted capacity of expression. This pattern of emotional functioning is similar to that found in antisocial and delinquent personality patterns (American Psychiatric Association, 1994; [Sakheim and Osborn, 1994](#); [Sakheim and Osborn, 1999](#); [Sakheim et al., 1991](#)).

The behavior of firesetting adolescents is characterized as restless, impulsive, mischievous, and defiant ([Gaynor and Hatcher, 1987](#); [Repo and Virkkunen, 1997](#); [Wooden and Berkey, 1984](#)). In addition, there is some work indicating that these adolescents demonstrate higher levels of risk-taking behavior ([Kafry et al., 1980](#)). These somewhat preliminary findings suggest that, if these youngsters are in a situation where ignition sources or fire materials are readily available, they will be less likely to control their impulse or urge to firestart and more likely to follow through with their aggressive and defiant firesetting behavior.

There is emerging work investigating the relationship between the presence of mental disorder, psychiatric diagnosis, and firesetting. Several studies indicate a relationship between the early childhood onset of conduct disorder and the development of antisocial behavior in adolescents ([Lahey et al., 1999](#); [Repo and Virkkunen, 1997](#); [Werry, 1997](#)). Studies of adolescents involved in recurrent firesetting resulting in arrest reveal that criminal recidivism was significantly related to alcohol dependence for boys, and self-mutilation and suicide attempts for girls ([Bernburg and Thorlindsson, 1999](#); [Coid et al., 1999a](#); [Coid et al., 1999b](#); [Repo et al., 1997](#)). In addition, it appears as if adolescent firesetters who carry a psychiatric diagnosis are more likely to recommit arson crimes than those firesetting adolescents who are not diagnosed with a mental disorder ([Barnett et al., 1997](#)).

There is clinical and empirical agreement on the relationship between the quality of family life and the prediction of firesetting behavior in adolescents ([Repo, 1998](#); [Sakheim and Osborn, 1999](#); [Scholte, 1999](#)). Clinical reports suggest that the characteristics distinguishing the families of firesetting children also may describe the families of adolescent firesetters ([Gaynor and Hatcher, 1987](#)). That is, firesetting adolescents come from single-parent households in which patterns of inconsistent supervision and discipline are typical ([Gaynor and Karchmer, 1988](#)). Increased parental control and decreased parental supervision appear to be related to delinquent firesetting behavior in adolescents ([Scholte, 1999](#)). There are some studies suggesting that firesetting adolescents are likely to have histories of physical abuse and other violent patterns of interaction in their family ([Jasper et al., 1998](#); [Jayaprakash et al., 1984](#); [Ritvo et al., 1982](#); [Showers and Pickrell, 1987](#)). Dissertation work demonstrated that families of adolescent firesetters showed significantly more pathologic functioning in the areas of problem solving, communication, responsiveness, and involvement than did families of nonproblem adolescents ([Reis, 1993](#)). Finally, there is a strong indication that parental psychopathology is related to firesetting behavior and arson arrest ([Group for the Advancement of Psychiatry, 1999](#); [Scholte, 1999](#)). Specifically, evidence suggests that paternal alcoholism and maternal psychosis increase the risk of adolescent firesetter recidivism ([Repo, 1998](#)). There is a great need for an increase in work to explain how these specific family factors contribute to the development of adolescent firesetting.

Just as with the behavior of normal adolescents, there is work indicating that peer group participation greatly influences the behavior of firesetting adolescents ([Bernburg and Thorlindsson, 1999](#); [Gaynor and Hatcher, 1987](#)). Current studies confirm the effect of a negative peer group on the development of delinquent behavior ([Dahlberg, 1998](#); [Rapp and Woodarski, 1997](#)). Most adolescents firestart with one or two friends ([Jackson et al., 1987](#)). Clinical cases indicate that the peer group supports, encourages, and condones firesetting, and to some extent provides a safe environment into which adolescents can retreat once they have intentionally set a destructive fire ([Gaynor J, unpublished reports from clinical case files, San Francisco, 2000](#)). Evidence suggests that continued affiliation with this type of peer group promotes the continuation of delinquent behavior during and beyond adolescence ([Fergusson and Lynskey, 1998](#)). Regardless of who leads the peer group, there may be an agreement among the members that firesetting is an acceptable behavior. In addition, clinical cases suggest that adolescents who firestart may believe that their behavior will gain them a certain degree of attention and recognition in the peer group ([Gaynor J, unpublished reports from clinical case files, San Francisco, 2000](#)). It is hypothesized that peer group support of firesetting behavior may be one of the most influential social factors in reinforcing the likelihood that the behavior will recur as long as the firestarting goes undetected and it results in no immediate nor long-term consequences.

Academic performance, behavior in school, and truancy are related to the development of delinquent behavior, including firesetting, in adolescents ([Kjelsberg and Dahl, 1999](#); [Lahey et al., 1999](#); [Loeber et al., 1999](#); [Su et al., 1998](#)). The academic achievement of firesetting adolescents is significantly below the average ([Kaufman et al., 1961](#); [Yarnell, 1940](#)). These youngsters have long histories of academic failures in school, and they may be one or more grades behind their class by the time they enter high school ([Kaufman et al., 1961](#)). Conduct reports also are less than favorable. One study indicates that firesetting adolescents often are disruptive in

class and they frequently engage in fights with their peers ([Wooden and Berkey, 1984](#)). Many of them either have been suspended several times or have been expelled from more than one school ([Kaufman et al., 1961](#)). In addition, statistical studies indicate that approximately 75% of middle and high school fires are caused by adolescents (National Fire Protection Association, 1978–1998). Hence, not only do these youngsters fail to achieve or adjust to their school environment, but there is evidence indicating that schools may be one of the primary targets of their firesetting.

There is some preliminary work suggesting that certain environmental conditions may be directly related to adolescent firesetting. Studies suggest that specific stressors may trigger firesetting in adolescents ([Fineman, 1980](#), [Fineman 1995](#)). Such stressors are likely to include frequent and sudden alterations in family relationships due to separation, divorce, or death ([Fineman, 1980](#), [Fineman, 1995](#); [Patterson et al., 1998](#); [Strachan, 1981](#); [Vandersall and Weiner, 1970](#)). In one study, parents of firesetting youngsters indicated more than twice the number of family disruptions than their nonfiresetting family counterparts ([Wooden and Berkey, 1984](#)). These parents also reported that their youngsters experienced a greater degree of stress in their lives 6 months before their firestart than at other times in their lives ([Wooden and Berkey, 1984](#)). Clinical reports suggest that, at least in some instances, immediately before firesetting, adolescents may engage in alcohol or drug consumption ([Gaynor J, unpublished reports from clinical case files, San Francisco, 2000](#); [Repo et al., 1997](#)). In addition, there are clinical cases in which firesetting also was accompanied by other delinquent acts, including petty theft and vandalism ([Gaynor J, unpublished reports from clinical case files, San Francisco, 2000](#)). It has been reported that, immediately after firesetting, adolescents may leave the fire scene and move to a safe spot to watch the fire burn. They are not likely to call for help to extinguish the fire. This is somewhat consistent with the notion that these youngsters also are unlikely to experience guilt or remorse once they have set the fire. Perhaps, if they did experience these feelings, they would take the appropriate actions to help suppress the fire. The attention and recognition that they may get from their peer group is likely to reinforce the firesetting behavior, especially if it goes undetected. It appears as if these adolescents experience relatively little fear of punishment for their delinquent activity, nor do they consider the potential negative outcomes of property loss or personal injury.

The following case describes one example of pathologic firesetting behavior in an adolescent.

---

#### CASE ILLUSTRATION

Sixteen-year-old Carl lives with his father and younger brother in an upper-class urban neighborhood. His mother and father divorced when Carl was 12, and his mother recently remarried. Carl's father, a prominent attorney, leaves for work early, comes home late, and does a great deal of traveling. Although Carl's father is absent much of the time, a loving, elderly aunt, as well as a housekeeper, share the responsibility for the two boys. Carl's mother lives in another city a few hundred miles away and visits the two boys on an irregular basis.

Carl's father describes his son as "basically a good kid" but wishes he were more obedient and respectful. His mother says he is hard to talk to and never takes her seriously. Carl's aunt describes him as a charming boy who always seems to get into trouble. Although Carl is very bright, he has been expelled from several private schools because of his inability to follow the rules. These schools characterize him as the class bully and ringleader, and he always seems to be responsible for major class disruptions. Carl currently is attending a private day school, where his grades are average and his conduct marginally acceptable.

Carl has a history of antisocial and delinquent behavior, which began around puberty. Shortly after his mother and father separated, Carl began missing several days of school for unexplained reasons. He would leave home early in the morning and return by dinner, offering no explanation of where he had been or what he had been doing while not attending school. After talking with the school staff, it was decided to move Carl to another educational environment. Several months later, Carl's father received a late night telephone call from the local police reporting that they had caught Carl and a few friends slashing car tires at a nearby shopping mall. Carl's father was able to convince the police not to press charges. There have been two additional incidents of shoplifting, one from a local drugstore and one from a large sporting goods store. On both occasions, apologies were accepted, and no punishment or retribution was implemented. Carl has an apparent knack for getting into trouble and an ability to avoid experiencing the consequences of his behavior.

Carl's firestarting emerged at age 9 years when he was caught setting trash can fires at school. Both his father and the school authorities admonished him, and he was suspended from school for 2 days. The latest known firestart occurred 6 years later. Carl had been invited to spend the night at the house of his friend Kevin. Kevin's parents went out for the evening, and the two boys decided to drink the beer that they found in the refrigerator. Both of the boys together consumed about two six-packs of beer. They then left the house and rode their bikes down to the local park and recreation area. They thought it would be easy and fun to break into the building and steal the petty cash from the park director's desk. Once they had entered the building through an open window, they worked for several minutes to break into the desk where the petty cash was kept. Unsuccessful and frustrated by their attempt to obtain the money, they spotted a lighter on a nearby counter and ignited the papers in the trash can. They fled from the building on their bikes without attempting to extinguish the fire. On their way home, they heard the sound of fire engines and assumed that they were responding to the fire.

#### Comment

Carl has a long-standing history of aggressive and antisocial behavior. It appears as if he seizes every opportunity to get into trouble. Lacking the appropriate attention and supervision at home, he pursues recognition in socially unacceptable ways. Attempts by school authorities to control his disruptive behavior have been unsuccessful. In fact, there do not seem to be any people who are effective in guiding or shaping Carl's behavior. Carl apparently felt no guilt or remorse over having set the fire at the park and recreation building. In addition, neither he nor his friend made any attempt to extinguish the fire or call for help. Hence, together these boys successfully started a significant fire and escaped immediate detection. Unless they are caught, they are unlikely to experience any consequences of their firestarting behavior. Their perceived success in this episode may encourage them to pursue more illegal and dangerous firesetting activities in the future.

---

## THEORY

There are several major theoretical frameworks that offer explanations specific to the development of firesetting behavior in youth. However, before they are presented, it is useful to explain firesetting behavior in the context of the development of aggressive and violent behavior in childhood and adolescence.

It is hypothesized that the development of aggressive and violent behavior is orderly rather than random and follows one or more behavioral pathways ([Loeber and Stouthamer-Loeber, 1998](#); [Nagin and Tremblay, 1999](#); [Vitaro et al., 1998](#)). Research supports a triple-pathway model to describe the development of aggressive and violent behavior in youth ([Loeber et al., 1993](#), [Loeber et al., 1997](#)). There is an overt or proactive pathway, that starts with minor aggression, and is followed by physical fighting, and then by personal violence such as assault, rape, and murder. The covert or reactive pathway is defined as a sequence of nonconfrontational behaviors such as frequent lying and shoplifting, and is followed by property damage such as vandalism, firesetting, and other moderate to serious forms of delinquency. The third pathway, unlike the previous two, exists only before 12 years of age and is an authority conflict pathway consisting of defiant, stubborn behavior that includes staying out late at night, running away, and truancy. Empirical work has validated this model and suggests that most aggressive behavior develops along either an overt or covert pathway, with the most severe forms of violence exhibiting both overt and covert behaviors ([Loeber et al., 1998](#); [Tolan and Gorman-Smith, 1998](#)).

Although this model explains the classification of firesetting as a covert aggressive behavior, it does not hypothesize the underlying causes that lead specifically to the development of firesetting behavior in youth. There are four theoretical frameworks—psychoanalytic, social learning, dynamic-behavioral, and functional analysis—that present hypotheses regarding the acquisition of firesetting behavior. Although they offer intuitively interesting explanations of firesetting, there is remarkably little empirical work to support or reject these theories. Therefore, the current value of these theories lies in their attempt to speculate on the psychological dynamics of firesetting.

Freud was the first to examine the psychological meaning of fire ([Freud, 1932](#)). His psychoanalytic theory hypothesized a relationship between sexual desires and fire. He wrote that fire symbolically represented the expression of libidinal and strong phallic-urethral drives. That is, men attempt to extinguish fires with their own urine, thereby symbolically engaging in a homosexual struggle with another phallus. Therefore, it is the relationship between sexual arousal and urination that is the underlying motive associated with the thrill of igniting and extinguishing fires. The act of firesetting represents a regression to the urethral-phallic phase of psychosexual development, and setting fire substitutes for forbidden masturbatory or sexual desires (Freud, 1932).

