Delays in hospital discharge frequently cause frustration and anxiety. Psychiatric consultation may be required, however, for the patient who insists that discharge is premature. This behavior may result from fear associated with unresolved symptoms or with transition from the close in-hospital monitoring by the surgical team to the less restrictive and possibly less supportive home environment.

Body Image Distortions

Cushingoid changes from prednisone are especially troublesome for young patients undergoing transplantation. One young liver transplant patient chose to undergo a series of cosmetic surgeries in young adulthood to rid her of unwanted adipose tissue. She was not obese, but she was dissatisfied with her appearance. Prednisone can increase body hair, and cyclosporine may also be associated with hirsutism. Common warts, which can flourish in immunosuppressed individuals, may also prove disfiguring and uncomfortable.

Castelnuovo-Tedesco[97] and others have been especially interested in the psychological impact of the transplant recipient's incorporation of a body part from the donor. Perhaps the most dramatic account was that of a Ku Klux Klan grand dragon who joined the National Association for the Advancement of Colored People on learning that his donor was an African American.[98] Some patients comment on changes in their food choices and wonder whether the donor's lifestyle may have been contributory. A middle-aged heart–lung recipient who determined the identity of her cadaveric donor told a national television audience, during an appearance on the Phil Donahue Show, that her subsequent vigor led to an affair with a postadolescent man whose age was similar to that of her donor.

One of the most unusual cases we have encountered was of a 43-year-old heart-transplant recipient who reported a recurrent dream in which he was driven by starvation to strip and chew the flesh of his own arm. Preoperatively, he had expressed anxiety about the prospect of receiving a cadaveric organ. Several months after his operation, a discussion of the dream led to a statement that it sounded like cannibalism. "Yes," he responded, "when I was in the Army working in the motor pool, there was a sign that said, 'Do not cannibalize!'" He explained that it had been an unsanctioned practice to take working parts from other vehicles to service ones in need of repair.

Depression

Postoperative depression may arise as a recurrence of affective illness. Steroid-induced depression is common and tends to be accompanied by irritability that is less evident to the patient than to the family and to the attending surgical staff. Rejection is another common cause of depression, and it may be related to the fear of graft loss, to cytokine production, or to end-organ dysfunction.

Also important for the transplant psychiatrist is awareness of the link between depression and infection.[10] Psychiatric consultation may sometimes precede a request for infectious disease consultation because mood changes may foreshadow a fever spike or evidence of systemic illness. Cytomegalovirus infection is especially common after transplantation, and it is associated with a significant increase in first-time psychiatric consultation.[99] Typically, these patients do not express hopelessness or suicidal ideation, but other neurovegetative signs such as appetite reduction, lethargy, and psychological withdrawal are common.

Psychological Rejection

Viederman[100] and others have raised the possibility of psychologically induced allograft rejection. This concept is interesting but speculative. More likely, psychologically based rejection results from noncompliance caused by depression, memory impairment, substance abuse, or adjustment reaction related to psychosocial stress, or by altered body image. Medication costs thousands of dollars annually, and nonadherence may follow loss of third-party funding or other adverse economic developments.

POSTOPERATIVE PSYCHIATRIC INTERVENTION

Long-Term Care

Transplant patients are often told that they will end up with a new set of medical problems once end-organ replacement has occurred. Morbidity may occur as a function of rejection, medication side effects, and progression of systemic disease. The care of transplantation patients is thus a

long-term prospect, and the consulting psychiatrist may be reconsulted at intervals, especially for those who are most ill or least able to adapt.

Patients who are at highest risk psychologically should have follow-up plans created before the operative intervention. Patients with affective disorders, schizophrenia, substance abuse, or moderate mental retardation can be managed with supportive counseling, psychopharmacologic care, and implementation of social resources.

Psychotherapeutic Interventions

Psychotherapy may include the reframing of expectations. For example, a patient who is recovering from a prolonged ICU stay will need help with assessment of his or her progress, which may be measured by absence of a monitor, reduction of IV lines, and signs of early mobilization. Guilt and shame may follow an encounter with delirium or result from the preoperative wish for a donor organ. Patients can be helped to understand that these experiences are common. Daily visits to delirious or acutely depressed patients are advisable and may be a source of relief to the patient, the family, and the surgical staff.

Behavioral interventions may be designed with the nursing staff, to assist in the management of excessive dependency, hostility, or resistance. Group therapy is of value for many patients and family members and may be conducted by the psychiatrist, social worker, psychologist, or psychiatric nurse clinician.

Psychopharmacologic Intervention

Treatment with antipsychotics requires modification of immunosuppressant protocols (when feasible), correction of metabolic abnormalities, and treatment of bleeding, infection, and rejection. Complex partial seizures should be considered as a cause of psychosis, but care must be taken in the choice of anticonvulsants. Anticonvulsants such as phenytoin, valproate, and carbamazepine are P450 enzyme inducers and may decrease levels of immunosuppressants. It is best to follow the serum level of calcineurin inhibitors to avoid risk for rejection. Haloperidol and atypical antipsychotic agents are effective in management of agitated delirious states. Care must be taken to observe for Q-T prolongation. Antipsychotic agents of the traditional or atypical (second-generation) variety are known to be associated with an increased risk for sudden death from arrhythmia, especially in older patients. An algorithm for use of IV haloperidol has been presented by Fricchione and co-workers.[91]

Use of antidepressants and anxiolytics should be accompanied by the precautions addressed earlier. A full range of agents, as well as electroconvulsive therapy, can be used after surgery. TCAs are often preferred for diabetics with peripheral neuropathy, or for management of migraine or insomnia in those patients who are not at cardiovascular risk. In the setting of hepatic dysfunction, serum levels should be followed. For the most part, bupropion and SSRIs are better tolerated. Monoamine oxidase inhibitors are best avoided, but we have encountered one heart transplant patient whose resistant depression responded only to tranylcypromine.

Posttraumatic Stress Disorder

Occasionally, a patient with recurrent nightmares and the spontaneous recollection of medically traumatic events associated with transplantation is encountered. The prevalence of posttraumatic stress disorder (PTSD) in transplant recipients is not known. Fukunishi and colleagues[7] documented PTSD in 4 of 40 donors who underwent right lobe hepatectomy; although this is an isolated report, transplantation psychiatrists should be mindful of the potential.

CONCLUSION

Psychiatric consultation on the transplantation unit is highly rewarding and places the psychiatrist in a pivotal role as a member of a multidisciplinary team. The transplantation unit is a challenging setting in which a full range of psychiatric skills and sensitivity is employed. The dearth of available organs necessitates a thoughtful and constructive approach to candidate selection. The participation of living donors is a unique circumstance that is worthy of both celebration and support. Transplant patients approach operative intervention carrying the burden of progressive organ failure and its attendant neuropsychiatric complications. The postoperative course of transplant patients is associated with improved quality of life and a requirement for long-term care.

Patients with Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

BJ Beck, M.S.N., M.D.
Oliver Freudenreich, M.D.
Jonathan L. Worth, M.D.

Human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS) are prevalent in disenfranchised populations, including addicts, gay men, sex workers, ethnic minorities, and the seriously mentally ill, who may have particular difficulty advocating for and accessing adequate care.[1] Not only is HIV infection more prevalent among the mentally ill,[2–4] but psychiatric illnesses are more prevalent in those who are HIV positive.[5–7] Personality disorders are overrepresented in the HIV-positive population as well,[8–10] possibly because certain traits (such as impulsivity, reckless disregard for safety, affective instability, or chronic feelings of emptiness) can predispose persons to risky behavior and to HIV infection.

As recently as the 1990s, HIV infection was a terminal illness. However, the advent of highly effective antiretroviral medication regimens has made HIV a manageable, chronic illness for many,[11,12] although it sometimes is associated with a high medication side-effects burden.[13] The emerging cohort of aging and elderly persons infected with HIV for many years[14] has now created the challenge of managing chronic diseases not necessarily related to HIV itself.[15] Unfortunately, poorly treatable cognitive impairment from HIV, age-related processes, and the possible interplay of the two,[16] have resulted in a growing number of infected persons with varying degrees of cognitive impairment including dementia.[17] Despite much progress, complacency, stigma, secrecy, and shame continue to interfere with HIV detection.[18] Culture, lifestyle, and socioeconomic barriers to prevention and to appropriate HIV care persist.[19]

HIV is a blood-borne, sexually transmitted retrovirus that contains RNA as its genetic material and the enzyme reverse transcriptase, which facilitates the (reverse) transcription of RNA to double-stranded DNA in infected human cells. This virion-derived DNA moves to the host cell nucleus, where it randomly integrates into host chromosomes, catalyzed by the virion-encoded enzyme, integrase. Once within the host chromosome, the pro-viral DNA can remain inactive (latent), or it can express a range of genetic activity, including functional virus production. Such now-functional viruses can go on to infect other cells, preferentially the CD4 subpopulation of T-lymphocytes, thereby causing severe (primarily cell-mediated) immune dysfunction for which the virus and the resulting syndrome were named. Immunodeficiency, a predilection for certain opportunistic infections, and AIDS-defining conditions correlate with a decline in CD4 lymphocyte count[20] (Table 26–1). This infection cycle repeats billions of times, the host mounts an immune response, and a set point (or dynamic equilibrium) is eventually reached. The set point varies from person to person, and it has been found to be of prognostic significance.[21,22] Notably, the virus also invades the central nervous system (CNS) early, possibly within hours to days of the initial infection.[23,24]

Although the science behind HIV infection and its treatment is changing at a rapid pace, the general tenets of this chapter should provide a consistent framework for the safe and comprehensive psychiatric evaluation and care of adults at risk for, or infected with, HIV/AIDS. Four general questions help set the context for such an evaluation: At what stage of HIV infection is the patient in terms of symptomatic disease and CD4 lymphocyte count? Is there evidence of HIV-associated CNS infection? Does the patient have a premorbid psychiatric history? How did the patient become infected with HIV? The important implications of the first three questions might seem more obvious and should be clear by the completion of the chapter. The fourth question is often a highly personal story, one that reveals the patient as a person. The answer to this question foreshadows how the patient will relate to illness and to medical care. This knowledge informs not only the psychiatrist's evaluation but also the patient's individualized treatment and management plans.

EPIDEMIOLOGY

Despite the existence of effective therapies, HIV/AIDS remains a terminal illness in much of the world; it cuts across all ages and socioeconomic groups, each with specific characteristics and considerations.[19] The numbers in the Global Summary published in December of 2007 by the Joint United Nations Programme on HIV/AIDS (UNAIDS) and the World Health Organization (WHO)[25] are the result of a revised statistical model

TABLE 26–1 AIDS-Defining Conditions that Emerge with Advancing Immunosuppression

CD4 CELL COUNT (CELLS/mm³)	CONDITION
200–500	Thrush
	Kaposi's sarcoma
	Tuberculosis reactivation
	Herpes zoster
	Herpes simplex
	Bacterial sinusitis/pneumonia
100–200	*Pneumocystis jerovicii* pneumonia
50–100	Systemic fungal infections
	Primary tuberculosis
	Cerebral toxoplasmosis
	Progressive multi-focal leukoencephalopathy
	Peripheral neuropathy
	Cervical carcinoma
0–50	Cytomegalovirus disease
	Disseminated *Mycobacterium avium-intracellulare complex*
	Non-Hodgkin's lymphoma
	Central nervous system lymphoma
	HIV-associated dementia

Modified from APA: Practice guideline for the treatment of patients with HIV/AIDS, *Am J Psychiatry* 157S:1–62, 2000.

and improved assessment processes in certain large regions (e.g., India, sub-Saharan Africa). Although the reported global prevalence is somewhat lower (33.2 million in 2007, versus 39.5 million reported in 2006[26]), this is more likely the result of the model, and not an actual change in prevalence. Women make up half of the infected adults worldwide, and roughly 2.5 million children younger than 15 years are infected.

The report estimates that there has been a gradual decrease in the incidence of new infections since a peak in 1998, with a 2007 incidence of roughly 2.5 million, with 420,000 of those new cases diagnosed in children younger than 15 years. This incidence is only partially offset by the (declining) total number of AIDS deaths (2.1 million in 2007), which means the number of persons living with HIV will continue to rise, although the prevalence (measured over a growing global population) has stabilized. Sub-Saharan Africa remains the most heavily infected region, accounting for 67% of all people living with HIV, for 72% of all AIDS deaths,[27] and for 68% of all new cases in 2007.[25] Still, this is significantly improved from the late 1990s, when 95% of all infected people lived in this region.[28]

In the United States, among the most heavily infected industrialized nations, more than a million people are infected with the virus, with an estimated 55,400 new infections yearly between 2003 and 2006, and possibly more (56,300) by some estimates.[29] The incidence is thought to have peaked in the mid-1980s, falling off sharply in the early 1990s, with a lower spike in 1997 followed by a fairly stable, though unacceptably high, incidence (55,000 to 56,000) of new infections in the third decade of the disease in this country. The advent of highly active antiretroviral therapy (HAART) in 1996 has decreased the incidence of AIDS onset and AIDS-related deaths, so more people in the United States are living with HIV infection than ever before.

A disproportionate number of the newly infected in the United States are ethnic and racial minorities (primarily African American and Hispanic[30]; less so Asian and Pacific Islanders[31]), and heterosexual women.[29,32] However, outbreaks of other sexually transmitted diseases (STDs) in gay men raise the specter of a possible HIV resurgence in this population and suggest that the success of HAART may have led to complacency and the resumption of unsafe sexual practices in men who have sex with men (MSM),[33,34] to some degree fueled by the recreational use of methamphetamine (crystal meth).[35] Up to 30% of patients with HIV disease are also infected with hepatitis C virus (HCV). These co-infected patients are rather different from HIV mono-infected patients with regard to risk factors and psychiatric illnesses: most patients have acquired HCV from injection drug use, which is the main mode of transmission for HCV.

HIV INFECTION AND THE CENTRAL NERVOUS SYSTEM

Within days of the initial infection, the virus is transported to the brain by monocytes that then differentiate into macrophages. These infected but not dead macrophages may be activated randomly, leading over time to excessive secretion of normal inflammatory substances and cell death without neuronal infection. That is, HIV infection causes neuronal destruction without infecting neurons.[36] The CNS appears to be an independent reservoir of HIV replication; CSF viral load does not consistently correlate with plasma levels.[37,38] HIV in the CNS might also have different characteristics, such as mutations with increased viral resistance or neurotoxicity, than those of the peripherally observed virus. Current antiretrovirals have variable blood–brain barrier (BBB) penetrance, they may be less potent inhibitors of viral replication within the CNS, and some are themselves neurotoxic. The optimal antiretroviral drug regimen to combat HIV in the brain remains to be determined, but peripheral suppression of viral replication will need to be coupled with neuroprotection. New therapies might target regulatory human genes involved in viral replication,[39] the identification and exploitation of brain HIV-inhibitory factors,[24] and the enhancement of intrinsic brain defenses that favor neuroprotective, as opposed to neurotoxic, responses to the virus.[24]

Although early studies concentrated on sampling and volume of the frontal cortex, it is now apparent that HIV infection does not uniformly affect the brain; instead, it has a predilection for subcortical structures, such as the hippocampus and basal ganglia, with lower concentrations in the cerebellum and mid-frontal cortices.[40,41] This distribution, further differentiation of viral burden within particular basal ganglia regions, and concomitant structural changes in the brain (including ventricular enlargement, hippocampal atrophy, decreased basal ganglia volume, and white matter lesions), might explain the more characteristic cognitive and behavioral impairments associated with

HIV infection of the CNS.[36,42,43] These types of lesions in the base of the skull are better visualized by brain magnetic resonance imaging (MRI) than by computed tomography (CT) scanning.

When evaluating neurocognitive impairment in the HIV-positive patient, HIV infection of the CNS should always be a diagnosis of exclusion, made only after a thorough investigation of other possible etiologies for neurocognitive impairment, especially if symptoms are new or of acute onset.[44,45] Opportunistic infection, neoplasm, other systemic illness, medication side effects, drug–drug interactions, use of recreational drugs, withdrawal syndromes, and metabolic and nutritional derangements should be considered. Primary psychiatric disease should be at the bottom of the list, especially if there is not a significant preinfection history.[20,46–48]

Although neuropsychologic testing might not be specific,[41] it helps to localize and quantify impairments. Recommended neuropsychological tests include an HIV-specific test battery based on measures found by the AIDS Clinical Trials Group (ACTG) and the Multicenter AIDS Cohort Study to be sensitive to HIV-related cognitive deficits. These measures include Trail Making A and B, WAIS-R (Wechsler Adult Intelligence Scale—Revised) digit span and digit symbol, grooved pegboard, finger tapping, Stroop color and word test, FAS test of verbal fluency, Odd Man Out test, and computer-based measures of complex reaction time.[49–52] Other measures are added as clinically indicated. Test battery times less than 60 minutes are less likely to produce patient fatigue, which confounds test interpretation and creates significant patient frustration or humiliation.

MEDICATIONS FOR HIV INFECTION

There are several classes of antiretroviral medications: nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, and fusion and entry inhibitors.[53] Drugs in the first four classes all interfere with viral replication inside infected host cells. By contrast, the next wave of drug development has targeted the prevention of viral entry into the host cell.[54] Antiretroviral medications are generally used in combinations of one or more drugs from more than one class. Single-drug therapy is discouraged because of the rapid development of resistance that can spread to an entire class of medications, thus limiting the prospects for further effective treatment. The most commonly recommended initial regimen (i.e., for the antiretroviral-naive patient) includes two NRTIs plus either an NNRTI or a PI, preferably with ritonavir boosting (i.e., addition of low-dose ritonavir to another PI). The different classes of medication differ in their therapeutic mechanisms and side-effect profiles (Table 26–2).

Nucleoside (and Nucleotide) Reverse Transcriptase Inhibitors

Nucleoside reverse transcriptase inhibitors are nucleoside analogues that inhibit the action of the enzyme reverse transcriptase. This enzyme inhibition slows or prevents viral replication. Most of the NRTIs require multiple daily doses, do not interact with other drugs, and can be taken with or without food. Didanosine (ddI), however, can decrease the absorption of other antiretrovirals if they are taken together, and it must be taken on an empty stomach. All NRTIs have been associated, albeit rarely, with a fatal syndrome of lactic acidosis and hepatic steatosis. Tenofovir is a nucleo*tide* reverse transcriptase inhibitor, a subclass distinguished by fewer chemical steps to intracellular activity and a negative charge that effectively keeps the compound in the cell and active longer, allowing once-daily administration.[54] The first antiretroviral drugs to be used, NRTIs remain the backbone of current HIV multidrug regimens.

Nonnucleoside Reverse Transcriptase Inhibitors

Like the NRTIs, the NNRTIs also interfere with reverse transcriptase. The NNRTIs have been shown to be active against viral strains of HIV that are resistant to NRTIs and PIs. However, if NNRTIs are used alone or with a single NRTI, resistance develops quickly, and it usually generalizes to the whole class (i.e., to all the NNRTIs). The NNRTIs can also cause a rash early on; it is thought to be more common and severe (including onset of Stevens–Johnson syndrome) with nevirapine. Drug interactions with PIs and other drugs can occur because of their metabolism by the cytochrome P450 (CYP) hepatic isoenzyme system. Efavirenz is an NNRTI noteworthy for its greater potential (as compared to other drugs in this class) for neuropsychiatric side effects (e.g., somnolence, agitation, insomnia, abnormal dreams, impaired concentration and attention, psychosis, and suicidality). Such side effects are thought to be related to plasma level and are pharmacogenetically predisposed.[55,56]

Protease Inhibitors

Protease inhibitors interfere with viral replication, maturation, and new infection of cells by inhibiting the enzymatic cleavage of necessary viral protein precursors. Like the NNRTIs, PIs are metabolized by CYP enzymes, leading to drug interactions. PIs can cause gastrointestinal (GI) side effects and liver transaminase elevations. In addition, PIs can worsen or cause diabetes, insulin resistance, lipodystrophy, and hyperlipidemia. They have also been associated with increased bleeding in hemophiliacs and an increased risk of myocardial infarction.[57]

Integrase Inhibitors

Integrase is the viral enzyme that catalyzes the integration of virally derived DNA into the host cell DNA in the nucleus, forming a provirus that can be activated to produce viral proteins. Raltegravir, the first approved integrase inhibitor, is a useful addition to therapy in the setting of multidrug resistance. However, it must be supported by other agents because of the high propensity for genetic mutations leading to raltegravir resistance.[58] A trial with treatment-naive HIV-1–infected patients demonstrated more-rapid decline in viral load (as compared to efavirenz) and suggests that there may be a future role for integrase inhibitors in initial therapy regimens.[59]

TABLE 26–2 Side Effects Profile of Antiretrovirals

AGENT	MAJOR SIDE EFFECTS
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)	
Zidovudine (Retrovir, AZT, ZDV)	Depressed bone marrow/anemia, neutropenia, GI symptoms, HA, insomnia
Didanosine (Videx, ddI)	Pancreatitis, peripheral neuropathy, GI symptoms
Zalcitabine (Hivid, ddc)	Peripheral neuropathy, stomatitis
Stavudine (Zerit, d4T)	Peripheral neuropathy, pancreatitis, lactic acidosis
Lamivudine (Epivir, 3TC)	Minimal
Abacavir (Ziagen, ABC)	Hypersensitivity (HLA-B*5701 pre-treatment screening)
Tenofovir (Viread, TDF)	Renal toxicity
Emtricitabine (Emtriva, FTC)	Minimal
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)	
Nevirapine (Viramune, NVP)	Rash (Stevens–Johnson syndrome), severe liver toxicity
Delavirdine (Rescriptor, DLV)	Rash
Efavirenz (Sustiva, EFV)	CNS symptoms, false-positive urine drug test for cannabis
Etravirine (Intelence, ETR)	Rash, GI symptoms
Protease Inhibitors (PI)	
Saquinavir (Invirase, SQV)	GI symptoms, paresthesias, hepatitis, HA, lipodystrophy; increased TGC, cholesterol, glucose, transaminases (liver enzymes)
Ritonavir (Norvir, RTV)	GI symptoms, paresthesias, hepatitis, asthma, lipodystrophy; increased TGC, cholesterol, glucose
Indinavir (Crixivan, IDV)	HA, asthma, blurred vision, dizziness, metallic taste, thrombocytopenia, increased glucose, nephrolithiasis, GI symptoms, lipodystrophy, rash, increased TGC and cholesterol
Nelfinavir (Viracept, NFV)	GI symptoms, lipodystrophy; increased TGC, cholesterol
Amprenavir (Agenerase, APV)/	GI symptoms, asthma, rash, HA
Fosamprenavir (Lexiva, FOS-APV)	GI symptoms, HA, depression, rash, fatigue, increased cholesterol/TGC/ glucose/transaminases
Lopinavir/Ritonavir (Kaletra, LPV/RTV)	GI symptoms, fatigue, HA, asthenia, lipodystrophy, pancreatitis; increased cholesterol, glucose, transaminases
Atazanavir (Reyataz, ATV)	GI symptoms, hyperbilirubinemia (25%-50%)
Tipranavir (Aptivus, TPV)	GI symptoms, rash (sulfa drug!)
Darunavir (Prezista, DRV)	GI symptoms
Fusion and Entry Inhibitors	
Enfuviritide (Fuzeon, T-20)	Skin irritation at injection site, bacterial pneumonia
Maraviroc (Selzentry, MVC)	Fever, cough, cold
Integrase Inhibitors	
Raltegravir (Isentress, RAL)	GI symptoms

GI, Gastrointestinal; *HA*, headache; *TGC*, triglyceride.
Antiretroviral combination pills: Atripla = FTC + TDF + EFV; Combivir = AZT + 3TC; Epzicom = 3TC + ABC; Trizivir = AZT + 3TC + ABC; Truvada = FTC + TDF

Fusion and Entry Inhibitors

Once the viral protein gp120 forms a complex with the CD4 receptor, conformational changes expose viral gp120 areas for binding with host cell chemokine co-receptors CCR5 and CXCR4, a necessary step for viral entry into the host cell. Maraviroc is a new chemokine co-receptor antagonist (CCR5 antagonist) drug that blocks the binding of HIV to CCR5 co-receptors in CCR5-tropic (R5 virus) HIV-1 infection. Despite relatively persistent efficacy against multidrug-resistant strains, maraviroc resistance has been attributed to the emergence of CXCR4-tropic (X4 virus) strains.[60] Studies are also exploring the utility of using maraviroc in initial treatment regimens.[61]

Enfuvirtide, the first approved drug in this new class, interferes with viral fusion to the host cell membrane by inhibiting the necessary conformational change in a particular viral envelope protein (gp41) that would otherwise trigger the formation of a transmembrane pore through which the virus would enter the host cell. Administered subcutaneously, enfuvirtide requires twice-daily injections. It is commonly associated with injection-site reactions, an increased incidence of bacterial pneumonia, and rare hypersensitivity reactions.[53] Although resistance to enfuvirtide has also been reported, the drug is recommended for treatment-experienced patients who develop viral replication despite continuous antiretroviral therapy.[54]

Other Medications

HAART regimens are often complicated by the addition of antibiotics, antivirals, and antifungals used to prevent or treat opportunistic infections. Lipid-lowering drugs or oral hypoglycemic agents may be necessary to treat the antiretroviral-induced abnormalities in lipid metabolism and glucose control. Antiretroviral GI side effects can require the

addition of antidiarrheals, proton pump inhibitors, or H_2 blockers. Pain syndromes may require antiinflammatory or narcotic medications, as well as antiseizure medications or tricyclic antidepressants (TCAs). The not uncommon co-morbidity of HIV infection with heroin (or other opiate) addiction can require the addition of an opiate agonist (e.g., methadone), a partial agonist (e.g., buprenorphine), or (less preferable[62]) an antagonist (e.g., naltrexone) medication. Treatment for co-morbid alcohol dependence may also include use of naltrexone, disulfiram, or acamprosate.

HIV-ASSOCIATED NEUROCOGNITIVE DISORDERS (HAND)[63]

In 1991, the American Academy of Neurology (AAN) developed criteria and nomenclature for the prevalent HIV-associated neurocognitive dysfunctions recognized at the time.[64] This system recognized HIV-associated dementia (HAD) (previously known as AIDS dementia complex) and minor cognitive–motor disorder (MCMD). HAD was further subdivided based on the presence of motor or behavioral features. This has been a useful organizational system to describe the greater (HAD) and lesser (MCMD) neurocognitive impairments associated with HIV.

However, since then, concurrent with the more standard use of increasingly effective antiretroviral therapies, there has been growing awareness of overlap between mild HAD with motor or behavioral symptoms and MCMD. This awareness, and the recognition that some infected patients without noticeable functional impairment do show deficits on neuropsychological testing, prompted leaders in the research field to develop new definitional criteria. This new nosology recognizes three conditions, including HAD, HIV-associated mild neurocognitive disorder (MND), and asymptomatic neurocognitive impairment (ANI).[63] Some decry this syndromic approach altogether and suggest that further research needs to provide cerebrospinal fluid (CSF) and MRI biomarkers of active HIV encephalitis, the putative etiology of HIV-associated neurocognitive symptoms.[65] The challenge, however, is to find such markers that remain relevant in the presence of HAART, because some researchers have discovered no correlation between markers and neurologic status in actively treated patients.[66]

HIV-Associated Dementia

HIV-associated dementia, a subcortical dementia similar to that seen in Huntington's disease,[41] is severe enough to cause functional impairment, and it has no other definable cause. HAD is an AIDS-defining condition with a prevalence in the United States of 21% to 25% before the advent of HAART; since then it has decreased to 7% to 10%. Associated with reduced white-matter volume, atrophy of the basal ganglia (reduced gray matter volume), and cell death, HAD is characterized by slowed information processing, deficits in attention and memory, and impairments in abstraction and fine motor skills.[36,41,67]

HIV-Associated Mild Neurocognitive Disorder

Mild neurocognitive disorder most closely relates to what has been called MCMD, a condition more common than HAD. The prevalence of MCMD prior to HAART was 25% in those with early symptomatic disease and 50% in those with AIDS.[68] With the advent of widely used HAART, those figures declined to 14% and 24.4%, respectively.[36]

By definition, MND involves mild to moderate cognitive impairment (1 standard deviation [SD] below demographically corrected norms), in at least two cognitive domains, that at least mildly interferes with daily activities.[63] For patients in cognitively taxing jobs, however, even "mild" problems may be significant enough to interfere with, and to preclude, continued employment.

Asymptomatic Neurocognitive Impairment

HIV-associated dementia and MCMD were clearly inadequate descriptors for the wide array of neuropsychological symptoms reported and observed in 22% to 30% of "asymptomatic" (i.e., subsyndromal) seropositive patients.[69] By definition, ANI also involves mild to moderate cognitive impairment (1 SD below demographically corrected norms) in at least two cognitive domains but without obvious impairment in daily function. It is extremely difficult to make the judgment that there are no obvious functional impairments without extensive third-person observation. Given the diagnostic ambiguity of this group, it is not clear whether the prevalence of subsyndromal (or "asymptomatic") symptoms has decreased with the advent of HAART. It may even be that this group has increased as HAART has changed the appearance of HAND.[70]

HAND in the Era of HAART

Diagnostic assignment for HAND fluctuates for roughly 20% of infected patients. For MND and ANI, it may be that neuronal dysfunction, rather than cell death, is the mediator. This is important because it suggests that the pathology may be treatable and that these syndromes are potentially reversible. Given that even mild functional impairment and subtle deficits might contribute to poor medication adherence, MND and ANI can contribute to worse overall prognosis. Because of the prevalence, prognostic implications, and possible reversibility, research and improved measurement efforts should focus on these less-severe forms of HAND.[36,42,67]

For patients with HAD, the fluctuation in neurocognitive status of some, versus the sustained deficits of others, might represent the array of individual experiences with the virus, treatment, other illnesses, and substance use.[71] Long-time survivors who have suffered high viral loads and poor immune function without benefit of HAART might have permanent neurocognitive deficits, which further interfere with treatment adherence, leading to a declining trajectory. This is in contrast to the patient with newly diagnosed HIV infection who might present with criteria for HAD but whose condition improves when effectively treated with HAART.[72,73] Substance use, head trauma, and co-infection with the neurotropic hepatitis C virus[74] also add to the neurotoxic insult of HIV and predispose to significant brain dysfunction.

DIFFERENTIAL DIAGNOSIS OF PSYCHIATRIC DISTRESS

Psychiatric symptoms are common in the HIV-infected population and can reach a level of severity to meet criteria for *Diagnostic and Statistical Manual for Mental Disorders*, 4th

edition (DSM-IV) disorders. Or, as with neurocognitive impairments, psychiatric symptoms may be subsyndromal; underlying causes should be identified and reversed when possible, although it might still be necessary to treat the psychiatric symptoms (Table 26–3[75]).

Mental Disorder Due to a General Medical Condition

Differential diagnosis should always begin with mental disorder due to a general medical condition.[44,46,76] HIV CNS infection, HAD, MND, and ANI should be considered, along with opportunistic infections[77] and neoplasms. Other considerations include side effects of medications including neurotoxic HIV medications, steroids, antibiotics, antifungals, over-the-counter (OTC) preparations, and herbal supplements; drug–drug interactions such as herbal and OTC preparations; alcohol and recreational drugs; substance intoxication or withdrawal.[47] Nutritional effects include nutritional deficits such as thiamine, folate, zinc, cobalamin (vitamin B_{12}), and pyridoxine (vitamin B_6); poor intake resulting from medication or disease-induced nausea, mood disorder, painful oral lesions, or addiction; poor absorption; abnormal losses such as from gastritis, diarrhea, vomiting, or nephropathy; or increased demand resulting from hypermetabolic state due to infection, stress, or neoplasm.[48] Metabolic derangements (e.g., electrolyte abnormalities), renal or hepatic dysfunction, and endocrinopathies (e.g., glucose intolerance, hyperadrenalism, hypocalcemia, or thyroid dysfunction)[78] can also cause psychiatric symptoms.

TABLE 26–3 Differential Diagnosis of Neuropsychiatric Symptoms in Patients with HIV Infection and AIDS

Psychiatric disorders
Psychoactive substance intoxication or withdrawal
Primary HIV-associated syndromes
- Seroconversion illness
- HIV CNS infection
- HIV-associated neurocognitive disorders (HAND)

CNS opportunistic infections
- Fungi: *Cryptococcus neoformans, Coccidioides immitis, Candida albicans, Histoplasma capsulatum, Aspergillus fumigatus*, and mucormycosis
- Protozoa/parasites: *Toxoplasma gondii* and amebas
- Viruses: CJ virus (progressive multifocal leukoencephalopathy [PML]), CMV, adenovirus type 2, herpes simplex virus, and varicella zoster virus
- Bacteria: *Mycobacterium avium-intracellulare, M. tuberculosis, Listeria monocytogenes*, gram-negative organisms, *Treponema pallidum,* and *Nocardia asteroides*

Other neurotropic infective agent
- Hepatitis C virus

Neoplasms
- Primary CNS non-Hodgkin's lymphoma
- Metastatic Kaposi's sarcoma (rare)
- Burkitt's lymphoma

Medication side effects
- Endocrinopathies and nutrient deficiencies
- Addison's disease (CMV, *Cryptococcus*, HIV-1, and ketoconazole)
- Hypothyroidism
- Vitamins A, B_6, B_{12}, and E deficiencies
- Hypogonadism

Anemia
Metabolic abnormalities: hypoxia; hepatic, renal, pulmonary, adrenal, and pancreatic insufficiency; hypomagnesemia; hypocalcemia; water intoxication, dehydration; hypernatremia; hyponatremia; alkalosis; and acidosis
Hypotension
Complex partial seizures
Head trauma
Non–HIV-related conditions

Adapted from: Querques J, Worth JL: HIV infection and AIDS. In Stern TA, Herman JB, editors: *Psychiatry update and board preparation*, New York, 2000, McGraw-Hill, p 208.

CJ, Creutzfeldt–Jakob disease; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus.

Delirium

Delirium is a common neuropsychiatric complication in hospitalized patients with AIDS,[79] and it may be a predictor of significantly decreased survival.[80] In patients with asymptomatic HIV infection or CD4 lymphocyte counts greater than 500/μL, it is rare for an HIV-related condition to cause delirium; substance intoxication or withdrawal is a more likely cause. This includes drugs (such as steroids) used as alternative HIV therapies.

Among patients with symptomatic HIV infection or a CD4 lymphocyte count less than 500/μL, HIV-related conditions and iatrogenic causes (Table 26–4) should be high on the differential diagnosis for delirium and should be at the top of the list for patients at advanced stages of AIDS or when the CD4 lymphocyte count falls below 100/μL. There should be a continued high index of suspicion for substance intoxication and withdrawal. Seizure disorder should also be in the differential diagnosis because HIV-infected patients are at increased risk for new-onset seizures, especially partial complex seizures.[81,82]

A sudden change in mental status is not characteristic of HAD alone; more often it is a result of underlying causes. Patients with advanced HAD experience symptomatic worsening with mild states of delirium during the late afternoon when they are increasingly fatigued or during the night (i.e., sundowning).

The primary goal in the management of delirium is the identification and treatment of causative factors. The need for laboratory tests, including anatomic brain imaging, electroencephalogram (EEG), CSF examination, and blood tests, must be guided by history and clinical examination. If delirium is a treatment-emergent adverse effect, the suspected medication should be discontinued or an alternative agent substituted.

Depression

The most common psychiatric complication of HIV infection or AIDS, depression, should never be considered appropriate. When a person suffers from clinical depression (i.e., experiences sufficient symptoms to meet DSM-IV criteria), the patient deserves to be treated.[83–85] The same criteria for a diagnosis of depression in a person without HIV infection should be used in a person with HIV infection.

TABLE 26–4 Neuropsychiatric Side Effects of Medications Commonly Used in Patients with HIV Infection and AIDS

DRUG	SIDE EFFECTS
Nucleoside Reverse Transcriptase Inhibitors	
Zidovudine (AZT)	Headache, restlessness, agitation, insomnia, mania, depression, irritability, delirium, somnolence, peripheral neuropathy
Didanosine	Insomnia, mania, peripheral neuropathy
Zalcitabine	Peripheral neuropathy
Stavudine	Mania and peripheral neuropathy
Lamivudine	Similar to AZT
Abacavir	Headache
Emtricitabine	Headache
Tenofovir	Headache
Nonnucleoside Reverse Transcriptase Inhibitors	
Nevirapine	Headache
Delavirdine	Headache
Efavirenz	Abnormal dreams, agitation, insomnia, euphoria, depression and suicidality, somnolence, confusion, psychosis; false-positive urine drug test for cannabis Headache, fatigue
Etravirine	Headache
Protease Inhibitors	
Indinavir	Headache, asthenia, blurred vision, dizziness, insomnia
Ritonavir	Circumoral and peripheral paresthesias, asthenia, altered taste
Saquinavir	Headache
Nelfinavir	Headache and asthenia
Amprenavir/fosamprenavir	Headache
Lopinavir/ritonavir combination	Asthenia, headache, insomnia
Atazanavir	Headache
Darunavir	Headache
Tipranavir	Fatigue, headache
Fusion/Entry Inhibitors	
Enfuvirtide (T-20)	Fatigue
Maraviroc	Insomnia
Integrase Inhibitors	
Rategravir	Headache
Other Antivirals	
Acyclovir	Headache, agitation, insomnia, tearfulness, confusion, hyperesthesia, hyperacusis, depersonalization, hallucinations
Ganciclovir	Agitation, mania, psychosis, irritability, delirium
Antibacterials	
Cotrimoxazole	Headache, insomnia, depression, anorexia, apathy
Trimethoprim-sulfamethoxazole	Headache, insomnia, depression, anorexia, apathy, delirium, mutism, neuritis
Isoniazid	Agitation, depression, hallucinations, paranoia, impaired memory
Dapsone	Agitation, insomnia, mania, hallucinations
Antiparasitics	
Thiabendazole	Hallucinations and olfactory disturbance
Metronidazole	Agitation, depression, delirium, seizures (with IV administration)
Pentamidine	Hypoglycemia, hypotension, confusion, delirium, hallucinations
Antifungals	
Amphotericin B	Headache, agitation, anorexia, delirium, diplopia, lethargy, peripheral neuropathy
Ketoconazole	Headache, dizziness, photosensitivity
Flucytosine	Headache, delirium, cognitive impairment
Others	
Steroids	Euphoria, mania, depression, psychosis, confusion
Cytosine arabinoside	Delirium with cerebellar signs

As is the case with certain other medical illnesses, it may be hard to interpret the more somatic neurovegetative symptoms (such as fatigue, loss of appetite, altered sleep patterns, or difficulty with concentration).

Fatigue

Clinically impairing fatigue affects at least one third of patients with HIV/AIDS.[86] Although the etiology may be multifactorial, a search for remediable causes is an important first step. Pain and sleep deprivation contribute to fatigue in many patients. Importantly, fatigue is not pathognomonic for depression. In fact, fatigue is associated with advanced HIV disease. It can also be disproportional to apparent disease status. However, reports of depressed mood, poor interest, and guilt, along with feelings of hopelessness, helplessness, and worthlessness, can facilitate the diagnosis of depression.[87]

Bereavement

The patient with HIV infection or AIDS often suffers multiple losses (including friends, health, physical ability, career, income, housing, child custody, independence, or a sense of freedom or autonomy). Mood and related symptoms require careful evaluation in the setting of loss or bereavement. If the patient meets criteria for major depression and is not responding to supportive interventions, pharmacologic treatment is warranted.

Suicide

Suicidal thoughts should always be assessed; they are more prevalent in patients with asymptomatic HIV infection than in those with AIDS.[88] The incidence of suicide in patients with HIV infection or AIDS has decreased since the advent of HAART; it is now similar to that seen with other medical illnesses. The incidence of suicide in this population of HIV-infected persons and those with other medical illnesses, however, is still higher than in the general population. Risk factors include symptomatic depression, persistent pain, drug use (specifically injection drug use[89]) or alcohol use, domestic violence,[90] altered cognition (i.e., delirium or HAD), social isolation, multiple losses, hopelessness, and personality disorders.[20,91] Serious thoughts of self-harm usually indicate the need for inpatient care. Electroconvulsive therapy (ECT) may be a lifesaving procedure for patients who are severely depressed and suicidal, especially when they are medically compromised and unable to tolerate medications or the delay in their effectiveness.

Anxiety

Prevalent in HIV infection, anxiety runs the gamut from an acute response to a devastating diagnosis, to a full-blown anxiety disorder. Patients with a history of an anxiety disorder are at increased risk, as are those with few social supports and poor coping skills. In susceptible patients, onset or recrudescence of anxiety symptoms may be predictably related to disease milestones or to signs of disease progression such as initial diagnosis, declining CD4 count, increased viral load, onset of opportunistic infections, chronic pain or paresthesias, wasting, or physical changes that make the disease more public.[20,92] The somatic symptoms often associated with anxiety (e.g., tremor, muscle tension or spasm, shortness of breath, dizziness, headache, sweating, flushing, palpitations, nausea, vomiting, or diarrhea) need to be carefully investigated for possible medical causes, medication side effects, drug interactions, use of activating recreational drugs, or withdrawal from opiates or sedative–hypnotics.

Mania

Mania in the setting of a personal history of recurrent mood episodes is a core feature of bipolar disorder and is considered primary (idiopathic) mania. Without such a history or a strong family history of bipolar disorder, any first episode of mania in the setting of HIV infection should be considered secondary (organic) mania as a result of the physiologic effects of HIV CNS infection, opportunistic infections, neoplasm, medications, or use of substances of abuse.[93] Current or previous treatment with zidovudine (AZT), which penetrates the blood–brain barrier, seems to be protective, whereas less-penetrating medications, such as ddI and zalcitabine (ddC), have not shown such benefit. A positive correlation exists between the manifestation of HIV-associated mania and the eventual development of HAD, MND, or ANI, although mean survival is not adversely affected. HIV-associated structural brain lesions might not be more common in patients who develop mania.[94]

HIV-related secondary mania accounted for more than 40% of hospital admissions for acute mania in a 6-month period in Uganda, where HIV is very prevalent.[95] Review of this cohort confirmed earlier suggestions that HIV-related mania is clinically distinct from primary (bipolar) mania, in that HIV-related mania typically manifests with more irritability and psychosis rather than euphoria.[87] The manic HIV patients tended to be more aggressive, paranoid, and talkative. They also had more auditory and visual hallucinations, tended to be older, and were more cognitively impaired.

Psychosis

A preexisting psychotic disorder may be a risk factor for HIV infection, and it is positively associated with psychosis in HIV-positive patients. The literature somewhat suggests that a history of substance abuse, depressive episodes, or certain personality disorders might also correlate with the onset of psychotic symptoms in HIV-associated disease and that antiretroviral therapy may be protective against the development of psychosis.[96–98] Secondary causes include more immediate psychoactive substance use (particularly methamphetamine use), CNS HIV infection (usually a late-stage manifestation) or opportunistic infections, neoplasms, nutritional deficits, metabolic derangements, or delirium. There are also case reports of psychosis induced by antiretroviral medication (e.g., efavirenz[99]). HIV-infected patients with psychosis tend to exhibit greater cognitive impairment.[98]

Sleep

Sleep problems are highly prevalent (30% to 40%) in HIV infection for a variety of reasons.[99–101] They may be related to the stage of HIV disease, persistent pain (e.g., from peripheral sensory neuropathy), or psychosocial issues.[101] Other related medical conditions can include sleep apnea, congestive heart

failure, paroxysmal nocturnal dyspnea, gastroesophageal reflux, polyuria, or delirium. Related movement disorders associated with sleep include restless legs syndrome (RLS) and periodic limb movement disorder (PLMD).

Medications such as antivirals, interferon, psychostimulants, antidepressants, and bronchodilators and substances such as alcohol, caffeine, nicotine, cannabis, and opiates can interfere with restorative sleep. Psychiatric disorders such as depression, anxiety, adjustment disorders, acute stress, and coping with life events can also disrupt normal sleep. In addition, lack of structure (e.g., from unemployment), daytime napping, and other contributions to disordered sleep hygiene can lead to reversal of the sleep–wake cycle.

Few things in life seem better when one is sleep deprived. Insufficient or inefficient sleep negatively affects energy, mood, memory, cognition and cognitive speed, work performance, and quality, enjoyment, and safety. Insomnia and fatigue also appear to be associated with increased morbidity and disability. One fourth of patients try OTC sleep aids (e.g., diphenhydramine, valerian root, or melatonin), 27% use alcohol, and less than 15% take prescribed sedative–hypnotics.[102]

Substance Use

Although injection drug use is the second most common risk factor HIV infection in the United States,[103] other modes of drug use and alcohol abuse also increase the risk of infection through unsafe sexual practices, drug-induced hypersexuality, disinhibition, impulsiveness, altered cognition, impaired judgment, or prostitution to obtain drugs or money for drugs.[20] In the substance-abusing population, HIV infection is associated with youth, homelessness, being from an ethnic minority, and having a history of sexual victimization. Prior psychiatric illness is also common, with bipolar disorder, major depression, schizophrenia, and schizoaffective disorder being the most prevalent Axis I disorders. Antisocial and borderline personality disorders are the most common Axis II disorders.[104]

HIV infection tends to be diagnosed at a more advanced stage of the disease in injection drug users and may have a more rapid downhill course. Injection drug use is also seen as a bridge of infection through heterosexual and mother-to-child transmission. Continued drug use can speed the patient's decline in several ways: suppressed immune function, increased risk for infections (e.g., STDs, hepatitis C virus [HCV] infection, pneumonia, abscesses, endocarditis, and tuberculosis [TB]), drug interactions with antiretroviral agents, poor ability to adhere to complicated medical regimens, and chaotic lifestyles that make scheduled medical follow-up difficult.[105] This population has a high tolerance to medications and possibly a low tolerance to pain, discomfort, or inconvenience. It is also a population at risk for impaired cognitive function from neurotoxic substances, poor nutrition, metabolic encephalopathies, ischemia, stroke, seizures, and head trauma.