Given this hypothesized relationship between sexual arousal, urination, and firesetting, it is expected that firesetting youngsters might display one or more conflicts with respect to these areas of psychological functioning. There is some clinical, as well as empirical, work suggesting that various groups of firesetting youngsters have a higher-than-average incidence of sexual conflicts ([Sakheim and Osborn, 1986](#), [Sakheim and Osborn, 1994](#), [Sakheim and Osborn, 1999](#); [Sakheim et al., 1985](#), [Sakheim et al., 1991](#); [Yarnell, 1940](#)), abnormal sexual behavior ([Jacobson, 1985a](#)), and sexual dysfunction ([Stekel, 1924](#); [Yarnell, 1940](#)). However, there is substantial controversy over whether there is a significant relationship between enuresis, firesetting, and general patterns of delinquent behavior. Early research indicated that the behavioral triad of animal abuse, enuresis, and firesetting predicted aggressive and violent behavior in children and adolescents ([Hellman and Blackman, 1966](#)). Although later work does not confirm the predictive value of the behavioral triad, it does indicate a significant relationship between enuresis and firesetting ([Heller et al., 1984](#); [Prentky and Carter, 1984](#); [Repo et al., 1997](#)). More recent work also points to a significant correlation between animal abuse and property offenses, including firesetting ([Arluke et al., 1999](#); [Sakheim et al., 1991](#)). Hence, it may be that both enuresis and animal abuse are independently related to firesetting, and children involved in one or both of these behaviors also are more likely to be firesetters. To date, the major tenets of psychoanalytic theory explaining the specificity of the connection between sexual arousal, enuresis, and firesetting remain open until further work can verify the nature of the hypothesized relationships.

Social learning theory offers a significantly different explanation of the development of firesetting behavior. Whereas psychoanalytic theory emphasizes the relationship between instincts and firesetting behavior, social learning theory emphasizes the impact of the environment on shaping the development of firesetting behavior. Learning experiences and cues, personal repertoires, and parent and family influences and stressors are hypothesized to be related to firesetting ([Kolko and Kazdin, 1986](#); [Patterson et al., 1989](#)). Firesetting occurs because youngsters learn the behavior, that is, they may observe it, imitate it, model it, and perhaps even be rewarded for it. Firesetting is a form of learned aggression, which may first surface in the patterns of family interaction ([Kolko and Kazdin, 1990](#); [McKerracher](#)

and Dacre, 1966; Vreeland and Waller, 1979). Later firesetting activities may be reinforced by the peer group. Undetected firesetting episodes in which no significant behavioral or social consequences are experienced also reinforce the likelihood that firestarting will recur. Hence, using a developmental framework, initially firesetting behavior emerges and may be learned within the family system; however, it is reinforced later by the peer group, and it recurs because of the lack of socially applied sanctions prohibiting or punishing the behavior ( Patterson et al., 1989).

There is minimal work investigating the application of social learning theory to the development of firesetting behavior. One clinical study reported that fathers of adolescent firesetters all had significant fire-related employment (fireman, furnace stoker, automobile burner at a junkyard), with one youngster not only watching but participating with his father in the burning of automobiles ( Macht and Mack, 1968). There have been no empirical attempts to confirm or disclaim these clinical observations. Another clinical study reported that in a small percentage of firesetting cases (three of 27), parents admitted to using fire to punish their children, obviously conveying the message that fire is an acceptable form of retaliation ( Ritvo et al., 1982). Although these clinical studies represent thin evidence in support of a social learning theory explanation of firesetting behavior, there is a long history of empirical studies that have identified family variables as consistent covariates for early forms of antisocial behavior and for later delinquency ( Group for the Advancement of Psychiatry, 1999; Loeber and Dishion, 1983; Loeber and Stouthamer-Loeber, 1998; Loeber et al., 1998; Patterson et al., 1998). These covariates, such as harsh and inconsistent discipline, little positive parental involvement with the child, and poor monitoring and supervision, are strikingly similar to those variables characterizing the families of firesetting youngsters ( Kolko and Kazdin, 1990). Hence, what remains to be accomplished is the identification of the specific linkages between social learning theory and those family variables characteristic of firesetting youngsters.

Dynamic-behavioral theory is a broad-based conceptual framework designed specifically to explain firesetting behavior. This theory identifies a number of psychosocial determinants related to the development of firesetting behavior in youngsters. Although there have been various attempts to categorize these determinants (Fineman, 1980, Fineman, 1995; Gaynor and Hatcher, 1987; Heath et al., 1985), there is consensus on at least three major dimensions related to the development of firesetting behavior: (a) personality and individual characteristics, (b) family and social circumstances, and (c) immediate environmental conditions. Each of these three dimensions comprises specific variables. For example, personality and individual characteristics can include demographics, intelligence, emotional style, and experiential and behavioral variables. Social circumstances can include family dynamics, peer relationships, and school performance. Environmental conditions are those antecedent events that trigger firesetting and the consequences that may or may not be experienced as a result of the behavior. It is hypothesized that these variables can be further classified as either risk or protective factors. Risk factors are positively related to the emergence of firesetting behavior in children and adolescents and include the individual variables of chronic illness, neglect and abuse, sexual conflict, impulsivity, and psychiatric diagnosis; the social circumstances of family dysfunction, parental psychopathology, inadequate social skills, and school failure; and the environmental conditions of stressful events and alcohol and substance use and dependence. Much less is understood about those protective factors that discourage or prevent firesetting behavior, but certain social conditions such as intact family structures, prosocial peer groups, and supportive communities are thought to be related to the development of healthy, nonviolent, and well adjusted children and adolescents. The most useful feature of these proposed risk and protective factors is that they can be observed and measured to confirm or reject their hypothesized relationship to firesetting.

The major contribution of dynamic-behavioral theory is that research related to describing the psychosocial characteristics of firesetting youngsters can be organized and classified utilizing this conceptual framework. It presents the first predictive model of firesetting behavior by trying to define the domain of independent variables, such as personality and social and environmental factors, that will predict the occurrence of the dependent variable, firesetting behavior. Unlike psychoanalytic or social learning theory, it is broad-based in that it does not assume that one major factor, such as instincts or the social environment alone, predicts firesetting. Rather it presents a multivariate approach to predicting levels of firesetting behavior. As research emerges describing the various characteristics of firesetting youngsters, dynamic-behavioral theorists must empirically identify both the risk and protective factors that are significantly related to firesetting behavior. The result will be a quantifiable description of various types of youngsters involved in various levels of firesetting behavior.

There is one final theoretical framework that represents the latest attempt to explain firesetting behavior. Functional analysis offers a model for predicting the occurrence of arson and recidivistic fire behavior ( Jackson et al., 1987). The application of this framework is more useful in explaining the firesetting behavior of older children and adolescents, who are more likely to be involved in recurrent firestarting. This paradigm hypothesizes that certain psychosocial stimuli, in the context of major environmental conditions, predispose individuals toward firesetting, which in turn is either positively or negatively reinforced. The psychosocial stimuli and environmental conditions that influence firesetting are not unlike those identified by dynamic-behavioral theory. They include psychosocial disadvantage, dissatisfaction with life, ineffective social interaction, previous experience with fire, the occurrence of emotionally significant events, and opportunities to set fire. Firesetting is viewed as an attempt by firestarters to exert some type of change in their environment, where alternative behaviors motivated by the need to change have proven ineffective. Firesetters are characterized as basically ineffective individuals who have been unable to develop the behaviors necessary to express and satisfy their emotional and social needs. Consequently, they firestart as one way to assert a sense of mastery and control over their environment. This description of recurrent firesetting behavior and the general underlying assumptions is consistent with clinical case reports of adolescent firesetting in which social ineffectiveness coupled with the need to express aggressive behavior have been the primary motivating factors for firestarting ( Gaynor, 2000). Hence, a preliminary application of the tenets of functional analysis theory appears to be useful in understanding the clinical dynamics of recurrent firesetting.

## DIFFERENTIAL DIAGNOSIS

Current empirical work consistently reports that the most frequently occurring psychiatric diagnosis associated with pathologic firesetting is conduct disorder (Jacobson, 1985a; Repo, 1998; Sakheim and Osborn, 1999; Sakheim et al., 1985, Sakheim et al., 1991; Showers and Pickrell, 1987). The essential clinical features describing this disturbance, such as behavioral difficulties at home or at school, low self-esteem, low frustration tolerance resulting in irritability or temper outbursts, and poor academic achievement, closely match the observed behavior patterns of pathologic firesetters ( Gaynor and Hatcher, 1987). In addition, studies suggest that the occurrence of firesetting behavior is a significant predictor of the persistence of aggressive and antisocial behavior in youngsters diagnosed with conduct disorder (Jasper et al., 1998; Kazdin, 1987; Kelso and Stewart, 1986; Taylor et al., 1998). Therefore, the probability is high that firesetting youngsters diagnosed with conduct disorder will have poor outcomes and will continue to be involved in broader antisocial and delinquent behavior.

There is some evidence indicating that a conduct disorder diagnosis with aggressive features may be accompanied by additional psychopathology differentiating male and female firesetters (Coid et al., 1999a, Coid et al., 1999b; Jasper et al., 1998; Taylor et al., 1998). Male firesetters diagnosed with conduct disorder are more likely to have significant histories of alcohol dependence (Repo, 1998; Repo and Virkkunen, 1997; Repo et al., 1997). For female firesetters, a conduct disorder diagnosis often is accompanied by an underlying mood disorders with histories of self-mutilation and suicide attempts (Coid et al., 1999a, Coid et al., 1999b; Jasper et al., 1998). It also is more likely that firesetting behavior diagnosed in the context of an early onset of conduct disorder for both male and female firesetters leads to more persistent and recidivistic criminal behavior (Coid et al., 1999a, Coid et al., 1999b; Lahey et al., 1998; Repo, 1999; Repo and Virkkunen, 1997; Werry, 1997).

A handful of studies report that youngsters diagnosed with hyperactivity and attention deficit/hyperactivity disorder have histories of firesetting behavior as well as participation in other delinquent activities (Broling and Brotman, 1975; Gruber et al., 1981; Lahey et al., 1999; Vitelli, 1998). Conversely, it has been observed that a proportion of firesetting youngsters display general learning disabilities, which may be related to their below-average levels of achievement in school (Jasper et al., 1998; Wooden and Berkey, 1984). It is unclear from this research whether these learning disabilities are related to diagnosed hyperactivity and accompanying shortened attention span. Although preliminary information suggests a relationship between hyperactivity, attention deficit, firesetting, and conduct disorder, clearly more empirical investigation is necessary to determine the exact extent and nature of these connections.

There are several studies indicating a relationship between firesetting and severe mental disturbances such as schizophrenia, organic brain dysfunction, and mental retardation (Barnett et al., 1997; Jasper et al., 1998; Pontius, 1999; Taylor et al., 1998; Wooden and Berkey, 1984; Yarnell, 1940). Some of these studies suggest that firesetting occurs in psychotic youngsters in response to delusions involving themes of persecution, self-abuse, and control (Wooden and Berkey, 1984; Yarnell, 1940). In some cases of severe mental disturbance it is likely that the firestarting represents a reactive behavior, rather than a major or essential aspect of the disturbance. The exact role firesetting plays in various types of severe psychopathology is unknown and remains open to theoretical speculation and empirical evaluation.

Although pyromania, the only *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) diagnosis related specifically to the behavior of firestarting, was initially reported in children in the classic treatise by Lewis and Yarnell (1951), subsequent empirical work shows that it is not used in diagnosing firesetting youngsters (Gaynor and Hatcher, 1987; Geller et al., 1997; Rider, 1980). The diagnosis of pyromania typically is reserved for adults (American Psychiatric Association, 1994). However, according to clinical and empirical observations, pyromania, described by the essential features of a recurrent failure to resist the impulse to set fires, an increased sense of tension before setting fires, and an experience of intense pleasure, gratification, or release at the time of ignition, occurs infrequently in adult populations and rarely is a psychiatric diagnosis attributed to adult firesetters (Barnett et al., 1997; Taylor et al., 1998; Zeegers, 1984). More than likely, adult firesetters, when detected, are legally apprehended and become the responsibility of the criminal justice system. Therefore, even if pyromania were an

appropriate diagnosis, most criminally incarcerated arsonists do not receive psychiatric evaluations and diagnostic classifications.

## TREATMENT

The goals of an effective treatment strategy are to abate firesetting behavior and sustain significant changes in the underlying psychopathology. Specific psychotherapies have been developed to work with youngsters presenting with firesetting as the primary behavior problem. Outpatient treatment is the method of choice; however, there are some inpatient settings that have programs designed exclusively for firesetting youngsters. Because theory and empirical evidence suggest that there is a complex set of variables associated with the development of firesetting behavior, there is a trend toward the application of multisystem or multicomponent therapies, as well as community-based interventions to the treatment of pathologic firesetting. Many of these therapeutic approaches are recently developed, and consequently, there is an absence of controlled empirical studies demonstrating their relative effectiveness. Nevertheless, preliminary clinical evaluations of many of these methods suggest that, at least in the short term, they are highly successful in eliminating firesetting behavior in youngsters. What is less clear is the relative impact these treatment strategies have on sustaining desirable changes in the underlying psychopathology.