Pain

The evaluation of pain and its adequate treatment and management are essential in the care of patients with HIV infection or AIDS. Pain is a common reason for psychiatric consultation and, rather than death, is often what patients fear most.[106] Pain control is one of the cornerstones in the care of patients with end-stage AIDS. Pain syndromes, including neuropathy, myopathies, and headache, are common among patients with HIV infection, particularly those who have received certain older antiretroviral drugs (see later). The psychiatrist might need to intervene when hospital staff who care for a patient with a history of substance disorder fail to distinguish between the management of the patient's addiction and the adequate treatment of pain or fail to provide adequate pain relief to patients from a racial or ethnic minority.[107]

Peripheral sensory neuropathy, the most common pain syndrome in patients with HIV-associated disease, affects up to 35% of patients with AIDS.[108,109] Most commonly the neuropathy manifests as a distal, symmetric polyneuropathy that can be caused by HIV infection or particularly by the "d" antiretroviral drugs, ddI, ddC, and stavudine (d4T). The diagnosis is confirmed on the basis of the neurologic examination and laboratory tests, including an electromyogram and nerve conduction studies. Treatment includes a change in the antiretroviral regimen to avoid nerve-toxic agents and the avoidance of other aggravating factors such as alcohol. One study found lamotrigine to be effective.[110]

APPROACH TO PSYCHIATRIC CARE

Screening and Prevention

It is estimated that a quarter of those infected with HIV in the United States are unaware of their seropositivity, that the unaware are responsible for the majority of new infections, and that many would take steps to change their risky behavior if they were informed of their status.[111] In 2006, the Centers for Disease Control and Prevention (CDC) Division of HIV/AIDS Prevention took steps to address this by issuing new recommendations advocating for universal HIV screening in all health care settings: medical inpatient and outpatient, mental health, and substance abuse settings. The recommendations require no special patient consent for screening, which is performed once the patient is so notified, unless the patient specifically delines consent; this is universal opt-out screening.[112] However, many states still have statutes that require written informed consent.

Psychiatrists care for an at-risk population.[113] Knowledge about HIV status and transmission is essential, but not sufficient. The first step in prevention is the assessment of the patient for risk factors and behavior. Patients must be able to perceive themselves as at risk in order for counseling to be effective.[114] Prevention models with individual and groups of chronically mentally ill and substance-abusing patients must be specific and tailored to the population being addressed. Programs with counselors whose cultural backgrounds are similar to those of the patient population have proved most effective. Programs geared toward the injection drug use community have enlisted community members as prevention leaders.

Collaboration

Although a number of demonstration projects have shown the efficacy of wrap-around services for HIV-infected patients,[115,116] it is the exception rather than the

rule to have medical, mental health, and addiction services, including methadone maintenance, in one coordinated site.[117] More commonly, patients with multiple diagnoses have complicated treatment regimens and have multiple providers at diverse sites of care, a situation that can parallel the chaos in the rest of their lives. In the absence of single-site treatment, intensive management of care can keep all treaters informed, provide outreach to improve attendance at appointments, assist with concrete services (e.g., housing, transportation, and child care), and help devise and implement an individualized medication adherence plan. The consultation psychiatrist has a unique opportunity to facilitate communication and to coordinate care among members of the patient's care team.

Adherence

Adherence is the cornerstone of successful therapy for HIV infection. Missed doses lead to treatment resistance and sometimes resistance to whole classes of medication. This, in turn, is correlated with increased morbidity and mortality, as well as the development of more treatment-resistant viral strains. Active substance abuse, homelessness, a lack of social supports, domestic violence, personality disorders, and psychiatric illness, especially major depression,[118,119] have long been recognized as risk factors for poor adherence.[120] However, the presence of one or more of these factors is not justification for exclusion from antiretroviral therapy. Rather, these factors are challenges to be addressed in preparation for initiating HAART, which may be postponed for several months while active treatment is initiated for addictions or psychiatric problems, along with readiness for concurrent medications and education about adherence.[121,122] The patient hospitalized with HIV infection is a captive audience for the initiation or reinforcement of this preparation for HAART.[76]

Effective adherence programs are tailored to the patient in terms of language, education, culture, lifestyle, and personality. Individualized adherence programs capitalize on or enhance the patient's social supports (e.g., family, intimate partners, friends, and groups), cognitive abilities, and personality style. They require accessibility, flexibility, and positively framed incentives (i.e., rewards, not punishments).[76,123] Adherence is further promoted when the patient has a high level of satisfaction with the physician,[123] understands the importance of taking every dose, believes that missed doses lead to resistance, knows and recognizes each specific medication, and is informed of possible side effects.

Simplifying the regimen (e.g., reducing the number of doses and food restrictions) and minimizing the pill burden helps fit the regimen into the patient's lifestyle. Clearly written instructions are helpful, if the patient is literate. Tying pill-taking to daily routines, along with pill boxes, alarms, pagers, directly observed therapy, or other reminder systems, can also increase adherence. Patients who are comfortable taking medications in front of other people also have an easier time incorporating HAART into their lives.[124] Adherence to scheduled medical appointments is associated with optimal viral suppression and might warrant appropriate outreach efforts.[125]

Adherence is not static; it needs to be inquired about, and promoted by, each provider at every visit. Pill fatigue, complacency, transient or prolonged relapse of substance abuse or depression, onset of morphologic or metabolic side effects, onset or exacerbation of other medical conditions, hospitalization, or psychosocial stressors (e.g., financial, housing, insurance and changes, family or relationship issues, and travel) can interrupt or decrease the patient's previous level of adherence.

TREATMENT

Nonpharmacologic Treatments

Case Management

Case management is often necessary to help with basic needs such as food, shelter, transportation, child care, medical coverage, and other entitlements, which may be needed in this population and are powerful barriers to adequate treatment. In particular, patients with cognitive impairment (executive dysfunction and memory problems) are at risk for falling through the cracks unless appropriate help and supervision are provided.

Groups

Groups of various types, often provided in the community or by AIDS activist organizations, offer a supportive, social network and positive affiliations for members of an often disenfranchised and stigmatized population. Self-help, 12-step, and peer-counseling groups are examples of such community-based programs. Therapy groups and other more formalized groups[126] might focus on aspects of living with HIV infection (e.g., disclosure, adherence, and parenting), participant characteristics (e.g., women, particular ethnic minorities, gay men, and substance abusers), or mission (e.g., risk reduction or prevention).[20]

Individual Psychotherapy

Individual psychotherapy can help patients cope with HIV infection or AIDS-related issues and distress with approaches such as coping strategies, problem-solving, disclosure of HIV status, discrimination, relationships, sexuality, and bereavement. For patients whose infection was diagnosed more than a decade ago, issues of facing a foreshortened life span may be replaced by issues of living with a chronic illness.[127] There may be themes of remorse and longing for missed opportunities referent to this erroneous life view. The focus and goals of therapy may be specific to the stage of HIV-associated disease; late in the course of AIDS, therapy may focus on end-of-life issues (such as concerns about ongoing childcare and guardianship, coping with loss, progressive disability, and unremitting pain).

For specific diagnoses, including depression or anxiety disorders, proven therapies, such as interpersonal psychotherapy or cognitive-behavioral therapy (CBT), respectively, have been shown to be effective in this population.[126,128,129] Self-hypnosis, guided imagery, meditation, muscle relaxation, massage, yoga, aerobic exercise, or acupuncture may be therapeutic for selected patients.

Adherence to medications for HIV infection and psychotropic medications should be reinforced or explored.

It should be stressed that the therapist is a member of the patient's treatment team, and appropriate releases should be obtained to allow all team members to communicate and to coordinate care. The therapist, for instance, may spend more time with the patient and be the first clinician to suspect cognitive dysfunction that requires medical work-up and intervention.

Pharmacologic Treatment

Drug–Drug Interactions

Patients with HIV infection or AIDS may be taking HIV-related medications, psychotropic drugs, OTC and herbal preparations, alcohol or drugs of abuse, and drugs to treat those addictions. Such drug combinations are prone to interactions, overlapping side effects, and toxicities. Drug side effects, such as diarrhea (common to many antiretroviral agents), can decrease the absorption of other drugs. One drug can inhibit or promote the enzymatic degradation of another drug and cause toxicity or a subtherapeutic level, respectively. Some drugs can also switch from being potentiators to inhibitors or vice versa. A drug can induce or inhibit its own metabolism over time. Certain drugs can displace other drugs from plasma protein-binding sites, effectively increasing the concentration of the displaced drug. Potential drug interactions do not necessarily preclude the concomitant use of such medications but require a careful risk-to-benefit assessment, possible dose adjustment, periodic drug level monitoring, and monitoring for or treatment of side effects. Some general principles and frequently updated resources (Table 26–5) can aid in the safe pharmacologic treatment of these patients.

Effects on the CYP enzyme system in the liver account for many of the drug–drug interactions.[130] Of the key CYP isoenzymes involved in the metabolism of psychotropics and antiretrovirals (1A2, 2C9/19, 2D6, and 3A4), 3A4 and 2D6 account for the majority of the metabolism of psychiatric medications. Allelic differences cause 10% of whites and 1% of Asians to slowly metabolize 2D6 substrates,[131] and 20% of African Americans and Asians and 5% of whites slowly metabolize 2C19 substrates.[132,133] Medications can rely on more than one metabolic pathway, which acts as a safeguard against drug interactions. In vitro studies of drug metabolism do not adequately portray the human experience that is complicated by individual genetic and nutritional differences and multidrug and substance regimens.[130,131] As a rule of thumb, the PIs, followed by the NNRTIs, have the broadest effects on the CYP system; the NRTIs are mostly devoid of drug interactions. The PI ritonavir also induces glucuronyl transferase, a non-CYP metabolic enzyme.[130]

Antidepressants

Antidepressants are largely metabolized, though not exclusively, by 2D6 and 3A4. Ritonavir, and to a lesser extent indinavir, inhibit metabolism of 2D6 substrates; all of the PIs inhibit 3A4 metabolism to varying degrees.[134] Inhibition of the metabolism of the SSRIs, venlafaxine, and mirtazapine by ritonavir and indinavir increases the levels of the antidepressants, which might allow a therapeutic response at a low or moderate dose. Although high doses of the antidepressants could lead to serotonin syndrome[135] or other toxicities, a wide range of concentrations are generally well tolerated. Tricyclic antidepressants (TCAs), however, have a narrow therapeutic window; metabolic inhibition at 2D6, from PIs (or most SSRIs), can lead to serious toxicity, including death. Safe concurrent use of these medicines requires therapeutic drug monitoring of the TCA levels (to determine the appropropriate dose) and monitoring electrocardiograms (ECGs).[130]

Bupropion continues to be in a class by itself. Initially thought to be a substrate of 2D6, bupropion was considered contraindicated in patients taking PIs because of the potential for seizures. It turns out, however, that a

little-studied isoenzyme, 2B6, is responsible for bupropion metabolism. Low doses and conservative titration are still recommended, but the actual risk seems much less than previously thought.[20,130] There has been one report of *in vitro* 2B6 inhibition by ritonavir, nelfinavir (PI), and efavirenz (NNRTI), causing significant interference with bupropion metabolism.[136] Whether this interference is significant *in vivo* is unclear. A prospective study that included the administration of bupropion to patients on PIs reported no serious adverse events and, specifically, no seizures.[137]

Nefazodone, no longer marketed under the trade name (i.e., Serzone) probably has no place as a newly started medication, but some patients may already be taking the generic form. It is a 3A4 substrate and inhibitor. When teamed with the PIs, a potentially dangerous synergistic inhibition diminishes the metabolism of other 3A4 substrates.[132,138,139] Use of this combination with astemizole, cisapride, or pimozide can cause cardiac arrhythmias; with benzodiazepines, respiratory depression can follow; with clozapine, seizures may be seen; with ergot alkaloids, systemic vasoconstriction can occur; and with sildenafil, priapism can arise.[130]

Citalopram and escitalopram have the least potential for clinically significant drug interactions.[138,139]

Psychostimulants, such as methylphenidate[140] and dextroamphetamine,[141] may be used to treat depression, to augment antidepressant therapy, or to treat the symptoms of fatigue and cognitive decline associated with HIV infection.[142] Methylphenidate can inhibit 2C9 and 2C19 metabolism, leading to increased levels of certain TCAs (i.e., desipramine, clomipramine, and imipramine), barbiturates, and warfarin. Dextroamphetamine, however, is a 2D6 substrate that neither inhibits nor induces the CYP isoenzymes, but it can compete at active sites.[20,130]

Benzodiazepines

Benzodiazepines are primarily 3A4 substrates, with the exception of lorazepam, oxazepam, and temazepam, which are metabolized by glucuronyl transferase. For this reason, these three exceptions are the drugs of choice when patients on (3A4-inhibiting) PIs require treatment with a benzodiazepine. Other benzodiazepines would be expected to have increased levels when co-administered with PIs, leading to possibly dangerous sedation or respiratory depression. However, use of these glucuronyl transferase substrates (e.g., lorazepam, oxazepam, and temazepam) with that enzyme's inducer, ritonavir, can require higher doses of benzodiazepines.[20,130] The NNRTIs efavirenz and nevirapine, along with the PI ritonavir, have the potential to induce the 3A isoenzymes. This 3A induction may be delayed and cause a drop in previously elevated benzodiazepine levels, resulting in decreased efficacy or withdrawal. This unpredictability precludes the regular use of such short-acting agents (e.g., alprazolam) because of the risk that withdrawal will precipitate seizures.[143]

Mood Stabilizers

Beyond optimizing the antiretroviral regimen, treatment of HIV-related secondary mania should be tailored to the patient's HIV status and general medical condition. In advanced HIV/AIDS, patients might find lithium or carbamazepine less tolerable. Valproate increases the risk of liver toxicity (especially in patients with chronic hepatitis C or other liver disease) and bone marrow suppression (especially in combination with zidovudine, whose levels may be increased via glucuronyl transferase inhibition[144]).

Although lithium does not interact with the CYP system, it should be avoided in HIV-positive patients with advanced illness because of its potential for toxicity with fluid and electrolyte shifts. Carbamazepine induces 3A4, lowering levels of the PIs and other antiretrovirals, a situation that could foster resistance, possibly to a whole class of medications.[130] It might be possible in certain instances to avert this resistance by using higher doses of the antiretroviral. However, carbamazepine is also relatively contraindicated in immune-suppressed patients because of its potential to cause leukopenia.[20] Lamotrigine bypasses the CYP system, but it is a glucuronyl transferase substrate and needs to be titrated slowly to reduce the risk of Stevens–Johnson syndrome.[130]

Neuroleptics

Plasma levels of clozapine, which has a complex metabolic pathway involving 1A2, 2C9/19, 3A4, and 2D6, can increase with concomitant use of PIs. Despite its relative contraindications given the potential for drug interactions and added bone marrow toxicity, clozapine may still be used, particularly because it is possible to monitor clozapine serum levels.[145] The rarely used pimozide, a 3A4 substrate, can cause fatal arrhythmias at high levels; therefore, it is contraindicated with the use of any 3A4 inhibitor and thus all PIs.[146]

Substance–Drug Interactions

Opiates also interface with hepatic metabolism, affecting and being affected by interactions with antiretroviral medications. Meperidine may be cleared more quickly, leaving a higher concentration of its neurotoxic metabolite that causes delirium and possibly seizures. Clearance of fentanyl, a 3A4 substrate, is decreased by ritonavir, which can cause nausea, dizziness, and possibly respiratory depression. Codeine and its derivatives are prodrugs that need to be converted to analgesics. PIs can block this conversion and make pain control more difficult. PIs can also induce withdrawal in heroin-addicted persons or patients on methadone maintenance. Conversely, ritonavir inhibits metabolism of ecstasy, ketamine, cocaine, and other stimulants, as well as γ-hydroxybutyrate (GHB). Fatal interactions between ecstasy and ritonavir have been reported.[130,147]

Considerations in Pharmacologic Treatment

Depression

For a variety of reasons, patients with HIV infection are very sensitive to small doses of medications, similar to what is seen in geriatric patients. Helping the patient tolerate medications is ultimately more important than is raising the dose quickly. The general principle is, start low and go slow. However, patients still need to receive an appropriately high dose of any psychotropic. Because of the

pill burden and complicated schedules patients with HIV infection must often endure, once-a-day antidepressant therapy is generally preferable. Anticholinergic medications should be avoided or minimized because of their deleterious effects on cognition and the possibility of delirium or even seizures. Decreased saliva can also predispose to the development of thrush.[46]

Selective Serotonin Reuptake Inhibitors

The SSRIs remain the drugs of choice for depressive disorders in HIV patients because of established efficacy[148] in this patient population and a favorable risk-to-benefit profile. Fluoxetine, with the longest half-life ($t_{1/2}$), is a good option for patients who have tumultuous lives and who might miss doses. Use of fluoxetine weekly is also an option. On the other hand, if there is a side effect or an unpleasant interaction, it will take 2 weeks or more for it to clear. Citalopram and its L-enantiomer escitalopram are the SSRIs that might have the fewest drug interactions. All SSRIs are associated with sexual side effects, akathisia-like activation (or the serotonin syndrome when toxic levels are present), and GI symptoms.

Tricyclic Antidepressants

The TCAs are often used in small doses for neuropathic pain, insomnia, or headaches. The side effect of constipation may be helpful in some HIV-infected patients with diarrhea. TCAs can be lethal with ingestion of a 2-week supply. The least anticholinergic ones, nortriptyline and desipramine, should be used with an awareness that anticholinergia can worsen cognition. TCAs should be monitored with ECGs and plasma levels.

Serotonin–Norepinephrine Reuptake Inhibitors

Venlafaxine, its metabolite desvenlafaxine, and duloxetine are serotonin and norepinephrine (hence, "dual") reuptake inhibitors. The extended-release form of venlafaxine is a reasonable first-line medication because of its once-a-day dosing and relative lack of drug interactions. SNRIs can be initially stimulating, and some patients have difficulty tolerating them. SNRIs can raise blood pressure unacceptably in hypertensive patients, and blood pressure monitoring is required. Milnacipran and sibutramine are SNRIs marketed in the United States for fibromyalgia and weight loss, respectively.

Bupropion

The antidepressant least likely to have sexual side effects, bupropion, does not treat anxiety. Bupropion's continued stimulant effect, if tolerable, can benefit patients with fatigue or apathy, although, unlike psychostimulants, bupropion tends not to improve HIV-related cognitive slowing.[46] Bupropion lowers the seizure threshold in a dose-dependent manner, which is a concern in patients who have a history of seizures, poorly controlled seizure disorders, head trauma, or other threshold-lowering pathology (e.g., space-occupying lesions, infections, or alcohol or psychoactive substance abuse). Patients with eating disorders or metabolic derangements from drug side effects (such as vomiting or diarrhea) may be at increased risk for seizures. The slow-release forms may be safer with regard to seizure risk.

Trazodone

Primarily used for its major side effect, trazodone makes people very sleepy within 20 to 30 minutes of ingestion, usually at a low dose of 25 or 50 mg. In low doses, it is minimally anticholinergic. Men of all ages must always be informed of its rare but serious side effect, priapism (prevalence is about 1/7000).

Mirtazapine

At low doses, mirtazapine is useful for patients who have difficulty eating and sleeping, even in the absence of clear depression. At higher doses, it is also an effective antidepressant, albeit with major long-term management issues related to histaminergic side effects (e.g., daytime drowsiness and significant weight gain). Patients who receive mirtazapine should be weighed at regular intervals.

Monoamine Oxidase Inhibitors (MAOIs)

Because of the myriad drugs patients with HIV infection might need over time, MAOIs are relatively contraindicated in these patients. They should specifically not be co-administered with zidovudine.

Psychostimulants

In low doses, psychostimulants can improve appetite, energy, and mood. They work quickly, often within hours, and have few side effects or interactions. Especially useful in patients who are unresponsive to or intolerant of other antidepressants, stimulants also effectively improve the early symptoms of cognitive decline; they help patients attend and stay more focused and organized. In late HAD, however, they can become toxic. Stimulants should also be avoided in the presence of psychotic symptoms or in those with a history of seizures. Abuse is rare in patients who have no history of a substance disorder. A history of a substance disorder is not a contraindication to the use of stimulants but it does require that the prescriber be more cautious. Modafinil is a wakefulness-promoting nonstimulant psychotropic drug that is sometimes used instead of a psychostimulant for HIV-related fatigue and depression.[149]

Anxiety

Anxiolytic Antidepressants

For prolonged use in anxiety disorders, the SSRIs as well as SNRIs and TCAs are beneficial, and they decrease the needed dose of benzodiazepines when these medications are co-administered.

Benzodiazepines

For more time-limited episodes of intolerable anxiety, short- to medium-acting benzodiazepines without active metabolites and the least drug–drug interactions (such as lorazepam or oxazepam) should be used. Alprazolam may be helpful for procedures in which a very quick onset and short duration are required. For more continuous use, however, the rapid offset of alprazolam predisposes to mild withdrawal or rebound anxiety. This rapid offset leads to extreme discomfort several times a day or to a gradually increased frequency of dosing and puts patients at risk for becoming addicted. Alprazolam and triazolam are contraindicated in patients who are being treated with a PI-based HAART regimen.

Buspirone

An option for patients on PIs, buspirone unfortunately takes several weeks to become effective. Concomitant use of benzodiazepines may be necessary to help the patient through the initiation and titration period. In advanced systemic illness, but not less-symptomatic disease, buspirone has worsened cognition and triggered mania.[46]

Antipsychotics

Although generally not recommended for anxiety because of potentially serious long-term toxicities, low doses of atypical antipsychotics may be effective if fear or pain are prominent. In addition, some of the second-generation antipsychotics are now indicated for use in depression. If antipsychotics are prescribed, medical monitoring, particularly to prevent tardive dyskinesia and the metabolic syndrome, is necessary, regardless of indication.[150]

Mania

Although lithium bypasses hepatic metabolism, it carries the risk of serious neurotoxicity and nephrotoxicity in patients prone to fluid loss from diarrhea, vomiting, inadequate intake, or HIV nephropathy. Valproic acid may be more effective for patients with secondary mania and brain abnormalities on MRI.[151] Carbamazepine is less useful because of its potent induction of the 3A4 isoenzyme (increased clearance of PIs) and possible blood dyscrasia. Although benzodiazepines have antimanic properties, they carry the risk of disinhibition, anterograde amnesia, and confusion; they are generally not considered to be primary pharmacologic treatment of mania. For medically complex patients with HIV disease, antipsychotics may be preferred over the standard mood stabilizers.

Psychosis

Antipsychotics are the treatment of choice for psychotic symptoms of almost any cause. Patients with HIV infection, however, are extremely sensitive to side effects of antipsychotics and are at risk for extrapyramidal symptoms (EPS) and neuroleptic malignant syndrome (NMS) with high-potency agents and confusion or seizures with low-potency agents.[20,98,152] The second-generation antipsychotics are often chosen because of better tolerability, particularly with regard to EPS. Very low starting doses and cautious titration are recommended. Risperidone and olanzapine have each been used effectively for HIV-related psychosis without causing undue sedation or cognitive impairment.[20,153] The deleterious effect of many second-generation antipsychotics on glucose metabolism, however, can limit their usefulness, especially in patients already at risk for diabetes, such as those taking PIs. Quetiapine is the least apt to induce parkinsonian symptoms, making it a reasonable first-line medication for advanced neuropsychiatric disease.

Substance Abuse

The treatment and management of hospitalized patients with HIV infection and substance abuse disorders has five main features, depending on the patient's level of addiction or recovery: prophylaxis against or treatment of withdrawal; encouragement to enter a recovery program, including referral to a comprehensive addictions program; maintenance of recovery during the stress of hospitalization; adequate pain control, including the use of narcotic medications, if appropriate; and careful monitoring for drug–drug interactions, especially for patients on methadone maintenance.

If the patient is on methadone maintenance and opiate analgesia is required, an agent other than methadone should be used to maintain clear boundaries for the patient and the methadone maintenance program. For patients with active addictions problems, HIV infection and AIDS community-based organizations might have addictions outreach programs that send a worker to the patient's bedside. Prescribed medications that are being abused might need to be discontinued. There are limitations to the model of harm reduction used in many addiction-treatment programs, and the psychiatrist should know that prescribing oral forms of abused injection drugs does not promote recovery from substance disorder. This practice might only introduce the problems of dependence on high doses of oral substances.[154] For patients on methadone maintenance with symptomatic HIV infection or with $CD4^+$ lymphocyte counts below 500/μL, the initiation of some antimicrobial agents can have pharmacologic consequences.[155] For example, methadone increases zidovudine serum levels, which can lead to increased toxicity. Treatment with rifampin can increase methadone metabolism and potentially precipitate acute opiate withdrawal. In this instance, the daily methadone dose needs to be increased. The discharge plan would need to include notifying the patient's methadone clinic of this dosage change.

Pain

The treatment of HIV-related neuropathy is similar to the approach used with a chronic pain syndrome. Low doses of TCAs can be effective, either alone or in combination with other analgesic therapies. No systematic studies have been conducted to compare the effectiveness of different TCAs, and no evidence exists for the superiority of amitriptyline for HIV-related neuropathy. Desipramine and nortriptyline are better tolerated and appear to be as effective.

Anticonvulsants in low doses can be effective for neuropathic pain, either alone or in combination with other analgesic therapies. Both carbamazepine and valproic acid have been effective, but hematopoietic and hepatic side effects and drug interactions must be monitored. Gabapentin may be effective for neuropathic pain; its use avoids hematopoietic and hepatic side effects. Low-dose clonazepam can be particularly effective for hyperpathic pain. Lamotrogine has support for its use for HIV-related sensory neuropathy from a controlled trial.[110]

Some antiarrhythmics also have local anesthetic properties and can be useful for some types of pain syndromes. Postherpetic neuralgia can be highly disabling in HIV-infected patients, particularly those who have had multidermatomal herpes zoster. IV lidocaine can offer relief, often with once- or twice-weekly infusions, and a significant dose reduction in narcotic analgesics.

Opiates are beneficial for short-term use or for periods of pain exacerbation, but they can induce tolerance and abuse or dependence. A history of a substance disorder does not preclude the use of opiates required for adequate analgesia, but it requires careful monitoring to prevent

unauthorized escalation of the dosage. In discharge planning for patients with advanced HIV disease, the psychiatrist should remember that cognitive impairment can make compliance with as-needed dosing schedules difficult, and patients can accidentally overuse analgesics. The use of a pill alarm or box can help. If long-term therapy with opiates is needed, the psychiatrist should consider long-acting oral or transdermal formulations. The latter are particularly helpful in the care of terminally ill patients, many of whom have odynophagia or dysphagia.

CONCLUSION

Neuropsychiatric symptoms are part of the HIV infection and AIDS and have multiple etiologies. HIV CNS infection and primary psychiatric disorders should always be considered. Other CNS infections or lesions, medications, drugs of abuse, drug–drug interactions, and metabolic derangements need to be explored. Whenever identified, underlying causes should be treated, but the psychiatric symptoms can require more immediate, symptomatic treatment.

Patients with HIV infection are often sensitive to small amounts of medication, and they should generally be given geriatric doses with careful monitoring and slow dosage titration; ultimately, however, an effective dose must be prescribed. The PIs, and to a lesser extent the NNRTIs, are responsible for the majority of the drug–drug interactions with psychotropic medications. These interactions occur largely because of interference with the hepatic CYP enzyme system. Having access to frequently updated and reliable resources assists with the choice of safe pharmacologic alternatives in this population. Optimal psychiatric care (e.g., effective remission of depression) can help patients achieve sufficient adherence to antiretroviral treatment and even improve their prognosis *quo ad vitam*.

27 Patients with Cancer

Ilana M. Braun, M.D.
William F. Pirl, M.D., M.P.H.
Donna B. Greenberg, M.D.

The seriousness of the diagnosis of cancer challenges the capacity to survive, set a course in life, and fulfill hopes and dreams. Over the 20th century, even as cancer treatments improved and some patients were cured, psychiatrists in the tradition of humane psychiatry used their skills to stand by patients who were overwhelmed and help them make complex treatment choices by which they can shape the rest of their lives or their end-of-life care. Psychiatrists have offered expert diagnosis and management of co-morbid psychiatric syndromes and collaborated with oncologists so that treatable psychiatric illnesses have not stood in the way of technical oncologic care. In addition, specific cancer-related or cancer treatment–related neuropsychiatric syndromes (Table 27–1)[1–5] can, and should, be recognized and treated.

Since Weisman and co-workers explored how to help patients cope with cancer when they were demoralized,[6–8] psychiatrists have tried to understand who their patient was before the diagnosis and the nature of the patient's existential predicament. The psychiatric interview can assess the personal past, present plight, anticipated future, regrets, salient concerns, physical symptoms, disabilities, coping strategies, and psychiatric vulnerabilities (Table 27–2).[7]

Denial and "Middle Knowledge"

Patients often seem to know and want to know about the gravity of their illness, yet they often talk as if they do not know and do not want to be reminded about their cancer.[9] Weisman used the expression "middle knowledge" for the space between open acknowledgment of death and its utter repudiation. Patients may deny facets, implications, or mortal threat of an illness.[9] Middle knowledge is most apparent at transition points (e.g., when a cancer recurs). However, denial is an unstable state; it is almost impossible to maintain denial against even the most reluctant patient's inner perceptions. To preserve a relationship, patients often deny their knowledge of impending death to different people at different times.[10] Tactful discussions of mortality allow patients to be responsive to those closest to them for as long as possible.[9]

Hope and the Doctor–Patient Relationship

Physicians convey respect when they explore the patient's capacity to cope. That respect allows the patient to nurture courage and resiliency[11] and regain a sense of control while appraising and reappraising his or her choices. Presenting the facts to a patient about an illness does not break the trust established between a patient and a doctor. Furthermore, hope is not merely related to prognosis. The patient's capacity to hope is also related to an ego ideal and the conviction of one's influence on the world. As the physician bolsters the patient's self-esteem, a sense of purpose adds value to life regardless of the time frame. The psychiatrist's capacity to listen nonjudgmentally allows patients to express doubts and weaknesses and accept who they are and why they see things as they do. The physician's presence protects patients from abandonment and offers a place where they can explore what is meaningful to them.[11,12]

Medical Choices

The psychiatrist also clarifies with the patient which choices are feasible. Unfazed by personal shock, anxiety, and denial and armed with a medical education, the psychiatrist is in an excellent position to understand (better than the patient) the individualized medical plan, as set forth by medical experts. Diagnosis, treatment, and prognosis are complex. As the psychiatrist learns how the patient thinks and adds appropriate psychopharmacologic treatments for symptoms or Axis I diagnoses, as needed, the psychiatrist can focus on necessary anticancer treatments that are most likely to give the best outcome. Focusing on problems, setting priorities, making clear what the patient is doing and not doing about a problem, and exploring strategies are key elements of care. By doing so, patients can make the decisions that are most important for them. Meanwhile, the psychiatrist, in collaboration with oncology staff, sorts through differential diagnoses as psychological symptoms develop and the medical condition and treatment progress. The psychiatric assessment involves an evaluation of affective, behavioral, cognitive, and physical symptoms and the creation of a differential diagnosis. The work also includes education about how to support significant others and how to allow help or relinquish control to those who have shown themselves trustworthy. Honest communication allows for acceptance, a reduction of bitterness, and replacement of denial with the courage to confront what cannot be changed.[10]

Distress

In the study of newly diagnosed cancer patients, Weisman and Worden found that the peak period of distress ranged from 1 or 2 days to 3 months but that the intense distress lessened over time.[13] Those who were more depressed and anxious, who had less financial and social support, who abused alcohol, who had more troubled relationships, and

TABLE 27–1 Neuropsychiatric Side Effects of Cancer Drugs

Hormones[1]

Anti-estrogens

Tamoxifen, toremifene: hot flashes, insomnia, mood disturbance
Anastrazole (Arimidex), letrozole (Femara), exemestane (Aromacin): hot flashes, fatigue, mood swings, and irritability
Leuprolide (Lupron), goserelin (Zoladex): hot flashes, fatigue, and mood disturbance

Androgen Blockade

Leuprolide (Lupron), goserelin (Zoladex): hot flashes, fatigue, and mood disturbance
Flutamide (Eulexin), bicalutamide (Casodex), nilutamide (Nilandron): hot flashes, fatigue, and mood disturbance

Glucocorticoids

Insomnia, hyperactivity, hyperphagia, depression, hypomania, irritability, and psychosis

Biologicals

Interferon-alpha[2,3]

Depression, cognitive impairment, hypomania, psychosis, fatigue, and malaise

Interleukin-2

Delirium, flu-like syndrome, dose-dependent neurotoxicity, and hypothyroidism

Chemotherapy

Vincristine (Oncovin), vinblastine (Velban), vinorelbine (Navelbine)

Neurotoxicity is dose-related and usually reversible; fatigue, malaise, and rarely seizures are noted; postural hypotension related to autonomic neuropathy

Procarbazine (Matulane)

Mild reversible delirium, depression, and encephalopathy

Asparaginase (Elspar)

Depression, lethargy, and delirium with treatment

Cytarabine (ARA-cell, Alexin)

Confusion, obtundation, seizures, coma, cerebellar dysfunction, and leukoencephalopathy

Fludarabine (Fludara)

Rare somnolence, delirium, and rare progressive leukoencephalopathy

5-Fluorouracil (5-FU)

Fatigue, cerebellar disfunction, encephalopathy lethargy, headache, and seizures

Methotrexate

Delirium and with administration, intrathecal seizures, motor dysfunction, chemical arachnoiditis, and coma
Dose- and route-related risk of delirium

Pemetrexed (Alimta)

Depression and fatigue

Gemcitabine (Gemsar)

Fatigue, flu-like syndrome, and a rare autonomic neuropathy

Etoposide (Eposin)

Postural hypotension and rare disorientation

Carmustine (BCNU)

Delirium, only at high dose, and rare leukoencephalopathy

Thiotepa

Rare leukoencephalopathy

Ifosfamide (Ifex)

Transient delirium, lethargy, seizures, drunkenness, parkinsonism, and cerebellar signs that improve within days of treatment
Leukoencephalopathy

Cisplatin

Rare reversible posterior leukoencephalopathy with cortical blindness
Peripheral neuropathy
Sensorineural hearing loss

Carboplatin

Neurotoxicity only at high doses

Oxaliplatin (Eloxatin)

Acute dysesthesias of hands, feet, perioral region, jaw tightness, and pharyngo-laryngodysesthesias

Paclitaxel (Taxol)

Sensory peripheral neuropathy and rarely seizures, transient encephalopathy, and motor neuropathy

Docetaxel (Taxotere)

Like paclitaxel but less neurotoxicity

Continued

TABLE 27–1 Neuropsychiatric Side Effects of Cancer Drugs—*cont'd*

Inhibitors of Kinase Signaling Enzymes[4,5]

Imatinib (Gleevec)
Fatigue, confusion, and papilledema

Sunitinib (Sutent)
Hypothyroidism

Sorafenib (Nexavar)
Fatigue, asthenia, and rarely hypophosphatemia

Bevacizumab (Avastin)
Fatigue and rarely reversible posterior leukoencephalopathy

Thalidomide
Drowsiness and somnolence, improving over 2-3 weeks, dose-related, associated with dizziness, orthostatic hypotension, tremor, loss of libido, hypothyroidism, and rarely confusion

Bortezomib (Velcade)
Postural hypotension and asthenia; confusion, psychosis, and suicidal thoughts have been reported

Rituximab (Rituxan)
Headache and dizziness

Trastuzumab (Herceptin)
Headache, insomnia, and dizziness

IV, Intravenous; *MAO,* monoamine oxidase; *SIADH,* syndrome of inappropriate antidiuretic hormone; *TSH,* thyroid-stimulating hormone.

who were burdened by illness were more distressed. The researchers learned that certain patients were unable to generate alternative coping strategies.[7] Vulnerable patients tended to overuse strategies that were ineffective for finding relief and resolution. Weisman and co-workers defined a treatment to reduce distress, correct deficits in coping, reclaim personal control, and improve morale and self-esteem. They asked patients to examine their relationship to cancer (their current concerns), articulate their understanding of what might interfere with effective coping, and envision options that might lead to satisfactory solutions. Staff viewed that change as possible; patients could be helped to help themselves, as problems were broken down into manageable portions. Members of the treatment team focused on coping and adaptation rather than on psychopathology; they conveyed an expectation of positive change, a sense that options and alternatives are seldom exhausted, and an awareness that perceiving problems in a flexible fashion helps to generate support. They studied both brief psychodynamic and behavioral techniques; both were effective in reducing distress and denial.[7]

Screening

Weisman and Worden defined a screening instrument and a concise interview to identify patients who were vulnerable and had ineffective coping skills (because those individuals were most apt to benefit from psychosocial intervention). To make screening more efficient, Zabora and co-workers validated the Brief Symptom Inventory–18[14] and the Index of Current Concerns (now a Brief Symptom Inventory–11)[15] to identify those with more anxiety and depression, somatic symptoms, and distress. To call the attention of oncology staff to distressed cancer patients, Holland and colleagues operationalized a visual nomogram (a distress thermometer score ≥ 5) with a variety of needs assessed (in the National Comprehensive Cancer Network [NCCN] guidelines).[16]

Psychosocial Interventions

Weisman's work foreshadowed larger studies of preventive psychosocial interventions for cancer patients. Fawzy and colleagues[17–20] described a 6-week structured group intervention for patients with melanoma (stages I and II); the intervention included health education, stress management, instruction about coping skills, and supportive group psychotherapy. They also taught simple relaxation exercises (e.g., progressive muscle relaxation, guided imagery or self-hypnosis, as well as problem-solving and coping methods). The interaction of the patients in the group also provided emotional support.[17–20] The group that received 6 weeks of treatment demonstrated a survival benefit at 5 to 6 years (but it was not as evident in the 10th year).

Spiegel and others went on to develop a group therapy supportive–expressive intervention for women with metastatic breast cancer. Although in two randomized multisite studies, the benefit for survival was not found, the intervention reduced distress, offered patients social support and safe conduct, and increased their ability to confront difficult challenges.[21–24]

More recently, Chochinov[25] focused on conserving dignity at the end of life by asking patients what they felt was most important and what they wanted their loved ones to remember. Informed by the work of Frankl,[26] Greenstein and Breitbart[27] and Breitbart and colleagues[28] reported on a group intervention for advanced cancer patients that focused on faith and meaning.

Combinations of interventions augmented patients' coping skills.[29] Teaching about relaxation has benefited cancer patients,[29,30] and a variety of educational interventions (e.g., stress management, cognitive therapy, behavioral training) tailored to disease type and phase have improved coping and decreased distress in adult patients[31] and the children of cancer patients.[32]

TABLE 27–2 Concerns of Patients with Specific Cancer Types

CANCER TYPE	POSSIBLE CONCERNS
Prostate cancer	Significance of serum prostate-specific antigen (PSA) test results: anxiety
	Once diagnosed, the initial choices are watchful waiting, surgery, or radiation treatment
	Side effects of surgery or radiation, including incontinence or erectile dysfunction
	Sexual function and dysfunction
	Androgen blockade and its effects on fatigue, mood, and sexual interest
Breast cancer	Body image related to mastectomy or to reconstruction
	Adjuvant chemotherapy and its side effects, including alopecia, weight gain, fatigue, and impaired concentration
	As a result of adjuvant treatment, anti-estrogens, or aromatase inhibitors, menopausal symptoms, including insomnia, sexual dysfunction, and hot flashes
	The question of prophylactic mastectomy
	Sexuality and fertility
	In those with known genetic risk factors, health of loved ones
Colon cancer	Adjustment to surgery or an ostomy
	Body image and sexual function
	Bowel dysfunction
	In those with known genetic risk factors, health of loved ones
Lung cancer	Physical limitations of reduced lung capacity
	Post-thoracotomy neuralgia
	Cough
	Guilt about nicotine addiction (past and present)
Ovarian cancer	Anxiety about the tumor marker CA 125
	Sexual dysfunction and infertility
	Pain and recurrent bowel obstruction
Pancreatic cancer	Maintenance of adequate nutrition
	Poor appetite
	Bowel function (and the need for pancreatic enzymes and laxatives)
	Pain
	Diabetes
	Depressed mood
Head and neck cancer	Facial deformity
	Dry mouth
	Poor nutrition
	A weak voice and difficulty with communication
	Post-treatment hypothyroidism
	Guilt about alcohol and nicotine addiction (past and present)
Lymphoma	Corticosteroid-induced mood changes
	The need for recurrent chemotherapy and its effects
Hodgkin's disease	Post-treatment hypothyroidism
	Fatigue
Osteosarcoma	Amputation/prosthesis vs. bone graft
	Impaired mobility
	Post-thoracotomy neuralgia

ANXIETY SYNDROMES

Claustrophobia becomes clinically important when magnetic resonance imaging (MRI) is required for diagnostic purposes or when patients are trapped in bed by orthopedic care (e.g., after repair of a leg riddled with osteogenic sarcoma). Needle phobias also occur and can be problematic; they may be treated with rapid desensitization.[33]

Some patients live on tenterhooks awaiting the results of the 3-month scans to assess disease recurrence. They develop significant anxiety a week or so before each reassessment. The roller coaster ride of life-threatening experiences and uncertainty associated with cancer treatment parallels the unpredictable aversive stimuli that provoke conditioned helplessness and depression.[34] For some patients the challenge of cancer generates chronic anxiety, but many patients come to cancer treatment with a predisposition to generalized anxiety disorder, phobias, or panic disorder. Patients anticipate the results of cancer markers (e.g., women with ovarian cancer who await the report of the CA 125 test); their mood rises and falls with the results of tumor markers or progressive disease.[35] Most patients are alert to physical symptoms after treatment and worry that such symptoms signify disease recurrence. A visit to the doctor can be reassuring for most, but for some the alarm signifying danger does not turn off. These patients are preoccupied with fear, and every symptom signals cancer recurrence. Fortunately, antidepressant medications suppress such anxiety. Benzodiazepines are best used for specific anxiety-provoking procedures. Implementation of cognitive-behavioral therapy (CBT) also improves coping.

Posttraumatic stress disorder (PTSD) is uncommon (occurring in 3% to 10%) in patients treated for cancer[36]; however, Pitman and colleagues[37] have shown that women with breast cancer have a physiologic response 2 years after hearing a narrative of the two most stressful experiences during their cancer treatment. Leukemia survivors who developed anticipatory nausea with treatment were also more apt to become nauseated in response to reminders of their treatment.[38] The numbness and tingling of peripheral neuropathy can also serve as a reminder of treatment; they can trigger intrusive thoughts and avoidant behaviors of PTSD[39] and be associated with co-morbid depression.[37]

Panic disorder and other anxiety disorders occur among cancer patients with the same frequency as they do in the general population.[40] However, specific cancer-related symptoms (e.g., embarrassment related to unexpected diarrhea) can contribute to anticipatory anxiety and agoraphobia. Disability and poor quality of life have been associated with co-morbid anxiety disorders and physical conditions.[41]

In patients with cancer, the differential diagnosis of panic attacks includes temporal lobe seizures, acute hypoxia resulting from pulmonary emboli, and congestive heart failure.

Nausea and Vomiting

A host of chemotherapy agents and radiation treatments cause nausea and vomiting. Even in this era of advanced antiemetics, highly and moderately emetogenic chemotherapy is associated with nausea in 60% of patients, and vomiting occurs in 36% of patients. Delayed nausea, which comes after the first days of chemotherapy, significantly compromises quality of life even more than vomiting does.[42] As a result of vomiting during chemotherapy, patients can develop conditioned nausea and anxiety associated with the smells and sights linked with treatment. They may have nausea and vomiting even before arriving at the hospital for treatment.[43] Conditioned nausea morphs into anticipatory anxiety, insomnia, and aversion to treatment. Hypnosis, CBT techniques, and antianxiety agents (e.g., alprazolam, lorazepam) can reduce phobic responses as well as anticipatory nausea and vomiting (both during and after chemotherapy).[44]

The best antiemetic drugs make conditioned vomiting less likely, but patients may continue to vomit after administration of doxorubicin, cisplatin, or carboplatin (even when a 5-hydroxytryptamine-3 [5-HT_3] receptor antagonist and dexamethasone are employed).[45] Some patients who develop anticipatory anxiety avoid the hospital and its routine smells long after cancer treatment has ended. Anticipatory nausea and vomiting are more likely to occur in younger patients, those who have had more emetic treatments, and those who have trait anxiety.[43] Nausea may also be a symptom of anxiety that persists as part of major depressive disorder (MDD).

DEPRESSION

In people with cancer, MDD is associated with poor quality of life, worse adherence to treatment, longer hospital stays, greater desire for death, and an increased rate of suicide and mortality.[46–49] Reports of its prevalence (10% to 25%) in people with cancer have varied widely.[50] However, people with a history of MDD are more likely to develop MDD after the diagnosis of cancer, and about half of the cases of MDD occur in those without a history of MDD.[51]

The diagnosis of MDD in people with cancer relies on the same *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) criteria as are used in those without cancer. However, the diagnosis can be complicated by symptoms that overlap with cancer and with cancer treatments. To address this issue, alternative criteria have been proposed, such as the Endicott criteria, which substitute psychological symptoms for physical symptoms in the DSM criteria. Although the inclusion of physical symptoms that could be related to cancer or cancer treatments in the diagnosis of MDD remains controversial, alternative criteria have not yielded markedly different results.[52]

As with the evaluation of other medically ill patients who appear depressed, the evaluator must consider possible medical contributions in the differential diagnosis. Untreated pain, hypothyroidism, and medications (e.g., corticosteroids, chemotherapies such as alpha interferon, pemetrexed, procarbazine) may contribute to MDD. Delirium, especially the hypoactive subtype, is often erroneously labeled as depression. Although mood symptoms may occur as part of delirium, key features of delirium include a generalized impairment of attention and cognition, symptoms that wax and wane in severity, and a disturbance of the sleep–wake cycle. Fatigue is a common cancer-related symptom that can be difficult to tease apart from MDD. Anhedonia may be one of the most surefire factors for MDD.[53] Apathy (e.g., that results from lesions in the frontal lobes) can also be reminiscent of MDD. With apathy there are delayed responses, cognitive impairment, and a loss of spontaneous action or speech.

The treatment (which consists primarily of antidepressant medications, psychotherapy, or both) of MDD in people with cancer is quite similar to the treatment of MDD in people without medical co-morbidities. Severe cases of MDD, especially those associated with wasting because of diminished appetite, may be treated with electroconvulsive therapy (ECT). Although complementary treatments (e.g., herbal preparations, acupuncture, massage) are available, little data exist supporting their efficacy in the treatment of MDD in cancer patients.

Although antidepressants are commonly used to treat MDD that is co-morbid with cancer, few placebo-controlled trials in cancer patients have been conducted, and there is some evidence to show that depression in patients with medical co-morbidities is more resistant to antidepressant therapy.[50,54,55] Potential side effects may affect the choice of an antidepressant medication in a person with cancer. Patients may already have constipation or nausea from their cancer medications, and an antidepressant should be chosen that does not exacerbate these symptoms. Frequently, antidepressants are selected for their side-effect profile (e.g., sedation, increased appetite), which in some cases may be desirable. Some of the selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine, fluvoxamine, paroxetine) and bupropion can interfere with the use of chemotherapeutic agents, including tamoxifen (because of their effects on cytochrome P450 2D6 system).[56] If an antidepressant is necessary in the setting of tamoxifen use, venlafaxine, escitalopram, or citalopram (which are less potent 2D6 inhibitors) should be selected.[57] Stimulants (e.g., methylphenidate, dextroamphetamine) may also be beneficial for MDD (i.e., insofar as they may lift mood, increase appetite, and improve cognitive difficulties and fatigue) in the medically ill, but there is little evidence to support this practice. When improvement follows use of stimulants, it is usually seen within the first week of treatment.

Although little research has been conducted on medications for MDD in people with cancer, several studies confirm the efficacy of psychosocial interventions.[50] Both the severity of cancer-related symptoms (e.g., fatigue, nausea) and the demanding schedules for anticancer treatments limit participation in traditional weekly 50-minute psychotherapy visits. Therefore psychotherapy visits should be flexible and involve shorter visits, meetings during chemotherapy treatments, and greater use of phone contacts.

FATIGUE

Fatigue is the most commonly reported symptom in people with cancer and the symptom that causes them the most functional impairment.[58] It is often confused with MDD.[59]

Although fatigue is not a psychiatric disorder, psychiatric conditions can cause fatigue; therefore fatigue could be considered a psychosomatic illness.

Prevalence

The prevalence (estimated at 60% to 90%)[60,61] of fatigue in people affected by cancer varies widely because of differing measures of fatigue and the heterogeneous populations studied.

Diagnosis

Fatigue may occur before the diagnosis of cancer, during active cancer treatment, and into the survivorship years. The diagnosis is made primarily by asking questions about the presence and severity of the symptoms. Although there are validated instruments for the measurement of fatigue[59] (e.g., the Functional Assessment of Chronic Illness Therapy–Fatigue scale [FACIT-F]), administration of these questionnaires may not be feasible in busy clinical settings. The National Comprehensive Cancer Network (NCCN) recommends screening for fatigue at visits with a one-item, 0-to-10 scale, similar to that used for the screening of pain, with 0 being "no fatigue" and 10 being "the most severe fatigue." Scores of 4 or greater should prompt further evaluation. (The full set of guidelines also includes a review of the literature and can be viewed at www.nccn.org.)

The NCCN recommends that the primary evaluation include exploration of the modifiable causes of fatigue (e.g., anemia, pain, sleep disturbance [insomnia, difficulty staying asleep, and sleep apnea], emotional distress [MDD and anxiety], poor nutrition, inactivity or deconditioning, use of medications and chemotherapies that cause fatigue [e.g., gemcitabine, corticosteroids, narcotics, antiemetics, and β-blockers], and other medical conditions [e.g., hypothyroidism, hypogonadism, adrenal insufficiency, hypercalcemia, hepatic failure, and cardiovascular or pulmonary compromise]). Fatigue may also be a side effect of radiation therapy.

Treatment

The primary treatment for fatigue is modification of its contributing factors; this should be done in conjunction with the patient's oncologist or primary care physician. Mental health clinicians can provide treatment for any underlying psychiatric disorder as well as offer fatigue-specific interventions (e.g., use of stimulants, exercise, behavioral interventions).

Stimulants

Stimulants (e.g., methylphenidate, dextroamphetamine, modafinil) are commonly used in the treatment of fatigue. However, there has been mixed support for this treatment in clinical trials. Open-label trials have suggested a benefit from their use, but response rates for placebos have also been remarkably high in the few randomized, placebo-controlled trials conducted.[62] In addition to reducing fatigue, stimulants also improve mood, concentration, and appetite. However, stimulants can raise blood pressure and heart rate and increase the risk of sudden death. For these reasons they should be used with caution in patients with cardiac disease. Common side effects include constipation, sleep disturbance, anxiety, and (at higher doses) anorexia.

Exercise

Abundant evidence supports exercise as a treatment of fatigue, with several studies demonstrating the benefit of exercise for fatigue in people with cancer.[63] Mental health clinicians can encourage exercise through motivational interviewing and through behavioral changes. Because patients can have serious physical morbidities, such as large bone metastases that could lead to fracture, consultation with the oncologist is recommended before initiating exercise. A physical therapist can assist in designing an exercise program that contains both strength and aerobic training and is appropriate for a person with physical limitations resulting from cancer or cancer treatments. For more medically complicated patients, exercise might best be done in a cardiovascular or pulmonary rehabilitation center.

Behavioral Interventions

Behavioral interventions (e.g., CBT, energy conservation) may be beneficial as both primary and adjunctive treatments for fatigue in cancer patients. CBT emphasizes managing fatigue rather than attempting to cure it.[64] Energy conservation is similar to CBT in some respects; it focuses on prioritizing activities and delegating, problem-solving difficulties caused by the fatigue, and improving organizational skills.[65]

CONFUSION AND COGNITIVE IMPAIRMENT

Whereas infections, metabolic abnormalities, and recent surgery account for an abnormal mental status in most hospitalized cancer patients, drugs (especially opiates and benzodiazepines) are the most common culprits causing delirium in cancer patients. Older patients, as well as patients with structural brain disease; vascular disease; or lung, kidney, or liver impairment, are predisposed to delirium.[66] Specific cancer-related syndromes involving cognitive impairment in cancer patients are listed in the subsequent paragraphs.

Hypercalcemia

Hypercalcemia (in patients with metastatic lesions to the bone or with tumor-related ectopic production of parathyroid hormone–related protein) secondary to cancer can cause cognitive impairment or delirium. Hypercalcemia is associated with both fatigue and thirst. A serum protein-bound calcium count below 11 mg/dL may initially appear normal when the free calcium is elevated or when serum albumin is low and not taken into consideration. Hypercalcemia can be treated with diphosphonates, hydration, and diuresis.

Hyponatremia

Hyponatremia, a common in-hospital metabolic abnormality, often results from the syndrome of inappropriate antidiuretic hormone (SIADH) (secondary to paraneoplastic syndrome, especially from small cell carcinoma, but also from non–small cell lung cancer, mesothelioma, pancreatic

cancer, duodenal cancer, lymphoma, endometrial cancer, leukemia, and other conditions). SIADH is associated with lung infections, cerebral tumors, brain injuries, and use of many psychotropic medications (e.g., phenothiazines, SSRIs, carbamazepine, and tricyclic antidepressants [TCAs]). If the sodium is less than 125 mmol/L or if it falls rapidly, it may cause agitation, confusion, and hallucinations; chronic hyponatremia is associated with falls and inattention in the elderly.[67]

Brain Tumors

Some patients with cancer become confused in association with brain metastases. The incidence of primary brain tumors is 6.6 per 1,000,000, but the rate of metastatic brain tumors is higher (ranging from 8 to 11 per 100,000). While the majority of brain metastases originate in the lung, melanoma is most likely to metastasize to the central nervous system. The incidence of brain metastases is 20% for lung cancer, 7% for melanoma, 6.5% for renal cancer, 5% for breast cancer, and 2% for colorectal cancer.[68] Brain metastases are less common but also occur with sarcoma and thyroid, pancreatic, ovarian, uterine, prostate, testicular, and bladder cancers. In patients with small cell lung cancer, brain metastases are anticipated, and prophylactic whole brain radiation is often recommended.[69] Isolated brain metastases caused by non–small cell lung cancer may be treated surgically, and modern radiation techniques target small areas of the brain.

Patients with primary brain tumors, particularly low-grade tumors, present problems for cancer diagnosis and chronic brain injury. Tumors (particularly of the frontal, temporal, and limbic lobes) that affect the hardwiring of motivation, attention, mood stability, and memory come to psychiatric attention. Temporal lobe epilepsy can be associated with neuropsychological symptoms (e.g., memory dysfunction, anxiety, hypergraphia, viscosity). For these patients neuropsychiatric consultation, testing, and cognitive rehabilitation may be of critical importance to define and treat the specific loss. Multimodal interventions for attention, memory, word-retrieval, and problem-solving abilities may be appropriate.[70] Loved ones can understand more clearly the basis of some limitations, and the patient can acknowledge his or her deficits and take whatever control is possible. Psychotropic medications, used appropriately, are adjuncts to anticonvulsants and anticancer treatment.

Leptomeningeal Disease

In the syndromes of carcinomatous meningitis, or leptomeningeal disease, cancer cells infiltrate the meninges or obstruct the flow of cerebrospinal fluid. If there are no focal signs or findings on neuroimaging, the associated malaise may be considered (erroneously) psychiatric. Cranial nerves (particularly III, IV, VI, and VII) may be affected. Mental changes, headache, difficulty with walking, limb weakness, and seizures are common. Dizziness and sensorineural deafness have also been noted. The tumors most often implicated are breast cancer, lung cancer, and melanoma; the histology usually involves adenocarcinoma. Leptomeningeal disease also occurs with non-Hodgkin's lymphoma, leukemia, and cancers of the head and neck, cervix, ovary, kidney, and bladder. Malignant cells in the cerebrospinal fluid confirm the diagnosis, but a sufficiently large fluid sample improves the chance for a positive diagnosis; 50% to 70% may be falsely negative. A magnetic resonance imaging (MRI) scan of the brain may be unremarkable in 20% but more likely will show hydrocephalus, brain metastases, or contrast enhancement of the sulci or cisterns.[71,72]

Delirium in Stem Cell Transplantation

In patients who receive a peripheral stem cell transplantation, delirium is common because of metabolic abnormalities, infection, and subdural or intraparenchymal brain hemorrhage. Wernicke's encephalopathy has occurred rarely. An engraftment syndrome may cause delirium with fever, headache, and rash. Usually this syndrome occurs when the neutrophil count is greater than 500/mm^3 and with a cytokine effect of the hematopoietic colony-stimulating factors.[73,74]

In the transplant setting, immunosuppressive drugs (e.g., cyclosporin, tacrolimus, the antifungal drug amphotericin B) can cause delirium. Hypertension, use of steroids, uremia, and previous radiation to the brain are risk factors.[75] Drug serum levels may facilitate diagnosis; tremor occurs in 40%, and paresthesias in 11%. Hypomagnesemia increases the risk of seizures. Immunosuppressants are rarely associated with a syndrome of reversible posterior leukoencephalopathy that causes headache, visual loss or blurring, visual hallucinations, and confusion.[76] Parkinsonism, ataxia, or dystonia may also occur. White matter edema is documented in the parieto-occipital area on fluid-attenuated inversion recovery (FLAIR) sequences. If this syndrome has occurred with one immunosuppressant, either tacrolimus or cyclosporin, the other may be used.[77]

Hyperviscosity Syndrome

Hyperviscosity syndrome in myeloma or lymphoma patients results from paraproteins that impair blood circulation in the brain. A serum viscosity level above 4.0 centipoise (1.56 to 1.68 cp) has been associated with symptoms.[78,79] The clinical signs are bleeding, visual signs and symptoms, and delirium.

Hyperammonemia

Idiopathic hyperammonemia may be associated with lethargy, confusion, ataxia, coma, and death in patients with cancer. Although extremely rare in this population, it occurs more often in those with hematologic malignancies who are neutropenic following bone marrow transplantation and in patients with solid tumors receiving 5-fluorouricil.[80] Management centers on limiting protein intake and on increasing ammonia excretion, both through use of ammonia-trapping agents and, if necessary, hemodialysis. Hyperammonemic encephalopathy is also an uncommon but severe complication of multiple myeloma and, in this instance, seems to improve with appropriate chemotherapy.[81]

Cushing's Syndrome

Cushing's syndrome may cause delirium, psychosis, and muscle weakness in adrenocortical carcinoma or tumors with paraneoplastic production of adrenocorticotropic

hormone (ACTH). Psychiatric disorders are a feature of the syndrome of ectopic ACTH production in 53% of patients. Specific treatments for this syndrome include steroidogenesis inhibitors or glucocorticoid receptor antagonists (e.g., ketoconazole, metyrapone, aminoglutethimide, opDDD, etomidate, or mifepristone).[82]

Paraneoplastic Neurologic Disorders

Paraneoplastic neurologic disorders include a myasthenic syndrome, cerebellar degeneration, or diffuse encephalomyelitis.[83] These syndromes may manifest before the cancer is diagnosed. An afflicted patient may develop an immune reaction against neural tissue when exposed to a tumor antigen that reacts against normal nervous system tissues in the setting of dying tumor cells. The exact mechanism of the immune reaction has not been established. Typically, there are more T and B cells and plasma cells in these tumors. Small cell lung cancer is the tumor most commonly associated with this syndrome, and anti-Hu antibody syndromes are often noted.[84]

Limbic Encephalitis

Limbic encephalitis is a specific autoimmune encephalopathy that causes memory difficulties, anxiety, depression, agitation, confusion, hallucinations, and complex partial seizures. This syndrome is most likely to occur in the context of small cell carcinoma of the lung and more likely related to anti-Hu antibody, but it also occurs with Hodgkin's lymphoma; thymoma; and cancers of the testes, breasts, ovaries, stomach, uterus, kidney, thyroid, and colon.[83,85] Changes in mood and personality occur over weeks. Recent memory is affected more than remote memory. In one third of patients the neurologic findings are limited to the limbic system. MRI findings, if present, include abnormal hyperintensity on the T_2-weighted image, sometimes with contrast. Anticonvulsants and empirical use of psychotropic medications may be the only aid as the tumor is diagnosed and treated. The prognosis is limited.

Toxic Leukoencephalopathy

White matter injury can be an early, a temporary, or a late consequence of cancer treatment. Whole brain radiation and certain anticancer drugs (including methotrexate, carmustine, cisplatin, levamisole, fludarabine, thiotepa, ifosfamide, cytarabine, and fluorouracil) can injure the projection fibers, association fibers, and commissural tracts that affect cognition and emotion. Acutely, confusion is related to patchy, reversible edema and later to widespread edema and demyelination. More severe delayed consequences result from loss of myelin and axons related to vascular necrosis and thrombosis. Risk of leukoencephalopathy is related to patient age, total dose of radiation, fraction size, and timing of chemotherapy. In most cancer protocols, the doses and timing have been adjusted to minimize these adverse effects. However, patients with vulnerable brains or delayed metabolism of the drug may be unexpectedly affected. Neurobehavioral sequelae occur acutely in 28% of patients and are a consideration in cancer survivors.[86]

The frontal lobes, the lobes with the most white matter tracts, are the ones most likely to be injured. Patients with mild leukoencephalopathy may complain of difficulty with concentration and vigilance as well as problems with attention. Apathy, anxiety, irritability, depression, or changes in personality may be seen with memory loss, slowed thinking, and failure of executive oversight. In more severe cases, dementia, abulia, stupor, and coma occur with necrotic areas and diffuse hyperintensity of white matter seen on the MRI scan. This injury, unlike that seen in Alzheimer's disease, spares language, praxis, perceptions, and procedural memory. The key bedside tests on mental status examination are the elements that test attention (e.g., digit span, serial sevens, three-word delayed recall, clock-drawing test for visual–spatial skills and alternating motor sequences for frontal function). The contribution of white matter injury should be documented on the T_2-weighted MRI.[87]

This toxicity is seen in patients who have received high-dose methotrexate and radiation treatment for childhood acute lymphoblastic leukemia (ALL) or primary central nervous system lymphoma. In the latter a rapidly progressive subcortical dementia with psychomotor slowing, executive and memory dysfunction, behavioral changes, ataxia, and incontinence can be seen. Diffuse white matter disease and cortical–subcortical atrophy are also noted.[88]

Toxic effects of drugs or radiation may add to white matter damage of hydrocephalus, trauma, alcoholism, and hypertension. Patients with a history of psychosis or affective disorder also tend to have more evidence of abnormal white matter on imaging.

Cognition and Sleep Changes Related to Chemotherapy or Hormonal Change

Patients receiving adjuvant chemotherapy for breast cancer complain about troubles with working memory and concentration. Despite the reputation of "chemo brain," subjective complaints often do not match the deficits seen on neuropsychiatric testing. At the very least, fatigue, catabolic treatment effects, and hormonal changes combine to cause impairment that seems to improve gradually. In half of the published studies that test breast cancer survivors in the neuropsychological domain, memory has been affected.[89] Patients in greater distress report more cognitive failures but not specific neuropsychiatric deficits.[90]

Women who receive adjuvant treatment for breast cancer often develop menopausal symptoms because of a direct effect on the ovary that decreases hormone levels and hastens menopause. Menopause is a goal of treatment for those with estrogen receptor–positive tumors.[91] Estrogen therapy, however, may selectively improve executive function during verbal-recall tasks, and women may notice the loss of estrogen.[92] Estrogen treatment during perimenopause has been associated with regional benefits, for instance in the posterior cingulum.[93] Raloxifene, a selective estrogen-receptor modulator (at 20 mg per day), tended to slow cognitive decline over 3 years in postmenopausal women (regarding verbal memory and attention).[94]

Tamoxifen is a mixed agonist–antagonist of estrogen that is associated with hot flashes and insomnia. Aromatase

inhibitors reduce estradiol to barely detectable concentrations. There seem to be no distinctions in quality of life measures in women taking tamoxifen or an aromatase inhibitor (e.g., anastrozole), and vasomotor symptoms are frequent with both drugs. Endocrine-related vaginal symptoms are worse at 3 months but improve slightly or stabilize thereafter. About 10% report mood swings and irritability.[95,96]

In menopausal women and women who undergo estrogen deprivation therapy for breast cancer, SSRIs reduce the frequency and severity of hot flashes and improve mood, sleep, anxiety, and quality of life. The reduction in hot flashes may be related to the affinity of the norepinephrine transporter because the benefit is not consistently seen with citalopram or fluoxetine.[97–100] Venlafaxine (extended release 75 mg per day) and paroxetine (20 mg per day) have shown benefit. Gabapentin (300 mg tid) has also been beneficial.[101] A pilot study suggested that bupropion did not have a similar benefit.[102] Hot flashes are also a problem for men with prostate cancer treated with pituitary antagonists (e.g., leuprolide).[103]

Treatment of Cognitive Deficits

Some causes of impaired cognition associated with cancer are treatable. Sobriety can lead to reversal of atrophy and to improved cognitive function in alcoholic dementia, a condition with disproportionate white matter damage, particularly in the frontal lobes. Oxygen treatment, at night or all day, may improve the cognition of lung cancer survivors who are chronically hypoxic. Stimulants may improve attentional deficits. Erythropoietin and an intervention with four visits and three phone calls, education about possible problems, stress management, arousal management, and compensatory strategies for memory and attention improve cognitive function and energy in patients with hemoglobin levels below 12.[104]

Diagnosis and treatment of delayed hypothyroidism may improve thinking in cancer survivors. Radiation over the neck, for instance, for Hodgkin's disease, can injure the thyroid, and radiation to the head may affect the pituitary. Thyroid-stimulating hormone is high if the thyroid itself is injured, but recognition of secondary hypothyroidism because of a pituitary injury would require measurement of free thyroxine.

Survivors of Childhood Cancer

The most common diagnoses for children with cancer are leukemia, lymphoma, brain tumors, osteogenic sarcoma, Ewing's sarcoma, and Wilms' tumor. Childhood cancer is now more commonly considered a serious chronic illness rather than a uniformly terminal illness. Child psychiatrists work side by side in the outpatient setting with the pediatric hematology–oncology teams to treat the emotional needs of the child in age-appropriate ways during active treatment and thereafter. With consideration of the child's stage of development, psychiatrists can judge what the child will understand and what the child will want and need to know.

The most common consultation questions include evaluation of the child with anticipatory anxiety, sleep disturbances, behavioral problems, or mood changes. Anticipatory anxiety still affects many children despite advances in antiemetic medication. The child may feel nauseated or vomit on approaching the hospital, clinic, or phlebotomist. Behavioral modification, visualization and relaxation, and medication are helpful. Sleep disturbances may be related to the child's worries about the illness or to medications such as steroids. Child psychiatrists are also consulted for behavior problems in younger children who become more aggressive or difficult to manage. The emphasis in treatment of depression or withdrawn states is on the child's ability to enjoy life. Overall, children tend to be quite resilient. Although children and parents are very distressed at the time of diagnosis, the prevalence of psychological problems among survivors of childhood cancer is similar to that in the community.[105]

Children treated for ALL or a brain tumor with cranial irradiation are at risk for cognitive decline,[106] which is progressive over at least 10 years (possibly related to a radiation-induced microvasculopathy). Children are particularly prone to radiotoxicity in the first 2 years of life because of the rapid growth of the brain and white matter development in those years. Cognitive defects have been seen in verbal comprehension, perceptual organization, distractibility, and memory in survivors of ALL, and visual–motor integration, sequential memory, fine motor coordination, processing speed, and math abilities may also be affected. Risk factors include young age, female gender, and time since radiation; the volume and dose of radiation are also thought to be factors. The combination of radiation treatment and intrathecal methotrexate increases the risk of cognitive impairment. Children exposed to cranial irradiation may also suffer from hypothyroidism and growth hormone deficiency. Children who have been treated for leukemia or brain tumors should be monitored for cognitive and endocrine dysfunction.

CONCLUSION

Psychiatrists can help patients cope with affective, behavioral, cognitive, and physical symptoms associated with cancer and its treatment as well as with developmental losses, changes in relationships, and the effects of cancer on families.[107]

Burn Patients

Megan Moore Brennan, M.D.
Atilla T. Ceranoglu, M.D.
Gregory L. Fricchione, M.D.
Frederick J. Stoddard, Jr., M.D.

Burn injuries are as ancient as fire. All afflicted individuals need help and many require psychiatric consultation; their psychiatric care is as challenging as their surgical care.[1] Physicians and nurses new to a burn unit often experience trepidation and fear, but these feelings moderate as they relieve pain, help patients survive, and see the repair of disfiguring scars. Nevertheless, the burn unit is stressful for all—viewing an acutely burned infant, child, or adult can satisfy the stressor criteria for posttraumatic stress disorder (PTSD) and evoke nightmares in staff and patients.

Burn units bring together specialists from several disciplines. The Massachusetts General Hospital (MGH) Level 1 Trauma Center treats burned adults at the MGH and children at the affiliated Shriners Burns Hospital; together they treat about 400 acute burn patients per year. Since 9/11, all burn centers in the United States have enhanced their disaster preparedness; psychiatric education regarding disasters is important for staff on burn units in order to enhance resilience and increase preparedness.[2]

HISTORY

The current era of burn treatment and research began more than 60 years ago at the MGH after the Cocoanut Grove fire on November 28, 1942. Cobb and Lindemann,[3] eminent early MGH psychiatrists, collaborated with other physicians and surgeons and chronicled the deliria and posttraumatic reactions of the survivors of that terrible tragedy in which 491 people died. Lindemann,[4] in a classic paper (based in part on his work with 13 bereaved disaster victims of the Cocoanut Grove fire and their close relatives and with relatives of members of the armed forces), reported for the first time the symptoms and psychotherapeutic management of acute grief. Their studies involved psychiatric treatment and subsequent research on grief that would be applied to soldiers, civilians, and the bereaved.

Burn injuries challenge hospital staff and hospital systems. In 2003, as in the Cocoanut Grove fire, The Station nightclub fire in Rhode Island wreaked havoc. It resulted in 100 deaths and tested emergency and burn trauma disaster plans at the MGH, the Shriners Burns Hospital, and the entire region; the triage system worked superbly. Unlike the September 11, 2001 terrorist attacks when staff readied for transfers to their burn units but were disappointed with how few survived to be treated, scores survived (despite severe burns to the lungs, face, hands and upper body) this nightclub fire because of the advances in modern burn care. As described earlier by Cobb and Lindemann,[3] some of these survivors, their children, and other relatives developed and were treated for survivor guilt, traumatic grief, and what is now recognized as PTSD.

In the last 35 years, strong leadership and new research have led to improved methods of resuscitation and transportation, excision and grafting,[5] anesthesia,[6] pain control,[7,8] anxiety management,[9] pulmonary care,[10] cardiovascular and infection control, application of artificial skin and skin substitutes,[11] psychiatric assessment and treatment (Table 28–1), plastic surgery techniques,[12] and rehabilitative efforts that include interventions for those with disfiguring facial and body burns. Taken together, these innovations have dramatically improved both mortality rates and the morbidity associated with burn injuries in the United States.

Just as Cobb and Lindemann did for adults, Bernstein,[13] Galdston,[14] and others pioneered the psychiatric care of burned children and their families; moreover, they conceptualized consultations to the burn team. Childhood injuries, including burns, are now, after years of neglect, a priority for medical research and treatment.[15] A key resource regarding education about, and research for, burn care is the American Burn Association,[16] which is linked to federal agencies, a variety of foundations, and the International Society for Burn Injuries. Many patients also benefit from self-help groups, like the Phoenix Society, which is an international organization for children and adults with burns (and their families).[17] Its mission is to increase our understanding of burned individuals and to support their care.

EPIDEMIOLOGY

Because of improved fire and burn prevention, and the expansion of burn centers in the United States, acute hospitalizations for burn injuries were cut in half between 1971 and 1991.[18] Between 2001 and 2002, the majority of acute burns admitted to burn centers shifted from referrals from outside hospitals to direct admissions from pre-hospital settings, likely a result of efforts to streamline triage to regional burn care centers.[19] Roughly 1.25 to 2.5 million burns occur annually in the United States; these account for about 5500 deaths,[15] of which about one third occur in children.

TABLE 28–1 Ten-Point Plan for Consulting to Burned Patients

1. Speak with the patient at the bedside, and ensure the patient's safety.
2. Consult directly to the burn or trauma team, the surgeons and other physicians, nurses, social worker, and others, about the patient, clarifying your time availability and role. Within psychiatry, arrange for supervision, peer consultation, and departmental support.
3. Obtain the history of the burn circumstances, psychopathology, or substance abuse, and social and family function.
4. Diagnose the patient: Assess the developmental stage, burn severity, other stressors, mental status (including pain, stress, memory), psychiatric risk (delirium, suicide, child abuse), prognosis, medical and surgical issues including medications and their interactions, alcohol or drug withdrawal, current risk factors, language/cultural factors, legal status, and staff or family concerns. Recommend special studies or consultations as indicated.
5. Monitor, explain, and treat pain, delirium, stress, insomnia, and depression. Provide staff support and, for complex cases, plan a team conference.
6. Assess, treat, and support the dying child or adult and the family, and assist the clarification and the resolution of ethical dilemmas.
7. When the patient has survived the acute phase, progress to treating residual mental disorders, substance abuse, and other problems.
8. Facilitate grieving and adaptation of the patient and family to cosmetic or functional losses.
9. Collaborate in planning plastic and reconstructive surgical follow-up if possible and communicate psychiatric findings and recommendations to the primary care physician. Support re-entry to school or work, including special education and rehabilitation services.
10. Remain available for follow-up consultation to the patient and caregivers, clarifying the psychiatric issues, and assist the patient and family in obtaining psychiatric services if needed.

According to the National Burn Repository 2007 report,[20] which compiled acute burn admission data between 1998 and 2005 at 73 hospitals in 33 states, nearly 70% of cases were men and the mean age was 35 years (children under the age of 5 years accounted for 12% of the cases, whereas those over the age of 60 years represented 14% of cases). Most (69%) individuals had less than 10% total body surface area (TBSA) burns. The two most common types of burns were from fire and scalds, the latter being most prevalent in children under the age of 5 years and in the elderly. Other mechanisms that led to burn care, in decreasing order of prevalence, included contact with hot objects, electrical burns, chemical burns, skin disease, and radiation exposure. The vast majority of burns are non–work accident related (63.9%); next are work-related accidents (15.4%), other (7.1%), recreational accidents (4.6%), and cases of suspected assault/abuse (1.6%), suspected child abuse (1.2%), suspected self-inflicted (1.2%), and suspected arson (0.1%).

The most common complications of burn treatment are pneumonia, respiratory failure, cellulitis, septicemia, and wound infection; these clinical complications are in large part a function of the number of days spent on the ventilator (with the risk increasing dramatically after four or more days). The average length of hospital stay for survivors is best approximated by figuring on one day per percent TBSA burns.

TYPES OF BURNS

Burns are classified by the depth of the injury (from first- through fourth-degree burns).[21] First-degree burns are characterized by intact epithelium (that is pink, dry, and painful); these burns require no specific care. Second-degree burns are wet, pink to red, and edematous; these changes signify that the dermis is damaged. These burns are further categorized into superficial and deep and they must be monitored closely. Third-degree, or full thickness (of dermis), burns are leathery, dry, and lack sensation; these burns require surgical treatment. The most severe burns are fourth degree; these extend through the subcutaneous tissue to the tendons, muscles, and bones and they require complex surgical reconstruction.

The operative treatment of burns includes wound débridement, escharotomy and fasciotomy (release of burned skin and muscle, respectively), and grafting. The nonoperative treatment involves daily wound care (performed multiple times each day) and systemic care and management of associated medical and surgical problems.[21]

RISK FACTORS

Risk factors for burn injuries are different for children, adults, and elderly. A combination of developmental and familial factors contribute to the risk of burns in children. Increased exploration by young children, access to scalding or flammable liquids or flames, childhood depression, behavioral disturbances, and parental psychopathology each predispose children to burns. Burns to children should not be indiscriminately labeled as due to neglect or to abuse because, on careful assessment, they may be the result of a combination of developmental, environmental, and family variables. However, child neglect or abuse accounts for between 6% and 20% of pediatric burns; the age of maximum risk of abuse is 13 to 24 months, and scalds are the most common type of inflicted burn.[22] Factors suggestive of abuse include a caretaker's changing the story of what occurred (from one interview to the next), prior injuries or accidents, a parent who neither visits nor is attentive, a consistently awake but withdrawn child who appears immune to pain, a burn distribution inconsistent with the history, and other signs of abuse (e.g., fractures).[23] Suspected abuse must be reported to the appropriate state agency in most states.

Among adults, risk factors for burns include drug and alcohol intoxication and dependence,[24] major mental illness, an antisocial personality disorder, and exposure to occupational hazards (Tables 28–2 and 28–3).[24–32] Certain populations, such as the homeless and the elderly, have an

increased risk of burns. Homeless patients are more likely to be assaulted by burning and to have higher rates of substance abuse and psychiatric illness as compared with domiciled burn patients.[33] Demented elders are also at risk for burns; scalds are more common than flame burns and typically occur during routine activities of daily living.[25]

PREBURN PSYCHOPATHOLOGY

Psychiatric illness is overrepresented in individuals with burn injuries. Dyster-Aas and associates,[34] in a prospective case series of 73 patients with burns, used structured clinical interviews and found that two thirds of patients had at least one lifetime psychiatric diagnosis (i.e., major depression [41%], alcohol abuse or dependence [32%], simple phobia [16%], and panic disorder [16%] were most common). Wisely and co-workers[35] looked at 72 patients admitted to a burn unit over a 5-month period and found that 35% had a psychiatric diagnosis before the burn; depression, drug and alcohol abuse, personality disorders, and psychotic disorders were most often detected.

Individuals with self-inflicted burns often have a high prevalence of severe mental illness (e.g., schizophrenia or major depression).[36–38] One review of 582 patients with self-inflicted burns found that 78% had a psychiatric history,[37] an increased likelihood of psychotic symptoms, of being prescribed psychotropic medication at the time of the burn, and of being a psychiatric inpatient.[39] Our experience also shows that patients with bipolar disorder (while manic), schizophrenia, a conduct-disorder, and alcoholism are at risk for self-immolation. Sometimes it is difficult to discern whether a burn was accidental, a parasuicidal gesture, or a *bona fide* suicide attempt. Attempts at suicide via self-immolation occur worldwide and often result in massive, disfiguring burns.[40]

A study of adolescent self-immolators revealed serious untreated or partially treated psychopathology (including drug abuse, psychosis, intense conflict with parents, and physical or sexual abuse). Studies of adults have similarly found elevated rates of alcoholism, depression, psychosis, and personality disorder as preexisting factors.[41–43] These patients tend to arouse intense feelings in caregivers and are among the most difficult surgical and psychiatric patients. Despite their burns and severe psychopathology, most patients cope well with psychiatric treatment that is initiated on the burn unit.

Finally, in some parts of the world, suicide attempts may turn out to be homicide attempts as part of the "honor killing" of victims accused of incest or of seducing a rapist.[44] The psychiatrist, consulting to units where patients may be admitted from around the world, must be aware of patients' cultural and ethnic background in order to understand the circumstances surrounding the burn injury. Unfortunately, because of barriers in reporting, an exact estimate of prevalence of these injuries is not known.

ASSESSMENT AND MANAGEMENT OF PATIENTS WITH BURNS

Psychiatrists who work in the general hospital are frequently called to assess burned patients. The role of the psychiatrist changes in parallel with the patient's recovery; in general, it begins with a brief assessment in the acute phase that focuses on management of delirium and pain, then it morphs to the evaluation and treatment of symptoms of PTSD in the months after the burn, and then it targets psychosocial adjustment to disfiguring burns in the years after the burn. These phases can be divided into acute, intermediate, and long-term recovery.

Diagnosis and Developmental Assessment

Setting the stage for a discussion of the acute, intermediate, and long-term management of burn patients, we will review a diagnostic approach that incorporates a developmental model; this aids in the formulation and treatment of all medical and psychological problems experienced by the burned patient. This is particularly important for assessing children; consideration of the developmental stage provides the necessary context for understanding children's responses to trauma.[45] A developmental model for the assessment of burned children follows[46]; it has been supplemented by a developmental model that is useful throughout the life cycle.[47] For infants through adolescents, additional discussion relating to developmental stage is provided before the case example.

Developmental Stage and Burns: Case Examples

Infancy (Birth to 2.5 Years Old)

Infancy is the period from birth to emergence of language (typically until 2 to 2.5 years old). Infants experience the world in the moment and require immediate gratification of needs, whether related to pain, hunger, or absence of nurturance. For infants there is little separation between them and their primary nurturer; burn injuries, with the

necessary procedures and monitoring involved, inevitably disrupt this primary attachment. As much as possible, pediatric burn care minimizes the disruption by providing surrogates to mitigate the depressive reactions to absent parents and by providing as soothing and nurturing an environment as possible. Because of infants' cognitive immaturity and inability to make sense of what is happening to them, they take their cues largely from parents and caregivers, who (witnessing their infant in pain, and having fears of death and disfigurement) typically experience significant guilt and distress over the burn circumstances. Care of the burned infant is inevitably intertwined with care of the parents; the more stable the parents, the better the infants' recovery.

Case 1: A 4-month-old girl was admitted with 20% TBSA scald injuries to the face, neck, and chest. Her parents felt intense self-reproach and feared future scars; intermittently they had difficulty soothing her because of their own distress. Psychiatric consultation was requested to deal with her refusal to eat, her crying in anticipation of painful dressing changes, and her anxiety that was aroused by her mother's departure for home to be with her older children. With support of nursing staff, social work, and child psychiatric staff, the mother roomed with the infant, pain was reduced by use of opiates, and the infant healed with skin grafting (over a 2-week period) and appeared to resume her normal developmental course. This case illustrated typical signs of distress in a burned infant, manifestations of parental stress, and an approach (involving the parents and the child) to intervention.

Preschool Age (2.5 to 6 Years Old)

Egocentricism (belief that world revolves around them and that others see the world from their perspective alone), magical thinking (interweaving of reality and fantasy such that medical events have magical causes), and preoccupations with body integrity are the hallmarks of preschool children. Children in this age group may develop notions of guilt and punishment during the hospitalization and see injuries and painful treatments as punishment for bad deeds or thoughts. Some may regress, withdraw, and stop speaking. The child psychiatrist provides understanding and reassurance to relieve guilt-ridden parents. Similar to infants, preschool children are generally interviewed with the parent present. As the children get older, therapeutic play with drawings, puppets, and games is often used as both a diagnostic and therapeutic tool. Through play they can safely show their cognitive skills, express their feelings and traumatic memories, and resume normal development.

Case 2: A 3-year-old boy with smoke inhalation and 30% TBSA burns, mostly partial thickness, became increasingly withdrawn, except when in his brother's company; when with his brother, he would play with toys and be more outgoing. He was interpersonally inhibited and afraid of wound dressing changes. His pain was only partially relieved by oral morphine and lorazepam; he clung to nursing staff, and he appeared to regress. His speech was indistinct; what he did say was repeated over and over. Consistently somber, he stared silently at staff and did not speak or interact in a meaningful way. Psychiatric assessment determined that he suffered from a combination of an acute stress disorder and a mild anoxic brain injury. These conditions,[48,49] and possibly depression, were the consequences of his burn.

School-Age (7 to 12 Years Old)

Ability to understand their bodies, curiosity, a rule-bound cognitive style, and continuous efforts to gain control are the hallmarks of school-age children. With respect to burn injuries, they will want to understand the injury and its treatment and seek to gain control over it. They benefit from having a schedule of the treatments and other activities.

Case 3: A 10-year-old boy sustained 40% TBSA electrical burns when his kite got entangled on high-voltage electrical wires. His treatment involved frequent wound dressing changes, which he tolerated well initially. However, he refused to start physical therapy and this reluctance spread to his participation in wound care; he would yell and cry upon seeing medical supplies. On interview, he told the psychiatrist that he never signed up for physical therapy and that the exercises were very painful; he felt the assignments were unfair. With the surgeon and nurse taking time to explain the need for, and the prospected course of, these treatments (providing the duration of each session and their frequency) and eliciting his questions, he became visibly relaxed and ready to work out a schedule that allowed him to watch his favorite cartoons before and after his wound dressing changes and physical therapy sessions.

Adolescence

Although adolescents have the capacity to understand the injury, its treatment, and ramifications on their lives, they remain quite vulnerable. This stage of development is marked by striving for independence while managing ongoing dependency on their parents. Additionally, fitting in with peers and maintaining one's body image are of paramount importance to teenagers; therefore the potential disfigurement related to burn injuries can be particularly devastating to them.

Case 4: A 15-year-old boy sustained 85% TBSA flame and inhalation injuries in a grease fire from a cookstove; a friend perished in the fire. Trouble sleeping, bad dreams, and flashbacks of the fire plagued him. Nightmares persisted for 6 weeks. He tried to think about "positive things during the day" so that his dreams would be positive. One month later, he described a different type of dream. He described romantic fantasies about a female staff member who was caring for him. He was relieved to hear from the psychiatrist that such dreams were not unusual when a close relationship develops between a patient and a caregiver. He became able to acknowledge age-appropriate emotions. Near discharge, his nightmares of the fire recurred, as did positive dreams related to returning home and resuming his life. This case illustrates how dreams of burned patients can evolve and how they can be used to adapt to severe injury.

Young Adulthood

Case 5: A 23-year-old father of two was admitted with 40% TBSA burns to his face, neck, upper torso, and arms following a house fire. He received morphine for pain and diazepam for anxiety. He became acutely delirious (with agitation, disorientation, and combativeness), which required physical restraints and 10 to 20 mg of IV haloperidol per day for the first few days of the admission. The delirium seemed secondary to smoke inhalation and cerebral anoxia. He healed well over a 2-week period, and all medications (except for morphine that was used for dressing changes) were tapered. He was observed to be inappropriate, "strange," and to be "more like a kid." Psychiatric reassessment also revealed terror and posttraumatic intrusive thoughts and nightmares of the fire. He faced several stressors (e.g., severe burns suffered by his wife, two young sons, and younger brother) and his grief was intense. He recalled, but was unable to cope with, images of the fire and the injuries to himself and his loved ones; they were all nearby, in various stages of recovery. He responded well to emotional support, to clarification, and to reassurance, as well as to tranquilizers that restored adequate sleep and reduced the intensity of his terror. This case illustrates the combined effects of anoxic brain injury, delirium, acute stress, and acute grief in a young adult.

Elderly

Case 6: A 77-year-old woman caught her housecoat on a gas stove and sustained 15% TBSA first-degree and second-degree burns to her left side. Care providers called her "lovely" but cognitively impaired. She had a history of valvular disease with congestive heart failure (CHF), metastatic breast carcinoma (requiring bilateral mastectomies), and deep venous thrombosis (DVT). Confusion decreased when doses of diazepam and morphine were reduced. This case involved an ill, elderly woman who responded slowly, but well, to acute care.

Acute Phase: Assessment and Treatment

From the day of admission, assessment and treatment proceed hand in hand. Initial assessment is often difficult and history must often be obtained from others,[46] because the patient may be unable to communicate.[50] When reviewing the record, the consulting psychiatrist pays particular attention to all aspects of the initial presentation (e.g., police and emergency medical service records [that describe the circumstances in which the patient was found], toxicology screens [that yield important information about drugs and alcohol and risk for withdrawal], and chemistries and tests of kidney and liver function [that reveal current contributions to delirium]). Special studies, including brain imaging (when there is concern for head injury, stroke, severe hypoxic insult, or worsening mental status not explained by available data) and electroencephalography (EEG) (when there is concern for seizure or to verify presence of delirium) are often indicated.

Explanations about the burn and its treatment are followed by an assessment of the efficacy of these interventions. Communication should involve a vocabulary that the patient can understand and should be appropriate to the patient's cognitive and emotional ability. Because a burned patient may be confused, afraid of death or dismemberment, and anxious about pain, the initial history may need to be obtained from other individuals. Explanation, reassurance, and relief of pain help to reduce fear and confusion. A formal mental status evaluation is necessary to diagnose subtle changes in mental function. The patient's initial emotional reactions (e.g., denial, fear, guilt, grief, anger, or emotional withdrawal) should be noted. A history of developmental, mental, or substance abuse disorders; medical illness; and psychiatric treatment should be obtained; the social context should also be established. When family members understand, feel supported, and are reassured, they are better able to calm their loved one; however, when this support is absent the opposite is often true. As an alliance with the patient and family develops, additional history typically clarifies the circumstances of the injury.

In the acute assessment of children, the psychiatrist routinely assesses for abuse and neglect. Clinginess to nursing staff, exacerbation of fear response in the presence of parents or caregivers, and co-existing injuries not explained by the burn (e.g., fractures, bruises, soft tissue contusion, cigarette burns), should raise concerns of child abuse or neglect. Protective measures should be taken and mandatory reporting to social services completed.

Burn-Induced Delirium

Burn-induced delirium usually occurs soon after the injury and it portends an increased risk of death. The confused, agitated, or aggressive patients can hit staff, attempt to leave the hospital, fall, self-extubate, and dislodge intravascular lines and skin grafts. Delirium occurs in approximately 10% to 30% of burn patients and signals the patient's unstable condition; the more severe the burn the more likely it is that delirium will develop. With severe burns, patients are often kept anesthetized and intubated until grafting is completed; thus, acute delirium is often masked. Delirium has multiple causes; a more complete discussion of this subject can be found in Chapter 10. Prompt evaluation, the maintenance of safety (which may necessitate the use of restraints), treatment of the causative factors, and institution of environmental changes and supportive personal contact with staff and family are indicated.[51,52]

Acute Stress Disorder

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)[53] criteria for acute stress disorder (ASD) include symptoms of dissociation, re-experience of the trauma, avoidance, and anxiety or arousal. The symptoms must last for at least 2 days and occur within 4 weeks of the trauma; the condition is not due to drugs or medications or to the patient's medical condition. Some studies have found symptoms of acute stress occur in 11% to 32% of burn patients; the rates vary in part by virtue of the measurement methods used.[31,54,55] Risk factors for developing ASD include the scope of the burn, poor premorbid mental health, and the tendency to blame others for the burn.[56] Awareness and recall of the injury may be delayed until

opiates and benzodiazepines are tapered, at which time the intrusive recollections, nightmares or night terrors, and associated arousal states may begin. In children, emotional withdrawal or overreactivity may occur in association with re-experiencing or with hyperarousal. They may become agitated or combative during wound dressing changes or other painful procedures; having parents leave the room during these treatments may exacerbate the child's reaction. Later in the recovery period depression may develop, with interpersonal withdrawal and a decreased appetite. In children, anhedonia, sleep and appetite disturbances, emotional withdrawal, and irritability are the most common accompaniments of depressed mood. Brief supportive psychotherapy, alliance building, treatment of pain and anxiety, and provision of appropriate reassurance are of benefit.