Individual and family psychotherapy are the two predominant modalities used in the outpatient treatment of firesetting youngsters. The primary focus of individual psychotherapy is on the immediate elimination of firesetting behavior, with a secondary emphasis on adjusting or changing the underlying psychopathology ( [Gaynor and Hatcher, 1987](#)). Cognitive–emotion and behavior therapy are the two most highly developed outpatient treatment approaches. The major goals of cognitive–emotion psychotherapy are to teach youngsters how to recognize the urge to firestart, interrupt the behavior before it starts, and substitute socially appropriate types of behaviors to express their underlying emotions ( [Bumpass et al., 1983](#), [Bumpass et al., 1985](#)).

The primary therapeutic mechanism of the cognitive–emotion approach is the construction of a written graph by youngsters with help from their parents and the therapist. [Figure 57.1](#) represents an example of a graph constructed by a firesetting youngster. Both the feelings and specific events leading up to and following the most recent firestart are graphed. The *vertical axis* of the graph represents the time before, during, and after firesetting. The *horizontal axis* represents the intensity of the various emotions experienced during this time period. The firestarting episode is graphed in the center of the vertical axis. Youngsters are asked to list on the vertical axis, in order of occurrence, the significant events leading up to and following the firestart. For example, Johnny came home after school, and no one else was home. He wanted to play with some friends, but after calling around, he found that they were all busy. He turned on the television, but there was not anything that he wanted to watch. He decided to make a trip to the corner store to get some candy. He bought his favorite snack and picked up the free book of matches lying on the counter. On his way home he began striking matches and extinguishing them. He passed a vacant lot, which he entered. When no one was looking, he set a small plant on fire and ran home. When he got home, he turned on the television and watched cartoons for the rest of the afternoon. In the early evening, his grandmother arrived to make his dinner. After dinner, Johnny and some of his friends walked over to see the damage that occurred as a result of the fire at the vacant lot.

**Figure 57.1.** Graphing firesetting behavior.

Once these events are graphed, youngsters are asked to describe their feelings associated with this period. Each type of feeling, such as loneliness, anger, excitement, fear, and guilt, is graphed separately and represented by an individual line. Because specific feelings wax and wane over this period, their various intensity levels are represented by the relative amplitude of the “feeling” lines on the graph. For example, when Johnny arrived home after school to an empty house, initially he might have felt lonely. After calling around to his friends and finding them all busy, these feelings might have increased. Once he discovered that the television was not going to satisfy him, his feeling of loneliness again may have intensified. However, once he decided on a trip to the store, some of his lonely feelings subsided and were replaced by other types of emotions. Hence, the amplitude of the “loneliness” feeling line would gradually increase once Johnny arrived home from school; it stays elevated during his struggle to find some form of entertainment, and then it begins to decrease once his trip to the store was underway. In this way, one or more feelings and their relative patterns of experienced intensity are graphically represented in relation to the significant firestarting incident.

A typical or usual graph is expected for most youngsters involved in pathologic firesetting. A major assumption of this graphing technique is that although the specific events surrounding firestarting may vary, the particular pattern of feelings connected with firestarting episodes is expected to be somewhat similar ( [Bumpass et al., 1983](#), [Bumpass et al., 1985](#)). It is the role of the therapist, through the process of constructing the graph with the youngsters, to bring to their awareness the usual feeling states associated with the impulse of firesetting. A typical graph indicates that one or more significant events triggers a sequence of sad, lonely feelings. These feelings are replaced by intense, angry feelings, which in turn are controlled by a destructive urge that is significantly relieved by firestarting. A feeling of fear usually emerges before the firesetting and continues for a brief time after the fire is set. Feelings of guilt, if experienced, follow the firesetting. The therapist emphasizes the importance of the relationship between these experienced feelings and the desire to firestart. This pattern of feelings, the associated significant events, and firesetting are the focus of this particular method of cognitive–emotion psychotherapy.

The graphing technique is used as the starting point to help youngsters learn that they can prevent themselves from setting more fires. Once the graph is complete, usually by the second or third session, it is used as a teaching tool for the remainder of the psychotherapy. Youngsters are taught that the feelings they experience early in the typical pattern leading to firesetting, such as loneliness or sadness, are a signal that the impulse to firestart may be imminent. They are reminded that they do not always have to act on their feelings, especially if they firestart. They are told that they have a choice of what to do about their feelings. They are asked what constructive behaviors they can pursue when they are feeling lonely and sad. These alternative behaviors are listed on the graph. Youngsters are told that they probably will not set any more fires, but if they have the urge to firestart, they should pay attention to their feelings so that they can talk about them with their therapist. If they become overwhelmed with their feelings and want to set a fire, they are asked first to telephone and talk with their therapist. If subsequent firestarts occur, these firesetting episodes are graphed and become the focus for future sessions. If youngsters are successful in redirecting their urge to firestart, they are supported and praised by their therapist and their family. This form of cognitive–emotion therapy averages six to eight sessions and can be considered a form of brief psychotherapy.

A follow-up clinical assessment evaluating the effectiveness of this type of cognitive–emotion therapy indicated that 2 of 26 youngsters exhibited single episodes of firesetting behavior subsequent to the termination of their treatment ( [Bumpass et al., 1983](#), [Bumpass et al., 1985](#)). For six youngsters, additional psychotherapy was recommended once the graphing technique had been successful in abating their firesetting behavior. Unfortunately, these recommendations were not pursued; these youngsters became involved in other acting-out and antisocial behaviors, such as petty theft and vandalism, and were subsequently treated in inpatient and residential treatment facilities. Although there was no control group included in this follow-up evaluation, this preliminary assessment indicates that this method shows some promise in eliminating firestarting behavior. It remains unclear how successful this approach is in addressing the underlying psychopathology that frequently exists in the lives of firesetting youngsters and their families.

There are a number of behavior therapy approaches that have been reported as successful in abating firesetting behavior. The predominant behavior therapy methods used either alone or in combination are punishment, reinforcement, negative practice or satiation, and operantly structured fantasies. Two case studies report the successful application of various methods of punishment, including the use of threats, such as work penalties ( [Carstens, 1982](#)). Sometimes the use of punishment is coupled with positively reinforcing youngsters when they find and return to their parents conspicuously hidden empty matchbooks ( [Holland, 1969](#)). Negative practice procedures, coupled with the use of positive reinforcement to encourage more socially appropriate behaviors, also have been reported as successful in stopping severe and recurrent firestarting behavior ( [Koles and Jenson, 1985](#); [Kolko, 1983](#), [Kolko, 1988](#)). One behavior therapy case study avoided the application of punishment methods or negative fire experiences by using a positive reinforcement program coupled with the implementation of operantly structured

fantasies ([Stawar, 1976](#)).

All of the reported behavior therapy techniques—punishment, positive reinforcement programs, negative practice and satiation procedures, and operantly structured fantasies—are successful in stopping pathologic firesetting behavior in single-case applications. In addition, these methods are short-term interventions that can be used within an average of 6 to 12 sessions. However, questions remain regarding the effectiveness of the techniques with more than one or two cases. Also, although these methods appear to be successful in stopping the specific firesetting behavior, there is little evidence indicating that these specific behavioral techniques change or adjust accompanying psychopathology. Measuring the relative success of behavior therapy is a challenge for the future.

There are only a handful of cases reported in the literature using brief (three to six sessions) family psychotherapy to treat firesetting youngsters successfully ([Eisler, 1974](#); [Madanes, 1981](#); [Minuchin, 1974](#)). In two of the three cases, family members were taught how to ignite and extinguish matches safely in a controlled setting in the therapist's office ([Eisler, 1974](#); [Minuchin, 1974](#)). This controlled firestarting task was used as a vehicle to restructure the existing patterns of family communication and interaction. In particular, attention was focused on restoring the appropriate amount of parenting authority and reestablishing communication between youngsters and their parents regarding household rules designed for the safety and protection of the family. In the third case, the youngster's firesetting was viewed as the overt symptom of a dysfunctional family system (Madanes, 1981). Family therapy sessions were focused on a recognition of the underlying distress and helping family members to identify the changes that needed to happen to reshape the nature of their interactions. In all three cases, follow-up studies indicated the successful elimination of firesetting behavior and a higher level of satisfaction among family members regarding patterns of communication and interaction. Although these clinical reports are encouraging, the success of family psychotherapy in treating firesetting cases deserves more systematic and widespread application and evaluation.

Inpatient treatment programs for firesetting youngsters have been influenced by two major types of therapeutic philosophies ([Gaynor and Hatcher, 1987](#)). The first is a more traditional, psychodynamic approach where the treatment emphasis is on the nature of the therapeutic alliance formed between youngsters and program staff. Both individual and family psychotherapy are the techniques used and the treatment program is long term (ranging from 6 months to 2 years). The second theoretical approach is behavioral, where specific behaviors are identified for change and discrete interventions are designed to adjust these behaviors. The firesetting youngsters are the primary focus of the behavior therapy methods, with parents and family members included in the therapeutic endeavor once the firesetting behavior has been eliminated. Behavior therapy programs tend to be relatively short term (4 to 8 weeks) and currently are the most widely offered inpatient approach to the treatment of firesetting youngsters.

Studies indicate that several different types of behavior therapy methods have been used successfully in inpatient settings ([Cox-Jones et al., 1990](#); [DeSalvatore and Hornstein, 1991](#); [Koles and Jenson, 1985](#); [McGrath et al., 1979](#)). One inpatient program consists of three phases designed to work with both the child and the parents. During phase one, children participate in a series of behavioral exercises in which a choice must be made between toys and firestarting materials. These exercises are observed by therapists out of the view of the youngsters. If they choose matches and lighters as opposed to non-fire-related toys, the therapist intervenes and conducts a debriefing. The debriefing focuses on helping youngsters to realize the experienced emotions associated with choosing firestarting materials. The result of these exercises is that children are left with a mild aversion to firestarting materials. During the second phase, intensive family psychotherapy is used to adjust those environmental conditions in the family that are associated with the emergence of firesetting behavior. The third phase focuses on reentry into the family and community. Outpatient family psychotherapy is used, and an intensive effort is made to provide special community support services such as schooling and structured activities. At the end of the third phase, it is expected that youngsters will return to the family and social environment, not participate in firestarting activities, and function adequately in their interpersonal and social milieu. Follow-up contact shows no relapses in 100 cases treated in a 2-year period ([Birchill, 1984](#)).

One other inpatient approach is worthy of mention. It also involves the treatment of firesetting with a combination of behavior therapy techniques and fire safety education, with the goals of improving ego functioning while providing information directed at developing more adaptive and socially appropriate behaviors ([DeSalvatore and Hornstein, 1991](#)). The program takes place in a short-term diagnostic inpatient unit, and uses a milieu approach consisting of three phases—assessment, didactic, and practice. The fire safety materials use Smokey the Bear as the primary teaching theme. At 1-year follow-up, results indicated that 1 of 35 children was found to have set another fire ([DeSalvatore and Hornstein, 1991](#)). Although these behaviorally oriented inpatient programs show promise, they must be evaluated in the more rigorous context of controlled clinical trials.

The application of a multisystem approach to the treatment of firesetting is consistent with current theory and empirical support suggesting the linkage between a complex set of individual, social, and environmental factors and the development of pathologic firesetting behavior in youngsters. It has been proposed that the formulation of a treatment plan should address the elimination of firesetting behavior, improve skill deficits in social, emotional, or academic functioning, and improve the level of fire safety knowledge and appropriate fire survival skills ([Stadolnik, 2000](#)). There are several examples of multisystem treatment programs designed for firesetting juveniles ([Clare et al., 1992](#); [Cox-Jones et al., 1990](#); [Koles and Jenson, 1985](#); [Kolko, 1983](#); [Zingaro and Pittman-Wagers, 1992](#)). Although settings can vary from outpatient to inpatient, there is a consistent treatment approach involving the identification of the specific causative factors leading to the development of pathologic firesetting and the implementation of intervention focused on multiple targets of therapeutic change. For example, [Koles and Jenson \(1985\)](#) present the case of a young boy with a history of chronic firesetting related to poor impulse control and frequent temper outbursts, inadequate parental supervision and discipline, little or no interaction with peers, and below-average knowledge of fire survival and safety information. This case was successfully treated using the multisystem approach of overcorrection, relaxation training, and covert sensitization to establish cognitive control of impulse and temper, behavioral contracting to improve parental involvement, social skills training to facilitate interaction with peers, and fire safety education to increase survival and safety skills. Replication of these case studies and controlled clinical trials are critical to validating the effectiveness of the multisystem treatment of firesetting.

Community-based intervention programs for juvenile firesetters and their families reflect the multisystem approach to the treatment of firesetting behavior. Juvenile firesetter intervention programs (JFIPs) typically are coordinated by the fire service in their local community and supported by technical assistance from the U.S. Fire Administration and other national and statewide fire service organizations ([Gaynor, 2000](#)). The primary goal of JFIPs is to create a community network of treatment options for juvenile firesetters and their families. JFIPs allow at-risk youth and their families access to a coordinated network of human service agencies, including the fire service, law enforcement, school programs, mental health, social services, and juvenile justice. The centerpiece of a JFIP is the ability to identify, screen, and evaluate the likelihood or risk that youth will become involved in future firesetting incidents. Once firesetting risk is determined, juveniles and their families can participate in a number of intervention options, including fire survival and safety education, organized youth groups, school programs, mental health services, human resource programs, and the rehabilitation and correction services of juvenile justice. There have been at least two reported attempts to evaluate the effectiveness of community-based programs, and results indicate that even minimal intervention may have a beneficial effect in reducing firesetting behavior over a long period ([Adler et al., 1994](#); [Kolko, 1996](#)). Clearly, more systematic program monitoring and evaluation is necessary to determine the impact and value of community-based intervention programs.