PAIN ASSESSMENT

Pain is ubiquitous in burn patients; partial thickness burns (with intact nerve endings) are more painful than are full-thickness burns (where nerve endings are largely destroyed). Although the burn itself is painful, a significant amount of the pain is associated with daily débridement and wound care. Pain is often underestimated and undertreated, because staff fear that respiratory depression or death will result from treatment[57]; organizational approaches (implementation of pain management guidelines and educational programs) have reduced this problem. In responding to this, Szyfelbein and associates[58] and others have used self-rating scales and measured serum endorphin levels; they proved that high-dose IV opiates were needed to provide relief from pain for those with severe burns. Improving pain relief[59,60] and sharpening the focus on psychological as well as pharmacological interventions is important to improve outcomes; unfortunately, pain in many burn patients remains undertreated.[61]

The addition of short-acting IV and oral agents (especially opiates, midazolam, and propofol) to target acute pain and anxiety has dramatically lessened the suffering secondary to acute burns. Initially the location(s), source, quality, intensity, course, and duration of pain are identified; then, with nursing staff, self-reported ratings of pain (from 0 to 10 with 10 equaling the most pain) are monitored in response to treatment. Burn pain correlates with endorphin levels and with the extent and depth of the burn.[62] Because infants cannot provide self-reports, behavioral measures (e.g., facial expressions, body movements, and crying) and physiological parameters (e.g., heart rate, blood pressure, respiratory rate, oxygen saturation), and if available, levels of epinephrine, norepinephrine, growth hormone, and cortisol are useful in monitoring pain responses.[63] For children who are unable to verbally communicate, self-reported measures (such as the Faces Scale, the Visual Analogue Scale, and the Oucher Scale) are useful; among staff-rated scales the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) has utility.[64] The most easily used self-rating scales for burn patients are 0 to 10 visual analogue scales[65]; these rate pain from 0 to 10, with 0 as no pain and 10 being the most severe pain experienced. In general, for patients unable to communicate (e.g., owing to use of paralytic agents or to intubation), much information about pain, anxiety, and fear may be gathered by noticing facial expressions (e.g., grimacing or wincing), body language (e.g., withdrawing, pushing away, or startle reactions), and autonomic signs (e.g., changes in heart rate and breathing rates with disturbing or soothing stimuli). When a patient is in a medically induced coma with no objective or subjective means to measure pain, estimates of maximum analgesic requirements for body weight are recommended.

Psychological Treatment of Pain

It is widely accepted that emotional and cognitive states modulate the experience of pain, and vice versa. Psychological techniques to ease burn pain include education, hypnosis, relaxation, patient participation in dressing changes, and biofeedback; these techniques do not predispose to side effects or toxic effects as do medications. Patients can be trained to use these methods,[61] and they can discover that they are capable of achieving self-control over pain.

Developmentally targeted psychological approaches to pain management are effective for both children and adults. Hypnosis for burn pain is effective and practical,[66–68] but it requires more staff time than when relying solely on the use of analgesics. Hypnosis[69] and simple and complex relaxation techniques (such as focused imagery) are in wide use and are practical for children (who are the most hypnotizable subjects) and for adults. Spiegel and Spiegel[70] described a method that is generally applicable for burn patients. Intriguingly, Ewin[71] has reported that hypnosis can acutely prevent the postburn inflammatory response, thereby lessening burn severity. Patient-mediated methods involve the patient's active participation and are designed to shift the locus of control in burned children to themselves.[59,72] This involves preparation for painful procedures and increases the patient's ability to choose when, for how long, and who will perform invasive procedures by encouraging their participation at each step. This structured method can lead to fewer maladaptive behaviors, improved outcomes, and use of lower dosages of narcotics.

Children may develop conditioned fear responses to recurrent painful procedures, such as dressing changes. These responses may escalate to the point that the child is terrified at the mere sight of someone in scrubs or white coats, or worse, the child is continuously afraid that someone may arrive to "hurt" them. Interventions depend on the developmental stage of the child; however, preprocedure treatment of anxiety often reduces the intensity of the experience and the expressed fear, and changing the location of the treatment helps children compartmentalize the reaction. For older children, explaining the procedures and providing schedules enhances their sense of control and improves their understanding and reactions.

Pharmacologic Treatment of Acute Burn Patients

Opiates

The vast majority of burn injuries require narcotic analgesia for adequate pain relief of baseline pain and procedure-related acute pain. This is true for patients in all age groups; a recent prospective descriptive study of

burn victim children under the age of 4 years revealed that 96% of children received at least one dose of morphine.[73] Initially, continuous infusions of morphine or fentanyl, or patient controlled analgesia (PCA) are used. When transitioning from continuous or high-dose IV opiates, background pain can be effectively managed with long-acting opiates (either long-acting preparations of morphine or oxycodone, or methadone). Procedure-induced pain is often treated with a short-acting opiate (such as fentanyl, morphine, or hydromorphone).[74,75] For the acutely burned child, morphine sulfate is often started as a continuous infusion (starting at 0.05 mg/kg per hour with intermittent IV boluses of 0.05 to 0.1 mg/kg every 2 hours); the guideline for midazolam (if anxiety is otherwise unrelieved) is to start at 0.01 to 0.02 mg/kg per hour and then administer an intermittent IV slow push every 4 to 6 hours (0.04 mg/kg per hour). Respiratory depression may require use of opiate or benzodiazepine antagonists. Reversible neurological abnormalities have been reported in children following long-term midazolam use.[76]

Pain reduction is effective whether the cause is biological or psychological, because pain "disrupts metabolic, autonomic, and thermoregulatory" as well as immune functions.[77] Studies have clarified the efficacy of high-dose morphine for relief of burn pain, using either IV or oral administration. PCA with burned adults has been universally useful, but PCA is still useful in selected patients, usually after the first few days of treatment. Adjuvants (e.g., methylphenidate, tricyclic antidepressants, and neuroleptics) can enhance the efficacy of opiates.

Benzodiazepines

Benzodiazepines are often used in hospitalized burn patients to induce sedation, reduce agitation, and decrease anxiety. Given that alcohol dependence and intoxication are risk factors for burn injuries, alcohol withdrawal is commonly encountered and benzodiazepines are used in the treatment of withdrawal. A host of benzodiazepines are available for use, including short-acting agents (e.g., midazolam [which has rapidly assumed a significant place for brief procedures],[78] lorazepam,[79,80] oxazepam, and triazolam) and long-acting agents (e.g., chlordiazepoxide, diazepam, clonazepam, flurazepam). There are few indications for use of psychotropics in recently burned children other than for the management of pain, anxiety, or delirium. As is true for pain, anxiety is often undertreated.

Neuroleptics

Neuroleptics or antipsychotics are frequently used to control delirium-related[81] agitation or severe insomnia in older adolescents and adults. IV haloperidol (although not approved by the Food and Drug Administration [FDA] for IV use) is the most widely studied and accepted neuroleptic for the management of delirium in critical care settings.[82] Before using any neuroleptics, a baseline electrocardiogram (ECG) is obtained to measure the QTc (ideally less than 450 msec); serum potassium and magnesium levels should be within normal range. For acute agitation in patients are who are smaller, younger, elderly, neuroleptic-naïve, or who have mild agitation, one should begin with small doses of IV haloperidol (0.5-2 mg) and titrate to an effective dose depending on the clinical response. A general rule of thumb when titrating IV haloperidol is to wait 20 to 30 minutes after giving the first dose; if it was ineffective, double the dose and repeat this until a dose is reached that calms the agitated patient. If a patient requires escalating doses of haloperidol, an ECG should be repeated to monitor the QTc, and one should also continuously re-evaluate whether other immediately reversible causes may be contributing to agitation (e.g., hypoxia or pain). Once an effective dose has been reached, that dose can be repeated every few hours as necessary to control agitation. Patients who are larger, have been on antipsychotics regularly, or have moderate to severe agitation, may need larger doses (5 to 10 mg) at the outset, after which a similar titration to an effective dose can be pursued. Very high doses have been used safely and with good results.[83] Extrapyramidal side effects (e.g., dystonia) may occur, but their incidence is exceedingly low,[84] and dystonia can be largely prevented by use of antiparkinsonian agents. Occasionally, when severe agitation occurs and when the goal is to enhance deep sedation, a propofol drip and/or IV haloperidol, lorazepam, and a narcotic may be necessary.[85] This state reduces the metabolic demand imposed by agitation, minimizes pain, and produces amnesia that may decrease the vulnerability to PTSD. Haloperidol is not indicated for use in young children with burns because of the risk of hypotension, which is common. Such children usually respond to benzodiazepines.

Newer oral, atypical antipsychotics (e.g., risperidone, quetiapine, ziprasidone, olanzapine, paliperidone, and clozapine) are increasingly used for adult burn patients, adolescents, and (primarily risperidone) with some children, though they have not been systematically studied in burn patients. Olanzapine (IM and oral forms), risperidone (oral forms), and quetiapine (oral forms) are more commonly used for management of agitation secondary to delirium, intense fear, and severe insomnia. See Chapter 10 for more information on management of delirium in the medically ill.

Drug Side Effects, Toxicity, and Adverse Interactions

Side effects, toxicity, and adverse interactions can occur with just about any agent used in burn care. Given that the consultation psychiatrist most frequently employs opiates, benzodiazepines, ketamine (in children), and antipsychotics in the acute management of burn patients, we will review those medications.

With antipsychotics, side effects and adverse reactions can be grouped by the following receptors or channel interactions: potassium-delayed rectifier channel (QT prolongation), anticholinergic side effects (e.g., tachycardia and constipation), antihistaminergic effects (e.g., sedation and weight gain), alpha antagonism (orthostatic hypotension), and dopamine antagonism (e.g., akathisia, dystonia, tardive dyskinesia, and neuroleptic malignant syndrome [NMS]). Of these, the gravest and least common are NMS and torsades de pointes (associated with QT prolongation). These syndromes are described in other chapters.

Opiates have an array of side effects (including exacerbation of delirium, respiratory depression, and development of physiologic and psychological dependence and

withdrawal) with which the consulting psychiatrist should be familiar. Burn patients who require high amounts of opiates over a matter of weeks will become physiologically dependent; tapering is recommended to prevent an uncomfortable withdrawal syndrome. Minor withdrawal symptoms may be managed with clonidine and dicyclomine (to reduce stomach cramps). The interaction of opiates and benzodiazepines may cause delirium, excess sedation, and respiratory depression.[86] Opiate toxicity can be reversed by naloxone.

Side effects and adverse reactions of benzodiazepines include paradoxical worsening of agitation, respiratory depression (which can be additive with other medications), and similarly to opiates, development of tolerance and therefore withdrawal. In children, midazolam infusions are not associated with lactic acidosis believed to result from the accumulation of propylene glycol, a problem seen occasionally with lorazepam infusions.[87] Benzodiazepine toxicity can be reversed by use of flumazenil; however, seizures may be induced if this medication is administered to benzodiazepine-dependent individuals. Signs and symptoms of benzodiazepine withdrawal include anxiety, dysphoria, insomnia, abdominal cramps, nausea, vomiting, sweating, tremors, and seizures. Benzodiazepines must be tapered because the withdrawal syndrome can be complicated by seizures.

Ketamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, is one of the most well known psychotomimetic drugs[88] frequently used for rapid sedation in children; the long-term neurodevelopmental effects of it are unknown. Though clinicians seek to balance the risks and benefits of aggressive pain management with ketamine, for years it has been in wide use in pediatrics because of its ability to manage procedure-related pain, without major adverse short-term or long-term effects.[89]

Pharmacologic treatment of patients with burns is often complicated by prior substance use and abuse, the possibility that use of pharmacologically-active agents will adversely alter mental state, the critical condition of the patient (especially with respiratory failure or renal insufficiency), drug interactions, altered pharmacodynamics, and the need to balance the benefits of the medication against the risks of unwanted side effects or toxicity.[90] When this is the case, reducing the dosage of medications or stopping medications in favor of psychotherapeutic interventions may be safest.

Of note, although patients with burns may develop a physical dependence to analgesics and anxiolytics, addiction is rarely caused by use of these agents in the context of burns. Additionally, substance abusers may at first require higher doses of opiates or benzodiazepines to effectively treat symptoms than do others without similar histories.

Intermediate Phase

The intermediate phase, during which the patient is healing, is less stressful. Lengthy hospitalizations, however, are the period for which the term *continuous traumatic stress* may be most fitting.[91] During this time, the psychiatrist may be called to see a burn patient with a premorbid psychiatric condition who is depressed, displaying symptoms of PTSD, or who is having special difficulty adapting to the frequent stresses of burn care. Even the most resilient of patients may have difficulty with body image disruption or a re-experience of trauma symptoms upon rehospitalization for ongoing burn treatment. These patients benefit from individualized psychological and psychopharmacologic treatment.

Psychological Interventions

A shift from the acute to the intermediate phase occurs when survival is assured, when most burn wounds are grafted, and when the patient approaches ambulatory status. At this time, it is possible to assess more fully the mental status and to begin differentiating issues of mourning the prior body image, grieving the loss of loved ones, depression, and PTSD. In addition, assessment and diagnosis of neurological or preexisting psychiatric impairment becomes feasible. The patient's awareness of functional losses and disfigurement is eased by responsive staff and by supportive, informed family members. Psychotherapeutic interventions also focus on phase-related issues (e.g., forthcoming surgery, return to home and school, and rehabilitation).

Adaptation of the family usually follows the course of the patient's recovery. Remarkably similar feelings and defensive responses are observed in the patient and his or her family. Psychotherapeutic support (often several sessions per week) during this phase, especially regarding guilt feelings and grief, assists the family and enables them to support the patient's coping through this phase.

Some hospitals provide groups that offer brief psychotherapy, education, and rehabilitation. Several types of group interventions have been used: a children's group structured to encourage expressive drawing and puppet play, an adolescent or adult group for hospitalized patients, and family groups for parents or families of acutely ill patients. These group interventions focus on education about treatment, grief, and one's response to hospitalization, surgery, stigmatization, discharge, and re-entry into society. In England, Rivlin and associates[92] conducted parent groups using a multidisciplinary approach, which the parents rated as helpful.

Body Image and Plastic and Reconstructive Surgery

After the acute treatment of burns, the intermediate phase often involves ongoing care with plastic and reconstructive surgeons. Although the surgeries they perform may begin early in treatment, they may continue for years after the initial burn. Many burn survivors with changed appearance have ongoing difficulties with psychological and social adaptation.[93] One longitudinal study of body image of survivors of severe burn injury found that one year after injury, body image satisfaction and distress was the most significant predictor of overall psychosocial function. [93] The more one defines one's self by physical appearance, the greater the self-consciousness about appearance.[94] Certain problems or mental disorders should prompt psychiatric consultation in those returning for postburn plastic and reconstructive surgery. For children, lack of age-appropriate preparation, preoperative panic, PTSD, parent–child disturbances, attention deficit hyperactivity disorder (ADHD), depression, and enuresis or encopresis are not unusual. For adults, PTSD, psychosis, substance abuse, malingering, or factitious disorder may occur. Certain burns that require

cosmetic surgery (e.g., of the face and head, breasts, or genitalia) and are associated with functional deficits (e.g., burns to the mouth, hands, arms, and lower extremities), including amputations and revisions, require special consideration and, at times, special expertise in preoperative psychological assessment and postoperative management.

Plastic surgeons develop psychological skills for the evaluation of burned patients and may seek psychiatric consultation for their patients.[95] Because much of acute treatment, even with recent improvements in care, is outside the control of the patient and the family, a central psychological goal at this point is to increase the patient's and the family's role in the treatment, its timing, and the long-term plans. Although staff assist the patient to see himself or herself anew,[96] the consultant, in turn, becomes aware of the experience of being burned through the eyes of the patient. By age 2 to 3 years, body image is a relatively stable part of the self-concept, although it is subsequently modified by growth, puberty, trauma, and aging. Interviewing a burned patient provides a window to the development of body image and, usually, on the adaptation and recovery that follow. Attitudes of family and staff toward the patient's physical defects help to shape body image. Burns in children and adults may profoundly alter the subsequent body image, level of self-esteem, interpersonal relations, and ego function,[97,98] but body image disturbances are not inevitable. Body image revision occurs through plastic surgery, allowing another stage of reintegration of body image and healing of the damage to appearance and to self-image. Focused, short-term supportive and educational psychotherapy is helpful, and protocols for these treatments have been developed.[99]

The capacity to tolerate fear and anxiety associated with rehospitalization should be assessed before embarking upon plastic and reconstructive surgery. If there is significant psychopathology, review of records and a preoperative assessment are indicated to reduce postoperative complications. Preoperative problems include phobic reactions to surgery, unrealistic expectations of "perfect" surgical results, embarrassment or shame related to severe disfigurement, and resurgence of PTSD symptoms (e.g., flashbacks or nightmares). Reality-oriented preoperative psychotherapeutic interventions support the patient's coping and facilitate a positive attitude following surgery.

Occasionally, evaluation of emotional readiness for elective surgery results in a recommendation to postpone the surgery. Though such readiness should be part of preadmission assessment, such reactions may not be apparent until the patient arrives for surgery and is immersed in the hospital environment. A patient who presents with panic upon admission and re-experiences prior burn-related trauma may require postponement of elective surgery until outpatient desensitization treatment for the phobia, treatment of panic disorder, or both can be started (before undergoing surgery).

Massively Burned Persons

Today, children and adults usually survive once they reach an acute burn unit, even with massive burns. Despite suffering severe burns to the bronchial tree, face, torso, or extremities (which may require deep, disfiguring excisions of fat and muscle, or amputations), people survive. In fact, in 1984 the percent of burns associated with a 50% mortality was 65% and by the early 1990s it increased to 81%.[100] Many of these survivors drew on personal strengths and family supports and were incredibly resilient.

Psychiatric treatment of those with massive burns initially focuses on the management of pain, stress, or delirium, then deals with grief and injury to body image. Next, treatment focuses on support, restoration of mobility, self-esteem, and hope. Finally, treatment helps the burn survivor resume educational, occupational, and social function. Encouragement, education, and advocacy for the massively burned patient is crucial to mobilize resources so that life, school, and work outside the hospital can be resumed and that the social stigma of disfigurement can be endured.

LONG-TERM PHASE AND OUTCOMES IN BURNS

In many ways, the long-term phase of postburn treatment is a continuation of the intermediate phase, with ongoing assessment and treatment of recurrent or emerging psychiatric illness and reintegration of a patient's sense of self, having been forced to grieve various aspects of their body, function, and even life roles. The general hospital psychiatrist should be aware of this dynamic phase of recovery.

General Outcomes

Many small studies of varying quality and a few larger ones relate to outcomes after burns.[101–103] Clearly, the quality of burn and reconstructive treatment has improved; this makes conclusions based on earlier studies unreliable when attempting to predict current outcomes. Tarnowski and Rasnake,[101] in a review of child outcome studies, believed that "collectively, findings indicate that little empirical data exists to support the contention that the majority of pediatric burn victims exhibit severe poor postburn adjustment." Patterson and colleagues[102] essentially agreed with these conclusions for adults from a rehabilitation psychology perspective. They suggested that poor outcomes were mainly a result of severe preburn psychopathology, which is significant. In another study, Park and co-workers [104] conducted a cross-sectional survey of 686 patients with burns; they found that lack of family support and living expense burden were the two most significant risk factors for patients with acute burns; and those factors, in addition to medical expenses burden, were the risk factors associated with psychosocial problems in chronic burn patients.

Although there is much preburn psychopathology in adults and some in children, this theory underemphasizes the severity and chronicity of posttraumatic reactions. Issues of vulnerability, resilience, and the effects of traumatic stress on emerging personality development[105] have been thoroughly summarized. Although pessimistic conclusions about outcomes are unwarranted, serious psychiatric and psychological morbidity after severe, disfiguring burns merit attention, especially for adolescents who are more vulnerable to depression. For instance, Stoddard and associates,[106] in a cross-sectional follow-up study of children aged 7 to 19 years with severe burns (mean injury, 38% TBSA) readmitted for plastic surgery, found that a majority had mental disorders (including PTSD, depression, and

enuresis) at some time following the burn, whereas 20% developed no disorders. Blakeney and colleagues,[103] while following a sample of 72 children with over 80% TBSA burns, found that 47 achieved "positive psychosocial adaptation," while moderate to severe difficulties in 24% to 30% of cases, a comparable level to those seen with lesser burn injuries.

Posttraumatic Stress Disorder (PTSD)

In child and adult studies, the prevalence of PTSD after burns ranges from 20% to 45%,[107–109] but partial PTSD is more frequent. In a longitudinal study of burn victims, van Loey and colleagues[110] showed that severe stress reactions immediately after injury are common and generally decrease over time; pain-related anxiety predicts posttraumatic stress symptoms 1 year after the burn; consecutive painful wound treatments related to burn severity have a cumulative effect and predisposes towards posttraumatic symptoms in the long term; however, the absence of early posttraumatic stress symptoms did not necessarily prevent development of chronic posttraumatic stress symptoms. Several studies have identified predictors of PTSD, including the presence of ASD,[31] premorbid personality,[32] and premorbid affective and substance abuse disorder.[108] For children, DSM-IV PTSD criteria include "disorganized or agitated behavior" in response to trauma and posttraumatic play, "frightening dreams without recognizable content," and "trauma-specific reenactment" as symptoms of re-experiencing. In a study of PTSD of 60 burned children readmitted for plastic surgery, Stoddard and associates[106] found that about one third had full-syndrome DSM III-R–defined PTSD, and more than half had posttraumatic symptoms. Similarly, Kravitz and co-workers[111] found both a high incidence of sleep disorders in 82 children and, like Stoddard and associates,[106] enuresis in 24%. In adult burn survivors, PTSD occurred among 20% to 45% of subjects, often with associated sleep disorders. Roca and colleagues[112] followed 43 patients (from discharge to follow-up 314 months later): 7% initially fulfilled criteria for PTSD; this increased to 22% at 4 months. Perry and co-workers[113] also found an increase from 35% at 2 months to 45% at 12 months. Powers and colleagues[114] found similar findings a year following discharge from the burn unit, with 38% fulfilling DSM-III-R criteria and 43% using the DSM-IV criteria. Most studies and clinical observation indicated a gradual attenuation of PTSD symptoms, but these studies suggested that it might not be so. Behavioral, cognitive, and pharmacologic therapies all have a place in treatment of PTSD; new short-term treatments are being tested.[115]

Additionally, early and aggressive treatment of pain may have an effect on the incidence of PTSD in burn victims. One study by Saxe and associates[116] demonstrated that early postburn administration of IV morphine reduced the emergence of posttraumatic stress symptomatology in older children, and probably in 1- to 4-year-old children.[117] Lastly, perioperative administration of ketamine was associated with reduced rate of PTSD in adult burn victims[118]; however, administration during the first 3 days was associated with an increased rate of ASD symptoms.[119]

Depression

Depression is also found to occur at higher rates in post-burn patients compared to those in the general population. Several studies have sought to evaluate the prevalence of depression among burn patients. Similar to PTSD, patients with premorbid mood disorders and particular coping styles are more likely to develop depression. One study found that patients with premorbid affective disorder were five times more likely to develop a mood disorder in the first year following a burn.[108] A review by Thombs and associates[120] found that major depression was identified (using structured interviews) in 4% to 10% of adult patients 1 year after a burn. The prevalence of depressive symptoms varied depending on the scale used; the Hospital Anxiety and Depression Scale yielded rates of 4% to 13%, whereas the Beck Depression Inventory yielded rates of 13% to 26% for moderate to severe symptoms and 22% to 54% for mild symptoms.

Surgical reconstruction improves appearance and strikingly enhances social and emotional adjustment. One study demonstrated a prevalence of at least mild to moderate symptoms of depression in 46% of patients undergoing burn reconstruction[121]; depressive symptoms were largely predicted by body image dissatisfaction and by physical function. Outcome studies in adults suggest that a majority adjusted well to their burns over the long term, but that those with facial burns are more likely to experience social rejection, impaired self-esteem, and withdrawal. These results do not resolve the likelihood of severe burn-related emotional disability in burned adults. As with children, improved treatment methods appear to improve outcomes, but definitive studies are lacking.

Chronic Pain

Although pain subsides once the burns heal, ongoing pain has been documented years following burns[122,123]; two studies found that about one third of burn patients 1 to 9 years out from a burn continue to have significant pain, and the majority of these patients had sleep, work, or social disruption related to the pain. In addition to pain, itching, particularly in deep thermal burns with hypertrophic scars, is one of the more disturbing physical complaints endorsed by patients with burns, and it can become chronic in some patients.[124] A study by Van Loey in 2008[124] prospectively followed burn patients for 2 years and found that at 3 months 87% of patients complained of mild to severe itching, and this decreased steadily over the next 21 months (such that at 2 years, 21% of burn patients had moderate to severe itching). The study showed that at 2 years, posttraumatic stress symptoms and the number of surgical procedures predicted itching. Although itching has a fairly well understood biological basis, psychological factors may also contribute to the chronicity of itching. Psychoactive medications, including naltrexone,[125] gabapentin, and doxepin[126] have been tried with some success. More research is needed in this area.

Lastly, observations of patients who do well following burn injuries has led to insights about resiliency factors and a growing body of literature regarding predictors of success in recovery. Positive emotions, self-efficacy, resilience, ability to sleep during recovery, and baseline resilience at the time of injury have all been identified as protective factors.[127–130]

END-OF-LIFE CARE

The mortality rate on adult units is much higher than on pediatric burn units because of more extensive burns, severe medical and psychiatric risk factors, an increased mortality risk associated with being older, and the limits of what medical care can achieve. Elderly patients with burns are more likely to require ventilatory support, more intensive care, and have higher mortality rates.[25] Most burn-related deaths occur during the initial phases, but some patients survive for months before death arrives, and some patients survive within the acute burn care setting and then fail in less intensive rehabilitation settings.

The psychiatrist is often consulted to assist in the care of dying patients and their families to minimize pain and suffering and to assist in the process of decision-making at the end of life.[131–133] With massive burns, decisions whether to continue treatment may arise. This is challenging emotionally and spiritually to all involved; patients may benefit from pastoral care; burn teams may benefit from optimal care or ethics committee consultations. Some patients and families, in collaboration with the burn team, choose palliative care (or "comfort care") rather than enduring the pain and suffering of treatment and the cosmetic, functional, and psychological sequelae of burns.

Although it is often traumatic when an adult dies, it is always emotionally traumatic when a child dies from burns.[131–134] It is essential to provide accurate explanations about the risk of death to families and to patients when possible, as well as emotional preparation for this possibility. Support in their grieving is helpful to relatives of burn patients who die, especially from members of the burn team who worked closely with them. Many grieving family members are very grateful for the care their loved ones have received.

STAFF SUPPORT, STAFF STRESS, AND BURNOUT PREVENTION

Psychiatric skills are especially valuable and valued by burn patients; stressed staff also know their benefits. It is useful to understand organizations in which one works, the rapid changes that affect hospitals and health care, and the virtues of developing a relationship with a multidisciplinary team to care for severely traumatized patients. One's introduction to the unit may be followed by shock, dismay, fear, frustration, and sadness as the full meaning of burn care takes hold.[13,133] Respect for the coping styles of the staff is crucial, since it may at times appear that individuals are harsh, regressed, or overinvolved. The psychiatrist on the team, simply by his or her presence, encourages communication; a reflective attitude about staff members' feelings as well as those of their patients is helpful. Encouraging staff to ask questions, the psychiatrist can enable them to think diagnostically and therapeutically about their patients' and their future and provide them with a sense of satisfaction and hope. Gratitude for sharing the burden of tragic or irreversible situations and for lending an ear may be forthcoming. The psychiatrist is often able to place trauma in a positive perspective and to broaden and deepen the psychiatric knowledge of the entire burn team.

ETHICAL CONSIDERATIONS

Ethical issues stimulated by burn care may be a source of difficulty for staff and the family; these issues may be magnified by costs, which may exceed $1 million for a single patient. Ethical issues[50] include consent to treatment, quality of life, prevention of intolerable pain, organ donation, decisions about resuscitation or withdrawal of life support, cost of care versus potential benefit, responsibility for long-term care of most severely burned, right to treatment, and determination of disability. Consultation by the ethics committee to the burn team in difficult cases is often helpful to provide optimal care to the patient and family.

Chronic Medical Illness and Rehabilitation

Thomas D. Stewart, M.D.
Gregory L. Fricchione, M.D.

Most of us take for granted our ability to function well physically: to open a tube of toothpaste, answer the telephone, tie our shoelaces, use the toilet, or comb our hair. We forget that each task took considerable time and effort to master. The same is true for our good physical health. When we are still quite young, we can depend on our bodies to get us from place to place, to keep us out of danger, and to adjust to changing environmental demands seamlessly and without much mindful input. However, the development of these capabilities is dramatically altered by the onset of a persistent medical illness in childhood (e.g., the effect of rheumatic fever on the heart, the impact of polio on the musculoskeletal system, or the effect of cystic fibrosis on the lungs). Likewise, the sudden loss of physical function (e.g., from traumatic amputation, or hemiparesis after a stroke) dramatically alters one's relationship to physical function.

For individuals with chronic medical illnesses or for those who need rehabilitation, the behaviors, functions, and outcomes that most of us expect in response to our brain's request that our body perform may never again be available in the same manner. This chapter addresses the unique problems and challenges faced by patients with chronic medical illnesses and by the psychiatrists who treat them.

PSYCHIATRIC COMPLICATIONS IN CHRONIC MEDICAL ILLNESS AND REHABILITATION

In the United States, discharging patients from acute care facilities as quickly as possible is common practice. Moreover, there is an increasing tendency to divert patients from acute care hospitals to other (lower-cost) facilities to keep costs in check.[1] Thus, there is a growing need for appropriate aftercare after acute treatment. Many larger hospitals have rehabilitation hospitals attached to them (or close by); smaller hospitals may have to rely on distant rehabilitation centers to provide the specialized, long-term care that they cannot offer.

Unfortunately, many who require rehabilitation and have a chronic illness are at substantial risk for developing one or more psychiatric complications. Rates of depression, for example, among amputees range from 35% to 58%; for those with multiple sclerosis, from 6% to 27%; and for those with cancer, 6% to 25%.[2]

Prevalence rates of suicide and of suicidal intent[3] are also substantially higher among those with chronic illnesses than among those without. For example, compared with the general population, individuals with cancer have suicide rates that are 15 to 20 times greater, those with spinal cord injuries have a rate 15 times greater, and those with multiple sclerosis have a rate 14 times greater.[2,4]

The consulting psychiatrist is often asked to evaluate and to help care for patients with affective, behavioral, and cognitive difficulties, and with a variety of diagnoses, while they are receiving rehabilitative care. The most challenging of these patients are those with traumatic brain injuries, spinal cord injuries, and prolonged and catastrophic medical illnesses. Patients with preexisting psychiatric conditions (including personality disorders) may decompensate under the stress of prolonged hospitalization, adding further complexity to their care.[5–7]

Problems That Occur during Rehabilitation

Patients receiving rehabilitative treatments tend to spend a large portion of their time worrying about the future. They anticipate (correctly or not) difficulties that they will face while adjusting to their new (more medically compromised) lives. A patient may worry about returning home, obtaining financial independence, driving, returning to work, adjusting to changes in appearance, socializing, dealing with stigmatization, engaging in sexual activities, and managing decreased functional capacity.[8–11]

Rehabilitative services may be obtained in a rehabilitation hospital or on an outpatient basis. This component of the treatment may continue for months or years—much longer than the acute treatment—causing serious disturbances in patients' usual schedules. During this phase of treatment, patients meet new caregivers, including physiatrists, nurses, occupational therapists, physical therapists, social workers, vocational therapists, recreational therapists, psychologists, clergy, and psychiatrists. Interactions with this many personnel may be stressful and may affect the quality of therapeutic relationships. Likewise, patients receiving rehabilitative treatments may be exposed to many new, uncomfortable, or painful procedures.

At times, the challenges that arise for clinicians and patients affect empathic connectedness. Cultural differences may play a role in this regard, and it takes time to

learn to trust a new consultant. Table 29–1 lists some characteristics of patients and caregivers that should be considered when a clinician, especially a psychiatrist, tries to make an empathic connection with a patient undergoing rehabilitation.

The Rehabilitation Environment

Patients must adapt to a large number of rehabilitation personnel and to the rehabilitation setting, which is often dramatically different from the acute hospital setting. Perhaps one of the most important issues for the rehabilitation patient is the possibility of lengthy physical displacement. The patient receiving treatment far from home and for an extended period, who is therefore separated from loved ones and familiar objects and surroundings, may be at increased risk for developing depressed mood, apathy, or hopelessness.

Other problems common to prolonged rehabilitation (e.g., disruptions in school or work attendance, stresses on a marriage or partnership and parent–child relationships) may hinder timely and successful recovery and may produce long-term negative effects for a recovering patient. Patients may also believe that they and their illnesses are a financial and emotional burden for loved ones, and they may feel guilty about the amount of time spent on them and on their care. This may lead to withdrawal from caregivers and loved ones in a paradoxical attempt to lessen their burden.

Psychiatric Problems Common in Patients Undergoing Rehabilitation

The consulting psychiatrist should expect to encounter the full spectrum of psychiatric conditions in patients with chronic illness who require rehabilitation. However, certain psychiatric diagnoses and conditions are more common in this population: depression, cognitive impairment, adjustment disorders, and behavioral difficulties.[1,2]

Many patients receiving rehabilitative care and coping with chronic medical illnesses appear depressed, confused, or anxious. However, when standard clinical criteria are employed, a large proportion of these patients do not meet diagnostic criteria for these conditions as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV).[12] The somatic symptoms used in standard assessments of depression (e.g., low energy, difficulty concentrating, sleep disturbance) are not useful. Other means of assessing and conceptualizing the patient's psychological reactions to medical illness (i.e., psychological instruments that do not use somatic indicators of depression, such as the Hospital Anxiety and Depression Scale) can give a more accurate assessment of depression and anxiety in the medically ill.[13]

These patients, nevertheless, may be demoralized by their circumstances. As characterized by Jerome Frank,[14] demoralization represents a persistent failure to cope with a chronic stressor. It is characterized by patients' having the experience of failing to live up to their own or others' expectations. It is accompanied by feelings of hopelessness, helplessness, confusion, and subjective incompetence. However, there is a lack of consensus on the definition of demoralization and on its differentiation from major depressive disorder (MDD), and it is difficult to distinguish between these two conditions. To address this issue, Clarke and colleagues[15,16] performed a factor analysis of the psychiatric symptoms of 312 medical patients selected at random, and they analyzed 108 different symptoms. They noticed that the symptoms could be divided into three clusters—anhedonic depression, demoralization, and grief—suggesting that these are three distinct syndromes experienced by patients with persistent medical illness, each of which requires a distinct diagnostic and therapeutic approach. Further research is required on demoralization to better characterize its contribution to depressed mood in patients with medical illness.[15,16]

Regardless of the syndrome underlying the depressed mood or anhedonia in these circumstances, it is most appropriate to treat symptoms rather than diagnoses. Moreover, the symptoms should be treated early and aggressively, as more (and more severe) symptoms often appear quickly and are more difficult to manage once they have developed fully.

The inability to reach a diagnostic threshold may result in part from difficulties in communication between the clinician and the patient. Many conditions that afflict rehabilitating patients impair their ability to communicate their most basic feelings and emotions. Likewise, clinicians may be fooled because the usual affective "music" associated with various mood states in the healthy population may not be present in the chronically ill. In these circumstances, it is far better to err on the side of too much treatment than too little.

Delirium is of particular importance in rehabilitation patients. A patient may have an acute confusional state during hospitalization, and it may continue at the rehabilitation center without having been detected or treated. This may adversely affect prognosis and lead to an increased length of stay or the need for a nursing home placement.[17] However, delirium may develop during rehabilitation when, for example, a new medication is administered or an infection develops.[18] Of 2158 subjects newly admitted to a rehabilitation facility after being in an acute care facility, 16% had delirium, and over two thirds had at least one

symptom of delirium.[19] Furthermore, in a study of 551 patients similarly transferred from an acute care to a rehabilitation facility, Marcantonio and colleagues found that 23% had symptoms of delirium on admission, and 1 week later, 12% had more symptoms of delirium.[20] Patients who have chronic illness and are undergoing rehabilitation often present with risk factors that predispose for, or precipitate the development of, delirium (e.g., a visual or hearing impairment, a cognitive impairment, a history of stroke, an intracranial lesion, an ongoing infection, the use of psychotropic drugs or polypharmacy, and medical complexity).[19]

The Potential Impact of Disabling Neurologic Conditions on Psychiatric Diagnosis and Treatment

Disabling conditions can limit the ability of patients to express their thoughts and feelings, confounding both psychiatric diagnosis and treatment. For example, depending on the location of a stroke, its clinical manifestations can interfere with the expression of cognition or affect, which are necessary for making the psychiatric diagnosis.[21] Furthermore, psychiatric treatment can be affected—for example, when acute cervical spinal cord injury is accompanied by psychosis and delirium.

The clinical manifestations of stroke depend on the location of the ischemic injury. Strokes can generate disorders of communication that can mislead treating physicians. The most common barrier to communication faced by stroke patients occurs in dominant-hemisphere injuries. The most prominent communication difficulties caused by dominant-hemisphere strokes are the aphasias. Fluent aphasia, such as Wernicke's aphasia, is a well-articulated incoherence and failure to comprehend without a motor–sensory deficit. This disordered, fluent speech can be confused with the loose thinking found in schizophrenia. History is the key for differentiating fluent aphasia with sudden onset in a previously well-functioning patient from schizophrenia, where an insidious onset along with emotional and social impoverishment is evident.

Nonfluent aphasia (e.g., Broca's aphasia) features slow and telegraphic, but coherent, speech with impaired word-finding ability. Through yes-or-no questions, such patients can be helped to express their feelings. Facial expressions associated with depression remain intact.

Lesions in the nondominant hemisphere can also cause disorders of communication and make the accurate diagnosis and treatment of psychiatric illness more challenging. Aprosodia is an example of dysfunctional communication after a stroke. It involves an impaired ability to receive or to convey affect (through inflection, gesture, and facial expression).[22] The damage is in the nondominant frontotemporal region, and it is an analogue of aphasia, which is associated with the frontotemporal region of the dominant hemisphere. Expressive aprosody disrupts the emotional undertone (i.e., the "music") of communication.

Aprosodic patients sometimes have depressive cognitions, but they cannot easily convey their depressive mood; this leads to underdiagnosis of depression. On the other hand, a patient with expressive aprosody is sometimes misdiagnosed as having depression when the unemotional speech is taken as a sign of a mood disorder. Several approaches can detect defects in prosody. First, confirm that the nondominant hemisphere is damaged (e.g., by physical findings, such as hemiplegia, or by brain imaging). Then ask the patient to repeat a neutral sentence, such as, "I am going to the store," with several different emotional tones (e.g., happiness, sadness, anger). Failure to do these well suggests expressive aprosody. On the other hand, if the patient cannot detect changes in tonality when the *examiner* recites the phrase (when the patient cannot see the examiner's face), a receptive aprosody is suggested. In aprosodic patients, careful observation of somatic signs and symptoms of depression (e.g., changes in appetite or sleep) takes on a greater significance, as does a personal and family history of depression.

Furthermore, strokes in the nondominant parietal lobe can produce anosognosia. This condition involves denial of deficits on the left side of the body; however, it can also involve irritability, crying, and denial of depression, which are all too evident to family and staff. The patient's failure to report depressive experience in anosognosia can also lead to underdiagnosis.[23]

On the other hand, strokes (as well as other neurologic illnesses, such as multiple sclerosis and Parkinson's disease [PD]) can lead to the overdiagnosis of MDD. For example, lesions of the frontal lobe can produce abulia, a syndrome featuring apathy, loss of motivation, and loss of goal-directed behavior. Abulia can lead to the misdiagnosis of depression as the cause for the observed amotivational state.

A few observations can reduce the likelihood of diagnostic error in patients with abulia. Sudden onset is characteristic of abulia related to a cerebrovascular accident, but not of MDD. Abulic, but not depressed, patients may display a wide affective range despite lacking motivation. They are also less apt to be preoccupied with suicide. As is true for patients with aprosodias, careful observation of vegetative symptoms along with knowledge of the patient's history can help in differentiating neurologic conditions from psychiatric ones.

Pathologic crying and pseudobulbar affect can mislead clinicians and patients about the presence of MDD. This type of crying, or sometimes laughing, is spontaneous and incongruent with the thought content. Neurovegetative symptoms of depression are minimal or absent between affective displays. Selective serotonin reuptake inhibitors (SSRIs) are recommended as first-line pharmacotherapy for this disorder. When they fail or are not tolerated, a variety of second-line treatments may be useful (including tricyclic antidepressants [TCAs], noradrenergic reuptake inhibitors, dopaminergic agents, and uncompetitive *N*-methyl-D-aspartate receptor antagonists).[24]

Other brain-related disabilities (e.g., PD, Alzheimer's dementia [AD], and temporal lobe epilepsy [TLE]) also create perplexing problems for the clinician diagnosing and treating depression in the rehabilitative setting. Apathy, masked facies, cognitive slowing, sleep disturbance, and fatigue are features of both PD and MDD, complicating the diagnosis. The symptoms that correlate most significantly with depression in patients with PD, as measured by the Hamilton Depression Scale, are suicidal thoughts and feelings of guilt.[25] The highest correlations using the Montgomery-Asberg Depression Rating Scale were

observed for depression (0.75) and anhedonia (0.74).[26] Moreover, although several studies have shown that, in general, neurovegetative symptoms do not help separate depression from underlying PD, appetite disturbance and early morning awakening do have discriminative power to help diagnose depression.[27]

Further complicating the clinical picture, the pathophysiology of PD overlaps with that of MDD. Reduced catecholamine neurotransmitter release in the midbrain is implicated in both, thus explaining the high incidence of depression in PD patients and raising interesting possibilities for treating both conditions with the same medication.[28] Unfortunately, convincing evidence is lacking that improvement in dyskinetic movements with dopaminergic treatment lessens depression. SSRIs, on the other hand, can lessen depression in this population; unfortunately, they may worsen dyskinesia through the reductions in dopamine release that accompany increased serotonin receptor activity. Conclusive evidence that dyskinesia worsens in patients with PD when SSRIs are used is lacking.[29] In a recent randomized, controlled trial of 52 patients with PD and depression, nortriptyline was found to be more effective than paroxetine controlled-release.[30] Electroconvulsive therapy is effective in both MDD and PD, relieving depression and reducing parkinsonian symptoms for up to several weeks.

AD shares several features with both PD and MDD.[31] All three have depleted brainstem aminergic nerve cell function. This common pathology contributes to the apathy, impaired concentration, and reduced short-term memory seen in all three. The high co-morbidity of MDD in patients with AD and PD is understandable. MDD may be the initial presentation in late-life AD, and it is prominent in the differential diagnosis for reversible dementias.[32] In addition, depression occurring at any time appears to increase the risk for AD.[33]

Several factors distinguish the presentation of late-life depression from the depression associated with AD. Depressed individuals with AD are less apt to experience excessive guilt, disturbed sleep, and feelings of worthlessness; however, they are more apt to describe indecisiveness and an inability to concentrate, which is consistent with cognitive decline. It is noteworthy that there is no change in the frequency of the features of MDD with the severity of AD, except for psychosis, which increases with the severity of AD.

When it is co-morbid with AD, depression is associated with poorer quality of life, greater disability in activities of daily living, a faster cognitive decline, a high rate of nursing home placement, higher mortality, and a higher frequency of depression and burden in caregivers.[34] Therefore, successful treatment of MDD in patients with AD can reduce the risk for all of these outcomes. Antidepressants with significant anticholinergic properties (e.g., TCAs or paroxetine) should not be used, because they undermine the already depleted cholinergic reserves seen in those with AD. In apathetic AD patients, it is reasonable to use antidepressants that increase synaptic catecholamines, such as bupropion and venlafaxine (with a dosage greater than 200 mg/day). For those who are anxious and agitated, an SSRI or mirtazapine is appropriate.[34]

Temporal lobe epilepsy, including complex partial seizures, is the type of seizure disorder most associated with psychiatric findings (roughly 20%); 14% of these patients exhibit psychosis during postictal and interictal states.[35,36] Psychiatric diagnoses associated with TLE should be made while patients have a clear sensorium, not when they are ictal or when they are in a postictal state.

There is psychopathology during interictal periods in people with TLE. The interictal syndrome (also known as Geschwind syndrome) features hypergraphia, seriousness, humorlessness, and an intense interest in philosophic, moral, or religious issues. In addition, afflicted patients are often experienced as viscous by others; that is, they have a tendency to talk at length and circumstantially about a restricted range of topics.[37] Two clinical clues should raise suspicion that TLE, and not primary psychiatric illness, is the driving force behind persistent psychiatric symptoms. The first is the presence of treatment-resistant psychosis. Neuroleptics can reduce the seizure threshold and can thus lead to unintentional worsening of the psychosis related to TLE.[38] The second is incongruity between the severity of the psychotic symptoms and the patient's level of function when psychotic symptoms are quiescent. Making the diagnosis of TLE leads to treatment of the underlying seizure disorder and to the amelioration of the psychosis. Nevertheless, there is a risk for interictal psychosis in these patients, which increases with the frequency of the seizure episodes.

However, TLE is often difficult to diagnose because the behavior associated with ictal periods can be highly complex (and sometimes not readily identifiable as seizure activity), and because the electrical activity of TLE may be deeply imbedded in the limbic system. Deep electric signals are not easily accessible to surface electrodes, and at times not even to sphenoidal electrodes used during sleep.[39] The failure to find those signals can lead to an incorrect diagnosis of conversion disorder or of malingering. Therefore, it is important to include TLE on the differential diagnosis when a case defies easy diagnosis. Ultimately, the diagnosis of seizures and epilepsy, particularly TLE, is based largely on the clinical state and not solely on the electroencephalogram.

Spinal cord injury can also confound psychiatric diagnosis and treatment. Acute high cervical injury can lead to sensory deprivation (because of the sudden loss of sensory input from the neck down, coupled with head restraint by tongs). The apathy and withdrawal under these conditions can be misread as MDD. However, patients with spinal cord injury have an increased risk of developing MDD in rehabilitative settings (about 30%) as well as when they return to the community (about 25%).[40] Treatment of depression should start after the first month of quadriplegia to allow increased sensory input as more stimulation becomes possible and depression-inducing steroids are no longer used to treat spinal cord edema. When symptoms of MDD persist 1 month after the injury, it is reasonable to begin treatment.[41]

Another potential psychiatric issue after spinal cord injury is the persistence of body perception (i.e., being in the same position as one was in at the time of the injury, such as riding on a motorcycle). The patient knows this compelling perception is untrue and may feel as if he or she

is becoming mentally ill. Asking "Do you have any strange sensations?" can unearth this problem and permit a reassuring explanation.

Psychiatric treatment considerations are particularly important for patients receiving rehabilitation because some may cause conditions that may adversely affect a patient's recovery. For example, oculogyric crisis after neuroleptic use for acute cervical injury can be minimized with the use of atypical neuroleptics. Should an injectable neuroleptic be required for severe agitation in the setting of acute cervical injury, IM ziprasidone or olanzapine is preferable to IM haloperidol because of a lower incidence of extrapyramidal symptoms, or one can use IV haloperidol.