Several outpatient, inpatient, multisystem, and community-based treatment methods report preliminary success in treating firesetting youngsters. The selection of the best intervention strategy depends on maximizing the fit between an assessment of the severity of the firesetting and associated clinical features and the philosophies, modalities, and targets of behavior change emphasized by the treatment approaches. If clinical assessments reveal youngsters who are a significant danger to themselves or others and there is evidence of severe psychopathology, then inpatient treatment must be strongly considered. If the need for inpatient treatment can be ruled out, then an outpatient therapeutic modality becomes a viable intervention option. In general, the cognitive-emotion approach uses the graphing technique to effect changes in emotional functioning, behavior therapy uses a variety of methods to extinguish firestarting and in some cases replace it with more socially acceptable behaviors, and family psychotherapy works within the family structure to adjust role relationships and patterns of communication and interaction. Because of the complex interaction of individual, social, and environmental risk factors related to the development of pathologic firesetting behavior, multisystem and community-based intervention programs have surfaced as viable treatment options for juvenile firesetters and their families. Until more rigorous standards of scientific evaluation can be applied to study the relative effectiveness of these therapeutic approaches, clinical evidence stands to support the success of these intervention strategies.

## RESEARCH DIRECTIONS

To date, there have been limited systematic attempts to mount an organized research effort to describe empirically the prevalence of firesetting in youngsters, to quantify the clinical features associated with firesetting, or to test the relative effectiveness of specific psychotherapies in treating the problem. Most work in the field consists of clinical studies, with little attention paid to rigorous standards of scientific evaluation. The state of the art with respect to research is, at best, qualitative. There is a desperate need for an organized effort to quantify empirically the clinical data from which emerges the bulk of our information on firesetting youngsters. The major priorities for future research include prospective epidemiologic studies focused on the prevalence of unsupervised firestarting behavior in normal populations of children, and an estimate of the proportion of these children who later become involved in pathologic firesetting; an empirical comparison of the clinical features of firesetting youngsters compared with those youngsters diagnosed with other specific delinquent or antisocial behaviors; and a randomized clinical trial comparing the relative effectiveness of two or more therapeutic approaches in not only eliminating firesetting behavior but in alleviating the associated psychopathology that

accompanies this destructive behavior. If these research goals are achieved, then significant steps will have been taken to prevent the occurrence of pathologic firesetting behavior in future generations of our youth.

## DEFINITION

At a nascent cognitive level, gender identity has been defined as a child's recognition that he or she is a member of one sex but not of the other sex. Four decades ago, [Stoller \(1964\)](#) coined the term *core gender identity* to refer to the development of a "fundamental sense of belonging to one sex," the "awareness" that one is a male or female. At an affective level, this sense of belonging is emotionally valued, so that a child experiences a sense of comfort or security from being a boy or girl. A child's gender identity is often closely tied to the adoption of culturally sanctioned behavioral markers of masculinity or femininity (*gender roles*).

What does one observe in children and adolescents who are said to have gender identity disorder (GID)? The most common feature is a strong identification with, and preference for, the gender role characteristics of the other sex. This can be inferred from various age-related behavioral manifestations of gender identification, such as toy interests, fantasy role and activity preferences, peer affiliation preferences, and personality traits. Cross-gender identification is also expressed through verbal statements that one is, or would like to be, a member of the other sex. Moreover, children with GID often have few positive things to say about their own sex and appear to experience a sense of *gender dysphoria*, or unease, about being of the sex that they are. By adolescence, when the clinical picture more closely resembles what one observes in adults with GID, the pervasive sense of gender dysphoria becomes even more difficult to ignore or dismiss.

## HISTORICAL NOTE

In the 1950s, two clinical developments led to an increased interest in the study of children with potential problems in their gender identity development. First, [Money and associates' \(1957\)](#) research on children with various forms of physical intersex conditions showed that key milestones in gender identity formation occurred sometime between 18 and 36 months of age, if not earlier. It was observed that, despite an ambiguous sexual biology, children with physical hermaphroditism could develop a stable gender identity if they were reared unambiguously as members of one sex or the other ([Zucker, 1999](#)). Second, retrospective clinical reports on the adult syndrome of GID, commonly known as *transsexualism* ([Benjamin, 1954](#)), led to the recognition that the behavioral markers of this condition were often expressed during the first few years of life.

Forty years ago, [Green and Money \(1960\)](#) reported on a series of five boys without detectable physical or biological abnormality who displayed what was described as "incongruous" gender role behavior, a pattern that was incorporated 20 years later into the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) diagnosis gender identity disorder of childhood. Since this initial report, many studies of such children have been conducted, directed at, among other things, developing accurate diagnostic and assessment procedures, evaluating etiologic hypotheses, examining the effects of treatment, and tracking long-term development ([Green 1974, 1987; Zucker and Bradley, 1995; Zucker and Green, 1992](#)).

By the early 1980s, thinking about children with gender identity problems was being influenced by a third development. A series of studies on adult homosexuality, perhaps peaking with the volume by [Bell and colleagues \(1981\)](#), indicated that the presence of patterns of childhood cross-gender behavior was a strong developmental predictor of later homosexuality, which was later confirmed in a meta-analytic review by [Bailey and Zucker \(1995\)](#). Although efforts to treat homosexuality have declined substantially since 1973, when homosexuality per se was deleted from the DSM as a mental disorder, interest in the determinants of sexual orientation has continued. Indeed, in the 1990s, there was a renaissance in research on the origins of sexual orientation development ([Gladue, 1997](#)).

## EPIDEMIOLOGY

### Prevalence

No studies have formally assessed the prevalence of GID in children. It has been suggested, however, that conservative estimates of prevalence can be inferred from data regarding the prevalence of GID (transsexualism) in adults. Such data are based on the number of persons attending clinics that serve as gateways for surgical and hormonal sex reassignment. Because not all gender dysphoric adults make themselves known, this method may underestimate the prevalence of GID; in any case, the number of adult transsexuals is small—one recent estimate from the Netherlands suggests a prevalence of 1 in 11,000 men and 1 in 30,400 women ([Bakker et al., 1993](#)).

The prevalence of GID might also be derived from the literature on the epidemiology of homosexuality. Unfortunately, this literature presents two main problems. First, the true prevalence of exclusive, or near-exclusive, preferential homosexuality remains a source of debate ([Laumann et al., 1994; Wellings et al., 1994](#)); second, the retrospective literature on childhood cross-gender behavior in homosexual men and women often does not specify how to determine a cutoff score to dichotomize cases as cross-gendered versus not cross-gendered. In addition, cases classified as cross-gendered would not necessarily meet the complete diagnostic criteria for GID in the DSM-IV ([American Psychiatric Association, 2000; Friedman, 1988](#)).

More liberal estimates of prevalence can be judged from studies of children in whom specific cross-gender behaviors have been assessed. For example, the standardization study of the Child Behavior Checklist (CBCL) ([Achenbach and Edelbrock, 1981](#)), a widely used parent-report questionnaire of childhood behavioral psychopathology, included information on the percentage of mothers of both clinic-referred and nonreferred boys and girls who endorsed two items pertaining to cross-gender identification: "behaves like opposite sex" and "wishes to be of opposite sex." [Table 58.1](#) shows the percentage of mothers of nonreferred boys and girls, across the age range of 4 to 11 years, who endorsed these two items by giving ratings of either a 1 (somewhat or sometimes true) or a 2 (very true or often true) on a 0- to 2-point scale for frequency of occurrence. For both items, more mothers of girls gave ratings of either a 1 or a 2 than did mothers of boys; however, chi-square tests showed that the differences were significant only for the rating of a 1 for the item "behaves like the opposite sex."

Sex	Age Group (Years)									
	4	5	6	7	8	9	10	11	12	Total
Boys	41	40	33	40	23	20	40	00	00	23
	00	00	00	00	00	00	00	00	00	00
Girls	33	00	01	40	00	00	00	00	00	00
	41	00	00	00	00	00	00	00	00	00
Total	4	5	6	7	8	9	10	11	12	Total
	33	00	00	00	00	00	00	00	00	00
Total	00	00	00	00	00	00	00	00	00	00
	41	00	00	00	00	00	00	00	00	00
Total	00	00	00	00	00	00	00	00	00	00
	00	00	00	00	00	00	00	00	00	00

**Table 58.1. Percentage of Nonreferred Children Whose Mothers Endorsed Child Behavior Checklist Items Relevant to Cross-Gender Identification**

These findings suggest that there is a sex difference in the occurrence of mild displays of cross-gender behavior, but not with regard to more extreme cross-gender behavior. Indeed, in another analysis of these data, it was reported that none of these 398 boys were given ratings of a 2 on both items and only two of the 398 girls were rated in this way (Zucker and Bradley, 1995).

The main problem with such data is that they do not differentiate enduring patterns of cross-gender behavior from transient phenomena (Zucker, 1985). Accordingly, data of this kind would probably overestimate cases of GID, although the methods of data collection may be reasonable screening devices for more intensive evaluation (Lindsay, 1994; Pleak et al., 1989; Sandberg et al., 1993).

### Incidence

Has the incidence of GID changed over the past several decades? Unfortunately, the types of child epidemiologic data required to answer this question do not exist. Indirect sources of information are available, but they are difficult to employ. Consider, for example, the contemporary debate regarding the incidence of homosexual partner preference. Some authors maintain that the incidence is rather stable, whereas others hold that it has increased (Fay et al., 1989). If the former view is correct, then one might also expect a stable incidence of GID, of which some unspecified percentage of homosexual adults probably experienced in childhood (at least in muted form). If the latter view is correct, then one might expect to find a greater number of children experiencing symptoms of GID. Changes in patterns of child rearing with regard to gender role behavior are another indirect source of information on changes in the incidence of GID. Lothstein reported his clinical experience that mothers who had attempted to “masculinize” their daughters or “feminize” their sons in order to prepare them for “radically new social roles” did not produce “androgynous” children, as they had hoped, but rather children who evidenced a “stereotypical cross-gender role which was frightening to their parents” (Lothstein, 1983, p. 248). Whether parental efforts to shape children's gender role behavior in less conventional ways is inadvertently inducing GID has, in fact, not been well studied; therefore, no firm conclusions can be drawn as of yet.

### Sex Differences in Referral Rates

Consistently, it has been observed that boys are referred more often than girls for concerns regarding gender identity. This has been reflected in both research studies and case reports of treatment; for example, Zucker and colleagues (1997a) reported a referral ratio of 6.6:1 (N = 275) of boys to girls.

How might this disparity be best understood? One possibility is that the sex difference in referral rates reflects a true sex difference in prevalence. Another possibility is that social factors play a role in accounting for the disparity. For example, it is well established that parents, teachers, and peers are less tolerant of cross-gender behavior in boys than girls (Fagot, 1985), which might result in a sex-differential in clinical referral (Zucker and Bradley, 1995). Weisz and Weiss (1991) devised a “referability index” (RI) that reflected the frequency with which a child problem, adjusted for its prevalence in the general population, resulted in a clinic referral. All 118 items from the CBCL were analyzed in a comparison of clinic-referred and nonreferred children. Among parents in the United States, the 20 most referable problems (e.g., vandalism, poor schoolwork, attacks people) appeared to be relatively serious. In contrast, the 20 least referable problems (e.g., bragging, teases a lot, likes to be alone) appeared less so. Weiss (personal communication, March 4, 1992) indicated that, for boys, the CBCL item “wishes to be of opposite sex” had an RI of 91/118 (i.e., in the upper quartile) and “behaves like opposite sex” had an RI of 80/118. For girls, the RI was lower: 55/118 for “wishes to be of opposite sex” and 14/118 for “behaves like opposite sex.”

Weisz and Weiss' study (1991), along with studies from the normative literature, led to the prediction that referred girls would display more extreme cross-gender behavior than referred boys, which might account, therefore, at least in part, for the disparity by sex in referral rates. Zucker and colleagues (1997a) provided some data that supported this prediction, suggesting that girls may need to display more cross-gender behavior than boys before a referral is initiated. However, it is important to note that the sexes did not differ in the percentage who met the complete DSM criteria for GID; thus, there was no gross evidence for a sex difference in false positive referrals.

## CLINICAL DESCRIPTION

The initial behavioral signs of GID most typically appear during the toddler and preschool years (Green 1974, 1987), the years in which more conventional patterns of sex-typed behavior can also first be observed. In some cases, however, parents recall that such behaviors as cross-dressing began prior to the second birthday. The central clinical issue concerns the degree to which a pattern of behavioral signs is present, because this pattern is the basis for inference on the extent to which a child is cross-gender-identified.

In boys, the clinical picture, in its full form, includes at least eight characteristics: (a) an occasional or frequently stated desire to be a girl or an insistence that he is a girl; (b) verbal or behavioral expressions of “anatomic dysphoria” (e.g., saying that he does not like his penis and would prefer a vagina or vulva; urinating in the seated position to enhance the fantasy of having female genitalia); (c) frequent cross-dressing in girls' or women's clothing or use of other apparel (e.g., towels) to simulate feminine attire; (d) a preference for female roles in fantasy play and an avoidance of male roles in fantasy play; (e) a preference for stereotypical feminine toys and activities and an avoidance of stereotypical masculine toys and activities; (f) recurrent display of stereotypical feminine or effeminate mannerisms; (g) a preference for girls as playmates and an avoidance or dislike of boys as playmates; and (h) an avoidance of rough-and-tumble play and/or participation in group sports with males.