Orthostasis is a problem for patients with quadriplegia because of disruption of central nervous system controls (both excitatory and inhibitory) over the paraspinal sympathetic ganglia. This autonomic vulnerability requires that psychotropic medication with potent α-blocking properties (e.g., TCAs and low-potency neuroleptics) be avoided immediately after the injury.

Managing sexual dysfunction is important for a patient's emotional and psychological well-being after a spinal cord injury. Complete spinal cord lesions can cause genital anesthesia, but some patients retain some genital sensation, genital response, and even orgasmic capability (if the lesion is partial). Some men can ejaculate without pharmacologic assistance, but most cannot. Many women and men report the development of new areas of arousal above the level of the lesion, sometimes leading to satisfying "phantom orgasms" with caressing or other tactile stimulation.[42,43]

Men may be able to achieve reflex erections sufficient for intercourse, or they may respond to treatment with prostaglandin E_2 agents (with variable results). Patients treated with sildenafil have improved erection response rates, and a substantial number of individuals with complete lesions, regardless of level or lower motor neuron lesions, also benefit from it.[42,44] Women are similarly affected but can use supplemental lubricants if vaginal lubrication is insufficient and intercourse is desired. Difficulties with positioning, bowel and bladder incontinence, autonomic dysreflexia, and spasticity during sexual activity can be a problem for both women and men. Some patients find that their sexual preferences evolve in a manner that supports their remaining physical capabilities (e.g., increased interest in providing the partner with oral–genital stimulation).[45]

After a spinal cord injury, many patients despair over the loss of present and future sexual intimacy. The treating psychiatrist can assist these patients in developing hope for continued psychological intimacy and sexual activity. Patients (and their sexual partners) find it beneficial to learn that many women and men who experience spinal cord injury–related losses regain active sexual lives. Sex therapists and physicians with expertise in assistive reproductive technologies can be consulted as a part of this process.

Depression, Cardiovascular Disease, and Cardiac Rehabilitation

Over the past 2 decades, research has established a bidirectional link between depression and cardiac disease: patients with depression are more likely to develop cardiac disease, and patients with cardiac disease are more likely to suffer from depression. In fact, MDD is recognized as an independent risk factor in the development of cardiovascular illness[46] (see Chapter 23). We will briefly discuss the interplay between cardiovascular disease and depression in the rehabilitation setting. Depression after a myocardial infarction (MI) has been found to have significant deleterious effects on recovery. A meta-analysis[47] found that depression after an MI was associated with an increased risk of recurrent cardiac events and death. It has been suggested that depression after an MI can be divided into clinical subtypes that are probably not prognostically equal. Compared with patients who have a prior history of MDD, patients with incident (new) depression after an MI experience a heightened risk of recurrent cardiac events and mortality during the subsequent 5-year period.[48]

Addressing depression after an MI is important in the rehabilitation setting. Some evidence suggests that patient participation in cardiac rehabilitation programs greatly improves the depressive symptoms. For example, Milani and colleagues[49] studied the effect of cardiac rehabilitation and exercise training on depression after a major cardiac event. They studied 338 consecutive patients who had experienced a major cardiac event 4 to 6 weeks previously and who were participating in cardiac rehabilitation (36 sessions over a 3-month period). Depression was prevalent in 20% of these patients. The researchers found that the symptoms of two thirds of the patients who were initially depressed resolved by study completion.[49] In a similar study, Milani and Lavie[50] evaluated the impact of cardiac rehabilitation on depression and its associated mortality in coronary patients. They followed 522 consecutive coronary patients in cardiac rehabilitation and compared them with a control group of 179 patients not completing rehabilitation. Depressive symptoms decreased 63% after rehabilitation, and depressed patients who completed rehabilitation had a 73% lower mortality rate than controls. This reduction in mortality was related to improvements in fitness, but only mild improvements in fitness level were required to produce these effects. Every effort should be made to enroll post-MI patients in cardiac rehabilitation programs.

However, for patients whose depression remains despite cardiac rehabilitation and for those who are unable or unwilling to attend such programs, medical treatment for depression may be indicated during the post-MI period. In large, randomized trials, sertraline, citalopram, and mirtazapine have been shown to be safe and effective for treating depression in cardiac patients. The other SSRIs may also be safe, but they have not been studied as extensively.[51–53] Thus far, there is no convincing evidence for using manualized psychotherapy techniques (e.g., cognitive-behavioral or interpersonal therapy) in cardiac patients (see Chapter 23).

DIAGNOSTIC DILEMMAS

Psychiatrists are sometimes asked to assess physically disabled patients when there is no established diagnosis for their pathophysiology. The question asked is, "Does this patient have conversion disorder?" As many as 50% of those diagnosed as having conversion disorder subsequently develop a medical diagnosis consistent with a disability. Often, multiple sclerosis is involved.[54,55] A more

recent study, possibly reflecting improved diagnostic techniques, has shown that only 4.3% of those with conversion disorder developed a subsequent medical illness that could have explained the prior findings.[56] The same study, however, revealed substantial psychiatric co-morbidity in this population, with 50% meeting the *International Statistical Classification of Diseases and Related Health Problems*, revision 10 (ICD-10) criteria for mental illness, especially personality disorder.

Although undetected medical illnesses in patients with conversion disorder now appear to be common, paraneoplastic disorders are an infrequent, but important, exception. Paraneoplastic neurologic disorders are characterized by the presence of neurologic dysfunction in the setting of a remote cancer, most commonly small cell lung cancer or gynecologic tumors.[57] Paresthesias and memory loss are two findings that can appear without a supporting medical diagnosis until it is discovered as a *forme fruste* of cancer.[58] These symptoms appear to be mediated by the immunologic response to the tumor that attacks neural tissue.[59] Thus, an oncologic evaluation and work-up for otherwise unexplained memory loss or paresthesia is warranted.

Conversion disorders can produce medical complications. For example, conversion-based lower extremity paralysis can lead to Achilles tendon contracture, decubitus ulcers, and pulmonary emboli. Psychiatric consultation for these patients should draw attention to the prevention of such complications. In addition, aggressive treatment of co-morbid psychiatric conditions (including depression and psychosis) can reduce emotional suffering. However, addressing psychiatric co-morbidity does not usually ameliorate the conversion-based physical findings.

Nonpsychiatric medical disabilities influence psychiatric diagnosis and treatment in ways that are specific for each condition. Although assessment currently relies as much on art as on science, psychiatric diagnosis and treatment can enhance quality of life among persons suffering from disabling conditions.

DIAGNOSIS AND TREATMENT

Psychiatric treatment in the context of rehabilitative medicine or chronic illness sometimes bears little resemblance to routine psychiatric care. Patients from these groups may be engaged in so many activities during the day that it is impossible to sit with them for long. They may require intensive physical and occupational therapy, time-consuming diagnostic studies, and longer and more frequent rest periods. In addition, visits from family and loved ones tend to take precedence over the treatments and interviews needed to treat their psychiatric conditions.

Psychiatrists unfamiliar with this milieu may become frustrated by their inability to capture enough quality time with a patient. However, this challenging group provides an opportunity for development of broader clinical skills and effective assessment, and treatment can take place over time. The initial step for a successful psychiatric consultation in a rehabilitation hospital is for the consultant to clarify the question embedded in the request for consultation. In addition, the psychiatrist should assess the personality and coping styles of the patient who faces the challenges of chronic medical illness. Often, it is maladaptive coping that delays or prevents improvement in the patient's condition. Supporting adaptive strategies is important in the psychiatric care of these patients. Table 29–2 presents domains that should be explored *before* a consultation is begun. Table 29–3 provides questions to be answered for all patients with chronic illness in a rehabilitation facility, and Table 29–4 offers more specific questions.

In the rehabilitative setting, psychiatrists have access to the same treatment modalities as in other settings (e.g., pharmacology, psychotherapy, somatic treatments). However, the way these treatments are delivered to these patients is often unique. Treatment guidelines for specific psychiatric diagnoses are covered elsewhere in this text.

The psychotherapeutic modality chosen should be appropriate to the particular patient,[2] many of whom have not experienced psychotherapy and may doubt its efficacy. Furthermore, most patients in rehabilitative settings are struggling with some basic physical and psychological problems (e.g., learning to walk with a prosthesis, adjusting to the need for continuous oxygen, adapting to loss of cognitive function). A psychotherapeutic approach that focuses on the chief complaint and on supporting enhancement of resilience is often most effective. The psychiatrist should expect to take an active role in the psychotherapy of these individuals (e.g., giving advice and guidance where appropriate). It may also be useful to include limbic probes. For instance, commenting on a patient's affect by saying, "You seem so down today. Are you feeling blue?" may give a patient who is emotionally guarded the opportunity to express emotions that are difficult to bear. Likewise, a nonoffensive joke or silly gesture may slide past cortical sentinels to the limbic system, evoking an expansive smile or a hearty laugh in someone who is despondent but who wants to feel better.

TABLE 29–2 Questions To Be Addressed Before Consultation

Who is requesting the consultation?
What is the problem? (or what are the problems?)
This is best determined through personal contact with the physician requesting the consultation, rather than from information obtained by secretaries or others.
Who will implement the recommendations?
Many recommendations are never implemented because of miscommunication between the consultant and the person requesting the consultation.
Orders should be written by the patient's attending physician (or designated house officer), except when waiting would significantly compromise patient care.
Does the patient know that a consultation has been requested?
If not, why not?
Is there a concern about capacity or competence?
If there is no concern about competence or capacity, the patient should be informed of the request for consultation and should consent to its performance.
When is the best time to see the patient?
Can time be reserved for an interview?
If not, what are potentially available times?
Can family/friends and important others (e.g., RN, LPN, and MD) be available if necessary?

TABLE 29–3 Questions for All Patients Receiving Rehabilitation or with Chronic Illness

Has the patient ever been under the care of the psychiatrist or received psychiatric treatment?
Does he or she take medications for a psychiatric condition?
Has he or she ever been suicidal or made a suicidal "gesture"?
Is there any history of violence or a threat of violence?
Has he or she ever received inpatient or outpatient treatment for substance abuse or dependence?
Has he or she ever been in trouble with the law?
  Any jail or prison time?
Has he or she ever received rehabilitative treatment before?
What was the outcome?
  Were they cooperative, disruptive, threatening, or violent?
Is there any history of delirium?
Is there any history of head trauma or brain injury?
Are there current concerns regarding intellectual or cognitive function?
  Has there been a change from baseline?
What are the patient's main social supports?
  Are they reliable, that is, providing consistent emotional support and logistical help?
  Have they been consistently helpful in the past?
Has the patient had contact with anyone who has a similar illness or injury?
  Is that person reasonably emotionally intact and functioning well?
Before the need for rehabilitation, how well did the patient function:
  In school?
  At work?
  With their partner or spouse and family?
  In the military?
  In new situations?

Adapted from Rabinowitz T, Stern TA: The patient requiring rehabilitation. In Stern TA, Herman JB, Slavin PL, editors: *The MGH guide to primary care psychiatry,* ed 2, New York, 2004, McGraw-Hill.

TABLE 29–4 Focused Questions for All Patients in Rehabilitation or Chronic Illness Settings

What is the meaning of the illness or injury to the patient?
Is the condition hereditary?
  Are there affected relatives?
  If yes, how are they doing?
  If the condition is hereditary, are there markers that can be searched for in others?
  How does the patient feel about such searches?
How has the condition or situation affected his or her self-esteem?
  Do not ask *if* self-esteem has been affected—this will give the patient the opportunity to say No and avoid further discussion of the topic.
How have relationships with friends and family been affected?
How is he or she adjusting to change or loss of function in the following areas:
  Academic
  Athletic
  Creative
  Intellectual
  Occupational
  Sexual
  Other
Is he or she taking medication for psychiatric symptoms, such as anxiety, fear, or depression?
  Is it helping?
  Are there side effects?
  What are they?

Adapted from Rabinowitz T, Stern TA: The patient requiring rehabilitation. In Stern TA, Herman JB, Slavin PL, editors: *The MGH guide to primary care psychiatry,* ed 2, New York, 2004, McGraw-Hill.

Intensive Care Unit Patients

John Querques, M.D.
Theodore A. Stern, M.D.

Including a chapter on the psychiatric care of patients in an intensive care unit (ICU) runs the risk of suggesting that the evaluation of patients is somehow different depending on their location in the general hospital and that provision of their psychiatric care likewise differs because of that locale. Such a risk evokes the unfortunate appellation "ICU psychosis," with its erroneous suggestion that a psychotic condition could be induced by a patient's mere residence in an ICU and the absurd conclusion that transfer out of that environment is curative. We maintain that patients and their needs transcend geography; however, we also recognize that the critical nature of illnesses treated in ICUs creates a unique environment for patients, staff, and consultation psychiatrists alike. In this chapter, the serial presentation of a typical ICU psychiatric consultation highlights the distinguishing characteristics of this distinctive setting, the common reasons for consultation requests in the ICU, and the clinical approach to consultative practice in the ICU.

THE INTENSIVE CARE UNIT SETTING

The chief difference between the ICU and other hospital units is the severity of the morbidity treated there. Patients are admitted to ICUs when they require life support for organ system failure, close monitoring or treatment for potentially life-threatening complications, or careful observation and treatment that cannot be safely provided elsewhere in the hospital.[1,2] Some of the conditions commonly treated in the ICU include stroke, myocardial infarction (MI), arrhythmias, severe pneumonia, sepsis, multisystem organ failure, trauma, and burns.

Commensurate with this degree of morbidity, the intensity of the treatment arrayed against these life-imperiling conditions contributes significantly to the ICU ambiance. The numerous lines—wires, catheters, and tubes—wending their way to and from critically ill patients attest to the high-technology care rendered in the modern ICU. Patients routinely require mechanical ventilation, which entails endotracheal intubation and sedation and sometimes pharmacologic paralysis; use of vasopressors, cardiac monitors, pacemakers, parenteral nutrition, and several intravenous (IV) antibiotics is common. In more severe situations, renal replacement therapies, intraaortic balloon pumps, left ventricular assist devices, and heart–lung machines become necessary. In the center of, and almost eclipsed by, this mechanical mélange lies the patient, usually sedated and still, seemingly lifeless.

The flashing lights, sounding alarms, and constant whirrings of machines in action create an almost surreal, dehumanized atmosphere that is difficult for patients, families, and staff to tolerate. It seems odd that human lives hang in the balance in such a mechanized setting, the nature and purpose of which has been indicted for engendering delirium, anxiety, and depression in patients; tension and stress that can progress to fatigue and burnout in ICU staff; and feelings of hopelessness, helplessness, frustration, despair, and anger in family members, as well as patients and staff. The acuity of illness and potential for rapid changes in clinical status create a tremendous pressure for the staff to stay ahead of the curve and a powerful stimulus for families to remain on high alert. When a patient succumbs to an illness that ultimately proves a foe mightier than the awesome therapeutic forces arrayed against it, the staff confronts death and their own personal feelings of weakness, imperfection, insecurity, and impotence that may be stimulated by the loss of a patient. Amid their own struggles, they must somehow comfort bereaved family and friends.

THE PSYCHIATRIST IN THE INTENSIVE CARE UNIT

The psychiatrist called to assess a patient in the ICU approaches the task with all of the preceding in mind. The consultant must brace himself or herself for the experience of intense pressure that surrounds the care of critically ill patients, lest he or she be disarmed by it. The consultant is aware of the strain borne by the physicians and nurses who toil in this environment daily and respects that they might be preoccupied or busy with a clinical matter more pressing than the consultant's own. In dealing with families, the consultant is cognizant that their extreme apprehension might color their account of the patient's history and their appraisal of the current situation. Family members may be unimpressed by the need for a psychiatrist when their loved one is seen as barely clinging to life; they may think of such a consultation as superfluous and they might even be insulted, annoyed, or angered by what feels like an intrusion. Even staff might not be immune to this reaction to the psychiatrist, feeling that the brain—let alone the psyche—is less important than the "real" problem.

The consulting psychiatrist anticipates the likely moribund state of acutely ill patients, their consequent inability to participate in the usual psychiatric examination, and the need to modify the examination accordingly. Even more than usual, the history from the patient may be vague and spotty, if not entirely nonexistent. The consultant appreciates that the rapidity of clinical change in patients in the

ICU necessitates frequent (probably daily, if not twice-daily) visits; careful review of clinical developments as discussed with the team, culled from the chart, and gleaned from laboratory results; and a degree of accessibility greater than that required on general medical–surgical floors.

In the account of a psychiatric consultation in the ICU that follows, we highlight each of these characteristics of the ICU setting and review three common reasons for psychiatric consultation requests in the ICU: depression, altered mental status, and decision-making capacity. The fictitious, but typical, case also demonstrates that the consultee's question often shifts as the patient's clinical status changes and that a single consultation in the ICU often is actually several consultations in one. The case is presented in segments, much as a real case typically unfolds.

CASE 1

Mr. A, a 70-year-old man with a history of diabetes mellitus, hypertension, a stroke, and an MI was admitted to the ICU with severe pneumonia. He was febrile, tachypneic, and hypotensive, and the team was concerned about the possibility of sepsis. IV antibiotics were started, and by the next morning, the chest film and Mr. A's clinical status had improved, although blood cultures were still pending and the possibility of sepsis still loomed.

Because Mr. A looked depressed, a psychiatrist was called to evaluate depression. When the psychiatrist arrived at the bedside, Mr. A was diaphoretic and taking 30 breaths per minute. In place were two IV catheters, a cardiac monitor, and a Foley catheter. Because his breathing was so labored, Mr. A initiated no speech and he kept his answers short; they were almost inaudible. At times, he appeared to drift off even though he remained awake, and the psychiatrist had to regain Mr. A's attention periodically. Though he was not feeling particularly "joyous," as he said with as much of a laugh as his shallow breath allowed, he denied feeling depressed, sad, or "down in the dumps." Given Mr. A's discomfort, the psychiatrist terminated the interview early; his family was too overwhelmed to talk to the psychiatrist.

The psychiatrist's impression was that Mr. A was delirious due to infection and hypotension. He also suspected an underlying dementia but could not be sure given the paucity of information in the history. In the face of Mr. A's denial of depressed mood, a demonstrable (albeit small) affective display, and inattention, a diagnosis of major depression could not be made. Because the delirium was mild and was not associated with agitation, the psychiatrist recommended checking and monitoring "the usual suspects" but not instituting a psychopharmacologic intervention. Some clinicians would have opted to suggest treatment with a dopamine-blocking agent even in the absence of agitation.[3–5]

Consultation requests to "rule out depression" are common in the ICU. One reason for this is the notion held by some physicians and nurses that a patient in extreme clinical circumstances *must* be depressed. In this belief, such clinicians consider psychiatric diagnosis to be merely a matter of intuitive common sense rather than of expert clinical judgment.[6] One expects a patient with a serious illness to have certain feelings about his or her plight (e.g., sadness, worry, anxiety, dread, or anger). However, intuition alone is insufficient to make a diagnosis; careful clinical assessment is required. In this case, the observation that Mr. A looked depressed tipped the scale and prompted the consultation request for a more comprehensive examination and for an expert opinion.

Another reason consultations to assess depression are common in the ICU is mistaking *biography* for *history*,[6] as may have occurred if Mr. A had been asked if he was depressed and he answered affirmatively. The syndrome of depression is not just feeling depressed, sad, or blue, however, but rather is a constellation of specific affective, behavioral, and cognitive symptoms and signs. *It is only after a patient's current affective state is embedded in the context of an historical perspective that a diagnosis of major depression can be made*. Under extreme pressure of time and stress, ICU teams often defer to a psychiatrist to elicit the requisite history and to rule depression in or out.

Mr. A's clinical state precluded a thorough elicitation of historical evidence for depression; it highlighted the need for flexibility in modifying the usual clinical examination according to the patient's needs. Faced with a paucity of historical detail, the consultant placed a high premium on the mental status examination; most importantly, he noted inattention, which a diagnosis of depression does not readily explain. Some might argue that the consultant should not have ruled out depression because he did not collect the data required by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[7] and depression might underlie the delirium. Others, as do we, contend that a diagnosis of depression in the face of delirium is difficult if not impossible to make and that even if it were feasible, the presence of delirium trumps it. If depression is still suspected after the sensorium clears, the consultant can reinterview the patient and also elicit history from family and friends.

The consultant noted the possibility of dementia underlying the delirium. This suspicion was based on a knowledge of Mr. A's history of diabetes and hypertension (both of which can cause microvascular changes in the cerebral circulation), as well as prior stroke and MI (evidence of disease in two separate vascular territories) and knowledge that a "bad brain" or an "insulted brain" (a brain affected by age, trauma, structural lesions, extensive substance use, human immunodeficiency virus, or dementia) predisposes to delirium. Given the discomfort of Mr. A and the emotional state of the family at this point, the consultant did not yet have enough data to make this diagnosis definitively. It must await a change in the clinical circumstances.

A discussion of the "usual suspects" invoked by the consultant and the decision to forego pharmacologic treatment is beyond the scope of this chapter; the interested reader is referred to Chapters 10 and 11.

CASE 1, *continued*

When the consultant returned the following morning, he found that Mr. A had become agitated overnight and had removed both of his IV catheters, thus missing a scheduled dose of antibiotics. Whereas the day before the consultant believed that Mr. A had a quiet delirium, today he believed that the delirium was an agitated one. After ensuring that serum potassium, calcium, magnesium, and albumin levels, as well as the QT interval corrected for heart rate, were normal, he recommended haloperidol 1 mg orally twice daily.

This turn of events highlights the importance of frequent visits to the patient in the ICU. Given the development of agitation, the diagnosis shifted slightly from a quiet to an agitated delirium, which warranted a change in management (i.e., empirical treatment of the agitation with an antipsychotic). Moreover, the agitation in this case had already jeopardized Mr. A's treatment and would very likely continue to do so if not treated. While the team addressed the underlying causes of the delirium (infection and hypotension), empirical treatment with an antipsychotic was essential to quell the agitation.

Low serum levels of potassium, calcium, and magnesium and the administration of certain medications (including haloperidol and atypical antipsychotics) can prolong the QT interval, which itself heightens the risk of torsades de pointes, a potentially fatal polymorphic ventricular tachyarrhythmia. The QT interval varies with heart rate, age, gender, time of day, and a host of other factors. The proper measurement of the QT interval; the most accurate method for its correction for heart rate; and the relationship among QT prolongation, torsades de pointes, and antipsychotics are the subjects of considerable uncertainty and disagreement, even among experts. Several reviews of this complicated topic are available.[8–15] In short, the administration of haloperidol (or another neuroleptic medication) to an agitated or delirious patient often allows necessary medical treatment to proceed uneventfully. This benefit generally outweighs the risk of a cardiac dysrhythmia.

CASE 1, *continued*

When the psychiatrist returned later that day, Mr. A's respiratory status had worsened and the team was concerned about needing to intubate him. They had solicited his informed consent, but he had refused to give it. Given his altered mental status, they asked the consultant if Mr. A was competent to refuse intubation and mechanical ventilation.

Again illustrated is the propensity for clinical change in ICU patients, the consequent importance of frequent visits, and the broadening of the consultation question. In this way, the psychiatrist often becomes an integral member of the extended team, much as an infectious-disease or endocrine consultant would in this case.

The team mistook *competency* for *capacity*, the former being a legal notion that can be determined only by a judge. *Capacity*, on the other hand, is a clinical term that refers to a patient's mental capability to understand his or her situation (e.g., the illness, the recommended treatment, alternative treatments, and the risks and benefits of those interventions) and to accept or to refuse a treatment recommendation consistent with his or her own personal ideals and values.[16] Whereas any physician, regardless of training, is able to assess a patient's capacity (and, in fact, does so routinely any time he or she does even simple procedures like phlebotomy and IV insertion on a patient), given their special training in examination of affect, behavior, and thinking, psychiatrists are often called on to render these opinions.

These consultations often arise only when a patient *refuses* a recommended course of therapy. Paternalistic physicians tend to think that the patient's thinking process *must* be impaired if he or she disagrees with the treatment plan; if the patient accepts, his or her capacity is presumed intact. However, this common occurrence belies a fundamental misconception about decision-making capacity; that is, it hinges not on *what* the patient decides but on *how* the patient decides it. Whether the patient opts for the course of treatment recommended by the physician, or the therapy that the doctor would choose for himself or herself if the doctor were in the patient's shoes, is irrelevant. Rather, the patient must make a stable choice based on a full understanding of the facts and an appreciation of those facts as they pertain to him or her specifically, and that is consistent with his or her own goals and values.[16]

A layperson's understanding of the medical facts is sufficient. In this case, the consultant wants to assure himself that Mr. A knows and understands the following:

- He might stop breathing because of the pneumonia, an infection of the lungs.
- Should this happen, a machine can breathe for him by means of a tube inserted into his windpipe; without the tube and the machine, he will die.
- Generally, as pneumonia resolves, patients who require a breathing machine eventually resume breathing on their own.
- The risks of the tube include intubation of the food pipe, bleeding, infection, and hoarseness when the tube is removed.
- No alternative treatments exist.

In addition, the consultant must be sure that Mr. A appreciates what these facts mean for him specifically. The following are examples:

- His previous MI renders his heart more vulnerable to the stress of labored breathing and inadequate oxygenation.
- Although small, the risk of infection from the endotracheal tube is greater because he has diabetes.
- Although diabetes compromises his ability to fight the pneumonia, Mr. A does not have a terminal illness and his doctors expect him to recover, even if he requires mechanical ventilation.

Finally, the consultant looks for evidence that Mr. A's choice coincides with his values and goals. For example, if Mr. A repeatedly indicated that he wanted to live while steadfastly rejecting intubation (without which, as he has been told, he would most assuredly die if he stopped breathing on his own), the consultant would rightly detect an inconsistency between the patient's decision and his desire to live.

Because capacity is not global, a patient may have capacity to make some decisions but not others. The reason for this discrepancy lies in the risk-to-benefit ratio of the proposed diagnostic or therapeutic intervention.[17] When the benefit of a treatment far outweighs its risk, the standard for capacity to accept is low, but the standard for capacity to refuse is quite high. In Mr. A's case, the relatively small risk of bleeding, infection, and so on, compared with the overwhelming benefit of mechanical ventilation sets a high standard for capacity to refuse this treatment.

CASE 1, *continued*

The psychiatrist offered his opinion that Mr. A did not have the capacity to refuse intubation and mechanical ventilation. When his respirations became even more labored, he was sedated and intubated; mechanical ventilation commenced. He then could not speak and he had no enteral route. The consultant recommended administration of IV haloperidol.

Psychiatric examination and treatment of Mr. A became exceedingly difficult, but not impossible. The psychiatric consultant in the ICU must be creative, resourceful, and ready to accommodate to the changing clinical status of the patient. Lack of an oral route is easily circumvented, because medications can be crushed and delivered through a nasogastric tube or delivered parenterally. Although haloperidol is not approved by the Food and Drug Administration for IV use, widespread experience with this agent attests to its safe and effective use by this method in delirious, medically ill patients, with the same caveats that apply to oral use.

Intubated patients can communicate in several ways: by writing; by mouthing answers; by pointing to letters on a letter board; or by responding to yes–no questions with head nods, eye blinks, or squeezes of the examiner's hand. Requiring practice for both the patient and the physician, these maneuvers can be quite time-consuming and frustrating, especially when the patient is sedated (which is the rule in intubated patients).

A psychiatric consultant can feel stymied by an obtunded patient's inability to engage in a verbal dialogue. However, a host of physical findings can be made by simple observation (e.g., diaphoresis, dry skin, flushing, mydriasis, miosis, tremor, myoclonus, and facial asymmetry). Muscle tone, reflexes (primitive and deep tendon), and pupillary reaction to light are also assessable in a somnolent patient, as are the vital signs. Scoring of verbal, motor, and eye-opening responses according to the Glasgow Coma Scale[18] rounds out the examination of the lethargic patient.

CASE 1, *continued*

Over the next several days, the pneumonia and the delirium steadily improved. Mr. A was successfully extubated, and haloperidol was discontinued. Now able to speak in full sentences, albeit hoarsely, he provided the consultant with additional history. This information, added to collateral data obtained from the family, allowed the consultant to confirm his preliminary impression of the absence of major depression but the presence of an underlying dementia.

CONCLUSION

The successful denouement of this case showcases again the critical importance of flexibility, responsiveness, and resolve on the part of the ICU psychiatric consultant. First a competent physician, the psychiatric consultant must accept responsibility for the patient's care, see it through from initiation of the consultation to its end, and approach the patient and the family fully aware that the arc of each consultation is unique and unpredictable. Patients' beclouded sensoria and family members' taxed emotional states yield information in piecemeal fashion; history emerges only when the bits and pieces are stitched together. Attention to linguistic nuance and limbic music take a backseat to keenness of observation and physical and neurologic examinations. No place for premature diagnostic closure, the ICU adheres to an unfixed timetable and the clinical state of affairs largely resembles a moving target. In the ICU, one minute's certainty becomes the next minute's wild speculation, and the consultation psychiatrist assigned there must always be in "Condition Red."

31 Genetics and Psychiatry

Daniel H. Ebert, M.D., Ph.D.
Christine T. Finn, M.D.
Joan M. Stoler, M.D.
Jordan W. Smoller, M.D., Sc.D.

Genetics strongly influences the incidence, clinical course, and treatment of psychiatric disorders. An assessment of the role of genetics in a patient who presents with psychiatric signs and symptoms in the general hospital setting enriches the formulation of a case. Unfortunately, the genetic basis of psychiatric disorders, and the role of genes in modifying treatment outcomes, is still largely unknown. Genes are beginning to be rigorously linked to neuropsychiatric disorders, allowing for opportunities to improve our understanding of the mechanism of disease for these disorders and to develop treatments specifically targeted to these mechanisms. We anticipate that over the next decade genetics will be increasingly important in the diagnosis and treatment of patients with psychiatric issues in the general hospital setting. For instance, psychiatric treatments may be tailored to specific genetic contexts.

In addition to primary psychiatric disorders, many genetic syndromes and metabolic diseases have psychiatric symptoms as part of their observed presentation. In fact, behavioral manifestations may be as important as other clinical features for the identification of underlying genetic illnesses. Whereas some patients may meet full *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) criteria for psychiatric disorders, others may have more general symptoms (e.g., hyperactivity, anxiety, aggression, cognitive deficits).

This chapter provides a brief overview of the genetics of major psychiatric disorders and a subset of genetic syndromes and inborn errors of metabolism that the general psychiatrist may encounter in the hospital or clinic setting. This chapter emphasizes several characteristics about the genetics of major psychiatric disorders. First, psychiatric disorders have a substantial genetic component. Second, the environment plays a substantial role in the expression of these disorders, and there are significant interactions between the genetic background and the environment that lead to disease expression. Finally, this chapter highlights several current approaches used to identify the genetic basis of psychiatric disorders and offers recent insights about psychiatric genetics derived from these approaches.

Although the genetic syndromes with psychiatric features presented in this chapter are relatively rare, knowing when to suspect that a genetic or metabolic issue may be contributing to the presenting condition of a patient is important in formulating a differential diagnosis. Proper identification of genetic and metabolic illness may allow for new opportunities for treatment or intervention directed at the primary process (e.g., correction of hyperammonemia in urea cycle disorders) rather than management of its downstream effects (e.g., delirium). For the most part, the disorders reviewed here may present in late childhood to adulthood; this chapter specifically excludes those disorders that are lethal in infancy or early childhood. Although it is not considered the role of the psychiatrist to diagnose specific genetic and metabolic illnesses, knowledge of these disorders aids clinical decision-making for all specialties. When an underlying genetic syndrome or metabolic disease is suspected, a consultation by a geneticist may greatly benefit the patient and help direct clinical management.

GENETICS OF PSYCHIATRIC DISORDERS

Epidemiology of Psychiatric Disorders

Epidemiologic studies have demonstrated that psychiatric disorders have a significant genetic basis. Twin, family, and adoption studies can assess the magnitude of genetic and environmental factors that lead to a phenotype.[1] Comparing concordance rates in monozygotic and dizygotic twins for various phenotypes can provide an estimation of the heritability of a disorder. A twin pair is concordant if both co-twins have the same phenotype or disorder. *Heritability* refers to the proportion of the phenotypic differences among individuals in a population that can be attributed to genetic factors. Heritability can be estimated by a formula comparing the co-twin phenotypic correlation for monozygotic twins and dizygotic twins. A disorder with a significant genetic etiology would be expected to be more concordant in monozygotic twins, who are genetically identical, than in dizygotic twins, who share, on average, 50% of their alleles. Heritability estimates the magnitude of genetic influences in a population and not in a particular individual. In addition, *heritability* refers to the additive sum of all the genetic influences on a trait in the population. Heritability does not provide information about the number of genes that are involved or the effect size of a given gene. For example, the heritability of breast cancer has been estimated at 27%, yet dominantly inherited single major genes, such as *BRCA1*, have been identified.[2]

Family studies usually measure the lifetime prevalence of a disorder among first-degree relatives of the index case. Adoption studies can help further disentangle genetic and environmental influences by comparing rates of a disorder in biological family members with those in adoptive

family members. In addition, comparing rates of a disorder in twins that were raised in the same household with twins reared in separate households and environments can provide further evidence about the genetic and environmental influences that lead to expression of the disorder.

Many epidemiologic studies have demonstrated that schizophrenia has a substantial genetic component. The concordance rate for monozygotic twins is approximately 50%, and for dizygotic twins it is 15%. The heritability of schizophrenia has been estimated at 70% to 89%. Family studies have shown that first-degree relatives of patients with schizophrenia have approximately a 10% risk of developing schizophrenia, compared with the population lifetime risk of approximately 1%. The risk drops to 4% for second-degree relatives and to 2% for third-degree relatives. Adoption studies have demonstrated that the prevalence of schizophrenia is approximately fourfold higher in biological relatives than in adoptive relatives.[3,4]

Bipolar disorder is also highly genetic. Concordance rates in monozygotic twins are approximately 40% to 45%, and in dizygotic twins the rate is 5%. The heritability of bipolar disorder has been estimated to be between 60% to 85%. Twin studies also suggest that genetic influences on bipolar disorder overlap with those contributing to major depressive disorder (MDD), schizophrenia, and schizoaffective disorder. From a host of family studies, the risk of bipolar disorder in first-degree relatives of patients with bipolar disorder is approximately tenfold higher than those in the general population. In addition, first-degree relatives have a twofold to threefold increased risk of developing MDD.[5]

MDD also has a significant genetic etiology, though less so than bipolar disorder and schizophrenia. Concordance rates between monozygotic twins range from 23% to 49% and for dizygotic twins between 16% and 42%. Heritability is estimated at 40%.[6] The largest twin study was of 15,000 Swedish twin pairs, and the heritability of MDD was estimated at 42% for women and 29% for men.[7] A meta-analysis of family studies found that the prevalence of MDD was threefold higher in relatives of patients with MDD than in relatives of unaffected controls.[6] Several clinical features—early onset, recurrent episodes, chronicity, suicidality, and greater levels of impairment—have been associated with increased familial risk.[8]

Anxiety disorders also are influenced by genetics. Concordance rates of panic disorder in monozygotic twins are approximately 24%, and in dizygotic twins they are 11%. The estimated heritability of panic disorder is 45%. First-degree relatives have an approximately fivefold increased risk of panic disorder compared with those in the general population.[9,10] Early-onset panic disorder confers an increased risk of the disorder for relatives.[11] Twin and family studies also suggest that the genes influencing panic disorder overlap with those influencing generalized anxiety disorder, phobic disorder, posttraumatic stress disorder, and depression. Heritability for phobic disorders has been estimated to range between 10% and 39%. First-degree relatives have a fourfold increased risk of phobic disorders compared with those in the general population.[9,10]

Substance use disorders, including those involving alcohol and drugs, have been shown to have a significant genetic component. For example, the heritability of alcohol dependence, a disorder commonly seen in the general hospital setting, has been estimated to be 35% to 60%.[12–14] Family studies demonstrate that first-degree relatives of individuals with alcohol dependence have a twofold to fourfold higher risk of developing alcohol dependence than those in the general population.[15] Adoption studies have indicated that there is an increased risk of alcohol dependence in adopted individuals who have a biological parent with alcohol dependence.[16]

Several disorders of childhood and adolescence have been demonstrated to have substantial genetic etiologies. For attention-deficit/hyperactivity disorder (ADHD), a bevy of twin studies have demonstrated a higher concordance rate in monozygotic twins than in dizygotic twins. The estimated heritability of ADHD is 75%. Family studies indicate that first-degree relatives of individuals with ADHD have a twofold to eightfold higher risk of developing ADHD than the relatives of controls.[17]

Autism is highly genetic. Concordance rates for monozygotic twins, 70% to 90%, are markedly higher than those for dizygotic twins (5% to 10%). The heritability of autism has been estimated to exceed 90%. The risk of autism in siblings of affected children is approximately 2% to 7%, which is 50 to 100 times higher than the prevalence in the general population. For first-degree relatives of individuals with autism, the risk for a broader autism phenotype, including autism spectrum disorders and milder abnormalities of social and language function, may be as high as 10% to 45%.[18–20]

These epidemiologic studies demonstrate that genetics substantially influences the expression of many psychiatric disorders (including psychotic, mood, anxiety, and substance use disorders; ADHD; and autism). Schizophrenia, bipolar disorder, ADHD, and autism have a particularly significant genetic basis. In addition, these epidemiologic studies suggest that the environment also contributes substantially to the expression of these psychiatric disorders, more so for MDD than for schizophrenia or autism. Environmental factors that contribute to the expression of these disorders include early life events, stressful life events, difficult family environments, lack of social supports, exposure to toxins and infectious agents, and a dysregulated immune system.[1]

Gene-by-Environment Interactions

Interestingly, genes and the environment can interact in individuals and contribute to expression of disorders. This gene-by-environment interaction was demonstrated in an often-quoted 2003 study of the interaction of the serotonin transporter gene and stressful life events in the onset of episodes of MDD.[21] The serotonin transporter is the target of selective serotonin reuptake inhibitor (SSRI) antidepressants. There is a common polymorphism in the promoter of the serotonin transporter gene that leads to a "long" allele or a "short" allele lacking a 44 base-pair sequence. The short allele is associated with a reduced expression of the serotonin transporter. The 2003 study by Caspi and colleagues examined a birth cohort of 1037 children followed to age 26 years for evidence of a linkage between the short or long allele of the serotonin transporter gene, stressful life events, and MDD.[21] Stressful life events included employment, financial, housing, health, and relationship problems. In the absence of stressful life events, the presence of either the short or long allele of the serotonin transporter gene was not associated with major depressive episodes or depressive symptoms

in these individuals. However, with an increasing number of stressful life events, individuals with the short allele of the serotonin transporter gene, compared with those with the long allele, have an increasingly greater number of major depressive episodes, depression symptoms, suicidal thoughts, and suicide attempts. The percentage of individuals with the short allele that had signs and symptoms of MDD increased as the number of stressful life events increased. In addition, individuals with the short allele had an increased probability of adult major depressive episodes with increasing childhood maltreatment, whereas individuals with the long allele did not have more adult depression with childhood maltreatment. In both of these examples, individuals heterozygous for the short and long alleles had an intermediate phenotype compared with individuals homozygous for the short or long allele.[21] These experiments show how an environmental factor, stressful life events, and childhood maltreatment interact with the genetic background of an individual, in this case a functional polymorphism in the serotonin transporter gene, to lead to psychiatric symptoms and disorders, MDD in this example. For a subset of patients in the general hospital, psychiatric signs and symptoms may be due to an interaction between genes and environmental factors, and such an interaction can be considered in the formulation of the case and creation of a treatment plan.

Identification of Genes and Genomic Regions Linked to Psychiatric Disorders

A major current undertaking in psychiatric neurosciences is to identify genes and genomic regions that influence the expression of psychiatric disorders. Identifying genes that lead to psychiatric disorders will provide opportunities to further understand the mechanism of disease and to develop new treatments. Like diabetes and many other medical disorders, the genetics of psychiatric disorders is complex. For many individuals with psychiatric disorders, a leading hypothesis is that many risk genes of small effect size interact with one another, and at times with environmental factors, to lead to the disease phenotype. However, there are examples of individual dominant genes that lead to a psychiatric disorder. For instance, more than 95% of Rett syndrome cases, an autism spectrum disorder discussed in the following section, are caused by mutations in *methyl-CpG-binding protein 2 (MeCP2).* Mouse models with alterations in expression of *MeCP2* led to autism-like phenotypes, providing further evidence that *MeCP2* dysfunction is the cause of an autism spectrum disorder.

Several approaches have been used to identify genes linked to psychiatric disorders. To find where in the genome a disease mutation or susceptibility locus may reside, linkage analysis measures the co-inheritance of alleles and phenotypes within families in which individuals have the disorder. In association analysis, the co-inheritance of alleles and phenotypes is assessed across families. One approach has been to pick candidate genes to examine in association studies. Candidate genes have included those involved in the monoaminergic neurotransmission (e.g., transporters, receptors, and enzymes involved in the metabolism of serotonin, dopamine, and norepinephrine). The serotonin transporter gene, discussed previously, is an example of a candidate gene that has been studied.

An exciting new approach is genome-wide association studies that test for associations of genomic regions with psychiatric disorders in a large sample of patients. In genome-wide association studies, new high-throughput genotyping technologies are used to measure single nucleotide polymorphisms (SNPs) throughout the genome and look for associations of particular SNPs with a disease phenotype. SNPs, in which one of the four nucleotide bases is substituted for another, are common forms of genetic variation. With the International HapMap project, SNPs throughout the genome were extensively cataloged, allowing for an assessment of an individual's SNPs throughout the genome. By associating particular SNPs with a phenotype, these genome-wide association studies determine which gene, or genomic region, variants occur more frequently with a particular psychiatric disorder. A critical parameter for these genome-wide association studies in psychiatric disorders is collection of sufficiently large samples of patients with the disorder so that the study has sufficient statistical power to detect an association between SNPs and phenotypes. Genome-wide association studies have been successful for other complex disorders (e.g., diabetes), providing hope for the study of psychiatric disorders.

An alternative approach to determine the genetics of psychiatric disorders is to identify, and find the genetic linkage to, intermediate phenotypes and endophenotypes. The hypothesis for this approach is that the clinical signs and symptoms that underlie diagnoses described in the DSM-IV may be far downstream of the more proximal effects of these genes on the brain. The effect of genes on intermediate phenotypes may be greater and more direct than the effect on the phenotype of a psychiatric disorder. Neuroimaging phenotypes are an example of an intermediate phenotype or endophenotype. For instance, the polymorphism in the serotonin transporter gene discussed previously has been associated with increased amygdala reactivity and reduced coupling of corticolimbic circuits.[22] Another intermediate phenotype that is studied is the inhibition of P50-evoked responses to repeated auditory stimuli, a phenotype that may underlie the abnormalities in sensory gating observed in schizophrenia.[23]

In molecular cytogenetic approaches, researchers study chromosomal abnormalities (e.g., balanced translocations, deletions, or duplications that correlate with psychiatric disorders). A compelling example of this approach was the discovery of the gene called *Disrupted-in-Schizophrenia-1 (DISC-1)* in a large Scottish family with a high incidence of schizophrenia. This family had a balanced translocation between chromosomes 1 and 11, and *DISC-1* was discovered at the breakpoint of this translocation.[24,25] Studies of *DISC-1* function are an active area of current neuroscience research. *DISC-1* is involved in regulating brain development, neuronal migration, and a signaling pathway important for learning, memory, and mood.[26–29] The translocation in this large extended Scottish family is associated with not only schizophrenia but also other major psychiatric disorders, such as bipolar disorder and MDD.[24,25] These findings highlight the concept that genes causing psychiatric illness may not fit neatly into DSM-IV diagnostic categories. Genes, such as *DISC-1*, that influence how the brain develops and function may impart a risk for multiple disorders and not be specific to a single disorder. In the future diagnostic categories for psychiatric disorders may be refined on the basis of findings about the genes involved in psychiatric disease.

An interesting new finding from psychiatric genetics is that patients with schizophrenia and autism have an increase in copy number variants (CNVs) compared with those in control populations.[30–35] CNVs are duplications or deletions of genomic segments ranging from 1 kilobase to several million bases. Through the use of high-throughput genomic technology and microarrays, CNVs and structural variants in the genome can be determined genome-wide in different patient populations. A 2008 study showed that novel deletions and duplications of genes were present in 15% of 150 individuals with schizophrenia and in 5% of controls, a difference that was highly statistically significant.[34] Most of the structural variants identified were different and rare, and these variants disrupted genes important for brain development. A larger study of 3391 patients with schizophrenia found a 1.15-fold increased burden of CNVs in patients with schizophrenia than in controls.[30] Rarer, single-occurrence CNVs were more strongly associated with schizophrenia. Several large deletions, including a deletion found in velocardiofacial syndrome (VCFS) discussed later, were found to be significantly associated with schizophrenia.[30] In addition, children with autism spectrum disorders were found to have a significantly increased burden of *de novo* deletions and duplications.[32,36–38] These studies indicate that schizophrenia and autism can be caused by specific genomic variations, including genomic deletions. These studies also suggest that a subset of schizophrenia and autism may be caused by mutations that have a large effect size on the disease phenotype and that these mutations may be rare and arise *de novo*, or of recent origin, in individuals and families.

SELECTED GENETIC SYNDROMES WITH PSYCHIATRIC FEATURES

The normal number of human chromosomes is 46, organized into 23 pairs. Chromosomes numbered 1 to 22 are autosomes; sex chromosomes make up the remaining pair. The sex chromosomes are made up of two X chromosomes in females (46, XX), and one X and one Y chromosome in males (46, XY). Abnormalities of chromosomes may include whole chromosomes (aneuploidy), chromosomal rearrangements (translocations or inversions), small deletions or duplications, or mutations in single genes. Visualization of chromosome number and gross structure is accomplished by karyotype analysis. More recently, other cytogenetic and molecular techniques have allowed for focused study of smaller regions of chromosomes or individual genes. Fluorescent in situ hybridization (FISH) is a cytogenetic technique that uses fluorescent probes to investigate the presence of small, submicroscopic chromosomal changes that are beyond the resolution of karyotype analysis.