In girls, the clinical picture is similar. It includes: (a) an occasional or frequently stated desire to be a boy or an insistence that she is a boy; (b) verbal or behavioral expressions of anatomic dysphoria (e.g., stating a desire to have a penis; urinating in the standing position in order to enhance the fantasy of having male genitalia); (c) an intense aversion to wearing stereotypical feminine clothing and an insistence on wearing stereotypical masculine clothing; (d) a preference for male roles in fantasy play and an avoidance of female roles in fantasy play; (e) a preference for stereotypical masculine toys and activities and an avoidance of stereotypical feminine toys and activities; (f) recurrent display of stereotypical masculine mannerisms; (g) a preference for boys as playmates and an avoidance or dislike of girls as playmates; and (h) a strong interest in rough-and-tumble play and participation in group sports with boys.

During childhood, several developmental issues should be considered. One issue concerns the child's remarks about wanting to be of the other sex or insisting that he or she is a member of the other sex. Stoller (1968) argued that boys who literally believed that they were girls constituted an etiologically distinct subgroup within the universe of feminine boys and were most at risk for development as transsexuals. Subsequent clinical observations and empirical data suggest that Stoller's view is not entirely accurate. Relatively young boys who show multiple signs of cross-gender behavior, as was the case in Stoller's (1968) sample, are the ones most likely to misclassify themselves as girls (Zucker et al., 1993b, 1999b). It is not clear whether this subgroup is etiologically distinct. Developmentally, one would expect younger children to have more difficulty with regard to correct gender self-labeling, and this has been verified by empirical studies of normal children. Among children with GID, then, one would expect more difficulties with correct gender self-labeling to occur during the preschool years when the overall clinical picture is extreme and, perhaps, when there are rather severe problems in general psychosocial functioning. The most common clinical presentation is that of a child who knows what his or her sex is but desires to be the other sex (Zucker et al., 1993b).

A second developmental issue concerns variation in age-related markers of cross-gender identification. Some behaviors, such as cross-sex peer affiliation

preference, appear to remain stable throughout childhood; however, other behaviors, such as activity and role interests, may show important changes. Young boys, for example, who show a preoccupation with female dolls and role play as a mother are much less likely to play with female dolls (or, for that matter, with any dolls) or to role play female characters as they approach adolescence but may well continue to manifest feminine preoccupations, such as an intense interest in feminine fashion and idealization of female actresses or rock stars. The effeminate mannerisms of such boys may become more prominent. In addition, older children are less likely than younger children to verbalize the desire to change sex ([Zucker et al., 1984, 1998a](#)), although the persistence of gender dysphoria in these children may be expressed in other ways, such as devaluation of their own sex and idealization of the other sex.

A final developmental issue concerns the meaning of the desire to change sex during the childhood and adolescent years. That desire may be related to several factors in early childhood. For example, a child might reason that because he or she prefers cross-sex activities, it would make sense to become a person of the other sex. Or a child might believe that engaging in cross-sex activities actually changes his or her sex, a manifestation of the preoperational thinking that takes place prior to the achievement of *gender constancy*. Familial factors may also be important for young children who perceive that a parent would actually like them to be of the other sex (or some subtle variation of this communication). Thus, it is highly unlikely that young children conceptualize the wish to change sex in the same manner as adolescents.

## ETIOLOGY AND PATHOGENESIS

### Biological Mechanisms and Hypotheses

Children with GID invariably do not show signs of a gross physical intersex condition, which would rule out a marked prenatal hormonal anomaly ([Meyer-Bahlburg, 1994, 1998](#)). Thus, the search for biological influences on the development of GID must focus on factors that do not affect the configuration of the external genitalia.

#### ACTIVITY LEVEL

Activity level (AL) is a commonly accepted dimension of temperament, with some evidence for a genetic basis ([Saudino and Eaton, 1991](#); [Willerman, 1973](#)) and possibly prenatal hormonal influences ([Ehrhardt and Baker, 1974](#)). Regarding children with GID, AL as a predisposing factor is a promising possibility, because it shows a rather strong sex difference, with boys having a higher AL than girls ([Campbell and Eaton, 1999](#); [Eaton and Enns, 1986](#)). Rough-and-tumble (RT) play, another sex-dimorphic behavior, bears some similarity to AL, in that it is often characterized by high energy expenditure; however, a distinguishing feature of RT is that it is a social-interactive behavior involving such sequences as “play fighting” and “chasing.” Unlike AL, marked avoidance of RT is one of the defining features of GID for boys in the DSM-IV ([Green 1974, 1987](#)).

Using parent-report measures of AL, two studies found that boys with GID had a lower AL than control boys ([Bates et al., 1979](#); Zucker and Bradley, 1995). [Zucker and Bradley \(1995\)](#) also found that girls with GID had a higher AL than control girls; indeed, the girls with GID had a higher AL than the boys with GID, whereas for the controls, the typical sex difference was observed. It is possible, therefore, that a sex-atypical AL is a temperamental factor that predisposes to the development of GID. For example, a low-active boy with GID may find the typical play behavior of other boys to be incompatible with his own behavioral style ([Ruble and Martin, 1998](#)), which might make it difficult for him to integrate successfully into a male peer group.

Perhaps these within-sex variations in AL are related to variations in patterns of prenatal hormonal secretion and converge with recent studies in the experimental animal literature. For example, among female rhesus monkey offspring, it has been possible, by varying the timing of exogenous administration of hormones during the pregnancy, to alter the normal patterning of sex-dimorphic behavior, but to keep normal genital differentiation intact ([Goy et al., 1988](#)). This animal model—which shows a *dissociation* between sex-dimorphic behavioral differentiation and genital differentiation—has the most direct relevance for explaining the marked cross-gender behavior of children with GID.

#### BIRTHWEIGHT

On average, males weigh more than females at birth ([Arbuckle et al., 1993](#)). There are, of course, many factors that influence variations in birthweight (BW). One hypothesized factor is the sex difference in prenatal exposure to androgens. In one study, girls with congenital adrenal hyperplasia (CAH) had a higher mean BW than unaffected girls ([Qazi and Thompson, 1971](#)). In another study, genetic males with the complete form of the androgen insensitivity syndrome were comparable in BW to that of genetic females ([de Zegher et al., 1998](#)).

[Zucker and associates \(1999a\)](#) compared the BWs of boys with GID and clinical control boys and girls. The clinical controls showed the expected sex difference in BW, with an effect size of 0.29 (Cohen's  $d$ ). The boys with GID had a significantly lower BW than the clinical control boys ( $d = 0.18$ ), but did not differ significantly from the clinical control girls. Although it is not clear what factor or set of factors account for the proband-control difference in BW, the results are consistent with the possible role of prenatal hypoandrogenization among the GID probands.

#### HANDEDNESS

Slightly more males than females show a preference for using the left-hand in unimanual behavioral tasks, such as writing. There is no established consensus for understanding the basis of this sex difference. Genetic factors clearly play a role in determining hand preference. Another line of research implicates adverse prenatal and/or perinatal events that result in an elevation in left-handedness above the approximate gold standard of 10% in the general population.

[Zucker and coworkers \(2001\)](#) found that boys with GID ( $N = 205$ ) had a significantly elevated rate of left-handedness (19.5%) when compared to three separate quasi-epidemiologic samples of boys (11.8%, total  $N = 13,253$ ) and with a diagnostically heterogeneous sample of clinical control boys (8.3%,  $N = 205$ ). This finding parallels studies of adult males with GID, who also appear to have an elevated rate of left-handedness ([Herman-Jeglinska et al., 1997](#)), as well as studies of adult men with a homosexual sexual orientation ([Lalumière et al., 2000](#)). At present, the explanation for the elevation remains unclear, but candidate factors have centered on some type of perturbation in prenatal development that, in some way, affects sex-dimorphic behavioral differentiation.

#### SIBLING SEX RATIO AND BIRTH ORDER

Boys with GID have an excess of brothers to sisters (sibling sex ratio) and have a later birth order ([Blanchard et al., 1995](#); [Zucker et al., 1997b](#)). Some additional evidence shows that boys with GID are born later primarily in relation to the number of older brothers, but not sisters. In the Blanchard and colleagues study, clinical control boys showed no evidence for an altered sibling sex ratio or a late birth order. These findings mesh nicely with studies of adult males with GID and who have a homosexual sexual orientation, who also have an excess of brothers to sisters and a later birth order ([Blanchard and Sheridan, 1992](#); [Blanchard et al., 1996](#); [Green, 2000](#)). One study on birth order in girls with GID showed that they had an early birth order as compared to clinical control girls ([Zucker et al., 1998b](#)).

One biological explanation to account for the results in males pertains to maternal immune reactions during pregnancy. The male fetus is experienced by the mother as more “foreign” (antigenic) than the female fetus. Based on studies with lower animals, it has been suggested that one consequence of this is that the mother produces antibodies that have the consequence of demasculinizing or feminizing the male fetus, but no corresponding masculinizing or defeminizing of the female fetus ([Blanchard and Klassen, 1997](#); [Green, 2000](#)). This model would predict that males born later in a sibling might be more affected, since the mother's antigenicity increases with each successive male pregnancy, which is consistent with the empirical evidence on sibling sex ratio and birth order among GID probands. At present, however, this proposed mechanism has not been formally tested in humans.

#### PHYSICAL APPEARANCE

The influence of physical appearance, including attractiveness, on social perception and interaction has been widely studied by social psychologists. In a clinical study of several very feminine boys, [Stoller \(1975\)](#) made this serendipitous observation about their physical appearance: “We have noticed that they often have pretty faces, with fine hair, lovely complexions, graceful movements, and—especially—big, piercing, liquid eyes” (p. 43).

[Green \(1987](#); [Green et al., 1985](#); [Roberts et al., 1987](#)) systematically studied physical attractiveness in a sample of GID boys and a male control group. At the time of assessment, the parents were asked to describe the faces of their infant sons. Masked ratings of audiotaped interviews showed that the parents of the GID boys were more likely than the parents of the controls to describe their sons during infancy as “beautiful” and “feminine.” The parents of the GID boys were also more likely to

recall that strangers commented, "He would make a beautiful girl." Retrospective distortion, however, could have operated in this situation. [Zucker and associates \(1993c\)](#) provided some data that were consistent with these parental recollections. University students, masked to group status, rated the attractiveness of boys with GID and clinical control boys from photographs taken at the time of clinical assessment. Boys with GID were judged to be significantly more attractive, beautiful, cute, handsome, and pretty than were the control subjects. In another study, girls with GID were judged to be significantly less attractive, beautiful, cute, and pretty than were clinical and normal control girls ([Fridell et al., 1996](#)). In a third study, boys with GID were judged to be significantly less "all-boy," masculine, and rugged than control boys, whereas girls with GID were judged to be significantly more masculine, rugged, and tomboyish in appearance than control girls ([McDermid et al., 1998](#)).

It should be noted that attractiveness need not be conceptualized as a fixed biophysical trait—social shaping of physical appearance is clearly possible. Clinical observations suggest that some parents subtly alter the physical appearance of children with GID so as to induce a "feminine" look in boys and a "masculine" look in girls. Moreover, some of the children themselves insist on altering their physical appearance. For example, some girls with GID insist on cutting their hair short and wearing clothing that will enable them to pass successfully as boys. Physical appearance, then, may be a predisposing factor in the development of GID, may serve to perpetuate the disorder, or may simply be one of the disorder's clinical signs.

### Psychosocial Mechanisms and Hypotheses

Psychosocial factors, to truly merit causal status, must be shown to influence the emergence of marked cross-gender behavior in the first few years of life. Otherwise, such factors would be better conceptualized as perpetuating rather than predisposing.

#### SEX ASSIGNMENT AT BIRTH

Because most children with GID do not have a co-occurring physical intersex condition, sex assignment at birth is invariably in accordance with the external markers of biological sex. In some physical intersex conditions, sex assignment is delayed and, on occasion, changed from the initial sex assignment. It has been argued that prolonged delay or uncertainty about the child's "true" sex can contribute to gender identity conflict in affected individuals ([Meyer-Bahlburg et al., 1996](#); [Money et al., 1957](#)). This does not, however, appear to be the situation for children with GID.

#### PRENATAL GENDER PREFERENCE

It is common for parents to express a prenatal gender preference. Other things being equal, parents will have a child of the nonpreferred sex about 50% of the time. Are parents of children with GID more likely than control parents to report having had a desire for a child of the opposite sex? The simple answer appears to be no, at least with regard to the mothers of boys with GID ([Zucker et al., 1994](#)). We did find, however, that the maternal wish for a girl was significantly associated with the sex composition and birth order of the sibship. Among the GID boys with only older brothers, the percentage of mothers who recalled a desire for a daughter was significantly higher than among the probands with other sibship combinations; however, the same pattern was observed in a control group ([Zucker et al., 1994](#)).

#### SOCIAL REINFORCEMENT OF CROSS-GENDER BEHAVIOR

Understanding the role of parent socialization in the genesis and/or perpetuation of GID (e.g., via reinforcement principles or modeling) has been influenced by the normative developmental literature on sex-dimorphic sex-typed behavior ([Ruble and Martin, 1998](#)). It has also been influenced by the seminal observations of [Money and colleagues \(1957\)](#) that the rearing environment was the predominant determinant of gender identity in children with physical intersex conditions.

It should be recognized that some critics are quite skeptical of the role of parent socialization in inducing sex differences in sex-typed behavior among ordinary children ([Lytton and Romney, 1991](#)) or within-sex variations. In recent years, the importance of the rearing environment has also been questioned within the literature on physical intersex conditions ([Zucker, 1999](#)). This literature has recently been discussed in relation to the long-term gender identity outcome of a normal boy, whose penis was accidentally ablated during a routine circumcision at 7 months, and subsequently reassigned as a girl around the age of 2. The patient apparently differentiated and maintained a female gender identity through at least age 9 years ([Money, 1975](#)). Longer-term follow-up, however, revealed that the patient reverted to living as a male in early adolescence ([Diamond and Sigmundson, 1997](#)), which has been interpreted by some to indicate a much stronger role for biological rather than psychosocial influences on gender identity differentiation. However, critics have pointed out that there are alternative interpretations to this case ([Meyer-Bahlburg, 1999](#)). Moreover, in another case of ablatio penis, in which a gender-reassignment to female occurred at 7 months, the patient's gender identity was judged to be unequivocally female at age 26 ([Bradley et al., 1998](#)). The literature on GID must be appraised against this backdrop of competing views on the role of socialization.

Clinicians of diverse theoretical persuasions have consistently reported that the parental response to early cross-gender behavior in children with GID is typically neutral (tolerance) or even encouraging ([Zucker and Bradley, 1995](#)). Regarding boys with GID, Green assessed parental recall of such responses taken from clinical and structured interviews at the time of assessment and concluded that "what comes closest so far to being a *necessary* variable is that, as any feminine behavior begins to emerge, there is *no* discouragement of that behavior by the child's principal caretaker" ([Green, 1974](#), p. 238, italics in original; [Green 1987](#); [Roberts et al., 1987](#)). In a structured interview study, [Mitchell \(1991\)](#) found that mothers of GID boys were more likely to tolerate or encourage feminine behaviors and less likely to encourage masculine behaviors than were the mothers of both clinical and normal control boys. The following vignette with parents of a 4-year-old boy is illustrative:

- Interviewer: What is the first memory that you have of Eric's interest in "girls' things?"  
(I):  
Mother (M): Well, when he was about 2, he started to wear my shoes. He would wear them every day.  
I: What did you think about that?  
M: I thought it was cute, the way he was clumping around in them.  
I: What about you (to father)?  
Father (F): I wasn't around much, working and all, so I didn't see much of it. She (his wife) told me about it, and I said that I didn't like it, but what can you do?  
I: What happened after that?  
M: Well, then he got interested in my dresses (laughs), and he looked so cute, running around in the heels and my long dress. We even took pictures of him like that.  
F: Yeah, right.  
I: Anything else?  
M: When I took him to the toddler group, he went immediately over to the girls and he got into the Barbie dolls. He seemed obsessed with their hair and we wound up buying him three or four of them. His favorite one is the Barbie with roller-blades. I asked his doctor about it when he was 3, and the doctor said that it was a phase and that he would grow out of it.  
F: Yeah, and then he was pretending that he was a girl all the time and said that he would grow up and be a mommy. And then he said that he wanted to cut off his penis.  
I: What happened when he said that?  
M: Well, that's why we're here. I'm getting worried that he won't grow out of it ... it's getting worse.  
I: Before he said that he wanted to cut off his penis, how do you think you have reacted to his interest in the girls' things over the past couple of years?  
M: Well, I've pretty well let him do what he wants, and, anyways, the doctor told me not to worry. I thought that if he played with the Barbies, maybe he'd be a good father, but he doesn't want to be the father; he's only pretending to be me.  
F: Yeah, I'm getting more worried myself, but my wife told me not to be so worried, and, well, you know, she's kind of the boss when it comes to raising the kids.

Of course, the limitations of this kind of interview data need to be recognized. Nonetheless, one aspect of these data deserves special comment. As noted, clinicians of diverse theoretical persuasions have observed the apparent tolerance, or even encouragement, of feminine behavior shown by parents of boys with GID. However, the fact that these parents have sought out a clinical assessment usually means that they are now concerned about their child's gender identity development ([Zucker, 2000](#)). From the standpoint of attribution theory ([Weiner, 1993](#)), one might predict that parents would minimize their encouragement or tolerance of cross-gender behavior, since it has such an obvious bearing on "causality." Yet a majority of the parents whom we have assessed do not recall systematic efforts to limit or redirect

their child's cross-gender behavior, particularly during the initial period of symptom onset and for various periods of time thereafter.

The reasons why parents might tolerate, if not encourage, early cross-gender behaviors appear to be quite diverse, suggesting that the antecedents to this "end state" are multiple in origin. As noted earlier, for example, some parents report being influenced by ideas regarding non-sexist child rearing. In other parents, the antecedents seem to be rooted in pervasive conflict that revolves around gender issues. For example, a small subgroup of mothers (about 10%) of boys with GID appear to experience something akin to what we have termed *pathologic gender mourning* (Zucker, 1996). During the pregnancy, there is a strong desire for a girl [in all of the cases, the mother had already borne at least one other son, but no daughter—except in three instances in which the daughter was given up for adoption (one case) or had died in infancy (two cases)]. After the birth of the "nonpreferred" son, this wish seems to color strongly the mother's perception and relationship with her newborn, and there are strong signs of ambivalence about his gender status. Zucker (1996) identified at least 10 possible signs of pathologic gender mourning, including severe postpartum depression related to the birth of a son, recurrent night dreams about being pregnant with a girl, delayed naming, and active cross-dressing of the boy (Zucker and Bradley 1995, 2000; Zucker et al., 1993a). The most common psychological trait associated with the strong wish for a daughter appears to be the need to nurture and be nurtured by a female child, which often reflects compensatory needs originating in childhood (Gibson, 1998).

#### PARENT-CHILD RELATIONSHIPS

Apart from attempts to examine the specific interactions that occur during the initial display of sex-dimorphic behavior, attempts have been made to examine the general quality of the relationships between gender-disturbed children and their parents.

In the case of boys, Stoller (1968, 1975, 1985) observed clinically an overly close relationship between mother and son and a distant, peripheral father-son relationship. He presented his hypothesis simply: "The more mother and the less father, the more femininity" (Stoller, 1985, p. 25). Stoller (1985) argued that GID in boys is a kind of "developmental arrest ... in which an excessively close and gratifying mother-infant symbiosis, undisturbed by father's presence, prevents a boy from adequately separating himself psychically from his mother's female body and feminine behavior" (p. 25). In several respects, Stoller's notions point to the crucial role of preoedipal events in the development of GID, a view that is shared by many other contemporary psychoanalytic clinicians and theorists.

Green (1987; Green et al., 1985; Roberts et al., 1987) had the parents of feminine boys and control boys rate the amount of "shared time" with their sons during the first 5 years of life. Contrary to prediction, the mothers of feminine boys recalled spending less time with their sons compared with the amount of time the mothers of control subjects remembered spending. Consistent with prediction, the fathers of feminine boys recalled spending less time with their sons from the second to fifth year compared with the amount of time the fathers of control subjects remembered and the father's shared time with masculine male siblings. Thus, this method of assessing parent-son relationships confirmed the paternal side of the equation but yielded results opposite from prediction for the maternal side. Thus, at least with regard to the mother, the quality of the mother-child interaction may have been more important than the sheer amount of time that mother and child spent together.

Despite Green's (1974, 1987) finding regarding shared time, there is little question that boys with GID feel closer to their mothers than to their fathers. In part, this may be a function of a boy's perception of similarity to the mother, but it also evolves from the day-to-day subtleties of parent-child interaction.

Unfortunately, no systematic studies on parent-child relationships have been conducted for girls with GID. Preliminary clinical studies suggest that for such girls the mother-daughter relationship is often impaired, leading to what might be described as a "disidentification" from the mother (Green, 1974; Stoller, 1975; Zucker and Bradley, 1995). During the early years of these girls, a variety of factors appear to impair the development of a close mother-daughter relationship; as a result, there is a devaluing of femininity and an overvaluing of masculinity, outcomes that the parents seem to encourage. These preliminary clinical studies suggest, therefore, that the quality of parent-child relationships in gender-disturbed boys is quite different from that in gender-disturbed girls.

#### GENERAL PSYCHOPATHOLOGY

The role of maternal psychopathology in the genesis and perpetuation of GID has received a great deal of clinical and theoretical attention but, unfortunately, only limited empirical evaluation. At the outset, it should be noted that the available empirical studies have been delimited to the mothers of boys with GID—comparable studies are not available regarding the mothers of girls with GID (Zucker and Bradley, 1995).

Marantz and Coates (1991) found that the mothers of boys with GID showed more signs of psychopathology than did the mothers of demographically matched normal boys, including more pathologic ratings on the Diagnostic Interview for Borderlines and more symptoms of depression on the Beck Depression Inventory.

Over the past several years, the author has collected systematic data on maternal psychopathology and marital discord, some of which was reported by Mitchell (1991) and Zucker and Bradley (1995). To date, the data show that, on average, mothers of boys with GID have levels of emotional distress and psychiatric impairment comparable to that of clinical control mothers, but higher than that of normal control mothers. There was not, however, a between-group difference on a measure of marital discord.

On one measure—the Symptom Checklist 90-Revised—mothers of GID boys had higher scores on most of the subscales and the composites than did the mothers of the normal control boys, whereas the scores of the clinical control mothers fell in between the two other groups. The GID mothers had peak scores on the obsessive-compulsive, depression, and hostility subscales. On another measure, the Diagnostic Interview Schedule (DIS), 30% of the mothers (total  $N = 140$ ) had two DIS diagnoses, and 24% had three or more DIS diagnoses. The most common diagnoses were major depressive episode (39.6%) and recurrent major depression (32.1%). Overall, the rate of psychiatric impairment appears to be higher than our available data on mothers of both the clinical control and normal boys. Because more control group mother data are required, these results should, of course, be viewed cautiously. Nonetheless, it is apparent by reference to epidemiologic data that, on average, mothers of GID boys have a history of elevated psychiatric disorder.

The emerging data on emotional distress and psychiatric impairment in the mothers of boys with GID indicate that it is more common than in the mothers of normal control boys and at least comparable to the mothers of clinical control boys. Still we are left with the problem of specificity (Garber and Hollon, 1991), in that these maternal characteristics are not unique to the mothers of GID boys, but common to the mothers of clinic-referred boys in general. Accordingly, maternal emotional distress/impairment functions, at best, only as a nonspecific risk factor in the development of GID. If the mother's emotional state truly is involved in the genesis of GID, then there should be evidence of psychiatric impairment prior to and during the emergence of the child's symptoms. The data are suggestive that this is the case, and that the presence of emotional difficulties in the mothers is not simply a reaction to having a child with GID (Zucker and Bradley 1995).

Coates and her colleagues have argued that the presence of psychopathology renders the mothers emotionally unavailable, which results in anxiety and insecurity in the son, and that it is this state of affairs that is partly responsible for symptom onset. Indeed, Coates and Person (1985) advanced a very specific hypothesis, namely that the erratic and uneven emotional availability of the mothers activated separation anxiety in the boys, which, in turn, activated the symptoms of GID: "In imitating 'Mommy' [the boy] confuse[s] 'being Mommy' with 'having Mommy.' [Cross-gender behavior] appears to allay, in part, the anxiety generated by the loss of the mother" (Coates and Person, 1985, p. 708). Indeed, boys with GID appear to have high rates of separation anxiety traits, as judged by maternal report on a structured interview schedule (Zucker et al., 1996) and their own responses on the Separation Anxiety Test (Birkenfeld-Adams, 1999).

The possible role of separation anxiety in the genesis of GID raises more general questions about the quality of the mother-son relationship. Over the past few years, the author's group has studied the quality of attachment to the mother among young boys and girls with GID (ages 3 to 6). Among a sample of 22 boys, Birkenfeld-Adams (1999) found that the majority (73%) were classified as insecurely attached, a rate comparable to that of an internal clinical control group and of other studies of clinical populations (Greenberg et al., 1991).

Because insecure attachments and separation anxiety are likely nonspecific risk factors (i.e., many boys who have these qualities do not have GID), the crucial question that remains is why only a small minority of boys develop the "fantasy solution" of wanting to be a girl. Various predisposing factors have been implicated, including temperamental characteristics of the child, the premorbid relationship with the mother, the position of the father in the family system, that the family psychopathology must occur during the putative sensitive period for gender identity formation (Money et al., 1957), and so on. At present, however, the question of specificity remains unanswered in any satisfactory manner.

One possible mediating variable might be the importance of the child's gender to the mother or her attitudes toward men and masculinity in general. In this regard, pathologic gender mourning, as discussed earlier, may be a potential prototype. As noted, pathologic gender mourning appears to be part of the family history in only a small minority of cases; thus, other pathways are required to account for the role of maternal impairment in the genesis of GID.

It appears therefore that there are diverse pathways that lead to how parents respond to the child's early cross-gender behavior (either by encouraging or tolerating it). Thus, from a clinical and therapeutic point of view, it is important to identify the putative motivations with regard to the selective reinforcement of sex-typed behaviors.

The role of paternal influences in the genesis and perpetuation of GID has also received a great deal of clinical and theoretical attention but, again, only limited empirical evaluation, which has been delimited to the fathers of boys with GID.