Genetic syndromes are disorders with a characteristic set of features that are due to an underlying common mechanism. Features may include congenital anomalies, specific physical features, associated medical disorders, cognitive deficits, and psychiatric or behavioral symptoms. When considering a diagnosis of a genetic syndrome, clinicians may be guided by several Web-based resources (OMIM, Geneclinics) and software packages (POSSUM) that allow the option of searching for disorders on the basis of observed findings and historical information.

Currently, there are no available treatments that can cure genetic syndromes or replace missing genetic material. For this reason treatment is directed at symptomatic management of physical malformations, surveillance for associated medical conditions, and early developmental interventions. Special education or additional academic supports may be needed. Management of psychiatric and behavioral symptoms is accomplished by a combination of pharmacologic treatment and other therapies, including behavioral techniques.

Assessment of the Patient for Genetic Syndromes

Certain features of the medical history, family history, and physical examination may indicate the possibility of a genetic syndrome that underlies observed psychiatric and behavioral symptoms. In addition to the comprehensive review of systems and medical history completed during the initial assessment of patients, inclusion of questions about pregnancy and the perinatal period, birth defects, and surgeries in infancy or early childhood that may have been performed to correct congenital anomalies may provide valuable clues to an underlying genetic syndrome. In addition, careful review of the developmental history (with special attention paid to early developmental milestones) may reveal the presence of specific developmental delays, mental retardation, or learning disabilities. When inquiring about family history, the clinician should ask specific questions about recurrent miscarriages; stillborn children; early infant deaths; and a family history of mental retardation, seizures, or congenital illness, which may help in uncovering an underlying genetic disease, especially when the pattern of illness appears to be mendelian (e.g., dominant, recessive, or X-linked inheritance). Physical examination may reveal abnormalities of growth, dysmorphic features, or involvement of various organ systems. Results of imaging studies may aid in the assessment of underlying malformations suggested by physical examination (e.g., echocardiogram to rule out structural heart defects when a murmur is appreciated).

Selected Genetic Disorders

CASE 1

Ms. A, an 18-year-old woman, presented to the psychiatric emergency room with auditory hallucinations and paranoid ideation. She had a history of ADHD and oppositional behavior. Her full scale IQ was 78, and her verbal IQ was 15 points greater than her performance IQ, characteristic of a nonverbal learning disorder. Review of systems revealed surgery in infancy for correction of a congenital heart defect and frequent episodes of sinusitis, otitis media, and pneumonia. On physical examination she was short with a flat facial expression. Facial features included a high-arched palate; a small chin; and a nose with a broad, square nasal root. Ms. A was admitted to the inpatient psychiatric service and treated with atypical neuroleptics with a good result. Consultation with the Genetics service for her dysmorphic facial features and congenital heart defect, along with her cognitive and psychiatric symptoms, resulted in a diagnosis of VCFS.

Disorders Due to Chromosomal Abnormalities and Microdeletions

Velocardiofacial syndrome/DiGeorge syndrome: The cohort of patients diagnosed with VCFS, which also includes most patients previously diagnosed with DiGeorge syndrome, is due to a microdeletion on chromosome 22q11.2, which results in the loss of up to 60 known and predicted contiguous genes.[39] VCFS has been called a "genetic subtype of schizophrenia," and it is estimated that as many as 2% of patients with schizophrenia may have this disorder and be undiagnosed.[40,41] This rate may be even higher among patients with childhood-onset schizophrenia.[42] Psychiatric symptoms in those with VCFS and schizophrenia do not appear to differ from those without VCFS and schizophrenia based on factors such as description of psychosis or co-morbid illnesses. Overall, between 60% and 75% of patients with VCFS have significant psychiatric morbidity, including mood disorders, ADHD, autism, substance abuse, anxiety disorders, and oppositional defiant disorder.[41,43–50] The physical features of people with VCFS include a characteristic facial appearance (broad and squared nasal root, midface hypoplasia, short palpebral fissures, retruded chin), cleft palate, and velopharyngeal insufficiency (which may manifest as hypernasal speech, nasal regurgitation in infancy, or frequent ear infections), congenital heart defects, aplasia of the thymus (leading to immune problems), problems with calcium homeostasis, low muscle tone, and scoliosis. Facial hypotonia may result in a somewhat flat, expressionless appearance. Learning disabilities, especially nonverbal learning disorder, are common. However, patients can exhibit only some of these features, and the spectrum of findings may vary even within families. Diagnostic testing is available on a clinical basis and involves testing for the microdeletion with FISH techniques.

Smith–Magenis syndrome: Smith–Magenis syndrome is due to a microdeletion of chromosome 17p11.2, resulting in the loss of several contiguous genes at that location. In infancy these patients may exhibit failure to thrive and hypotonia. Physical findings, which may change over time, include short stature, scoliosis, eye abnormalities, renal problems, heart defects, peripheral neuropathy, and hearing loss (both conductive and sensorineural). Characteristic facial features include a square face with prominent forehead, deep-set and upslanting eyes, a broad nasal bridge with a short nose and fleshy nasal tip, full cheeks, and a "cupid's bow" tented upper lip. The jaw becomes more prominent with age. Although they may have hypersomnolence in infancy, a striking feature of this syndrome is marked sleep disturbance, with absence of rapid eye movement (REM) sleep in some patients. In addition, abnormalities of circadian rhythms and melatonin secretion have been documented.[51–53] Most patients have developmental delay, and their intelligence quotients (IQs) may range from borderline intelligence to moderate mental retardation. Patients are described with symptoms of ADHD, tantrums, impulsivity, and a variety of self-injurious behaviors, including onychotillomania (pulling out finger and toe nails) and polyembolokoilamania (insertion of foreign bodies), headbanging, face-slapping, and skin-picking.[52,54,55] In addition, they may show stereotypies, most commonly a "self-hug" when happy.[56] Abnormalities of lipid profiles have been seen in these patients, with elevations of cholesterol, triglycerides, and low-density lipoprotein.[57] Diagnostic testing involves testing for the microdeletion with FISH or quantitative polymerase chain reaction (PCR) techniques.[52,57]

Williams syndrome: A microdeletion on chromosome 7q11.23 results in Williams syndrome. Loss of the gene for elastin *(ELN)* is hypothesized to contribute to at least some of the observed phenotypic features, including short stature and microcephaly, cardiac defects (most often supravalvular aortic or supravalvular pulmonic stenosis), and connective tissue disease (joint laxity, hernias, soft skin). Patients with Williams syndrome are described as having an elfin facial appearance with a broad forehead that narrows at the temples, a short nose with a fleshy nasal tip, large and prominent ear lobes, a wide mouth with full lips, and a small jaw. The iris of the eye has a stellate or lacy appearance. Other characteristics include a hoarse voice and hyperacusis (hypersensitivity to sounds). Mental retardation in the mild to severe range is usually present, with an average IQ of 56. Specific learning deficits in visual–spatial skills are in marked contrast to strengths in verbal and language domains and are important for the identification and care of these patients. Psychiatric symptoms and conditions include autism, ADHD, depression, and anxiety. Patients with this syndrome may show circumscribed interests or obsessions and may be somatically focused. Despite being socially disinhibited and overly friendly, they tend to have difficulty with peer relationships and may become socially isolated. Affected individuals are described as overly talkative, a feature that may be, in part, reflective of generalized anxiety. Diagnostic testing involves the detection of the microdeletion with FISH techniques.[58–61]

Prader–Willi syndrome: Although several genetic mechanisms may result in Prader–Willi syndrome, the absence of a critical region of the paternally inherited chromosome 15q11-q13 is central to the disorder. This region of chromosome 15 undergoes the process of imprinting, by which genes are switched on or off depending on whether they are of maternal or paternal origin. In contrast to Prader–Willi syndrome, the absence of the maternally derived region results in Angelman syndrome (severe mental retardation, seizures, ataxia, and characteristic behaviors). Prader–Willi patients may be hypotonic and show failure to thrive in infancy. Most have short stature and small hands, feet, and external genitalia; some have fair skin and hair coloring. A characteristic facial appearance with upslanting almond-shaped eyes and a thin upper lip is seen. The hallmark behavior of this disorder is hyperphagia, with resultant morbid obesity, which develops early in childhood. Behavioral interventions have been effective in controlling this behavior if started at an early age. Psychiatric symptoms and conditions include obsessional thoughts, compulsions, repetitive behaviors, mood disorders, anxiety, psychosis, ADHD, autism, skin-picking, and temper tantrums. Afflicted individuals may have a high pain threshold, and they rarely vomit. These patients may show decreased IQ and learning problems, although they also show areas of relative strength in visual–spatial skills (e.g., as with jigsaw puzzles). Diagnostic testing for Prader–Willi syndrome involves analysis of the critical region for methylation status (the process that determines whether genes are turned on or off) or the detection of the deletion by FISH techniques.[62–65]

Down syndrome: The majority of individuals with Down syndrome are diagnosed soon after birth. This disorder is included in this chapter because of its known association with Alzheimer's dementia, in which cognitive decline or changes in behavior in adults with Down syndrome may prompt psychiatric consultation. In 95% of cases, Down syndrome is due to an extra free copy of chromosome 21; the remainder of cases are due to unbalanced translocations or duplications involving the Down syndrome critical region on chromosome 21. Down syndrome is the most common genetic cause of mental retardation; an increased incidence is observed with older maternal age. Most clinicians recognize the characteristic Down syndrome face, which consists of eyes with upslanting palpebral fissures, epicanthal folds, and Brushfield's spots (white spots in the iris), a flat nasal bridge, low-set ears, and a protruding tongue. In addition, they have a short neck, short stature, and single transverse palmar crease. These patients may also have a variety of congenital malformations, including heart defects and duodenal atresia, and they have high rates of hypothyroidism. Mental retardation is seen in the majority of patients, with an average IQ of 24. Social skills are usually more advanced than would be expected given the level of mental retardation. Decline in cognition or changes in behavior in middle-aged adults with Down syndrome may indicate Alzheimer's disease. The presence of an extra copy of the amyloid precursor protein *(APP)* gene (one of the causative genes in early onset Alzheimer's disease) on chromosome 21 is thought to contribute to increased rates of dementia in these patients. Nonspecific behavioral symptoms, depression, and anxiety may also be seen. Diagnostic testing for Down syndrome involves karyotype analysis of chromosomes.[66–69]

Turner's syndrome: The majority of cases of Turner's syndrome are due to the loss of an entire X chromosome, which is designated as 45, X. These patients are female, with physical characteristics of short stature; a webbed neck; and a flat, broad chest. Diagnosis may be delayed until adolescence, when these girls fail to develop secondary sexual characteristics (as a result of gonadal dysgenesis). Use of hormonal therapy can help afflicted girls achieve pubertal changes but will not result in fertility. These patients may also have involvement of other organ systems, including congenital heart or kidney disease. Psychiatric symptoms and conditions include ADHD, depression, anxiety, and problems with social skills. Specific learning disabilities (especially visual–spatial deficits) have been reported. Diagnostic testing for Turner's syndrome involves karyotype analysis of chromosomes.[70–72]

Klinefelter's syndrome: Klinefelter's syndrome is due to the addition of an extra X chromosome, resulting in 47, XXY. These patients are male and usually described as tall, and they may be somewhat hypotonic and clumsy. They typically have a small penis and testes. Contrary to earlier descriptions, they have a male distribution of body fat and hair, although gynecomastia may be seen. Again, these patients may be first diagnosed in adolescence, after they fail to enter puberty, or as part of an infertility workup. Use of testosterone can help with the development of secondary sexual characteristics. An increased incidence of ADHD, immaturity, and depression has been reported in these patients. Cognitively, specific learning disabilities are seen. Diagnostic testing for Klinefelter's syndrome involves karyotype analysis of chromosomes.[73]

47, XYY: Males with an extra copy of the Y chromosome have been of interest to the psychiatric profession for many years because of reported increased criminality and antisocial behaviors in these patients. Although early studies conducted on criminal populations were limited by ascertainment bias, more recent studies have continued to show small increases in these behaviors in 47, XYY males compared with controls. However, increased rates of antisocial or criminal behavior appear to be related to the cognitive deficits seen in some of these patients.[74] Physical findings may include accelerated linear growth in childhood and tall stature as adults. They may have a lower than average IQ or specific learning disabilities, especially in reading and language domains. Psychiatric conditions include ADHD and conduct disorders.[75] Overall, the majority of these patients may never receive medical attention because they may lack any identifying features. Diagnostic testing for 47, XYY involves karyotype analysis of chromosomes.

Autosomal Dominant Single-Gene Disorders

Huntington's disease: Huntington's disease is due to an increased number of CAG triplet repeats in the *HD* gene on chromosome 4p16. The normal number of CAG repeats ranges from 10 to 26 in unaffected individuals, where patients with Huntington's disease have between 36 and 121 repeats. The number of repeats may expand from one generation to the next, and increased severity and earlier onset of illness (known as anticipation) may be seen in subsequent generations. Psychiatric symptoms are prominent in the early presentation of this disorder and may include changes in personality, depression, and apathy. Later, progressive cognitive decline and dementia occur. Mood lability and psychosis may also be seen. A high suicide rate is reported in these patients. Early physical findings include dysarthria and clumsiness with deterioration in both voluntary and involuntary movements and the development of chorea. The abnormal movements are often treated with high-potency neuroleptics, but there is no treatment that stops the progressive neurologic decline in this disease. Characteristic atrophy of the caudate and putamen may be apparent on MRI or CT of the brain. Diagnostic testing involves molecular detection of increased number of CAG repeats in the *HD* gene.[76–78]

Tuberous sclerosis: Tuberous sclerosis is due to mutations in the *TSC1* (on chromosome 9q23) or *TSC2* (on chromosome 16p13.3) genes. Patients with tuberous sclerosis exhibit characteristic skin findings of flat hypopigmented macules (ash leaf spots), shagreen patches (raised area with dimpled texture), and angiofibromas (red papular lesions). They may have small pits in their tooth enamel. Tumors occurring in different organ systems are seen, including central nervous system (CNS) tubers, retinal hamartomas, cardiac rhabdomyomas, and renal angiomyolipomas. Seizures are a common feature of this disorder. Patients with tuberous sclerosis have been reported to have symptoms of pervasive developmental disorder and

ADHD. Mental retardation may occur, depending on the extent of CNS involvement. The diagnosis is most often made on a clinical basis, but mutation analysis of the *TSC1* and *TSC2* genes is now available.[79–81]

Neurofibromatosis type I: Neurofibromatosis type I (NF1), previously known as von Recklinghausen's disease, is due to a mutation in the *NF1* gene on chromosome 17q11.2, which is believed to result in loss of tumor suppressor function. Abnormalities of skin pigmentation *(café au lait* spots, freckling in axilla or groin), Lisch nodules (small brown spots) on the iris, bony abnormalities, neurofibromas (cutaneous, subcutaneous, or plexiform), and macrocephaly are some of the physical findings in NF1. Complications may arise depending on the size or location of neurofibromas or because of the development of malignant tumors. Psychiatric symptoms may include learning disabilities and ADHD. Diagnosis is usually made on a clinical basis; mutation analysis of the *NF1* gene is available on a limited basis.[79,82,83]

X-Linked Dominant Disorders

Fragile X syndrome: In contrast to Down syndrome, which is the most common *genetic* cause of mental retardation, fragile X syndrome is the most common *inherited* (i.e., transmitted from a parent who carries the abnormal gene) cause of mental retardation. Fragile X is the result of dysfunction of the *FMR1* gene at Xq27.3 caused by increased numbers of trinucleotide repeats. Normal alleles have approximately 5 to 44 repeats, and borderline alleles have approximately 45 to 58 repeats. Having greater than approximately 200 CGG repeats results in the full syndrome; a "premutation" allele with approximately 59 to 200 repeats may expand to the full syndrome when passed on from a mother to her children. The full syndrome is most often found in male subjects, but female subjects who carry a full-length mutation on one of their X chromosomes may have features of the disorder of variable severity. Approximately one third of female subjects with a full-length mutation are thought to be normal, one third are mildly affected, and the remaining one third have findings similar to the full syndrome in males. In addition to mental retardation in the moderate to severe range, physical features, such as large testes, connective tissue disease (loose joints), low muscle tone, and characteristic facial appearance (large head with prominent forehead and jaw, long face with large ears) may help identify males with this disorder. Of note, the facial features and testicular size may be more apparent after puberty. Psychiatric symptoms include autistic features, ADHD, oppositional defiant disorder, mood disorders, and avoidant personality disorder and traits. Although carrying a premutation-length allele has not traditionally been associated with cognitive or behavioral findings, a variety of studies have shown increased rates of psychiatric symptoms, including social phobia and mood disorders, in these women. Diagnostic testing to determine the number of trinucleotide repeats in the *FMR1* gene is widely available.[84–88]

Rett syndrome: Rett syndrome is due to a mutation in the *MECP2* gene on chromosome Xq28. This syndrome is described in girls who appear normal at birth and during the first several months or years of life. They then experience a progressive loss of developmental skills associated with acquired microcephaly. Additional features include impaired language, loss of purposeful hand movements (replaced by stereotyped hand movements), gait abnormalities, seizures, and bruxism. It is classified as a pervasive developmental disorder in DSM-IV. Mutations in the *MECP2* gene, once thought to be fatal in males, have been recognized as a cause of developmental disorders in boys. Diagnostic testing for analysis of the *MECP2* gene is available.[89–92]

METABOLIC DISEASE

Inborn errors of metabolism are a class of genetic disorders that result in dysfunction of production, regulation, or function of enzymes or enzyme co-factors. The disruption of normal metabolic processes may lead to a buildup of pathway by-products or production of alternate substances that cause toxicity. In addition, the absence of essential pathway end products may lead to disease states. Classically, disorders of metabolism have been described in children. However, presentation or recognition of disease may be delayed in patients with relative preservation of enzyme activity that is seen in milder forms of disease, and many disorders have later-onset forms. Metabolic disorders are most often classified on the basis of the abnormal substances involved or by the cell location where the enzyme dysfunction occurs.

Testing for metabolic illness begins at birth, by population screening for a variety of illnesses by state-mandated newborn screening programs. However, the number of diseases tested for varies widely by state, and even the most comprehensive testing has been available only for the past several years. Thus it is unlikely that older children and adults would have benefited from these screening programs. Furthermore, even the most comprehensive state panels do not rule out all, or even most, genetic and metabolic diseases. For this reason suspicion of a metabolic disease should be pursued vigorously. Early identification of metabolic illness is crucial to maximize good outcome.

Assessment of the Patient for Metabolic Illness

Essential to the evaluation for possible metabolic illness is careful history-taking. Questions about dietary history (e.g., food intolerances, unusual food preferences, colic or reflux), a history of decompensation associated with minor illness, or history of transient neurologic symptoms (e.g., lethargy, encephalopathy, ataxia, confusion) may lead to detection of an underlying metabolic illness. In addition, careful review of developmental history, especially a history of a developmental regression, loss of skills, or decline in cognition, is important. Because many metabolic illnesses are inherited in an autosomal recessive fashion, a review of family history should include questions about consanguinity and ethnicity. In addition, a history of stillbirths or early infant deaths may prove informative. For example, it is thought that many children who died of Reye's syndrome (manifested by vomiting, liver dysfunction with fatty infiltration, and hypoglycemia) may have had underlying problems with disorders of fatty acid oxidation.

TABLE 31–1 Laboratory Studies to Evaluate Metabolic Illness

LABORATORY TEST	METABOLIC STATE/ DISORDERS TESTED FOR
Electrolyte panel	Acidosis, calculation of anion gap
Liver function tests	Storage of abnormal substances in liver
Blood gas	Determination of pH (acidosis vs. alkalosis)
Ammonia (NH_3)	Urea cycle disorders—primary elevation organic acidemias, disorders of fatty acid oxidation—secondary elevation
Lactate, pyruvate	Disorders of energy metabolism
Plasma amino acids	Amino acid disorders (e.g., urea cycle defects, homocystinuria)
Urine organic acids	Organic acidemias
Acylcarnitine profile	Disorders of fatty acid oxidation, organic acidemias
Very long chain fatty acids	Peroxisomal disorders
Urine mucopolysaccharides	Lysosomal storage disorders
Urine oligosaccharides	Lysosomal storage disorders

Abnormal results of routine and specialized laboratory studies may indicate a primary metabolic illness. Of note, laboratory findings may be abnormal only during the period of acute illness or metabolic decompensation. For this reason following up on a suspicion of metabolic illness with prompt collection of indicated specimens is crucial for diagnosis. Some general laboratory tests to consider when evaluating a patient for metabolic illness are listed in Table 31–1. Abnormal results on preliminary testing may direct more specific assessment of certain metabolic pathways.

Many patients with metabolic illness have completely normal physical features, although characteristic findings, when applicable, are indicated later. Thorough ophthalmologic examination may prove particularly helpful when evaluating metabolic illnesses because the retina provides a window through which to observe the metabolic processes in the brain.

Many metabolic illnesses affect the brain, either directly (e.g., via destruction of white matter in metachromatic leukodystrophy) or indirectly (e.g., as encephalopathy in urea cycle disorders). For this reason neuropsychiatric symptoms associated with metabolic disease may vary widely. Conversely, many metabolic illnesses may have similar acute presentations (e.g., delirium). As is the case with genetic syndromes, some patients meet full criteria for psychiatric disorders, whereas others may exhibit nonspecific behavioral findings.

Selected Metabolic Disorders with Psychiatric Features

CASE 2

Mr. B, a 57-year-old man, was admitted to the medical service for a change in mental status. He was reported to have prominent mood lability, disorientation, and disorganized and racing thoughts. His medical history was significant for hypertension, dental surgery, and a history of hepatitis 6 months previously (attributed to alcohol intake and medication side effects). Mr. B had been consuming six beers at a time several times a week. His family history was unremarkable. On evaluation, he appeared anxious and restless, and a tremor was noted. He had difficulty with speech and had abnormal facial movements. He exhibited mood lability and had difficulty completing cognitive tasks. Laboratory studies showed a mild elevation of liver transaminases, a low serum ceruloplasmin, and a greatly increased urine copper excretion, which led to a diagnosis of Wilson's disease.

Autosomal Dominant Disorders

Porphyrias/acute intermittent porphyria: The porphyrias are a group of disorders with dysfunction of heme biosynthesis. One of the more common porphyrias is acute intermittent porphyria (AIP), which results from mutations in the *hydroxymethylbilane synthase (HMBS)* gene on chromosome 11q23.3 that causes decreased activity of porphobilinogen (PBG) deaminase. AIP is inherited in an autosomal dominant manner. Episodic neurovisceral attacks are the predominant manifestations of AIP; they consist of recurrent abdominal pain, vomiting, generalized body pain, and weakness. Photosensitivity is not a feature of AIP as it is with some types of porphyria. Psychiatric symptoms and conditions, such as delirium, psychosis, depression, and anxiety, may accompany the acute attacks. Between attacks, constitutional and psychiatric symptoms resolve, although anecdotally these patients are often described as having a distinct personality with long-standing histrionic traits. Over time, indications of demyelination may develop. Of importance to the psychiatric consultant is that medications that upregulate heme biosynthesis may worsen attacks. For this reason patients treated with medications that upregulate the cytochrome P450 system may make symptoms worse, because heme is an essential part of the cytochrome ring; these patients may be incorrectly labeled as treatment refractory. Offending agents include benzodiazepines, some tricyclic antidepressants, barbiturates, some anticonvulsants (valproate and carbamazepine), oral contraceptives, cocaine, and alcohol. Diagnostic testing focuses on identification of by-products of heme synthesis in the urine or measurement of PBG deaminase levels in the blood. Urine that is left standing may discolor, turning dark red or brown as a result of the presence of porphobilinogen and aminolevulinic acid. Treatment for AIP includes supportive care during attacks and the avoidance of offending agents. In addition, a high-carbohydrate diet, folic acid (a PBG diamine co-factor), and the use of medications that suppress heme synthesis may be helpful.[93–97]

Autosomal Recessive Disorders

Homocystinuria: Classic homocystinuria is due to mutations of the *cystathionine β-synthase (CBS)* gene on chromosome 21q22.3 that results in decreased enzymatic activity of *CBS* and problems with conversion of homocystine to cystine and remethylation of homocystine to methionine. Patients with preservation of some enzyme activity may respond to high dosages of pyridoxine (vitamin B_6), which acts as a co-factor for *CBS.* Deficiencies of other enzyme co-factors (e.g., B_{12} and folate) may also lead to symptoms. Patients with homocystinuria usually have unremarkable early histories, with development of symptoms in childhood. The patients tend to be tall and thin and are sometimes described as "marfanoid." They may have features of connective tissue disease, such as a pectus excavatum, lens dislocation, scoliosis, and a high-arched palate. Unlike patients with Marfan's syndrome, they may have restricted mobility of their joints. It is thought that high levels of homocystine may interfere with collagen cross-linking, which results in connective tissue symptoms. In addition, abnormalities in collagen can lead to disruptions of the vascular endothelium and thrombotic events with disabling or fatal consequences. High levels of homocystine or other factors are also thought to be neurotoxic and, when left untreated, lead to mental retardation and learning disabilities. During the 1960s and 1970s, these patients were reported to have increased rates of schizophrenia, which was attributed to the hypothesized central role of methionine in both disorders. More recent studies have not supported an increased risk of schizophrenia or psychosis but have shown depression, obsessive–compulsive disorder, personality disorders, and other behavioral disturbances. Urinary nitroprusside testing for disulfides and measurement of high levels of homocystine and methionine (the precursor of homocystine) in the blood help make the diagnosis. Newborn screening for homocystinuria has been available in some states for more than 30 years. Molecular testing is also available. Treatment focuses on providing a diet low in methionine and supplementation with vitamin co-factors and cystine (which becomes an essential amino acid in these patients). Use of the supplement betaine also aids in lowering homocystine levels.[98–100]

Wilson's disease: Wilson's disease is due to mutations in the *ATP7B* gene, located on chromosome 13q14.21, which lead to copper deposition in the CNS as a result of decreased levels of copper-transporting adenosine triphosphatase (ATPase). Signs and symptoms of liver dysfunction (e.g., jaundice, hepatomegaly, cirrhosis, hepatitis) may be present, along with abnormal liver function tests. Of particular importance to psychiatrists are changes in personality, mood lability (including pseudobulbar palsy), cognitive decline, and other behavioral changes that may be among the earliest symptoms of Wilson's disease. Neurologic symptoms are most often extrapyramidal in nature and can include tremor, dysarthria, muscular rigidity, parkinsonism, dyskinesia, dystonia, and chorea. Seizures may also occur. The hallmark of this disorder is the Kayser–Fleischer ring, a yellow-brown ring (a consequence of copper deposition in the cornea) that is visible on slit lamp ophthalmological examination. Accumulations of copper in other organ systems may result in a variety of complications, including arthritis, renal tubular dysfunction, and cardiomyopathy. Confirmatory diagnostic testing includes measurement of reduced bound copper and ceruloplasmin in the serum and increased copper excretion in the urine. Copper deposits may be seen on head magnetic resonance imaging (MRI) or in the liver by way of a liver biopsy. Treatment, in the form of chelation of copper (with medications such as d-penicillamine) and supplementation with antioxidants, is available. Avoidance of copper-rich foods, such as shellfish, liver, chocolate, and nuts, is recommended. Unfortunately, liver damage may progress to liver failure and necessitate liver transplantation in some patients.[101–103]

Metachromatic leukodystrophy: Metachromatic leukodystrophy is a lysosomal storage disorder with deficiency of the enzyme arylsulfatase A and mutations in the *ARSA* gene located on chromosome 22q13.31. As a result, abnormal storage of galactosyl sulfatide (cerebroside sulfate) occurs in the white matter of the central and peripheral nervous systems. The disorder may occur in infancy, childhood, or adulthood. For the later-onset forms, psychiatric symptoms may be an earlier manifestation of the disease, with a decline in cognition, personality changes, and psychotic features (including hallucinations and delusions). In some cases, psychosis may predate the onset of other symptoms by several years. Neurologic symptoms may include ataxia and walking difficulties, dysarthria and dysphagia, and pyramidal signs. Vision loss may also occur. Brain MRI may show periventricular changes; eventually white matter atrophy caused by loss of myelin may be noted. Diagnostic testing involves measurement of elevated urine sulfatides and decreased levels of arylsulfatase A in blood. No treatment is currently available, although bone marrow transplantation may delay the progression of symptoms.[93,104,105]

Niemann–Pick disease, type C: Niemann–Pick disease, type C (NPC) is a condition that results in abnormal cholesterol esterification and lipid storage in lysosomes caused by mutations in the *NPC1* gene on chromosome 18q11-q12. The disorder may appear in childhood or adolescence (and rarely in adulthood) with early findings of ataxia, coordination problems, and dysarthria. Vertical supranuclear palsy is the hallmark of the disorder. Seizures and hepatosplenomegaly may be present. Psychiatric symptoms include progressive cognitive decline and dementia. In addition, several reports have documented the initial presentation of this disorder as psychosis or schizophrenia. Diagnosis is based on demonstration of characteristic pathologic findings in the skin or bone marrow; abnormal cholesterol esterification in fibroblasts; and molecular analysis of the *NPC1* gene, which is positive in 95% of cases. Of note is that panels testing blood and urine specimens for lysosomal storage diseases will be normal in NPC, so diagnostic suspicion must direct a more comprehensive work-up.[106–109]

Tay–Sachs disease, late-onset type: Tay-Sachs disease is another lysosomal storage disease, with accumulation of GM2 gangliosides in neurons. Mutations in the *HEXA* gene on chromosome 15q23-q24, which encodes the alpha subunit of hexosaminidase A, lead to an enzyme deficiency. Most clinicians are familiar with the infantile-onset form of the disorder but may not be aware of the later-onset forms that can occur with preservation of some enzymatic activity. Patients may present with psychiatric symptoms of psychosis, mood lability, catatonia, and cognitive decline. Physical findings are those of progressive neurologic

dysfunction and include early ataxia, coordination problems, dysarthria, and progressive neurologic dysfunction (e.g., with dystonia, spasticity, and seizures). Macular cherry-red spots, the hallmark of the early-onset form, are not present in the later-onset form. Diagnosis is based on analysis of enzyme levels in the blood or mutation analysis. Tay–Sachs may occur in people of various ethnic and racial backgrounds, and prenatal screening is offered, especially to those of Ashkenazi Jewish descent, wherein the carrier rate is estimated to be 1:30, and to French Canadians, who have a carrier rate of 1:50. There is no treatment available for Tay–Sachs disease.[110,111]

X-Linked Disorders

X-linked adrenoleukodystrophy: X-linked adrenoleukodystrophy is also a disorder of abnormal storage but in the peroxisome instead of the lysosome. In this disorder deficiency of lignoceroyl-CoA ligase results from mutations in the *ABCD1* gene on Xq28 and leads to accumulation of very long chain fatty acids (VLCFAs) in the cerebral white matter and adrenal cortex. On account of its X-linked manner of inheritance, male subjects are described with the full syndrome. Female carriers, however, can also exhibit a spectrum of associated symptoms with varying degrees of severity, and they may be misdiagnosed with other disorders, including multiple sclerosis. Often, the first signs and symptoms of the disorder result in a diagnosis of ADHD for affected males. In the adult-onset form, high rates of mania and psychosis are reported. Other early signs may include difficulty with gait, handwriting, or speech. Progressive loss of motor skills, vision, and hearing, accompanied by continued decline in cognition, occurs over a period of months to years. Accumulation of VLCFAs in the adrenal cortex may cause elevation of adrenocorticotropic hormone and other findings associated with adrenal dysfunction. These adrenal abnormalities, brain MRI findings, and elevated levels of VLCFAs in the blood can lead to the diagnosis. Confirmatory molecular testing for mutations in the *ABCD1* gene is available. Treatment for adrenal dysfunction is recommended, but there is no treatment available for the neurologic sequelae of this disease, insofar as the use of Lorenzo's oil has not proven to be effective. Bone marrow transplantation has been proposed as a possible treatment for this disorder, but concerns about the high morbidity and mortality rate associated with the procedure have limited its use.[112–114]

Urea cycle defects—ornithine transcarbamylase deficiency: Disorders of the urea cycle interfere with the normal urinary excretion of excess nitrogen via conversion to urea. Several enzymes make up the urea cycle, and deficiencies of these enzymes lead to variable failure to manage nitrogenous waste from protein. Ornithine transcarbamylase (OTC) deficiency is one of the more common urea cycle disorders, and it is inherited in an X-linked manner as a result of mutations in the *OTC* gene on Xp21.1. Although male subjects with this disorder usually present in the neonatal period with marked hyperammonemia and resultant sequelae, female carriers of the *OTC* gene may have a more variable course, owing to lyonization of X chromosomes. Their presentations may occur at any age, and female carriers range from being asymptomatic to being as severely affected as their male counterparts. Psychiatric symptoms in affected female carriers may include intermittent episodes of delirium, ataxia, lethargy, and confusion.[115–120] Patients may report a history of self-restriction of protein in the diet or severe decompensations with vomiting illnesses or fasting (which may result in an endogenous protein load via catabolism of muscle). During symptomatic episodes elevations of ammonia, urine orotic acid, and liver function, accompanied by a characteristic pattern of plasma amino acids, aid in diagnosis. Confirmatory molecular diagnostic testing by mutation analysis, or enzymatic assay of liver tissue, is available. Treatment is focused on maintaining a low intake of dietary protein and providing supplemental essential amino acids and urea cycle intermediates. Acutely, medications that allow alternate excretion of nitrogen compounds may be used for high ammonia levels; in some cases hemodialysis is required for rapid control of hyperammonemic episodes. Of note, the use of valproate has been reported to cause acute liver failure in patients with OTC and also to precipitate a hyperammonemic crisis in female carriers. It is thought that valproate inhibits urea synthesis and can lead to hyperammonemia.[121–123]

Lesch–Nyhan syndrome: Lesch–Nyhan syndrome is a disorder of purine metabolism owing to deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT), caused by mutations in the *HPRT1* gene at Xq26-27.2. Hyperuricemia and hyperuricuria occur and can result in deposition of urate crystals in the joints, kidneys, and bladder. Affected males exhibit hallmark behaviors of self-injury and self-mutilation (including head-banging and biting of lips and fingers). Mutilation may be severe enough to warrant removal of teeth or the use of restraints. Mental retardation may occur, although progressive loss of cognition does not. Diagnostic testing reveals increased uric acid production and excretion, decreased HPRT activity, and confirmatory molecular analysis of the *HPRT1* gene. Although allopurinol may control sequelae of high uric acid, it does not ameliorate the neurologic or psychiatric symptoms. There is some suggestion that dysfunction of dopamine metabolism may be related to the CNS pathology in this disorder.[124–126]

Mitochondrial Disorders

Disorders that involve dysfunction of the mitochondria are diverse and include disorders of fatty acid beta-oxidation or pyruvate metabolism and dysfunction of the Krebs cycle or oxidative phosphorylation by the electron transport chain. Commonly, they may be thought of as disorders of energy metabolism. Mitochondrial disorders are inherited from the mother, in the case of those coded for by genes located in the mitochondrial genome, or from either or both parents in those coded for by genes located in the nuclear genome. Mitochondrial syndromes may be characterized as specific disorders (e.g., mitochondrial encephalopathy with lactic acidosis and strokelike episodes) or may involve dysfunction of multiple organ systems (e.g., cardiomyopathy, diabetes, and hearing loss). Body tissues with high energy demands, including the brain, may be

preferentially affected. Psychiatric symptoms and conditions in mitochondrial disorders are largely uncharacterized but may include depression, delirium, dementia, and psychosis. Mitochondrial dysfunction may be suggested by elevations of lactate or pyruvate or by presence of byproducts of fatty acid oxidation or other mitochondrial pathways. Diagnosis by analysis of specific mutations is available for some disorders, whereas others require functional analysis of pathways using skin or muscle tissue. Dietary and vitamin supplementation, prevention of lactic acidosis with acute decompensations, and management of associated medical conditions are the mainstays of treatment for mitochondrial disorders.[127–129]

Teratogen Exposure

A variety of reproducible syndromes and characteristic features are associated with prenatal exposure to prescribed medications, alcohol and drugs of abuse, maternal illnesses (e.g., diabetes) and infectious agents, chemicals, radiation, and other toxins. Observed physical, cognitive, and psychiatric findings vary depending on the amount and timing of exposure. When possible, a detailed prenatal history should be obtained as part of a comprehensive evaluation of a patient.

Fetal alcohol syndrome: Alcohol is the major teratogen to which fetuses are exposed; it can result in a wide spectrum of cognitive, behavioral, and physical findings known as fetal alcohol syndrome (FAS). The severity of symptoms appears to be dose related, although a critical threshold of alcohol intake has not been identified. High levels of blood alcohol (achieved by binge drinking) may result in more severe manifestations. Psychiatric symptoms and conditions include ADHD, depression, mood lability, anxiety, aggression, and oppositional defiant behaviors. Physical features include prenatal and postnatal growth deficiency and a characteristic facial appearance manifested by a small head, a flattened midface, the presence of epicanthal folds, a flat philtrum with a thin upper lip, and small jaw. Learning disabilities and cognitive limitations are common. Diagnosis rests on clinical features with recognition of characteristic findings in the context of a known history of prenatal alcohol exposure. Diagnosis of FAS spectrum, partial FAS, or alcohol-related

TABLE 31–2 Additional History and Physical Examination Assessment for Genetic and Metabolic Illness

PRENATAL HISTORY	MULTIORGAN REVIEW OF SYSTEMS
Any complications with pregnancy?	History of decompensation with illness?
Timing of complication(s)?	Dietary history of food intolerances, or unusual food preferences?
Maternal diabetes, systemic illness?	Episodic neurologic symptoms?
Maternal hypertension, eclampsia, or toxemia?	Problems with linear growth or weight gain? HELLP (*H*emolysis, *E*levated *L*iver enzymes, *L*ow *P*latelets)?
Maternal infection or high fevers?	
Toxic exposures (medications, illicit substances, alcohol, radiation, chemicals)?	
Any abnormalities on ultrasound?	
Any indications for amniocentesis/chorionic villus sampling (CVS)? Amniocentesis/CVS results?	
BIRTH/PERINATAL HISTORY	**PHYSICAL EXAMINATION**
Mode of delivery (vaginal vs. cesarean section, natural vs. induced vs. emergent)?	Asymmetry of features?
Complications with delivery?	Presence of dysmorphic features?
NICU or prolonged hospital stay in infancy?	Signs of neurologic dysfunction?
Issues with feeding or growth?	
DEVELOPMENTAL HISTORY	**PSYCHIATRIC REVIEW OF SYSTEMS**
Timing of major verbal and motor milestones?	Nonspecific behavioral problems (e.g., tantrums, violent behavior)?
History of speech, occupational or physical therapy?	History of developmental regression? outbursts, hyperactivity)?
Decline in school performance?	Self-injurious behaviors?
History of special education services, academic supports?	
FAMILY HISTORY	Difficulties with sleep?
Ethnicity/race of parents?	
History of consanguinity?	
Patterns of illness in family members?	
History of infertility, miscarriages?	
History of infant/child deaths?	
Family members with surgeries in childhood?	

NICU, Neonatal intensive care unit.

neurodevelopmental disorder may also be made. Exposure to multiple drugs *in utero* should also be considered in all patients evaluated for FAS. No confirmatory laboratory or imaging tests are available, although recent MRI studies have documented structural abnormalities of the brain with absence or small size of the corpus callosum being reported in FAS patients.[130–132]

CONCLUSION

Many psychiatric disorders have a substantial genetic etiology. Psychiatric disorders are also greatly influenced by the environment. Genes and the environment can interact to lead to expression of psychiatric disorders. An active area of research is identifying genes and genomic regions linked to psychiatric disorders. Discovering the genetic basis of psychiatric disorders will provide opportunities to further understand the mechanisms underlying these disorders and guide the development of new treatments. Diagnostic classifications of psychiatric disorders may be refined in light of this increased understanding of the genetic basis of psychiatric phenotypes. We anticipate that genetics, in the years to come, will be increasingly important for the diagnosis and treatment of psychiatric disorders in the general hospital.

Because the selected genetic and metabolic syndromes described in this chapter are frequently associated with psychiatric symptoms, an awareness of these disorders is important for the general psychiatrist. A comprehensive assessment that includes attention to family history (Tables 31–2 to 31–5), highlighting psychiatric and neurologic diseases, dementia, or other medical illness in family members; review of systems, including developmental and cognitive status, dietary history, and involvement of other organ systems; and noted abnormalities on physical examination, especially neurologic findings and dysmorphic features may uncover clues that can help determine which psychiatric patients may require more extensive organic work-ups. Consultation by a geneticist may help with diagnostic and management issues in individual patients with known or suspected genetic and metabolic disorders. Determination of the molecular and physiologic basis of psychiatric and behavioral symptoms of disorders in which the underlying cause is known may add to our understanding of psychiatric disorders as a whole, aid in refinement of diagnostic criteria, and offer novel treatment approaches to common psychiatric diseases.

TABLE 31–3 Selected Disorders with Associated Cognitive Decline/Dementia

GENETIC SYNDROMES	INBORN ERRORS OF METABOLISM
Rett syndrome	Wilson's disease
Huntington's disease	Homocystinuria
Down syndrome (with associated Alzheimer's disease)	X-linked adrenoleukodystrophy
	Niemann–Pick disease, type C
	Metachromatic leukodystrophy
	Tay–Sachs disease
	Mitochondrial disease

TABLE 31–4 Selected Disorders with Associated Delirium

Acute intermittent porphyria
Wilson's disease
Ornithine transcarbamylase deficiency (including female carriers)
Mitochondrial disease

TABLE 31–5 Selected Disorders with Associated Psychosis

GENETIC SYNDROMES	INBORN ERRORS OF METABOLISM
Velocardiofacial syndrome/DiGeorge syndrome	Acute intermittent porphyria
	X-linked adrenoleukodystrophy
Prader–Willi syndrome	Niemann–Pick disease, type C
Huntington's disease	Metachromatic leukodystrophy
	Tay–Sachs disease
	Wilson's disease
	Mitochondrial disease

Coping with Illness and Psychotherapy of the Medically Ill

Steven C. Schlozman, M.D.
James E. Groves, M.D.
Anne F. Gross, M.D.
Avery D. Weisman, M.D.

Management of psychiatric illness in medically ill inpatients and outpatients requires knowledge of medicine and psychiatry as well as specialized psychotherapeutic techniques. In hospital settings, challenges to compassionate psychological care are abundant (e.g., decreasing length of stays, severe medical and surgical illnesses, prominent side effects of treatment, threats to privacy, and procedures and technology that limit a patient's ability to communicate). Nonetheless, consultation psychiatrists strive to improve the patient's ability to cope with trying circumstances that surround their illness and its treatment.

Illness is a stress that requires both the afflicted patients and the systems that surround them them to adapt (e.g., to pain, impaired cognition, loss of bodily function, threats to life, and disruptions in everyday function) via improvements in coping strategies and interpersonal relationships. Coping with illness can be a serious problem for both the patient and the physician. However, when addressing this phenomenon, it is important to recognize that few medical schools or residency programs train physicians in the management of interpersonal stress and discomfort engendered by medical illness (in patients and in themselves). This absence stands in stark contrast to the way the art of medicine was conceptualized 100 years ago. Indeed, it is ironic, and yet understandable, that we experience a profound sense of impotence when a cure cannot be found in the face of our increasing ability to heal the sick.[1,2]

Fortunately, the consultation–liaison (C-L) psychiatrist is ideally suited to assist both patient and physician with the demands of caring for the medically ill. From a psychological standpoint, the psychiatrist appreciates the powerful emotions and defense mechanisms that swirl in and around the hospital bed. These observations are relevant in both the consultative setting and in the outpatient office. In fact, specific psychotherapeutic techniques (e.g., cognitive behavior therapy [CBT] and group therapy) have been developed for work with the medically ill. This chapter addresses the fundamentals of coping, the process of adaptation to illness, as well as the art of working psychotherapeutically with the medically ill.

WHAT EXACTLY IS COPING?

Coping is best defined as problem-solving behavior that is intended to bring about relief, reward, quiescence, and equilibrium. Nothing in this definition promises permanent resolution of problems. It does imply a combination of knowing what the problems are and how to go about reaching a correct direction that will help resolution.[3,4]

In ordinary language, the term *coping* is used to mean only the outcome of managing a problem, and it overlooks the intermediate process of appraisal, performance, and correction that most problem-solving entails. Coping is not a simple judgment about how some difficulty worked out. It is an extensive, recursive process of self-exploration, self-instruction, self-correction, self-rehearsal, and guidance gathered from outside sources.

At virtually every step of patient care, physicians and patients actively assess coping ability. Though this appraisal is not always conscious, the conclusions drawn about how a patient is processing his or her illness has a tremendous impact on therapeutic decisions, on psychological well-being, and indeed on the overall course of illness. However, accurate appraisal of coping skills is hampered by muddled definitions of coping, by competing methods of assessment, by a general lack of conscious consideration of how a patient copes, and by uncertainty about whether particular coping styles are effective.[3–6]

Early conceptualizations of coping centered around the Transactional Model for Stress Management, put forth first by Lazarus[7] and colleagues in the late 1960s. This conceptualization stressed the extent to which a patient interacts with his or her environment as a means of managing the stress of illness. These interactions involve appraisals of one's medical condition in the context of psychological and cultural overlays that vary from patient to patient. Although this definition of coping persists, it may be too broad to allow for standard assessments of patients. Thus, though multiple studies of patient coping exist, most clinicians favor a more open-ended approach to evaluation that considers the unique backgrounds that the patient and the doctor bring to the therapeutic setting.[6]

Coping with illness and its ramifications cannot help but be an inescapable part of medical practice. Therefore the overall purpose of any intervention, physical or psychosocial, is to improve coping with potential problems beyond the limits of illness itself. Such interventions must take into account both the problems to be solved and the individuals most closely affected by the difficulties.