One account implicates the father's role by virtue of his absence from the family matrix. Across 10 samples of boys with GID, the rate of father absence (e.g., owing to separation or divorce) was 34.5% ([Zucker and Bradley, 1995](#)). It is unlikely, however, that this rate would differ significantly from the rate found in clinical populations in general, if not the general population. [Green \(1987\)](#) found that paternal separations occurred earlier in the families of GID boys than normal control boys; therefore, it is possible that timing is an additional variable to consider. [Green \(1987\)](#) also found that the fathers of GID boys (both father-present and father-absent) recalled spending less time with their sons than did the fathers of control boys during the second year of life, years 3 to 5, and at the time of assessment. The inclusion of a clinical control group would be helpful in gauging the specificity of this finding.

Unfortunately, there is little in the way of systematic research on paternal psychopathology. [Wolfe \(1990\)](#) conducted a small but detailed study of 12 fathers, predominantly of an upper middle-class background, of boys with GID. On the Structured Clinical Interview for DSM-III, all of the fathers received an Axis I diagnosis for either a current or past disorder (most frequently substance abuse and depression) and eight also received at least one Axis II diagnosis. Unpublished DIS data from the author's clinic on 90 fathers indicate that alcohol abuse (22.2%) has been the most common diagnosis. This percentage may underestimate the prevalence of alcohol abuse in fathers of GID boys because we were not able to interview a substantial number of fathers who were no longer part of the family matrix. On the other hand, it should be noted that about half the fathers who were interviewed did not meet criteria for any DIS diagnosis. Whatever the exact patterning of paternal emotional functioning proves to be, the same issues of interpretation discussed earlier regarding mothers apply.

## LABORATORY STUDIES

### Biological Assessment

There are no known biomedical tests that can identify children with GID. As noted, various parameters of biological sex, such as the sex chromosomes and the appearance of the external genitalia, are invariably normal ([Green, 1976](#)). As noted in the section on differential diagnosis, children with certain physical intersex conditions may be at some risk for gender dysphoria. For these youngsters, pediatric endocrinologic and urologic or gynecologic evaluations are warranted, because certain biomedical treatments may be required; however, it is rare that such conditions have not already been identified prior to psychiatric evaluations.

### Psychological Assessment

A number of parent-report and behavioral measures can be used to assess sex-typed behavior in children with GID ([Green, 1974](#); [Zucker, 1992](#); [Zucker and Bradley, 1995](#)). From a diagnostic standpoint, it should be recognized that no one test is a replacement for a diagnosis that is established by a clinical interview that covers the behavioral signs for GID. Nevertheless, these measures have strong discriminant validity and constitute one strong line of evidence that GID is, in fact, a distinct syndrome. [Green \(1987\)](#), for example, found that a discriminant function analysis of parent interview data required 6 of 16 sex-typed behaviors to classify correctly all boys as members of either the group of boys with GID or the control group of boys. As reviewed elsewhere, data from psychological tests, in general, show a consistent pattern in that the percentage of false negatives appears to be higher than the percentage of false positives ([Zucker, 1992](#); [Zucker and Bradley, 1995](#)).

## DIFFERENTIAL DIAGNOSIS

### Childhood Diagnostic Issues

During childhood, several differential diagnostic issues should be considered in relation to GID. There is a type of cross-dressing in boys that appears to be qualitatively different from the type of cross-dressing that characterizes GID. In the latter, cross-dressing typically involves outerwear, such as dresses, shoes, and jewelry, that helps enhance the fantasy of being like the other sex. In the former, cross-dressing involves the use of undergarments (e.g., panties and nylons). Clinical data show that other signs of cross-gender identification do not accompany such cross-dressing; in fact, the appearance and behavior of boys who engage in it are conventionally masculine. Clinical experience suggests that this type of cross-dressing has some sort of self-soothing function. Many male adolescents and adults who display transvestic fetishism recall such cross-dressing during childhood ([Zucker and Blanchard, 1997](#)). It should be noted, however, that prospective study has not verified the assumption that this behavior pattern is contiguous with later transvestism.

When all the clinical signs of GID are present, it is not difficult to make the diagnosis. But the clinician who accepts the notion that there is a spectrum of cross-gender identification must be prepared to identify what Meyer-Bahlburg described as the "zone of transition between clinically significant cross-gender behavior and mere statistical deviations from the gender norm" ([Meyer-Bahlburg, 1985](#), p. 682). Clinical experience suggests that boys who fall into this ambiguous zone do poorly in male peer groups, avoid rough-and-tumble play, are disinclined toward athletics and other conventionally masculine activities, and feel somewhat uncomfortable about being male; however, these boys do not wish to be girls and do not show an intense preoccupation with femininity. [Friedman \(1988\)](#) coined the term *juvenile unmasculinity* to describe such boys, who, he argued, suffer from a "persistent, profound feeling of masculine inadequacy which leads to negative valuing of the self" (p. 199). It is not clear whether this behavior pattern actually constitutes a distinct syndrome or is simply a mild form of GID; in any case, the residual diagnosis gender identity disorder not otherwise specified (GIDNOS) could be employed in such cases.

In girls, the primary differential diagnostic issue concerns the distinction between girls with GID and tomboys. The study of a community sample of tomboys by [Green and colleagues \(1982\)](#) showed that these girls shared a number of the cross-gender traits observed in clinic-referred gender-disturbed girls ([Zucker and Bradley, 1995](#)). In part, the DSM-III-R criteria for GID in girls were modified in the hope of better differentiating these two groups of girls ([Zucker, 1982](#)). At least three characteristics may be most useful in making the differential diagnosis: (a) By definition, girls with GID indicate an intense unhappiness with their status as females, whereas this should not be the case for tomboys; (b) girls with GID display an intense aversion to the wearing of culturally defined feminine clothing under any circumstances, whereas tomboys do not manifest this reaction, although they may prefer to wear casual clothing, such as jeans; and (c) girls with GID, unlike tomboys, manifest a verbalized or acted-out discomfort with sexual anatomy.

The final differential diagnostic issue concerns children with physical intersex conditions. In DSM-III, an intersex condition was an exclusion criterion for the adult diagnosis of transsexualism, but this criterion was eliminated in DSM-III-R. The DSM-III-R did not formally address the issue of whether children who display significant cross-gender identification and have an intersex condition should be given a diagnosis such as GID. Consider, for example, girls with CAH, in which there is excessive prenatal exposure to androgens. On average, these girls display more masculine behavior than do nonaffected girls ([Berenbaum and Hines, 1992](#)). A small percentage of these girls also appear to be gender dysphoric ([Zucker, 1999](#)). The phenomenology in these cases appears similar to that observed in physically normal girls with GID, but the etiology may well be different ([Meyer-Bahlburg, 1994](#)). Thus, there may be a risk in applying the same diagnosis as that used with physically normal children. On the other hand, the risk is reduced if it is recognized that a particular diagnosis does not dictate identical treatment across cases. The DSM-IV Subcommittee on Gender Identity Disorders debated these issues ([Bradley et al., 1991](#); [Meyer-Bahlburg, 1994](#)). The final decision was to not diagnose GID in children or adults with a co-occurring physical intersex condition.

### Adolescent Diagnostic Issues

During adolescence, the clinician is likely to encounter at least four types of psychosexual problems ([Sullivan et al., 1995](#); [Zucker and Bradley, 1995](#)). Children with an unresolved GID are at risk for seeking hormonal and surgical solutions to their distress. The DSM-IV criteria for GID for adolescents or adults emphasize the persistence of cross-gender identification and discomfort with one's assigned sex, including the desire for hormonal or surgical sex-reassignment. Diagnostically, it is important to assess the strength and persistence of the desire to change sex, because clinical management decisions are influenced by the relative intractability of the condition. The residual diagnosis GIDNOS can be used for clinically gender dysphoric individuals who do not meet the complete diagnostic criteria for GID.

A second type of psychosexual problem occurs among adolescents who have had a history of GID or a variation of it. These adolescents continue to show signs of cross-gender identification but do not acknowledge a homosexual orientation or profess a desire to change sex. They are often referred because of continued social ostracism. The degree of felt distress varies with regard to the continued cross-gender identification. It is unlikely that any formal DSM-IV diagnosis would apply in

such cases, although the residual diagnosis GIDNOS could be employed to indicate that the adolescent continues to struggle with gender identity issues.

A third type of psychosexual problem characterizes adolescents who have been referred by either themselves or by significant others because of homosexual behavior or orientation. Some of these youngsters have a history of GID or a variation of it. The reason for referral varies, but from a differential diagnostic standpoint it is important to rule out continuing problems that center on gender identity. For those youngsters who are distressed about their sexual orientation, the diagnosis of sexual disorder NOS can be given.

The last type of psychosexual problem concerns adolescent boys who cross-dress, in part, for the purpose of sexual arousal. The extent of the cross-dressing varies. In its full form, the diagnosis of transvestic fetishism can be applied. These boys appear to have a nascent heterosexual orientation and appear unremarkably masculine in their demeanor. A history of GID is not part of the clinical picture, but some of these boys think about sex-reassignment surgery and are at risk for transsexualism. In DSM-IV, adolescents who meet the criteria for GID with this type of developmental history typically have a heterosexual sexual orientation.

## TREATMENT

Several therapeutic approaches have been employed to treat children with GID, including behavior therapy, psychotherapy, family therapy, parental counseling, group therapy, and eclectic combinations of these strategies ([Green 1974, 1987](#); [Zucker 1985, 1990](#); [Zucker and Green, 1989](#)). As reviewed elsewhere ([Zucker, 1985](#); [Zucker and Green, 1989](#)), all of these strategies appear to have clinical utility; unfortunately, formal comparative studies have not been conducted; therefore, the most efficacious types of treatment remain unclear. (For specific references to the case report literature, see [Zucker, 2001](#); [Zucker and Bradley, 1995](#).)

Three general comments about treatment of GID will be made. First, clinical experience suggests that intervention can more readily reduce gender identity conflict during childhood than adolescence. The prognosis for reducing severe gender dysphoria after puberty is rather poor. Accordingly, the earlier treatment begins the better. Second, the importance of working with the parents of children with GID has been much discussed in the literature. When there is a great deal of marital discord and parental psychopathology, treatment of these problems greatly facilitates more specific work on gender identity issues. Management of the child's gender behavior in his or her daily environment requires that the parents have clear goals and a forum in which to discuss difficulties. Because parental dynamics and ambivalence about treatment may contribute to the perpetuation of GID ([Newman, 1976](#)), it is important for the therapist to have an appropriate relationship with the parents in order to address and work through these issues. Last, the therapist needs to consider closely the goals of treatment ([Coates and Zucker, 1988](#); [Green 1974, 1987](#); [Zucker 1985, 1990, 2001](#); [Zucker and Green, 1989](#)). In part, this issue is conceptualized within the therapist's theoretical framework, but is also a function of the parents' concern and, to some extent, of the child's concerns. Two short-term goals have been discussed in the clinical literature: The reduction or elimination of social ostracism and conflict and the alleviation of underlying or associated psychopathology. Longer-term goals have focused on the prevention of postpubertal gender dysphoria and homosexuality. Little disagreement about the advisability of preventing gender dysphoria in adolescence or adulthood has been expressed in the clinical literature. Contemporary and secular-minded clinicians are, however, sensitive to the importance of helping people integrate a homosexual sexual orientation into their sense of identity ([Friedman, 1988](#); [Green, 1987](#)). Not surprisingly, however, most parents of children with GID probably prefer the development of a heterosexual orientation. It is, therefore, important that clinicians point out to such parents that, as of yet, there is no strong evidence that treatment affects later sexual orientation. The author, as well as other experienced clinicians in the field, has preferred to emphasize the merit of reducing childhood gender identity conflict per se and, when it is present, associated behavioral problems, and to orient the parents of children with GID to the short-term goals of intervention.

## OUTCOME AND FOLLOW-UP DATA

[Green \(1987\)](#) has conducted the most comprehensive long-term follow-up study of boys with GID. An original sample of 66 feminine and 56 control boys was assessed initially at a mean age of 7.1 years (range, 4 to 12), and about two-thirds of the boys in each of these groups were reevaluated at a follow-up mean age of 18.9 years (range, 14 to 24). A semistructured interview was employed to assess sexual orientation in fantasy and behavior, using Kinsey scale criteria ([Green, 1987](#)). All 35 control boys were heterosexual in fantasy at follow-up; of the 25 control boys who had had overt sexual experiences, one was classified as bisexual, and the remainder were classified as heterosexual. In contrast, 75% (33 of 44) of the GID boys were classified as either bisexual or homosexual in fantasy; of those who had had overt sexual experiences, 80% (24 of 30) were classified as either bisexual or homosexual. The remaining boys were classified as heterosexual. One of the GID boys, who was erotically attracted to males, was seriously entertaining the notion of sex-reassignment surgery.

[Green's \(1987\)](#) controlled follow-up study has shown that the most common long-term outcome of GID is homosexuality, a finding that has been reported in other studies, albeit without comparison groups ([Zucker, 1985](#)). As discussed in more detail elsewhere ([Green, 1987](#); [Zucker 1985, 1990](#)), these data converge neatly with the retrospective studies of adult male homosexuals that have evaluated the presence of childhood cross-gender behavior ([Bailey and Zucker, 1995](#)).

Adults with GID, particularly those with a homosexual orientation (i.e., erotic attraction to persons of the same biological sex), invariably recall a childhood cross-gender history. Prospective studies of children with GID, mainly boys, have found that only a very small proportion persist in their wish to change sex after puberty, although the percentage does appear considerably higher than what one would expect based on general population rates for transsexualism. Why is this? As noted elsewhere ([Zucker, 1985](#)), there are two main possibilities. One possibility is that the low base rate of adult GID, even within the population of children with GID, would require a large sample size to identify the few cases of gender dysphoria; the other possibility is that the assessment process and therapeutic intervention (when it occurs) alter the natural history of cross-gender identification. It should be noted that these two explanations are not mutually exclusive.