How anyone copes depends on the nature of a problem as well as on the mental, emotional, physical, and social resources one has available for the coping process. The hospital psychiatrist is in an advantageous position to evaluate how physical illness interferes with the patient's conduct of life and to see how psychosocial issues impede the course of illness and recovery. This is accomplished largely by knowing which psychosocial problems are pertinent, which physical symptoms are most distressing, and what interpersonal relations support or undermine coping.

Assessment of how anyone copes, especially in a clinical setting, requires an emphasis on the "here and now." Long-range forays into the past are relevant only if they illuminate the present predicament. In fact, more and more clinicians are adopting a focused and problem-solving approach to therapy with medically ill patients. For example, supportive therapies for medically ill children and adults in both group and individual settings have reduced psychiatric morbidity, and had measurable effects on the course of nonpsychiatric illnesses.

WHO COPES WELL?

There are few paragons who cope exceedingly well with all problems. For virtually everyone, psychiatrists included, sickness imposes a personal and social burden, threat, and risk; these reactions are seldom precisely proportional to the actual dangers of the primary disease. Therefore effective copers may be regarded as individuals with a special skill or with personal traits that enable them to master many difficulties. Characteristics of good copers are presented in Table 32–1. These characterizations are collective tendencies; they seldom typify any specific individual (except the heroic or the idealized). No one copes exceptionally well at all times, especially with problems that are associated with risk and that might well be overwhelming. However, effective copers appear able to choose the kind of situation in which they are most likely to prosper. In addition, effective copers often maintain enough confidence to feel resourceful enough to survive intact. Finally, it is our impression that those individuals who cope effectively do not pretend to have knowledge that they do not have; therefore they feel comfortable turning to experts that they trust. The better we can pinpoint which traits a patient seems to lack, the better we can help a patient cope.

WHO COPES POORLY?

Bad copers are not necessarily bad people, nor even incorrigibly ineffective people. In fact, it is too simplistic merely to indicate that bad copers have the opposite characteristics of effective copers. As was stressed earlier, each patient brings a unique set of cultural and psychological attributes that impacts the capacity to cope. Bad copers are those who have more problems in coping with unusual, intense, and unexpected difficulties because of a variety of traits. Table 32–2 lists some characteristics of poor copers.

TABLE 32–1 Characteristics of Good Copers

1. They are optimistic about mastering problems and, despite setbacks, generally maintain a high level of morale.
2. They tend to be practical and to emphasize immediate problems, issues, and obstacles that must be conquered, even before visualizing a remote or ideal resolution.
3. They select from a wide range of potential strategies and tactics, and their policy is not to be at a loss for fallback methods. In this respect, they are resourceful.
4. They heed various possible outcomes and improve coping by being aware of consequences.
5. They are generally flexible and open to suggestions, but they do not give up the final say in decisions.
6. They are composed, although vigilant, in avoiding emotional extremes that could impair judgment.

TABLE 32–2 Characteristics of Poor Copers

1. They tend to be excessive in self-expectation, rigid in outlook, inflexible in standards, and reluctant to compromise or to ask for help.
2. Their opinion of how people should behave is narrow and absolute; they allow little room for tolerance.
3. Although prone to firm adherence to preconceptions, they may show unexpected compliance or be suggestible on specious grounds, with little cause.
4. They are inclined to excessive denial and elaborate rationalization; in addition, they are unable to focus on salient problems.
5. Because they find it difficult to weigh feasible alternatives, they tend to be more passive than usual and they fail to initiate action on their own behalf.
6. Their rigidity occasionally lapses, and they subject themselves to impulsive judgments or atypical behavior that fails to be effective.

Indeed, structured investigations into the psychiatric symptoms of the medically ill have often identified many of the attributes of those who do not cope well. Problems such as demoralization, anhedonia, anxiety, pain, and overwhelming grief all have been documented in medical patients with impaired coping.

WHAT INTERFERES WITH OUR ABILITY TO ADAPT TO ILLNESS?

Adaptation to medical illness is affected by individual factors, by intrahospital factors, and by extrahospital factors[8]; understanding all three is crucial to an assessment of how an individual will adapt to illness. Individual (intrapersonal) factors include psychiatric diagnoses (including, but not limited to, depression, anxiety, delirium, dementia, substance abuse, posttraumatic stress disorder [PTSD], factitious disorders, somatoform disorders, and sleep disorders; their developmental stage, their experience with trauma, and their understanding of the illness). In addition, personality style and personality disorders (including histrionic, obsessive, paranoid, narcissistic, and borderline personality disorders) affect how a person copes with receiving bad news, how they interact with

medical staff, and how they communicate with others in their life.[8] Holland and colleagues described the "Five D's" when discussing what the illness means to a patient (e.g., distance [the interruption of interpersonal relationships], dependence [having to rely on others], disability [inability to achieve], disfigurement, and death).[9] Intrahospital factors include the characteristics of the illness (e.g., its time course, the intensity of pain, its impact on sleep, surgical interventions, and chemotherapy), whereas extrahospital variables (e.g., finances, housing, interpersonal relationships, and sociocultural/language barriers) are also key issues.[8]

THE ROLE OF RELIGION

The significance of religious or spiritual conviction in the medically ill deserves special mention. Virtually every C-L psychiatrist works with patients as they wrestle with existential issues (such as mortality, fate, justice, and fairness). Such ruminations cannot help but invoke religious considerations in both the patient and the physician; moreover, there is a growing appreciation in the medical literature for the important role that these considerations can play.

In some investigations, being at peace with oneself and with one's sense of a higher power was predictive of both physical and psychiatric recovery.[10,11] However, other studies have suggested that resentment toward God, fears of God's abandonment, and a willingness to invoke satanic motivation for medical illness were all predictive of worsening health and an increased risk of death.[12]

Because the C-L psychiatrist's role involves identification and strengthening of those attributes that are most likely to aid a patient's physical and emotional well-being, effective therapy for the medically ill involves exploration of the religious convictions of a patient; fostering those elements is most likely to be helpful. It is *never* the role of the physician to encourage religious conviction *de novo*. At the same time, ignoring religious content risks omitting an important element of the psychotherapeutic armamentarium.

THE MEDICAL PREDICAMENT—BRINGING IT ALL TOGETHER

Coping refers to how a patient responds and deals with problems within a complex of factors that relates to disease, sickness, and vulnerability. In approaching chronically ill patients, it is helpful to conceptualize *disease* as the categorical reason for being sick, *sickness* as the individual style of illness and patienthood, and *vulnerability* as the tendency to be distressed and to develop emotional difficulties in the course of trying to cope.

Given these definitions, the psychiatrist needs to first ask *why now*? What has preceded the request for consultation? How does the patient show his or her sense of futility and despair? How did the present trouble, both the medical and the corresponding coping challenges, come about? Was there a time when such problems could have been thwarted? It is also important to note that not infrequently the treatment team is even more exasperated than the patient. In these instances, one must guard against the assumption that it is only the patient who is troubled by the medical predicament.

In fact, if there is any doubt about the gap between how the staff and a patient differ in cultural bias and social expectations, one should listen to the bedside conversation. Good communication may not only reduce potential problems, but it actually help patients to cope better. Good coping is a function of empathic connection and respect between the patient and the doctor regarding the risks and points of tension related to treatment. The psychiatrist is not the sole vessel of professional concerns about coping, but has unique skills that are ideally suited to address the challenges of how patients cope. As already mentioned, much of chronic disease evokes existential issues (such as death, permanent disability, low self-esteem, dependence, and alienation); these are fundamentally psychiatric concerns.

Given all of this, it is important to remember that psychiatry does not arbitrarily introduce psychosocial problems. If, for example, a patient is found to have an unspoken, but vivid, fear of death or to be suffering from an unrecognized and unresolved bereavement, fear and grief are already there, not superfluous artifacts of the evaluation itself. Indeed, open discussion of these existential issues is likely to be therapeutic; active denial of their presence is potentially detrimental, because it risks empathic failure and the poor compliance that accompanies the course of patients who feel misunderstood or unheard.

Being sick is, of course, much easier for some patients than for others, and for certain patients, it is preferred over trying to make it in the outside world. There is too much anxiety, fear of failure, inadequacy, pathological shyness, expectation, frustration, and social hypochondriasis to make the struggle for holding one's own appealing. At key moments of life, sickness is a solution. Although healthy people are expected to tolerate defeat and to withstand disappointments, others legitimize their low self-esteem by a variety of excuses, denial, self-pity, and symptoms, long after other patients return to work. Such patients thrive in a complaining atmosphere and even blame their physicians. These are perverse forms of coping and they complicate the task of the hospital psychiatrist.

The clinician must also assess the motivation of staff and patients when a psychiatric intervention is requested. Additionally, clinicians need to be aware that the real question is not always the problem for which one is consulted. For example, the request for psychiatric consultation to treat depression and anxiety in a negativistic and passive–aggressive patient is inevitably more complicated than a simple recognition of certain key psychiatric symptoms. Those with primitive defenses can generate a profound sense of hopelessness and discomfort in their treaters. It is often an unspoken and unrecognized desire by physicians and ancillary staff that the psychiatrist shifts the focus of negativity and aggression onto himself or herself and away from the remaining treatment team. If the consulting psychiatrist is not aware of these subtleties, the intent of the consultation will be misinterpreted and the psychiatrist's efforts will ultimately fall short.

COPING AND SOCIAL SUPPORT

Every person needs, or at least deserves, a measure of support, sustenance, security, and self-esteem, even if they are not patients at all, but human beings encountered at a critical time.

In assessing problems and needs, the psychiatrist can help by identifying potential pressure points (e.g., health and wellness, family responsibility, marital and sexual roles, jobs and money, community expectations and approval, religious and cultural demands, self-image and sense of inadequacy, and existential issues) where trouble might arise.

Social support is not a hodgepodge of interventions designed to cheer up or straighten out difficult patients. Self-image and self-esteem, for example, depend on the sense of confidence generated by various sources of social success and support. In a practical sense, social support reflects what society expects and therefore demands about health and conduct.

Social support is not a "sometime" thing, to be used only for the benefit of those too weak, needy, or troubled to get along by themselves. It requires a deliberate skill that professionals can cultivate, in recognizing, refining, and implementing what any vulnerable individual needs to feel better and to cope better. In this light, it is not an amorphous exercise in reassurance, but a combination of therapeutic gambits opportunistically activated to normalize a patient's attitude and behavior. Techniques of support range from concrete assistance to extended counseling.[13,14] Their aim is to help patients get along without professional support. Social support depends on an acceptable image of the patient, not one that invariably "pathologizes." If a clinician only corrects mistakes or points out what is wrong, bad, or inadequate, then insecurity increases and self-esteem inevitably suffers.

COURAGE TO COPE

Most psychiatric assessments and interventions tend to pathologize, and to emphasize shortcomings, defects, and deviation from acceptable norms. Seldom does an examiner pay much attention to positive attributes (such as confidence, loyalty, intelligence, hope, dedication, and generosity). One of the commonly neglected virtues in clinical situations is that of courage.

Courage in a clinical sense should not be confused with "bravery under fire." The derring-do of heroes is seldom found among ordinary people, who usually have more than their share of anxiety and apprehension when facing unfamiliar, unknown, and threatening events. Threats are manifest on many levels of experience, ranging from actual injury to situations that signify failure, disgrace, humiliation, embarrassment, and so forth. In a sense, threat is "negative support" because it may do or undo everything that positive support is supposed to strengthen. It pathologizes. The courage to cope is a real but seldom recognized element in the attributes that affect the coping process. Nevertheless, in coping well, the courage to cope means a wish to perform competently and to be valued as a significant person, even when threatened by risk and anonymity.

Hope, confidence, and morale go together and can be directly asked about because most patients know what these terms mean without translation. Naturally, few people readily admit their tendency to fail, shirk, or behave in unworthy ways. Nevertheless, a skillful interview gets behind denial, rationalization, posturing, and pretense without evoking another threat to security or self-esteem.

Courage requires an awareness of risk as well as a willingness to go it alone despite a substantial degree of anxiety, tension, and worry about being able to withstand pressure and pain. Courage is always accompanied by vulnerability, but it engages itself in the courage to cope.

ASSESSMENT OF VULNERABILITY

Vulnerability is present in all humans, and it shows up at times of crisis, stress, calamity, and threat to well-being and identity.[15–21] How does a patient visualize threat? What is most feared, say, in approaching a surgical procedure, a diagnosis, anesthesia, possible invalidism, failure, pain, or abandonment (by one's physician or family)?

Coping and vulnerability have a loosely reciprocal relationship; the better one copes, the less distress he or she experiences as a function of acknowledged vulnerability. In general, a good deal of distress often derives directly from a sense of uncertainty about how well one will cope when called on to do so. This does not mean that those who deny or disavow problems and concerns are superlative copers. The reverse may be true. Courage to cope requires anxiety confronted and dealt with, not phlegmatic indifference to outcome.

Table 32–3 shows 13 common types of vulnerability. Table 32–4 describes how to find out about salient problems, the strategy used for coping, and the degree of the resolution attained.

TABLE 32–3 Vulnerability

Hopelessness:	Patient believes that all is lost; effort is futile; there is no chance at all; a passive surrender to the inevitable
Turmoil/ Perturbation:	Patient is tense, agitated, restless, hyperalert to potential risks, real and imagined
Frustration:	Patient is angry about an inability to progress, recover, or get satisfactory answers or relief
Despondency/ Depression:	Patient is dejected, withdrawn, apathetic, tearful, and often unable to interact verbally
Helplessness/ Powerlessness:	Patient complains of being too weak to struggle anymore; cannot initiate action or make decisions that stick
Anxiety/Fear:	Patient feels on the edge of dissolution, with dread and specific fears about impending doom and disaster
Exhaustion/Apathy:	Patient feels too worn out and depleted to care; there is more indifference than sadness
Worthlessness/ Self-rebuke:	Patient feels persistent self-blame and no good; he or she finds numerous causes for weakness, failure, and incompetence
Painful Isolation/ Abandonment:	Patient is lonely and feels ignored and alienated from significant others

Continued

TABLE 32–3 Vulnerability—*cont'd*

Denial/Avoidance:	Patient speaks or acts as if threatening aspects of illness are minimal, almost showing a jolly interpretation of related events, or else a serious disinclination to examine potential problems
Truculence/ Annoyance:	Patient is embittered and not openly angry; feels mistreated, victimized, and duped by forces or people
Repudiation of Significant Others:	Patient rejects or antagonizes significant others, including family, friends, and professional sources of support
Closed Time Perspective:	Patient may show any or all of these symptoms, but in addition foresees an exceedingly limited future

Seven different existential states were identified by Griffith and Gaby[22] that can be regarded as moving toward (resilience), or away from (vulnerability), assertive coping techniques (Table 32–5). They argued that an essential job of the psychiatrist is to help patients sustain characteristics of resiliency and to combat vulnerability. Confusion, defined as "an inability to make sense of one's situation," can be seen in patients who have delirium or dementia or for whom a clear medical diagnosis does not exist. Asking "How do you make sense of your experience?" can be helpful in organization, planning, and judging and can lead to the improved coherence. Communion, defined as the "felt presence of a trustworthy person," versus isolation can be assessed by asking, "Who do you believe understands your situation?" Despair, or hopelessness, has been associated with poor coping. Questions that assess hope include "What sorts of things keep you from giving up?" Feeling meaningless can be detrimental to one's ability to fight illness; questions that enhance purpose include "Who keeps you alive?" Agency, defined as "the sense that one can make meaningful choices and that one's actions matter," can combat helplessness by empowering patients to be heard by their doctors. Asking "What issues involved in your treatment concern you the most?" embraces a sense of agency and diminishes helplessness. Showing courage, as opposed to cowardice, in the face of fear, can be elicited by asking "Have there been times when you wanted to give up but you didn't?" Finally, experiencing a sense of gratitude rather than a sense of resentment can help combat feelings of depression and anxiety. The clinician can ask, "What things in your life are you most grateful for?" or "Has your illness taught you anything meaningful?"[22] While speaking with patients it is helpful to establish which of these areas of vulnerability can be improved upon.

The consulting psychiatrist frequently asks patients to fill out forms that provide an indication about their degree of anxiety, level of self-esteem, perceived illness, and so on. Although such queries are often sources of valuable information, these standardized inquiries are no substitute for careful and compassionate interviews. There is a strong element of social desirability present in any attempt to assess how a patient copes. How a patient deals with illness may not be the same as how he or she wishes to manage. Vulnerability, except in extreme forms (such as depression, anger, and anxiety), is difficult to characterize exactly, so the astute clinician must depend on a telling episode or metaphor that typifies a total reaction.

TABLE 32–4 How To Find Out How a Patient Copes

Problem:	**In your opinion, what has been the most difficult for you since your illness started? How has it troubled you?**
Strategy:	**What did you do (or are doing) about the problem?**
	Get more information (rational/intellectual approach)
	Talk it over with others to relieve distress (share concern)
	Try to laugh it off; make light of it (reverse affect)
	Put it out of mind; try to forget (suppression/denial)
	Distract myself by doing other things (displacement/dissipation)
	Take a positive step based on a present understanding (confrontation)
	Accept, but change the meaning to something easier to deal with (redefinition)
	Submit, yield, and surrender to the inevitable (passivity/fatalism)
	Do something, anything, reckless or impractical (acting out)
	Look for feasible alternatives to negotiate (if *x*, then *y*)
	Drink, eat, take drugs, and so on, to reduce tension (tension reduction)
	Withdraw, get away, and seek isolation (stimulus reduction)
	Blame someone or something (projection/ disowning/externalization)
	Go along with directives from authority figures (compliance)
	Blame self for faults; sacrifice or atone (undoing self-pity)
Resolution:	**How has it worked out so far?**
	Not at all
	Doubtful relief
	Limited relief, but better
	Much better; actual resolution

HOW TO FIND OUT MORE ABOUT COPING

Thus far, we have discussed the following: salient characteristics of effective and less effective copers, methods by which deficits in patients can be identified and how clinicians can intervene, potential pressure points that alert

TABLE 32–5 How to Assess Areas of Vulnerability Versus Resiliency

Confusion versus coherence	How do you make sense out of your experience?
Isolation versus communion	Who do you believe understands your situation?
Despair versus hope	What sorts of things keep you from giving up?
Helplessness versus agency	Who keeps you alive?
Meaninglessness versus purpose	What issues about your treatment concern you the most?
Cowardice versus courage	Have there been times when you wanted to give up but did not? What prevented you from giving up?
Resentment versus gratitude	What things in life are you most grateful for? Has your illness taught you anything meaningful?

Adapted from Griffith J, Gaby L: Brief psychotherapy at the bedside: countering demoralization from medical illness, *Psychosomatics* 46:109-116, 2005.

clinicians to different psychosocial difficulties, types of emotional vulnerabilities, and a format for listing different coping strategies, along with questions about resolutions and increasing resiliency.

The assessment and identification of ways in which a patient copes or fails to cope with specific problems requires both a description by the patient and an interpretation by the psychiatrist. Even so, this may not be enough. Details of descriptive importance may not be explicit or forthcoming. In these situations, the clinician must take pains to elucidate the specifics of each situation. If not, the result is only a soft approximation that generalizes where it should be precise. Indeed, the clinician should ask again and again about a topic that is unclear and rephrase, without yielding to cliches and general impressions.

Psychiatrists have been imbued with the value of so-called empathy and intuition. Although immediate insights and inferences can be pleasing to the examiner, sometimes these conclusions can be misleading and totally wrong. It is far more empathic to respect each patient's individuality and unique slant on the world by making sure that the examiner accurately describes in detail how problems are confronted. To draw a quick inference without being sure about a highly private state of mind is distinctly unempathic. Like most individuals, patients give themselves the benefit of the doubt and claim to resolve problems in a socially desirable and potentially effective way. It takes little experience to realize that disavowal of any problem through pleasant distortions is itself a coping strategy, not necessarily an accurate description of how one coped.

Patients who adamantly deny any difficulty tend to cope poorly. Sick patients have difficult lives, and the denial of adversity usually represents a relatively primitive defense that leaves such patients unprepared to accurately assess their options. Carefully timed and empathic discussion with patients about their current condition can help them address their treatment more effectively and avoid maladaptive approaches.

On the other hand, patients may attempt to disavow any role in their current illness. By seeking credit for having suffered so much, such patients reject any implication that they might have prevented, deflected, or corrected what has befallen them (see Table 32–4). Helping these patients does not necessarily require that they acknowledge their role in their particular predicament. Instead, the empathic listener identifies and provides comfort around the implicit fear that these patients harbor (i.e., that they somehow deserve their debilitation).

Suppression, isolation, and projection are common defenses. Effective copers seem to pinpoint problems clearly, whereas bad copers, as well as those with strong primitive defenses, seem to seek relief from further questions without attempting anything that suggests reflective analysis.

In learning how anyone copes, a measure of authentic skepticism is always appropriate, especially when it is combined with a willingness to accept correction later on. The balance between denial and affirmation is always uncertain. The key is to focus on points of ambiguity, anxiety, and ambivalence while tactfully preserving a patient's self-esteem. A tactful examiner might say, for example, "I'm really not clear about what exactly bothered you, and what you really did. …"

The purpose of focusing is to avoid premature formulations that gloss over points of ambiguity. An overly rigid format in approaching any evaluation risks overlooking individual tactics that deny, avoid, dissemble, and blame others for difficulties. Patients, too, can be rigid, discouraging alliance, rebuffing collaboration, and preventing an effective physician–patient relationship.

HOW TO BE A BETTER COPER

Coping with illness is only one special area of human behavior. It is important to recognize that in evaluating how patients cope, examiners should learn about their own coping styles and, in effect, learn from patients. Clearly, it is not enough to mean well, to have a warm heart, or to have a head filled with scientific information. Coping well requires open-ended communication and self-awareness. No technique for coping is applicable to one and all. In fact, the concept of technique may be antithetical to true understanding. A false objectivity obstructs appraisal; an exaggerated subjectivity only confuses what is being said about whom.

Psychiatrists and patients can become better copers by cultivating the characteristics of effective copers. Coping is, after all, a skill that is useful in a variety of situations, although many modifications of basic principles are called for. Confidence in being able to cope can be enhanced only through repeated attempts at self-appraisal, self-instruction, and self-correction. Coping well with illness—with any problem—does not predict invariable success, but it does provide a foundation for becoming a better coper.

ADDITIONAL PSYCHOTHERAPEUTIC TECHNIQUES IN THE MEDICALLY ILL POPULATION

Cognitive-behavioral therapy (CBT) is a structured and often short-term psychotherapeutic modality that has been effective in the treatment of many psychiatric conditions (including anxiety, depression, PTSD, and suicidal crises); it is a technique that involves assessment of the relationship among a patient's cognitive process, emotions, and behaviors. More recent literature has shown its efficacy in reducing anxiety and depression associated with a host of medical conditions (including cancer, chronic pain, and HIV infection). Typically, such research has assessed its efficacy in the outpatient setting; however, the psychiatrist in an inpatient medical setting can also use these techniques.

In a meta-analysis of various psychosocial interventions for the treatment of anxiety and depression in cancer patients, Osborn and associates[23] found that limited CBT treatment was effective for the treatment of depression and anxiety over the short term and that quality-of-life measures improved over both the short- and long-term analyses. More recently the combination of CBT and hypnosis effectively decreased negative affect and improved positive affect in breast cancer patients receiving radiation therapy.[24] CBT changed maladaptive cognitions and behaviors in these patients while leading to more adaptive cognitive process; hypnosis (involving direct suggestion of decreasing negative affect and increasing positive affect) also led to improvement. In those infected with HIV, rates of depression are high, and co-morbidity is associated with increased rates of risky behaviors, poorer disease outcome (e.g., with a decreased CD4 count, an increased viral load, an increased progression to AIDS, and an increased mortality rate), and poor treatment adherence. In a recent randomized clinical trial, CBT improved adherence and decreased depressive symptoms in a significant proportion of patients.[25] Multiple studies support the efficacy of CBT in those with chronic pain; this may result from altering perceived pain control, self-efficacy, and psychological distress (including depression and anxiety).[26]

A recent meta-analysis (by Chida and colleagues[27]) demonstrated that stress-related psychological factors led to increased rates of cancer incidence in healthy people, decreased survival in patients with cancer, and increased cancer mortality; this may be related to the chronic stress that cancer imposes on the body and to abnormalities in catecholamine and glucocorticoid secretion, with subsequent suppression in the immune response. Many psychosocial interventions (including group psychotherapy) may lead to improvements in cancer-related mortality; however, this remains controversial. Data from an 11-year follow-up study of breast cancer patients (by Anderson and associates[28]) showed that psychosocial interventions (including groups that taught about muscle relaxation, communication, diet, treatment compliance, coping with medication side effects, and problem-solving) led not only to improvements in distress level, quality of life, and health behaviors, but also led to decreased cancer recurrence and cancer mortality. Others have argued that group psychotherapy, and other psychosocial interventions, do not affect cancer recurrence or mortality rates.[29] The debate regarding the impact on mortality in cancer and other chronic medical conditions of psychosocial interventions remains; however, most authors agree that group psychotherapy helps patients as it improves depression, anxiety, and quality of life. This modality remains another critical psychotherapeutic technique to offer to the medically ill.

Electroconvulsive Therapy in the General Hospital

33

Charles A. Welch, M.D.
Carlos Fernandez-Robles, M.D.
Cristina Cusin, M.D.

Electroconvulsive therapy (ECT) remains an indispensable treatment in the general hospital because of the large number of depressed patients who are unresponsive to drugs or intolerant of their side effects. In the largest clinical trial of antidepressant medication, only 67% of depressed patients achieved a full remission, and the rest were nonresponders or achieved only partial remission.[1] On the other hand, remission rates of 70% to 90% have been reported in clinical trials of ECT for depression.[2,3] Depression requires effective treatment because it is associated with morbidity and an increased risk of mortality (mainly due to cardiovascular events or suicide).[4] Furthermore, among all diseases, depression currently ranks fourth in global disease burden, and it is projected to rank second by the year 2020.[5] ECT is currently the most promising prospect for addressing the unmet worldwide need for effective depression treatment.

INDICATIONS

The symptoms that predict a good response to ECT are those of major depression: anorexia, weight loss, early morning awakening, impaired concentration, pessimistic mood, motor restlessness, increased speech latency, constipation, and somatic or self-deprecatory delusions.[6,7] The cardinal symptom is the loss of interest in activities that formerly gave pleasure. These are exactly the same symptoms that constitute an indication for antidepressant drugs. At the present time, there is no way to predict which patients will ultimately be drug resistant. Currently, there is little consensus on the definition of drug-resistant depression,[8] and the designation of drug failure varies with the adequacy of prior treatment.[9] Medical co-morbidities also affect this definition. Young, healthy, nonsuicidal patients can safely receive four or more different drug trials before embarking on a course of ECT, whereas older patients with depression may be unable to tolerate more than one drug trial without developing serious morbidity.

Other factors also affect the decision to move from drug therapy to ECT. Thoughts of suicide respond to ECT 80% of the time,[10] and they are an indication for an early transition from drug therapy.[11] Lower response rates to ECT have been reported in depressed patients with a co-morbid personality disorder[12] and with a longer duration of depression,[13] but there are conflicting reports as to whether a history of medication resistance is associated with a lower response rate to ECT. However, if neurovegetative signs are present, none of these factors constitutes a reason to avoid ECT.

Psychotic illness is the second indication for ECT. Although it is not a routine treatment for schizophrenia, ECT, in combination with a neuroleptic, results in sustained improvement in up to 80% of drug-resistant patients with chronic schizophrenia.[14,15] Furthermore, a recent review found preliminary evidence that supports the safety and short-term efficacy of clozapine and ECT in patients with schizophrenia or schizoaffective disorder.[16] A subgroup of young psychotics conforming to the schizophreniform profile (acute onset, affective intactness, and family history of affective disorder) appear to be more responsive to ECT, often developing a full and enduring remission of their illness, than those with chronic schizophrenia.[17–19]

Mania is also known to respond to ECT,[20,21] but drug treatment remains the first-line therapy. Nevertheless, in controlled trials, ECT has been as effective as lithium (or more so), and in drug-refractory mania, more than 50% of cases have remitted with ECT.[22] A recent review found that ECT is an effective, safe, and probably underutilized treatment for those with mixed affective states.[23] Preliminary evidence also shows that ECT stabilizes refractory bipolar disorder in adolescents and the elderly.[24,25]

Although most patients initially receive a trial of medication regardless of their diagnosis, ECT is a primary treatment for several categories of patients:

1. Mood-disordered patients who are severely malnourished, dehydrated, and exhausted. Such patients with protracted depressive illness are medically at risk and should be treated promptly after careful rehydration.
2. Patients with complicating medical illness (e.g., cardiac arrhythmias or coronary artery disease). Such patients are often more safely treated with ECT than with antidepressants.
3. Patients with delusional depression. Although most delusionally depressed patients do not improve on an antidepressant alone,[26] the reported response rate with ECT in delusional depression is 80% to 90%.[27–29] The combination of a tricyclic antidepressant (TCA) and an antipsychotic may be effective,[30] but many patients cannot tolerate the side effects of this regimen.
4. Patients who have been unresponsive to medications during previous episodes.
5. Patients with catatonia (see Chapter 21); the majority of patients with catatonia respond promptly to ECT.[31–33]

Although catatonia is most often associated with affective disorders, it may also be a manifestation of schizophrenia, metabolic disorders, structural brain lesions, or systemic lupus erythematosus. Prompt treatment is essential, because the mortality in untreated catatonia is as high as 50%; even its nonfatal complications (including pneumonia, venous embolism, limb contracture, and decubitus ulcer) are serious. ECT is effective in up to 75% of patients with catatonia, regardless of the underlying cause, and it is a primary treatment for most patients with catatonia.[34] Lorazepam has also been effective for the short-term treatment of catatonia,[35] but its long-term efficacy has not been confirmed. At times, neuroleptic malignant syndrome (NMS) may be clinically indistinguishable from catatonia,[36] although high fever, opisthotonos, and rigidity are more common in the former. More than 50 case reports suggest that ECT is effective for NMS, even when drug therapy has failed,[37] but the essential components of management are intensive (supportive) medical treatment, discontinuation of neuroleptics, and use of dantrolene and bromocriptine.

Several case reports and case series have suggested that ECT can be effective for the treatment of behavioral disturbances, aggression, and pathologic yelling associated with severe dementia (that has been unresponsive to several medication trials).[38–42] Because of the risk of cognitive impairment associated with ECT, a careful discussion of the risks and benefits of this treatment modality in those with dementia must take place before a course of ECT is attempted. Depressed patients with preexisting dementia are likely to develop especially severe cognitive deficits after ECT; fortunately, most individuals return to their baseline level of cognition after treatment, and many actually improve.[43,44]

ECT has also been useful in the treatment of myriad medical conditions. Several case reports, case series, and open trials have documented the efficacy of ECT in treatment of motor symptoms in patients with Parkinson's disease (both with and without concurrent psychiatric illnesses).[45–48]

In addition, ECT has been effective in the treatment of delirium due to toxic or metabolic encephalopathies,[49,50] and in the control of intractable pain (secondary to neuropathic pain, fibromyalgia, and complex regional pain syndrome, among other syndromes).[51–54]

RISK FACTORS FOR ADVERSE EVENTS

As the technical conduct of ECT has improved, factors that were formerly considered absolute contraindications have become relative risk factors. The patient is best served by weighing intelligently the risk of treatment against the morbidity or lethality of remaining depressed. The prevailing view is that there are no longer any absolute contraindications to ECT; however, several conditions warrant careful work-up and management when ECT is considered.[55]

Without question, the heart is physiologically stressed during ECT.[56] Cardiac work increases abruptly at the onset of the seizure, initially because of sympathetic outflow from the diencephalon, through the spinal sympathetic tract, to the heart. This outflow persists throughout the seizure and is augmented by a rise in circulating catecholamine levels that peak about 3 minutes after the onset of seizure activity.[57,58] After the seizure ends, parasympathetic tone remains strong, often causing transient bradycardia and hypotension, with a return to baseline function after 5 to 10 minutes.

The cardiac conditions that most commonly worsen under this autonomic stimulus are ischemic heart disease, hypertension, congestive heart failure (CHF), and cardiac arrhythmias., However, if properly managed, these conditions have proved to be surprisingly tolerant to ECT. Duration of the QTc in the baseline electrocardiogram (ECG) appears to be a helpful predictor of arrhythmias during ECT.[59] The idea that general anesthesia is contraindicated within 6 months of a myocardial infarction has acquired a certain sanctity; this is surprising considering the ambiguity of the original data.[60] A more rational approach involves careful assessment of the cardiac reserve, a reserve that is needed as cardiac work increases during ECT.[61] Vascular aneurysms should be repaired, if possible, before ECT[62,63]; however, more than 30 case reports have documented the safe use of ECT in the presence of intracranial and aortic aneurysms, stressing the importance of blood pressure control in this situations.[64–66] Case reports and one case series have also demonstrated safe ECT administration to patients with moderate to severe aortic stenosis and preserved left ventricular function,[67–69] but, if possible, critical aortic stenosis should be surgically corrected before a course of ECT (to avoid ventricular overload during the seizure). Patients with cardiac pacemakers are known to tolerate ECT uneventfully: safety precautions should include proper grounding of all monitoring devices, insulating the patient's stretcher, ensuring that the patient is not touched by somebody who is in ground contact during presentation of the electrical stimulus. Also a magnet should be available, in the unlikely event of pacemaker inhibition and symptomatic bradycardia, to convert the pacemaker from demand mode to fixed mode. The current recommendation for patients with an automatic implantable cardioverter defibrillator is to turn it off during ECT, to carefully monitor the rhythm, and to have an external defibrillator available.[70] Patients with compensated CHF generally tolerate ECT well, although a transient (5 to 10 minutes) decompensation into pulmonary edema may occur in patients with a baseline ejection fraction below 20%. It is unclear whether the underlying cause is a neurogenic stimulus to the lung parenchyma or a reduction in cardiac output because of increased heart rate and blood pressure. A retrospective study examining blood pressures before and after ECT in hypertensive and nonhypertensive patients concluded that a course of ECT does not worsen blood pressure in hypertensive patients beyond the time around the treatment period.[71]

The brain is also physiologically stressed during ECT. Cerebral oxygen consumption approximately doubles, and cerebral blood flow increases several-fold. Intracranial pressure increases and the blood–brain barrier becomes more permeable during ECT. These acute changes may increase the risk associated with ECT in patients with a variety of neurologic conditions.[72]

In years past, space-occupying brain lesions were considered an absolute contraindication to ECT, and case reports described clinical deterioration when ECT was given to patients with brain tumors.[73] Now, the general

consensus is that if a lesion is relatively small, solitary, and not associated with significant mass effect, edema, or increased intracranial pressure, ECT probably does not present a greater than usual risk of neurologic deterioration; however, a large mass, multiple masses (e.g., metastatic lesions), edema, increased intracranial pressure, or mass effect should be considered relative contraindications for ECT, and measures should be taken to reduce edema and the increase in intracranial pressure if treatment is undertaken.[74] The most common intracranial risk factor is probably recent cerebral infarction. Case reports of ECT after recent cerebral infarction indicate that, when the treatment is properly performed, the complication rate is low.[72] Consequently, ECT is often the treatment of choice for poststroke depression.[75] The interval between infarction and treatment with ECT should be determined by the urgency and need for depression treatment.

ECT has been safe and efficacious in patients with hydrocephalus, arteriovenous malformations, cerebral hemorrhages, multiple sclerosis, systemic lupus erythematosus, Huntington's disease, and mental retardation. ECT also appears to be safe in patients with asthma[76]; recent guidelines recommend the administration of prescribed inhalers (to patients with chronic obstructive pulmonary disease) on the morning of the ECT treatment. However, caution is recommended when performing ECT on patients taking theophylline, because this drug has been associated with prolonged seizures and status epilepticus.[77]

A severely depressed pregnant mother may require ECT to prevent malnutrition or suicide. Limited data indicate that ECT is an effective treatment for severe mental illness during pregnancy and that the risks to the fetus and to the mother from ECT are low.[78] Preparation for ECT during pregnancy should include a pelvic examination, discontinuation of nonessential anticholinergic medications, uterine tocodynamometry, IV hydration, and administration of a nonparticulate antacid. During ECT, elevation of the pregnant woman's right hip, external fetal cardiac monitoring, intubation, and avoidance of excessive hyperventilation are recommended.[79] The fetus may be protected from the physiologic stress of ECT by virtue of its lack of direct neuronal connection to the maternal diencephalon, which spares it the intense autonomic stimulus experienced by maternal end organs during the ictus.

Last, depolarizing muscle relaxants, such as succinylcholine, may generate adverse effects in patients with certain conditions (e.g., myasthenia gravis, amyotrophic lateral sclerosis, genetic or acquired pseudocholinesterase deficiency, and NMS). In such conditions, a substitute nondepolarizing agent appears indicated. Barbiturates are considered unsafe in patients with porphyria; they should receive alternative anesthetics.[80]

TECHNIQUE

The routine pre-ECT work-up should include a thorough medical history and physical examination, with a chest film, ECG, urinalysis, complete blood cell count, and determination of blood glucose, blood urea nitrogen, and electrolyte levels. Additional studies may be necessary, at the clinician's discretion. In patients with cognitive deficits, it is sometimes difficult to decide whether a CNS work-up is indicated because depression may cause this deficit. A metabolic screen, a computed tomography scan, and magnetic resonance imaging are often useful to rule out non–depression-related causes of impaired cognition. Whenever a question of primary dementia arises, neurologic consultation should be requested; neuropsychological testing does not definitively distinguish between primary dementia and depressive pseudodementia.[81]

If at all possible, the patient's medical condition should be optimized before beginning ECT. Elderly patients often arrive at the hospital severely malnourished and dehydrated, and ECT should be delayed until they have had several days of rehydration, with alimentation via feeding tube if necessary. If a patient is receiving digitalis, its serum level should be in the middle to low therapeutic range. Antihypertensive regimens should be optimized before treatment to reduce the chance of developing a severe hypertensive reaction. Most patients with diabetes are more stable if their morning dose of insulin is held until after their ECT treatment. The insulin requirement usually decreases as a diabetic patient recovers from depression, and blood glucose levels must be monitored frequently during the course of ECT.

The issue of whether to combine a psychotropic medication with ECT is a matter of much speculation; little controlled research has been conducted on this issue. In general, a patient should be taken off medications that have not been beneficial despite adequate dosage and duration of therapy. Older case reports cautioned that patients undergoing ECT who are concomitantly taking lithium may be particularly prone to severe cognitive disturbance, to prolonged time to awakening or breathing, or to prolonged or spontaneous seizures; however, a more recent case series indicated that the combination may be used safely and with optimal efficacy in certain clinical circumstances.[82] For the bipolar patient already taking lithium, the clinician must consider the risk of mania if lithium is abruptly discontinued, or that the washout of lithium in anticipation of starting ECT will delay treatment. Benzodiazepines, which are antagonistic to the ictal process, should also be decreased or discontinued whenever possible.[83] For sedation, patients receiving ECT usually tolerate a sedating phenothiazine, such as perphenazine (Trilafon) 4 to 8 mg every 6 hours, or a nonbenzodiazepine hypnotic, such as hydroxyzine (Vistaril) 50 to 100 mg, or diphenhydramine (Benadryl) 25 to 50 mg twice daily. TCAs make cardiovascular management more difficult and they should be discontinued. Monoamine oxidase inhibitors (MAOIs) are typically withheld, as the potential adverse interactions between MAOIs and ECT include effects on the induced seizure itself and interactions with the medications used for anesthesia (anticholinergic agents, anesthetic induction agents, muscle relaxants, antihypertensives, and narcotics); a washout period before ECT is unnecessary.[84] In the patient with a preexisting seizure disorder, anticonvulsants should be maintained for patient safety and the elevated seizure threshold overridden with a higher-intensity stimulus.

Because of the profound physiologic disturbances unique to this treatment, ECT should not be performed in collaboration with an anesthesiologist unfamiliar with the techniques and the cardiovascular effects of ECT. Although ECT was formerly thought to be a trivial exercise in anesthetic management, quite the contrary is true, and a careful

reading of the literature is essential for the anesthesiologist.[85,86] The use of cardiac monitoring and pulse oximetry on all patients undergoing general anesthesia has been endorsed by the American Society of Anesthesiologists. Existing ECT machines record the ECG only during the treatment itself; however, recording of baseline and postictal rhythms is essential, and a separate operating room monitor with paper recording capability is necessary to monitor the ECG adequately.

General anesthesia is induced with methohexital or propofol; succinylcholine is used to achieve muscle relaxation. Anticholinergics, such as atropine or glycopyrrolate, have long been used in ECT to eliminate parasympathetically mediated dysrhythmias. However, such agents increase heart rate and myocardial workload and may increase the risk of adverse cardiac events. Therefore, anticholinergics are not routinely administered, and their use is reserved for patients who are prone to bradycardia.[87]

For patients with coronary artery disease or hypertension, short-acting IV β-blockers effectively reduce stress on the heart. These agents attenuate hypertension, tachycardia, ectopy, and cardiac ischemia, and with proper use they rarely result in hypotension or bradycardia. Esmolol 100 to 200 mg or labetalol 10 to 20 mg given IV immediately before the anesthetic induction is usually sufficient.[88] Although these drugs may result in decompensation of CHF, this has yet to be reported. A second method of reducing cardiac work involves administration of nifedipine 10 mg sublingually, 15 minutes before treatment.[89] Nitroglycerine, infused at 0.5 to 3.0 mg/kg per min, may be used to blunt the hypertensive response of patients who are already receiving β-blockers or calcium channel blockers and who require additional antihypertensives. If an infusion is used, the patient must be observed for hypotension at the first treatment, at the very least.

Treating hypertension adequately before a course of ECT usually reduces the hypertensive response during the treatment itself. Maintenance β-blockers, such as atenolol 25 to 50 mg, orally every day, may render the use of a short-acting antihypertensive during treatment unnecessary.

Patients with cardiac disease have a significantly higher rate of cardiac complications during ECT.[90] Conduction system abnormalities during treatment have been reported in 20% to 80% of ECT patients,[91] but they are usually transient. Persistent or severe arrhythmias occasionally require treatment; the approach depends on the type of arrhythmia. Supraventricular tachycardia is generally best treated with calcium channel blockers, whereas ventricular ectopy is most rapidly stabilized with IV lidocaine. Many arrhythmias can be prevented by pretreatment with a short-acting IV β-blocker before subsequent treatments.

Decompensation of CHF is usually treatable with oxygen and elevation of the head. Occasionally, IV furosemide (Lasix) and morphine become necessary, but this is extremely rare. Most patients recompensate within 10 to 15 minutes of the treatment without aggressive intervention.

Cardiac arrest is a rare complication of ECT. Some patients have a period of asystole after the ECT stimulus that may last up to 8 seconds, and this may be mistaken for a true arrest.[56,92] Patients who receive nonconvulsive stimuli may be especially at risk, because the intense parasympathetic outflow caused by the stimulus is not counteracted by the sympathetic outflow of the seizure itself, and severe bradycardia or arrest may ensue.

There are a few large studies of the morbidity and mortality associated with ECT.[93,94] A recently published retrospective review of 2279 patients, who went through a total of 17,394 ECT treatments, reported that 21 of them (0.92%; 95% confidence interval, 0.57%-1.41%) experienced a complication at some time. Cardiac complications, mostly arrhythmias, constituted the majority, but none of the complications caused permanent injury, and none of the patients died during or immediately after ECT.

The choice of electrode placement in ECT remains controversial. Both right unilateral (RUL) and bilateral (BL) placements have advantages and disadvantages. RUL ECT causes less cognitive impairment than BL ECT, but its efficacy is not as great as that of BL ECT (the latter being indicated as first choice for those with more severe depression and for patients with poor response to RUL).[7,95] At Massachusetts General Hospital, unilateral nondominant ECT is used at the outset for all patients, with the exception of patients with treatment-resistant mania. Approximately 5% of depressed patients at this hospital prove refractory to 6 to 12 unilateral treatments; when that occurs, they are switched to ECT with a BL electrode placement. Ineffective unilateral ECT is associated with use of threshold stimulus intensity[96] and a short distance between electrodes.[97] Consequently, a unilateral stimulus should be at least 50% above the threshold with the electrodes placed in the d'Elia position.[96]

Brief-pulse waveforms have become the standard of practice in the United States. Although sine-wave stimuli were common in years past, the brief-pulse waveform more efficiently induces seizure activity and is associated with less posttreatment confusion and amnesia.[59] Ultrabrief pulse-width (0.3 msec) right unilateral (known as RUL-UB) ECT, for selected patients, can minimize cognitive effects while preserving efficacy.[98]

The schedule of administration is usually three times a week, even if a few studies postulated that ECT twice weekly was as effective in alleviating depression as ECT delivered three times weekly. Although this schedule of treatment induces less memory impairment, the improvement is slower[99]; Kellner and colleagues[100] found that decreasing the frequency of ECT administration to once a week slowed the antidepressant effect to a clinically unacceptable level.

Generalization of the seizure to the entire brain is essential for efficacy.[101] The simplest way to monitor seizure generalization is to inflate a blood pressure cuff on the arm or ankle to above the systolic pressure, just before injection of succinylcholine. The convulsion can then be observed in the unparalyzed extremity. In unilateral ECT, the cuff is placed on the limb ipsilateral to the stimulus. Most ECT instruments have a built-in, single-channel electroencephalographic monitor, but this is not a reliable indicator of full seizure generalization, because partial seizures may also generate a classic seizure tracing. No consistent relationship has ever been detected between the clinical antidepressant response to ECT and either the threshold or the duration of the induced seizure.[102]

After ECT, patients should not be left in the supine position; instead, they should be turned on their side to allow better drainage of secretions. They should be monitored

carefully by a recovery nurse; vital signs should be taken regularly and pulse oximetry monitored. About one in 20 patients, typically young, healthy individuals, develop an agitated delirium with a vacant stare, disorientation, and automatisms immediately after treatment. This clinical picture is usually the result of tardive seizures; the state clears promptly with midazolam 2 to 5 mg IV, or diazepam 5 to 10 mg IV.