Clearly, childhood cross-gender identification is a behavioral marker for either later homosexuality or unresolved adult GID. Can more fine-grained predictions be made (e.g., predicting later homosexuality versus GID; homosexuality versus heterosexuality)? Clinical experience has suggested that children who do not move away from extreme cross-gender identification as they enter adolescence may be at greater risk for later gender dysphoria. [Zucker and associates \(1986\)](#) found that the persistence of gender dysphoria, including the desire to change sex, was considerably higher among patients who were first assessed during adolescence and followed-up later, compared with patients who were first assessed during childhood and followed-up later. This suggests that the clinical situation at or near the transition from childhood to adolescence may be crucial in differentiating a gender dysphoric outcome from other outcomes.

[Green \(1987](#); [Green et al., 1987](#)) compared a number of childhood variables in the feminine boys who were subsequently classified as bisexual or homosexual with the feminine boys who were subsequently classified as heterosexual. Although some feminine behaviors distinguished the two subgroups, a composite childhood femininity score only approached conventional levels of significance and only for the rating of sexual orientation in fantasy, not behavior. The lack of a stronger correlation is somewhat surprising because one might have expected that the degree of cross-gender identification would be related to long-term outcome. However, Green did find that the continuation of certain feminine behaviors throughout childhood was associated with later homosexuality. Thus, it may be that the persistence of the feminine behavior is more important than its extent during the early childhood years.

Less father-son shared time in the first 2 years of life was also associated with later homosexuality, but the amount of mother-son shared time was not. Involvement in treatment also did not distinguish the two subgroups. It should be noted, however, that Green's study was not formally designed to assess the effects of therapy. Cases were not randomly assigned to receive or not receive treatment, and the therapy that occurred was quite variable with regard to length, type, experience of the therapist, and so on.

## RESEARCH DIRECTIONS

Over the past 40 years, considerable progress has been made in demarcating the phenomenology of GID. Assessment procedures for a proper diagnostic work up are now widely available ([Zucker, 1992](#)). The strong connection between GID and later homosexuality has been verified by prospective study. Treatment appears to be capable of interrupting the natural progression toward adult GID, but it is far less clear whether treatment can (or should) influence later sexual orientation.

The biology of gender identity, gender role, and sexual orientation remains an area of intense inquiry. Continued study of the effects of prenatal sex hormones on postnatal sex-dimorphic behavior should help clarify the boundaries of their predisposing influence ([Collaer and Hines, 1995](#)). Research over the past decade has begun to identify some characteristics of children with GID, particularly boys, which may well have a specific biological basis. Corresponding studies of girls have been fewer in number, largely because of problems in sample size that limit statistical power. In many respects, it has been easier to rule out candidate biological explanations, such as the influence of gross anomalies in prenatal hormonal exposure, than it has been to identify the relevant biological mechanisms that are involved in affecting sex-dimorphic behavioral differentiation, but not sex-dimorphic genital differentiation. However, the identification of new potential biological markers may open avenues for further empiric inquiry.

Data on psychosocial influences have been able to rule out some hypothesized pathways and have lent some support for others. Social reinforcement of

cross-gender behavior when it first appears in the toddler and preschool years appears to be the most common psychosocial influence on the disorder's consolidation. The role of family influences, including parental psychiatric impairment and emotional distress, appears to be an important area for further empiric inquiry.

The relation between GID and sexual orientation calls for a better understanding of the development of eroticism in its own right, including its development during the years prior to puberty (Bem, 1996, 2000a, 2000b; Green, 1987; Herdt and McClintock, 2000). How do children eroticize stimuli? How is meaning given to the state of sexual arousal? How fixed or flexible is sexual orientation? Over the past few decades, and even in the short time since previous editions of this volume (Lewis, 1991, 1996), important advances have occurred in our understanding of psychosexual differentiation and its disorders. In the third millennium, there will be more to come.

Tic disorders are transient or chronic conditions associated with difficulties in self-esteem, family life, social acceptance, or school or job performance that are directly related to the presence of motor and/or phonic tics. Individuals with tic disorders may manifest a broad array of behavioral difficulties, including uninhibited speech or conduct, impulsivity, distractibility, motoric hyperactivity, and obsessive-compulsive symptoms. Some of these associated “non-tic” symptoms may be a major source of impairment.

Historically, tic disorders have been the province of both neurologists and psychiatrists. They are remarkable disorders that provide a glimpse into some of the processes that govern the interface between mind and body. The psychological dimension is offered not only by the associated behavioral difficulties but also by the “choice” and timing of the tic behaviors themselves.

Although tic symptoms have been reported since antiquity, systematic study dates only from the 19th century, with the reports of [Itard \(1825\)](#) and [Gilles de la Tourette \(1885\)](#). Gilles de la Tourette, in his classic study of 1885, described nine cases of tic disorder characterized by motor “incoordinations” or tics, and “inarticulate shouts accompanied by articulated words with echolalia and coprolalia.” This report also hinted at the hereditary nature of the syndrome and the association between tic disorders and obsessive-compulsive symptoms.

The current classification of tic disorders in *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) includes Tourette's disorder, chronic motor or vocal tic disorder, transient tic disorder, and tic disorder not otherwise specified ( [American Psychiatric Association, 1994](#)). The diagnostic criteria for these conditions are presented in [Table 59.1](#). These criteria focus on the phenomenology and natural history of the disorder and are readily applied in clinical settings. They also serve as the basis for the diagnostic descriptions contained in the [World Health Organization's International Classification of Diseases \(ICD-10\) \(1988\)](#).

Table 59.1. DSM-IV Tic Disorder Classification

## DEFINITIONS

A tic is a sudden, repetitive movement, gesture, or utterance that typically mimics some aspect of normal behavior. Usually of brief duration, individual tics rarely last more than a second. They tend to occur in bouts and, at times, have a paroxysmal character. Individual tics can occur singly or together in an orchestrated sequence. Tics vary in their frequency and forcefulness. Many tics can be temporarily suppressed. Young children experience their tics as being involuntary. Older children and adults, however, often describe their tics as being associated with unwanted somatosensory “urges” that are momentarily relieved with the performance of the tic ([Bliss, 1980](#); [Leckman et al., 1993](#)). Motor tics vary from simple, abrupt movements, such as eye blinking, head jerks, or shoulder shrugs, to more complex, purposeful-appearing behaviors, such as facial expressions or gestures of the arms or head. In extreme cases, these movements can be obscene (copropraxia) or self-injurious (e.g., hitting or biting). Phonic or vocal tics can range from simple throat-clearing sounds to more complex vocalizations and speech. In severe cases, coprolalia (obscene speech) is present.

## PREVALENCE AND EPIDEMIOLOGY

Tic behaviors are commonplace among children. Community surveys indicate that 1% to 13% of boys and 1% to 11% of girls manifest “frequent tics, twitches, mannerisms, or habit spasms” ([Zohar et al., 1998](#)). The instability of these estimates owes in part to the timing of the interviews in relation to the waxing and waning course of tic symptoms, wording of items on symptom inventories, identity of the informant, and demographic characteristics of the sample studied. Children between the ages of 7 and 11 years appear to have the highest rates. Although boys are more commonly affected with tic behaviors than are girls, the male:female ratio in most community surveys is less than 2:1. Urban living may be associated with elevated rates ([Zahner et al., 1988](#)). Although race and socioeconomic status have not been shown to influence the point prevalence of tics, some authors have suggested that tic symptoms may be more common among white and Asian racial groups.

Much less is known concerning the prevalence of tic disorders per se. Once thought to be rare, current estimates from registers of clinically diagnosed subjects suggest that 1% to 2% of the general population may be affected. Unfortunately, these estimates are preliminary, because only a few rigorous population-based studies have been performed. For example, [Apter and colleagues \(1993\)](#) screened 28,037 16- to 17-year-old individuals prior to their induction into the Israeli army, and reported a point prevalence of 4.3 per 10,000 for Tourette's disorder. Although the rate of any tic disorder was not reported, their data suggest that this figure

would be approximately an order of magnitude higher—in the range of 47 per 10,000. Using a similar design, [Costello and associates \(1996\)](#) examined 4,500 children 9, 11, and 13 years of age in rural North Carolina. The children were directly examined, as was one parent; both were asked about symptoms during the previous 3-month period. Altogether, 10/10,000 children met criteria for Tourette's syndrome, 13/10,000 for boys and 7/10,000 for girls. These figures are consistent with the view that children are more likely to be identified as having a tic disorder than adults and that males are more commonly affected than females (with male:female ratios of 9:1 and 3:1 for children and adults, respectively) (Burd et al., [1986a](#), [1986b](#)).

The true prevalence rate for Tourette's disorder, however, may be substantially higher based on studies that have used longitudinal classroom monitoring techniques. For example, [Mason and coworkers \(1998\)](#) completed a study of all 13- to 14-year old pupils in a mainstream secondary school in the United Kingdom. Students were investigated using a two-stage procedure employing standardized questionnaires completed by parents, teachers, and pupils. Personnel trained to identify tics carried out classroom observations. Those pupils identified as having tics underwent a semistructured interview to determine whether they had Tourette's syndrome (TS). Five subjects were identified as having TS, yielding a prevalence estimate of 299 per 10,000 pupils in this age group. If confirmed, these results suggest that TS in the community as a whole is more common and milder than earlier population-based studies suggest.

## CLINICAL DESCRIPTIONS

Relatively few longitudinal studies of tic disorders have been performed with the exception of TS ( [Bruun, 1988](#); [Goetz et al., 1992](#); [Leckman et al., 1998b](#); [Shapiro et al., 1988](#)). Thus, most of the information provided in the following is based on cross-sectional studies and anecdotal clinical experience.

### Transient Tic Disorder

Almost invariably a disorder of childhood, transient tic disorder is usually characterized by one or more simple motor tics that wax and wane in severity over weeks to months. The anatomic distribution of these tics is usually confined to the head, neck, or upper extremities. More rarely transient phonic tics, in the absence of motor tics, can occur. The age of onset is typically 3 to 8 years. Boys are at greater risk. The initial presentation may be unnoticed. If medical consultation is sought, family practitioners, pediatricians, allergists, and ophthalmologists are typically the first to see the child. Missed diagnoses are common, particularly because the symptoms may have completely disappeared by the time of the consultation. As prescribed by the prevailing diagnostic criteria, the subsequent natural history of this condition is limited to fewer than 12 consecutive months of active symptomatology. As such, this is often a retrospective diagnosis because the clinician is unable to know with certainty which children will show progression of their symptoms and which children will display a self-limiting course.

---

#### CASE ILLUSTRATION

Todd is a 6-year-old boy with a history of intense eye blinking of 2 weeks duration. The symptom was noticeable to others and interfered with his ability to maintain visual attention. The symptoms began toward the end of a family vacation, shortly before Todd was to enter first grade. By the time a visit to the family pediatrician was arranged, the symptoms had diminished considerably. In light of a positive family history of tic disorder in the father and an older sibling, the pediatrician tempered his reassurance but indicated to the family that the condition might well be transient in nature. The family was counseled to avoid central nervous system (CNS) stimulants, decongestants, and other sympathomimetics.

#### Comment

Although the value of avoiding CNS stimulants has not been convincingly demonstrated in prospective studies, such recommendations are commonplace and may have merit in light of the available anecdotal literature. Recently, systematic studies of the use of stimulants in children with Tourette's disorder have rekindled this controversy ([Sverd et al., 1999](#)) and have shown that short-term treatment with stimulants is not usually associated with increased tic symptoms. Definitive longer-term studies have not been reported.

---

### Chronic Motor or Vocal Tic Disorder

This chronic condition can be observed among children and adults. As with other tic disorders, a waxing and waning course and a broad range of symptom severity characterize this condition. Chronic simple and complex motor tics are the most common manifestations. A majority of tics involve the head, neck, and upper extremities. Although some children may display other developmental difficulties, such as attention deficit hyperactivity disorder (ADHD), the disorder is not incompatible with an otherwise normal course of development. This condition also can appear as a residual state, particularly in adulthood. In such instances, a predictable repertoire of tic symptoms may only be seen during periods of heightened stress or fatigue.

Chronic vocal tic disorder, by all accounts, is a rare condition. Some authors exclude "chronic cough of adolescence" from this category ( [Shapiro et al., 1988](#)).

---

#### CASE ILLUSTRATION

Richard is 16-year-old sophomore in high school. His coach observed chronic motor tics during baseball practice. These included a mouth stretching movement and a head tilt that occurred together at times. The coach was impressed by how little awareness Richard seemed to have concerning these movements despite their disfiguring character and the occasional teasing they prompted by his teammates. When approached, Richard's mother indicated that tic symptoms had been present off and on since he was 7 years old and that the family had noticed that they had been more frequent as he approached the end of the school term. She mentioned that they were in regular contact with a clinic and that, thus far, no medications had been used to control the symptoms.

#### Comment

A conservative approach (as illustrated in this vignette) is often indicated given the potential unwanted physical and psychological effects of many of the medications used to treat tic disorders.

---

### Tourette's Syndrome (Chronic Motor and Phonic Tic Disorder)