The average number of ECT procedures necessary to treat major depression is consistently reported to be between 6 and 12, but occasional patients require up to 30. The customary timing is three sessions per week with one full seizure per session. The use of more than one seizure per session (multiple-monitored ECT) has not shown any advantage over conventional ECT.[103]

ADVERSE COGNITIVE EFFECTS

Although there is no evidence for structural brain damage as a result of ECT,[104] there are important effects on cognition.[105] Posttreatment confusion and general disorientation in the immediate period after ECT is a well-documented and common occurrence; it is associated with bilateral electrode placement, high stimulus intensity, inadequate oxygenation, prolonged seizure activity, older age, and the presence of neurologic disease. It has also been shown to resolve in a predictable fashion. In addition to the discrete periods of post-ECT disorientation, which are relatively frequent, longer and more severe confusional states (generally classified as delirium) can occur. Such post-ECT delirium is more common in older patients and in those with an underlying neurologic condition.[106]

The most common cognitive side effect is difficulty recalling new information (anterograde amnesia), which normally resolves within a month after the last treatment. Evidence suggests that autobiographical memory impairment also occurs as a result of ECT. Objective measures have found memory loss to be relatively short term (<6 months after treatment), whereas subjective accounts have reported amnesia to be more persistent (>6 months after ECT). ECT predominantly affects memory of prior personal events that are near the treatment date,[107] with BL ECT causing more memory disturbance than RUL ECT; this holds true for both retrograde and anterograde memory function and for both verbal and nonverbal recall.[108] The least memory deficit is seen with a unilateral brief and ultra-brief pulse stimulus.[109]

Development of a severe organic brain syndrome after ECT is rare, and it may require discontinuation of treatment. Usually, substantial improvement occurs within 48 hours of the last treatment; if symptoms become more severe after cessation of treatment, a full neurologic workup is indicated to assess whether there is an underlying cause other than ECT.

MAINTENANCE TREATMENT

After successful treatment, the risk of relapse is greater than 50% at 12 months without the use of maintenance medication.[110] A few prospective studies have provided mixed results with TCA maintenance.[111,112] The efficacy of maintenance with MAOIs, lithium, bupropion, or fluoxetine has never been evaluated in a well-controlled trial. In general, maintenance ECT (i.e., one treatment per month, on average) has been efficacious, safe, well tolerated, and cost effective compared with maintenance pharmacotherapy,[113–115] with its greatest impact consisting of reducing relapse, recurrence, and rehospitalization in treatment-resistant patients. A recently published multicenter, randomized, controlled trial showed similar efficacy for continuation ECT or nortriptyline plus lithium at 6 months, with more than half of the patients either experiencing disease relapse or dropping out of the study.[116]

SUMMARY

In recent years, the technique of ECT has become more sophisticated,[117] and this has made the treatment safer in the general hospital setting, where growing numbers of high-risk patients are seen. Increasingly, the practice of ECT is regarded as a distinct subspecialty that requires specific training and privileges.[118] In view of its efficacy in patients unresponsive to medication, it is likely that ECT will be an essential part of psychiatry in the general hospital for the foreseeable future.

The psychiatrist in the general medical setting faces many challenges posed by co-morbid medical disorders and concurrent medications that hinder the detection of psychiatric symptoms and alter the effectiveness, tolerability, and safety of psychiatric drug treatment.[1–4] Most clinical trials designed to establish the efficacy and safety of psychotropic medications exclude persons who suffer from unstable nonpsychiatric medical conditions or who take nonpsychiatric medications with appreciable central nervous system (CNS) effects. Fortunately, inroads are being created, as controlled multicenter pharmacotherapy trials are gradually extended to subjects with unstable medical illnesses[5] and large effectiveness trials in psychiatry are designed to allow participation of patients in primary care settings who have co-morbid medical illness and complex medical regimens.[6] As a guide to making informed decisions about use of psychotropic medication in the medical setting, this chapter focuses on principles of psychopharmacologic practice and on the rapidly expanding knowledge base regarding pharmacokinetics and drug–drug interactions. This chapter also reviews some of the important psychiatric uses of nonpsychiatric medications that have emerged.

PRINCIPLES OF PSYCHOPHARMACOLOGIC PRACTICE

The complicated clinical and psychosocial contexts in which psychotropic medications are often administered in the general hospital call on a sound understanding of basic principles that underlie the practice of psychopharmacology.[7] If pharmacologic efforts fail to achieve their intended goals, a review of these principles often helps to uncover potential explanations and to redirect treatment.

Initiating Treatment

The appropriate use of psychotropic medications starts with as precise a formulation of the diagnosis as possible. The use of an antidepressant alone for a depressed college student presenting to an emergency department might be appropriate if the diagnosis is of a major depressive episode; less pertinent if the diagnosis is of an adjustment disorder; and seriously inadequate and quite possibly harmful if the diagnosis is of a bipolar disorder, psychotic depression, or cocaine or alcohol abuse. As a rule, it is best to defer pharmacologic treatment until a good working diagnosis can be reached. The establishment of a psychiatric diagnosis, however, often requires longitudinal assessment of course and treatment response. Many symptoms of psychiatric disorders may be obscured or altered by co-occurring medical conditions. Therefore, in acute clinical situations, it is often not possible to defer the implementation of psychotropic medications until a diagnosis is fully clarified. In this context, it is particularly crucial to document probable and differential diagnosis, to outline the rationale for selecting a particular treatment over others, and to indicate the kind of information needed to achieve greater diagnostic certainty. When a disorder appears to present in a subsyndromal form, such as minor depression, the rationale for proceeding with psychopharmacologic treatment should be well defined.

The identification of a particular set of target symptoms plays an integral role in establishing a pretreatment baseline and in later efforts to monitor the success of treatment. These symptoms might include anger attacks, insomnia, anhedonia, delusions of reference, hallucinations, or the frequency and intensity of suicidal longings. The identification of target symptoms serves to focus attention on the symptoms that are causing greatest danger, disability, and distress to the patient while also more fully informing the patient about the core symptoms of his or her illness and the specific goals for which psychotropic medications have been recommended.

For some conditions, clinician-rated instruments, such as the Brief Psychiatric Rating Scale,[8] the Hamilton Rating Scale for Depression,[9] the Hamilton Rating Scale for Anxiety,[10] and the Young Mania Scale,[11] provide useful, well-studied templates for the serial assessment of relevant symptoms. In addition, the patient and family or other caregivers can be recruited in formal efforts to monitor progress. In the case of episodic or complex presentations, the use of daily mood charts, patient-rating scales such as the Quick Inventory for Depressive Symptomatology,[12] or behavioral logs—analogous to patient monitoring of blood pressure or glucose—can reveal temporal patterns (e.g., rapid mood cycling) and associations (e.g., to menstrual cycle or medication changes) that are not apparent cross-sectionally during office or bedside visits.

Along with the assessment of target symptoms, evaluation of current levels of function and subsequent changes with treatment relevant to quality of life are an integral part of good psychopharmacologic practice. Thus, for example, for an outpatient, the clinician might query about improvement in work or school function, family and other

social relationships, and use of leisure time, whereas for an inpatient, progress in the level of independence and reduction in the overall degree of anguish can help confirm the adequacy of treatment, because lack of improvement along these dimensions directs attention to residual symptoms or to problems not initially apparent.

The Global Assessment of Function scale, a routine part of *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) multiaxial assessment, provides a composite index of symptoms and dimensions that pertain to quality of life, which is useful for documenting treatment course over time.[13] Some clinicians also make use of the Clinical Global Impression (CGI) scale.[14] This scale, widely used in clinical trials, rates severity of disease on a scale of 1 to 7 (from normal to most extreme) and improvement on a scale of 1 to 7 (from very much improved to very much worse) and provides another simple quantitative means to document overall treatment outcome.

The understanding that a patient's psychiatric condition is influenced by psychosocial factors does not imply that psychotropic medications should be withheld. A major depression evolving in the setting of a spouse's chronic illness or panic attacks emerging in the weeks following the breakup of a significant relationship may well be as severe and as responsive to pharmacologic treatment as the same disorders that developed in other patients without similar precipitants. Vague referrals to counseling do not constitute sufficient treatment under such circumstances and may be viewed by patients as dismissive. If psychotherapy is recommended and pharmacotherapy deferred, the referral to psychotherapy—whether, for example, to individual cognitive therapy, to couples therapy, or to a pain management group (i.e., behavioral treatment)—must be viewed with the same deliberateness as the prescription of medication, and it should include a plan for follow-up. If substantial progress is not made within a clinically appropriate time frame (e.g., no more than 8 to 12 weeks for a moderately severe episode of major depression) then the adequacy of the psychotherapy should be re-evaluated. Severity, chronicity, and risk of recurrence of symptoms are often more relevant in determining the need for pharmacotherapy of psychiatric conditions than the presence of aggravating life circumstances or a caricatured description of illness as chemical or reactive.

Reciprocally, the expanding range of safe and well-tolerated psychotropic agents, such as the selective serotonin reuptake inhibitors (SSRIs) and other newer antidepressants, does not alter the imperative to explore the use of nonmedication interventions whenever medications are considered. An assessment of a patient for psychiatric medications should include an equally careful evaluation for other targeted interventions instead of, or in addition to, pharmacotherapy or psychotherapy. Often uniquely helpful are judicious referrals to parenting classes; elder care; Alcoholics Anonymous, Narcotics Anonymous, and Al-Anon; vocational assessment and rehabilitation; support groups for persons who are bereaved, who are going through separation, and who have medical disorders (e.g., epilepsy, human immunodeficiency virus [HIV] infection); and psychiatric self-help groups, such as those sponsored by the National Manic-Depressive and Depressive Association (MDDA).

Patient education and informed consent are important legal and ethical imperatives that are also critical to the success of a course of treatment with psychotropic medications. If the capacity of the patient to make his or her own decisions fluctuates or is questionable, the clinician should obtain the patient's permission to include family or other patient-appointed persons in important treatment decisions. When a patient is clearly not competent to make such decisions, formal legal mechanisms for substituted judgment should be used. Such mechanisms, however, in no way diminish the importance of educating a patient about medications and target symptoms to the fullest extent possible. When one presents recommendations to a patient about medications, information about diagnosis, target symptoms, treatment options, and anticipated means of follow-up should be included, as well as the medication's name, class, and dosing instructions. Side effects that are common (e.g., dry mouth, nausea, tremor, drowsiness, sexual dysfunction, and weight gain) should be reviewed together with side effects that are uncommon but require immediate attention, such as a hypertensive crisis on a monoamine oxidase inhibitor (MAOI), dystonia on an antipsychotic, or a rapidly progressing rash on lamotrigine. Patients should be specifically cautioned about the risks of abrupt discontinuation of a psychotropic drug. Dietary and drug restrictions must be clearly described and, particularly in the case of MAOIs, should be provided in written form as well.

In the context of urgent, life-threatening conditions (such as acute mania), counseling about some potential adverse effects, particularly those not anticipated in the foreseeable future (e.g., tardive dyskinesia or perinatal risks), can be deferred until greater clinical stability is achieved and the risks and benefits of longer-term treatment can be meaningfully addressed.

All too often omitted in discussions preceding the initiation of medications is clear information about the anticipated time course of response (whether to anticipate improvement in hours or weeks), the anticipated length of treatment, and the ready availability of strategies to address side effects or lack of efficacy. A patient's reluctance to initiate treatment might arise from a variety of concerns, including the fear that medication will be stigmatizing, might engender physical or psychological dependence, will be "mind-altering" or personality transforming, is being used to mask a problem rather than treat it, implies consignment to lifelong treatment, or reflects a narrow therapeutic philosophy. The faithfulness of a patient to a recommended course of treatment is invariably strengthened by a physician's dedicated efforts to elicit and address misgivings and potential misunderstandings at the outset. Referral to relevant pamphlets, websites, and books on diagnosis and treatment are often welcomed by patients and family members as a source of more detailed information, particularly when longer-term treatment is anticipated.

Selecting and Administering Medication

Fortunately, for the majority of psychiatric disorders, there exist at least several agents within a single class that are known to have roughly equivalent efficacy. Decisions regarding choice of a particular medication for a

patient should give considerable weight to previous treatment response and the current feasibility of the medication in terms of cost, tolerability, and complexity of dosing. Anticholinergic, hypotensive, and sedative effects of drugs must be considered carefully, particularly when prescribing medications to elderly patients or patients who are medically frail.

Once a drug is chosen, the goal should be to achieve a full trial with adequate dosages and an adequate duration of treatment. Inadequate dosing and duration count among the principal factors in treatment failure for patients with accurate diagnoses. In the service of decisions regarding a patient's care weeks or months later, it is crucial to document whether a trial of medication succeeded, failed, or was abbreviated because of clinical deterioration, medication side effects, poor adherence to treatment, or drug abuse. Suffering is unnecessarily prolonged and resources are poorly used when medications that were previously ineffective have been tried again because of inadequate documentation of failure or when medications that could have been effective are avoided because previous trials of those medications had not been flagged as having been incomplete.

Medication dosages should be adjusted to determine the lowest effective dosage and the simplest regimen. There is significant variability among individual patients with respect to response, blood levels, the expression of side effects, and the development of toxicity, such that the recommended dosage ranges provide only a general guide. Documentation of a patient's response to a particular dosage becomes a much more meaningful reference point for future treatment. As a rule, elderly patients should be started on lower dosages than younger patients, and the interval between dosage changes should be longer because the time to achieve steady-state levels is often prolonged. In the elderly, often there is also prolonged storage of medication and active metabolites in body tissues. Nevertheless, the goal of reaching an effective dosage must be pursued with equal determination in elderly as in younger patients.

For patients with chronic psychiatric conditions, exacerbation of symptoms might prompt increases in the dosages of medications or addition of other medications. So too, for patients presenting acutely with severe disorders, medication dosages may be titrated up more rapidly than usual or combined with other psychotropic medications at an early point such that the lowest effective dosage and simplest regimen is likely to be unclear. Under these circumstances, re-evaluation for cautious reduction of dosage when an appropriate interval of stability has followed should be routine. When a patient's care is likely to be transferred to another clinician or another setting, such as a chronic care facility or a community health center, it is essential that such a plan be communicated to the accepting clinical staff to avoid committing a patient to long-term treatment with dosages or regimens that are excessive.

The attentive management of side effects plays an important role in developing a therapeutic alliance and improving the quality of life for a patient who may be on psychopharmacologic treatment for months or years. Although some adverse events require immediate discontinuation of the drug (e.g., serotonin syndrome or neuroleptic malignant syndrome [NMS]), most can be addressed initially with a dosage reduction, modification in the timing or by dividing doses, taking the medication with or without food, a change in the preparation of medication (e.g., from valproic acid to divalproex sodium), or guidance about sleep hygiene, exercise, or diet (e.g., caffeine, fluids, or fiber). When such measures prove unhelpful in addressing a side effect that is causing distress or that poses a safety risk, other measures must be considered, such as prescribing bethanechol for urinary retention on tricyclic antidepressants (TCAs) or sildenafil for sexual dysfunction on SSRIs, or replacing the offending medication with a more tolerable agent. For side effects that are likely to be transient and not dangerous, a patient's understanding that a variety of straightforward strategies are available in the case of persistence or worsening may be enough to help the patient endure the side effects until they subside.

It is best to avoid responding to short-term crises with long-term changes in medication. The decision to discontinue a successful antidepressant and substitute another in the setting of despair and insomnia following a traumatic event offers the patient only the prospect of benefit from the new medication weeks hence while currently depriving the patient of active treatment known to have been effective. Although it may seem tempting to respond proportionally to a patient's marked distress with a fundamental change in established treatment, exacerbations that are thought likely to be transient are most reasonably addressed with interventions that are short term and focused coupled with adequate follow-up.

Approach to Treatment Failure

Lack of improvement, clinical worsening, or the emergence of unexpected symptoms require a concerted re-evaluation of diagnosis, dosage, drugs, and disruptions. Some patients require combined-medication regimens.

Diagnosis

Among at least one third of patients with major psychiatric disorders, initial treatment fails to bring about significant improvement despite accurate diagnosis. Nevertheless, treatment failure should motivate a careful review of history, initial presentation, and symptoms that seem incongruous with the provisional diagnosis (e.g., confusion in a patient with a seemingly mild depression; olfactory hallucinations in a patient presenting with panic attacks). A patient with fatigue out of proportion to other depressive symptoms might have a primary sleep disorder, such as obstructive sleep apnea. A depressed and cachectic elderly patient who fails to improve despite a series of adequate courses of antidepressant might turn out to have a psychotic depression, early dementia, carcinoma, or a frontal lobe tumor. An adolescent with obsessive–compulsive disorder who appears increasingly bizarre and erratic on an SSRI might have an undiagnosed bipolar disorder exacerbated by the antidepressant.

Dosage

Apparent treatment refractoriness is often the result of prescribing subtherapeutic dosages or the patient's noncompliance, and when treatment fails, the onus is on the clinician to confirm the adequacy of the dosage. Whenever

possible, blood levels of prescribed medications help establish whether a patient is taking the medications and, for medications with established dosage ranges (e.g., lithium, anticonvulsants, TCAs, but not generally antipsychotics or SSRIs or other newer-generation antidepressants), whether the medication dosages are likely to be in a therapeutic range. When adequate dosages of a drug prescribed to a conscientious patient fail to achieve consistent plasma concentrations or clinical response, the clinician must consider factors that affect drug metabolism, such as cigarette smoking, chronic alcohol use, or use of concurrent medications that result in lower levels of the drug. Less commonly, patients experience clinical deterioration after changes in their prescription brand, such as when generic preparations are substituted for brand name medications, causing variation in the bioavailability of the active agent.

Drugs

Many patients compartmentalize their use of medications and forget to mention as-needed or over-the-counter (OTC) medications or treatments prescribed in different settings. When psychopharmacologic treatments fail, a careful re-evaluation of the patient's current nonpsychiatric medication use is warranted. Thus, a patient whose panic disorder responds incompletely to full dosages of a high-potency benzodiazepine may be unaware that his or her condition is aggravated by use of a β-agonist inhaler or a sympathomimetic decongestant. So, too, a patient with bipolar disorder, previously stabilized on lithium but now presenting with hypomania, might not have realized the importance of reporting the initiation of prednisone for a flare of inflammatory bowel disease.

It has become increasingly apparent that widely consumed herbal and other natural remedies marketed as dietary supplements (e.g., St. John's wort) can participate in clinically important drug interactions[15,16]; the possibility of such interactions may be easily missed, however, because the use of alternative and complementary therapies is typically reported by patients only on direct inquiry by their clinician. Details of alcohol and illicit drug use must also be carefully elicited as factors that, when excessive, often masquerade as, and at the very least exacerbate, other psychiatric disorders and can jeopardize the safety and efficacy of pharmacotherapy.

Disruptions

Although psychosocial stressors are not an excuse for psychopharmacologic nihilism, neither can they be meaningfully ignored as potential impediments to treatment. Incomplete remission of depressive symptoms in a patient living with an alcoholic spouse or of a psychotic exacerbation in a patient with schizophrenia whose community residential treatment facility has closed should be met both by aggressive efforts to ensure the adequacy of pharmacologic treatment and by equally determined efforts to develop a plan to address the environmental factors that appear to be compromising a patient's recovery.

Combined Therapy

In clinical practice, many patients—particularly the elderly, the medically ill, or the medically complex—receive multiple medications. Moreover, general medical co-morbidity is common among patients with psychiatric disorders, elevating the likelihood of complex medication regimens and polypharmacy.[17]

The term *polypharmacy* has taken on a pejorative connotation in recent years suggesting a thoughtless, irrational, or non–evidence-based approach to the prescribing of medicine. Polypharmacy puts patients at risk due to an increased likelihood of adverse medication reactions and drug–drug interactions. In contrast, "rational" or "strategic" combined psychopharmacologic approaches can be used for the treatment of psychiatric or medical co-morbidity, as an augmentation strategy for patients with an insufficient response to a single agent, and for the management of treatment-emergent adverse effects.[18] Examples of the rational use of combined treatment include the addition of a benzodiazepine to an SSRI to hasten treatment response in panic disorder[19] or the use of lithium and a medication for attention-deficit/hyperactivity disorder (ADHD) to treat co-occurring bipolar disorder and ADHD.[20]

Therefore, a patient's use of two or more psychotropic medications ought not be viewed reflexively as in need of dismantling. One patient might arrive at a precisely adjusted, albeit complicated, regimen through a series of careful trials guided by a single experienced clinician, whereas another may accumulate multiple medications in a haphazard fashion across diverse treaters and settings. For the former patient, even a modest dosage change can result in a severe relapse that threatens the patient's safety or livelihood, whereas for the latter, a directed plan to taper medications and perhaps even to "start from scratch" is likely to be most helpful.

Discontinuing Medications

The discontinuation of psychotropic drugs must be carried out with as much care as their initiation. For patients on complicated regimens of psychotropic medications, periodic review for dosage reduction and potential discontinuation must be standard. Because data providing guidelines for drug discontinuation are scarce, the process is often empirical. Successful discontinuation, therefore, relies heavily on a good knowledge of a patient's history together with adequate follow-up.

Assessment of a patient for discontinuing a drug involves appreciating the short-term risks of rebound and withdrawal as well as the long-term risks of relapse and recurrence. Rebound effects are the transient return of symptoms for which a medication has been prescribed (e.g., insomnia or anxiety), and withdrawal effects are the development of new symptoms characteristic of abrupt cessation of the medication, such as muscle spasms, delirium, or seizures following discontinuation of high-dosage benzodiazepine; hot flushes, nausea, unusual shock-like sensations, or malaise following discontinuation of an antidepressant.

To make sound decisions regarding the re-instatement of medications, it is essential to distinguish rebound and withdrawal effects from relapse. *Relapse* is typically a persistent rather than self-limited state associated with a more-delayed onset, and the re-emergence of clinically significant symptoms of the underlying illness in the absence of (or sometimes despite the continuation of) active treatment. The return of daily panic attacks after a remission of

several months and an exacerbation of psychosis requiring hospitalization after 2 years of exclusively outpatient treatment are examples of relapse.

For disorders that can occur episodically, such as major depression, the term *relapse* refers more precisely to the recrudescence of symptoms during an initial period of remission, whereas the additional term *recurrence* refers to return of symptoms following a defined period of full remission (at least 4 to 6 months) on or off continued treatment. In the case of recurrence, the reappearing symptoms are conceptualized as denoting a new episode rather than a continuation of the one previously treated.

In parallel with the concepts of relapse and recurrence, continuation of treatment refers to the ongoing use of medication prescribed to consolidate a remission of symptoms brought about by an initial (acute) phase of treatment to prevent relapse. *Maintenance treatment* refers to a more extended course of medication thereafter aimed at preventing recurrences and is reserved for patients with an illness characterized by chronicity, past recurrences, or particular severity. For major depression, acute treatment is typically in the range of 6 to 12 weeks, whereas continuation treatment extends 4 to 6 months beyond that point, and maintenance treatment may extend a further 1 to 5 years or more depending on the clinical context. Although antidepressants appear to be more effective than placebo during long-term treatment, the number of controlled antidepressant trials focusing on treatment of depression beyond the first year remains quite limited.[21]

A taper of medications over 48 to 72 hours is typically adequate to minimize the risk of rebound or withdrawal. With respect to relapse or recurrence, however, patients at risk may well benefit from a more protracted, carefully monitored taper of medications. This allows rapid re-instatement of full-dosage treatment at the early signs of worsening to avert a more serious escalation. Analyses of discontinuation of lithium[22,23] and antipsychotic agents[24] suggest that a too-rapid cessation of psychotropic medications can, in fact, increase the risk of relapse when compared with a more gradual taper. Findings such as these suggest that for elective discontinuation of psychotropic medications, a taper lasting at least 2 to 4 weeks should be considered.

With patients for whom the consequences of relapse are likely to be severe (e.g., most patients with bipolar and psychotic disorders), an extended taper with dosage reductions of no more than 25% at intervals of no less than 4 to 6 weeks is likely to be a more prudent course. For patients who have anxiety disorders and are maintained on high-potency benzodiazepines, the introduction of a targeted course of therapy (e.g., a cognitive–behavioral panic disorder group) in preparation for a drug taper is likely to further reduce the risks of relapse (see Chapter 13).

Far from being an afterthought, decisions regarding the timing and pace of drug discontinuation should be regarded as an integral part of psychopharmacologic management and remain an important topic for further study.

PHARMACOKINETICS

Pharmacokinetic processes refer to absorption, distribution, metabolism, and excretion, factors that determine plasma levels of a drug and the local availability of drug to biologically active sites—in short, what the body does to the drug. Pharmacokinetics also refers to the mathematical analysis of these processes. Advances in analytic chemistry and computer methods of pharmacokinetic modeling[4,25,26] and a growing understanding of the molecular pharmacology of the hepatic isoenzymes responsible for metabolizing most psychotropic medications have furnished increasingly sophisticated insights into the disposition and interaction of administered drugs.

Because the pharmacokinetics of a medication are subject to myriad influences, including age, genes, gender, diet, disease states, and concurrently administered drugs, a working knowledge of pharmacokinetic principles is of particular relevance to psychopharmacology in medical settings. Although pharmacokinetics refers to only one of the two broad mechanisms by which drugs interact, pharmacokinetic interactions involve all classes of psychotropic and nonpsychotropic medications. An overview of pharmacokinetic processes is a helpful prelude to a discussion of specific drug–drug interactions.

Absorption

Factors that influence drug absorption are generally of less importance in determining the pharmacokinetic properties of psychiatric medications than factors influencing subsequent drug disposition (e.g., drug metabolism). The term *absorption* refers to processes that generally pertain to orally (rather than parenterally) administered drugs, for which alterations in gastrointestinal (GI) drug absorption can affect the rate (time to reach maximum concentration) or the extent of absorption, or both. The extent or completeness of absorption, also known as the *fractional absorption*, is measured as the area under the curve (AUC) when plasma concentration is plotted against time. The bioavailability of an oral dose of drug refers, in turn, to the fractional absorption for orally compared with intravenously (IV) administered drug. If an agent is reported to have a 90% bioavailability (e.g., lorazepam), this indicates that the extent of absorption of an orally administered dose is nearly that of an IV-administered dose, although the rate of absorption may well be slower for the oral dose.

Because the upper part of the small intestine is the primary site of drug absorption through passive membrane diffusion and filtration and both passive and active transport processes, factors that speed gastric emptying (e.g., metoclopramide) or diminish intestinal motility (e.g., opiates or cannabis) can facilitate greater contact with, and absorption from, the mucosal surface into the systemic circulation, potentially increasing plasma drug concentrations. Conversely, antacids, charcoal, kaolin-pectin, and cholestyramine can bind to drugs, forming complexes that pass unabsorbed through the GI lumen.

Changes in gastric pH associated with food or other drugs alter the nonpolar, un-ionized fraction of drug available for absorption. In the case of drugs that are very weak acids or bases, however, the extent of ionization is relatively invariant under physiologic conditions. Properties of the preparation administered (e.g., tablet, capsule, or liquid) can also influence the rate or extent of absorption and, for an increasing number of medications (e.g., lithium, bupropion, quetiapine, and methylphenidate), preparations intended for slow release are available.

The local action of enzymes in the GI tract (e.g., monoamine oxidase [MAO] and cytochrome P450 [CYP] 3A4) may be responsible for metabolism of drug before absorption. This is of critical relevance to the emergence of hypertensive crises that occur when excessive quantities of the dietary pressor tyramine are systemically absorbed in the setting of irreversible inhibition of the MAO isoenzymes for which tyramine is a substrate.

Following gut absorption, but before entry into the systemic circulation, many psychotropic drugs are subject to first-pass liver metabolism. Therefore, conditions that affect hepatic metabolism of drug (e.g., primary liver disease) or conditions that impede portal circulation (e.g., congestive heart failure) are likely to increase the fraction of drug available for distribution for the majority of psychotropic drugs, thereby contributing to clinically significant increases in plasma levels of drug.

Distribution

Drugs distribute to tissues through the systemic circulation. The amount of drug ultimately reaching receptor sites in tissues is determined by a variety of factors, including the concentration of free (unbound) drug in plasma, regional blood flow, and physiochemical properties of drug (e.g., lipophilicity or structural characteristics). For entrance into the CNS, penetration across the blood–brain barrier is required. Fat-soluble drugs (e.g., benzodiazepines, antipsychotics, and cyclic antidepressants) distribute more widely in the body than water-soluble drugs (e.g., lithium), which distribute through a smaller volume of distribution. Changes with age, typically including an increase in the ratio of body fat to lean body mass, therefore, result in a net greater volume of lipophilic drug distribution and potentially greater accumulation of drug in adipose tissue in older than in younger patients. A similar potential exists for female compared with male patients because of their generally higher ratio of adipose tissue to lean body mass.[27]

In general, psychotropic drugs have relatively high affinities for plasma proteins (some to albumin but others, such as antidepressants, to α-acid glycoproteins and lipoproteins). Most psychotropic drugs are more than 80% protein-bound. A drug is considered highly protein-bound if more than 90% exists in bound form in plasma. Fluoxetine, aripiprazole, and diazepam are examples of the many psychotropic drugs that are highly protein-bound. In contrast, venlafaxine, lithium, topiramate, zonisamide, gabapentin, pregabalin, and memantine are examples of drugs with minimal protein binding and therefore minimal risk of participating in drug–drug interactions related to protein binding.

A reversible equilibrium exists between bound and unbound drug. Only the unbound fraction exerts pharmacologic effects. Competition by two or more drugs for protein-binding sites often results in displacement of a previously bound drug, which, in the free state, becomes pharmacologically active. Similarly, reduced concentrations of plasma proteins in a severely malnourished patient or a patient with a disease that is associated with markedly lowered serum proteins (e.g., liver disease or the nephrotic syndrome) may be associated with an increase in the fraction of unbound drug potentially available for activity at relevant receptor sites. Under most circumstances, the net changes in plasma concentration of active drug are, in fact, quite small because the unbound drug is available for redistribution to other tissues and for metabolism and excretion, thereby offsetting the initial rise in plasma levels. It is important to be aware, however, that clinically significant consequences can develop when protein-binding interactions alter the unbound fraction of previously highly protein-bound drugs that have a low therapeutic index (e.g., warfarin). For these drugs, relatively small variations in plasma level may be associated with serious untoward effects.

An emerging understanding of the drug-transport proteins, of which P-glycoproteins are the best characterized, indicates a crucial role in regulating permeability of intestinal epithelia, lymphocytes, renal tubules, biliary tract, and the blood–brain barrier. These transport proteins are thought to account for the development of certain forms of drug resistance and tolerance, but they are increasingly seen as likely also to mediate clinically important drug interactions.[4,28] Little is known yet about their relevance to drug interactions involving psychiatric medications; the capacity of St. John's wort to lower blood levels of several critical medications (including cyclosporine and indinavir) is hypothesized to be related, at least in part, to an effect of the botanical agent on this transport system.[15]

Metabolism

Metabolism is the best-characterized mechanism of all of the pharmacokinetic processes implicated in drug–drug interactions. *Metabolism* refers to the biotransformation of a drug to another form, a process that is usually enzyme mediated and results in a metabolite that might or might not be pharmacologically active and might or might not be subject to further biotransformations before eventual excretion. Most drugs undergo several types of biotransformation, and many psychotropic drug interactions of clinical significance are based on interference with this process. A growing understanding of hepatic enzymes, and especially the rapidly emerging characterization of the CYP isoenzymes and other enzyme systems including the uridine-diphosphate glucuronosyltransferases (UGTs) and flavin-containing monooxygenases (FMOs),[4,29–31] has significantly advanced a rational understanding and prediction of drug interactions and individual variation in drug responses.

Phase I reactions include oxidation (e.g., hydroxylation or dealkylation), reduction (e.g., nitro reduction), and hydrolysis, metabolic reactions typically resulting in intermediate metabolites that are then subject to phase II reactions, including conjugation (e.g., glucuronide and sulfate) and acetylation. Phase II reactions typically yield highly polar, water-soluble metabolites suitable for renal excretion. Most psychotropic drugs undergo both phase I and phase II metabolic reactions. Notable exceptions are lithium, which is not subject to hepatic metabolism, and a subset of the benzodiazepines (lorazepam, oxazepam, and temazepam), which undergo only phase II reactions and are therefore especially appropriate when benzodiazepines are used in the context of concurrent medications, advanced age, or disease states in which alterations of hepatic metabolism is likely to be substantial.

The synthesis or activity of hepatic microsomal enzymes is affected by metabolic inhibitors and inducers, as well as distinct genetic polymorphisms (stably inherited traits). Table 34–1 lists enzyme inducers and inhibitors common in clinical settings. These should serve as red flags that beckon further scrutiny for potential drug–drug interactions when they are found on a patient's medication list. In some circumstances an inhibitor (e.g., grapefruit juice) or an inducer (e.g., a cruciferous vegetable, such as Brussels sprouts) is a drug but it may be another ingested substance.

Inhibitors impede the metabolism of a concurrently administered drug, producing a rise in its plasma level, whereas inducers enhance the metabolism of another drug, resulting in a decline in its plasma levels. Although inhibition is usually immediate, induction, which requires enhanced synthesis of the metabolic enzyme, is typically a more gradual process. A fall in plasma levels of a substrate might not be apparent for days to weeks following introduction of the inducer. This is particularly important to keep in mind when a patient's care is being transferred to another setting where clinical deterioration may be the first sign that drug levels have declined. Reciprocally, an elevation in plasma drug concentrations could reflect the previous discontinuation of an inducing factor (e.g., cigarette smoking or carbamazepine) just as it could reflect the introduction of an inhibitor (e.g., fluoxetine or valproic acid).

Although the CYP isoenzymes represent only one of the numerous enzyme systems responsible for drug metabolism, they are responsible for metabolizing, at least in part, more than 80% of all prescribed drugs. The capacity of many of the SSRI antidepressants to inhibit CYP isoenzymes has fueled great interest in the pattern of interaction of psychotropic and other drugs with these enzymes in the understanding and prediction of drug–drug interactions in psychopharmacology. The CYP isoenzymes represent a family of more than 30 related heme-containing enzymes, largely located in the endoplasmic reticulum of hepatocytes (but also present elsewhere, including gut and brain), which mediate oxidative metabolism of a wide variety of drugs as well as endogenous substances, including prostaglandins, fatty acids, and steroids. The majority of antidepressant and antipsychotic drugs are metabolized by or inhibited by one or more of these isoenzymes. Table 34–2 summarizes the interactions of psychiatric and nonpsychiatric drugs with a subset of isoenzymes that have been increasingly well characterized: CYP 1A2, 2D6, 2E1, 3A4, and the 2C subfamily. In addition to the numerous publications in which these interactions are cited,[4,30,31] several relevant websites are regularly updated, including www.drug-interactions.com and www.mhc.com/Cytochromes. The relevance of these and other interactions is highlighted in a later section of this chapter in which clinically important drug–drug interactions are reviewed.

TABLE 34–1 Commonly Used Drugs and Substances that Inhibit or Induce Hepatic Metabolism of Other Medications[4,30,31]

INHIBITORS	INDUCERS
Antifungals (ketoconazole, miconazole, itraconazole)	Barbiturates (e.g., phenobarbital, secobarbital)
Macrolide antibiotics (erythromycin, clarithromycin, triacetyloleandomycin)	Oxcarbazepine
Fluoroquinolones (e.g., ciprofloxacin)	Phenytoin
Isoniazid	Rifampin
Antiretrovirals	Primidone
Selective serotonin reuptake inhibitors (fluoxetine, fluvoxamine, paroxetine, sertraline)	Cigarettes
Nefazodone	Ethanol (chronic)
β-blockers (lipophilic), e.g., propranolol, metoprolol, pindolol	Cruciferous vegetables
Quinidine	Charbroiled meats
Valproate	St. John's wort
Cimetidine	
Calcium channel blockers (e.g., diltiazem)	
Grapefruit juice	
Ethanol (acute)	

Knowledge continues to evolve concerning genetic polymorphisms that affect drug metabolism. Within the group of CYP isoenzymes, there appears to be a polymodal distribution of metabolic activity in the population with respect to certain isoenzymes (including CYP 2C19 and 2D6). Most people are normal (extensive) metabolizers with respect to the activity of these isoenzymes. A smaller number are poor metabolizers, with deficient activity of the isoenzyme. Probably very much smaller numbers are ultrarapid metabolizers, who have more than normal activity of the enzyme, and intermediate metabolizers, who fall between extensive and poor metabolizers. Persons who are poor metabolizers with respect to a particular CYP isoenzyme are expected to have higher plasma concentrations of a drug that is metabolized by that isoenzyme, thereby potentially being more sensitive to or requiring lower dosages of that drug than a patient with normal activity of that enzyme. These patients might also have higher-than-usual plasma levels of metabolites of the drug that are produced through other metabolic pathways that are not altered by the polymorphism, thereby potentially incurring pharmacologic activity or adverse effects related to these alternative metabolites.

Studies on genetic polymorphisms affecting the CYP system suggest ethnic differences.[32,33] Approximately 15% to 20% of Asian Americans and African Americans appear to be poor metabolizers with respect to CYP 2C19 compared with 3% to 5% of whites. Conversely, the proportion of frankly poor metabolizers with respect to CYP 2D6 appears to be higher among white (approximately 5% to 10%) than among Asian Americans and African Americans (approximately 1% to 3%). Current understanding of the clinical relevance of genetic polymorphisms in drug therapy in psychiatry remains rudimentary. Commercial genotyping tests for polymorphisms of potential relevance to drug metabolism are increasingly available. For the use of certain drugs, notably carbamazepine, the U.S. Food and Drug Administration (FDA) recommends genotyping Asians for the *HLA B*1502* allele owing to data[34] implicating the allele as a marker for carbamazepine-induced Stevens–Johnson syndrome and toxic epidermal necrolysis in Han Chinese.[35]

TABLE 34–2 Selected Cytochrome P450 Isoenzyme Substrates, Inhibitors, and Inducers*[4,30,31]

ISOENZYME	SUBSTRATES	INHIBITORS	INDUCERS
1A2	Acetaminophen, aminophylline, caffeine, clozapine, cyclobenzaprine, estradiol, fluvoxamine, haloperidol, mirtazapine, olanzapine, phenacetin, procarcinogens, propranolol, ramelteon, riluzole, ropinirole, tacrine, TCAs, theophylline, verapamil, warfarin, zileuton, zolmitriptan	Amiodarone, cimetidine, fluoroquinolones, fluvoxamine, grapefruit juice, methoxsalen, ticlopidine	Charbroiled meats, cigarette smoking (tobacco), cruciferous vegetables, modafinil, omeprazole
2C	Barbiturates, diazepam, fluvastatin, glipizide, glyburide, irbesartan, losartan, mephenytoin, NSAIDs, nelfinavir, phenytoin, primidone, proguanil, propranolol, proton pump inhibitors, rosiglitazone, tamoxifen, tertiary TCAs, THC, tolbutamide, warfarin	Fluoxetine, fluvoxamine, ketoconazole, modafinil, omeprazole, oxcarbazepine, sertraline	Carbamazepine, norethindrone, prednisone, rifampin, secobarbital
2D6	Aripiprazole, atomoxetine, β-blockers (lipophilic), codeine, debrisoquine, dextromethorphan, diltiazem, donepezil, duloxetine, encainide, flecainide, haloperidol, hydroxycodone, lidocaine, metoclopramide, mexiletine, mCPP, nifedipine, odansetron, phenothiazines (e.g., thioridazine, perphenazine), propafenone, risperidone, SSRIs, tamoxifen, TCAs, tramadol, trazodone, venlafaxine	Amiodarone, antimalarials, bupropion, cimetidine, citalopram, duloxetine, escitalopram, fluoxetine, methadone, metoclopramide, moclobemide, paroxetine, phenothiazines, protease inhibitors (ritonavir), quinidine, sertraline, terbinafine, TCAs, yohimbine	Dexamethasone, rifampin
3A3, 3A4	Alfentanil, alprazolam, amiodarone, amprenavir, aripiprazole, bromocriptine, buspirone, cafergot, calcium channel blockers, caffeine, carbamazepine, cisapride, clozapine, cyclosporine, dapsone, diazepam, disopyramide, efavirenz, estradiol, fentanyl, indinavir, HMG-CoA reductase inhibitors (lovastatin, simvastatin), lidocaine, loratadine, methadone, midazolam, nimodipine, pimozide, prednisone, progesterone, propafenone, quetiapine, quinidine, ritonavir, sildenafil, tacrolimus, testosterone, tertiary TCAs, triazolam, vinblastine, warfarin, zaleplon, ziprasidone, zolpidem, zonisamide	Antifungals, calcium channel blockers, cimetidine, efavirenz, indinavir, fluoxetine (norfluoxetine), fluvoxamine, grapefruit juice, macrolide antibiotics, mibefradil, nefazodone, ritonavir, verapamil, voriconazole	Carbamazepine, glucocorticoids, modafinil, oxcarbazepine, phenobarbital, phenytoin, pioglitazone, rifampin, ritonavir, St. John's wort, troglitazone

*Drugs.com: *Drug interactions checker*. Retrieved from www.drugs.com/drug_interactions.php. Accessed February 12, 2010.

HMG-CoA, Hydroxy-methylglutaryl co-enzyme A; *mCPP*, m-chlorophenylpiperazine; *NSAID*, nonsteroidal antiinflammatory drug; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant; *THC*, tetrahydrocannabinol.

Systematic study of genetic polymorphisms and their relevance to the prediction of drug response is needed before additional testing can be meaningfully incorporated into routine psychopharmacologic practice.

Excretion

Because most antidepressant, anxiolytic, and antipsychotic medications are largely eliminated by hepatic metabolism, factors that affect renal excretion (glomerular filtration, tubular reabsorption, and active tubular secretion) are generally far less important to the pharmacokinetics of these drugs than to lithium, for which such factors can have clinically significant consequences. Conditions resulting in sodium deficiency (e.g., dehydration, sodium restriction, and use of thiazide diuretics) are likely to result in increased proximal tubular reabsorption of lithium, resulting in increased lithium levels and potential toxicity. Lithium levels and clinical status must be monitored especially closely in the setting of vomiting, diarrhea, excessive evaporative losses, or polyuria. Factors, such as aging, that are associated with reduced renal blood flow and glomerular filtration rate (GFR) also reduce lithium excretion. For this reason, as well as for their reduced volume of distribution for lithium because of the relative loss of total body water with aging, elderly patients typically require lower lithium dosages than younger patients, and a low starting dosage (i.e., 150 to 300 mg/day) is often prudent. Apparently separate from pharmacokinetic effects, however, elderly patients may also be more sensitive to the

neurotoxic effects of lithium even at low therapeutic levels. Factors associated with an increased GFR, particularly pregnancy, can produce an increase in lithium clearance and a fall in lithium levels.

For other medications, renal excretion can sometimes be exploited in the treatment of a drug overdose. Acidification of the urine by ascorbic acid, ammonium chloride, or methenamine mandelate increases the rate of excretion of weak bases such as the amphetamines and phencyclidine (PCP). Therefore, such measures may be important in the emergency management of a patient with severe phencyclidine or amphetamine intoxication. Conversely, alkalinization of the urine by administration of sodium bicarbonate or acetazolamide can hasten the excretion of weak acids including long-acting barbiturates, such as phenobarbital.

Mildly to moderately impaired renal function does not typically prompt routine changes in the dosage or dosing intervals of psychotropic medications other than lithium. Increased plasma concentrations of hydroxylated metabolites of TCAs have been measured in patients with kidney disease and patients on dialysis, and more modest increases in TCA plasma levels have been measured in patients on dialysis.[36] The clinical significance of these findings, however, appears to be limited to suggesting more cautious dosage titration and surveillance in the patient with kidney disease rather than routine dosage adjustments. A similar empirical strategy is prudent for use of SSRIs, as well as for most antipsychotic medications and anxiolytics. In patients with severe impairment of kidney function, however, there may be accumulation of metabolites and, to a lesser extent, of the parent compound across repeated doses. An increase in the dosing interval and possible reduction in drug dosage should therefore be considered in this setting, particularly in the case of chronically administered agents with active metabolites.

Renal excretion is only one contribution to the *elimination half-life*, a pharmacokinetic construct that refers to the time required for the plasma concentration of a drug to be reduced by one half. The elimination phase (also referred to as the β-phase) reflects all processes that contribute to drug removal, including renal excretion, hepatic metabolism, and, to a much lesser extent, other factors (e.g., loss of drug in sweat or biliary secretions) potentially affecting drug clearance (the volume of blood or plasma cleared of drug per unit time). For the majority of drugs, whose elimination follows first-order kinetics (i.e., their rate of elimination is proportional to the amount of drug in the body rather than equal to a constant amount), steady-state drug levels are reached in four to five elimination half-lives, whereas, on discontinuation, almost all drug is out of the body within five half-lives.

For drugs that are administered for their single-dose effects (e.g., an as-needed benzodiazepine) rather than for long-term effects of repeated administration (e.g., antidepressants), the duration of action of the drug depends not only on elimination half-life but also often more critically on the initial phase of drug redistribution from the systemic circulation to other tissues, such as muscle and fat.

DRUG INTERACTIONS

The scientific literature on psychotropic drug–drug interactions has grown immensely since first reviewed in the *Massachusetts General Hospital Handbook of General Hospital Psychiatry* in 1978.[37] Despite impressive advances in clinical and molecular pharmacology, much of the literature on drug–drug interactions remains a patchwork of case reports, postmarketing analyses, extrapolation from animal and *in vitro* studies, and inferences based on what is known about other drugs with similar properties. Fortunately, well-designed studies of drug–drug interactions are an increasingly integral part of drug development.

Drug–drug interactions refer to alterations in drug levels or drug effects (or both) attributed to the administration of two or more prescribed, illicit, or OTC agents in close temporal proximity. Although many drug–drug interactions involve drugs administered within minutes to hours of each other, some drugs can participate in interactions days or even weeks after they are discontinued because of prolonged elimination half-lives (e.g., fluoxetine) or owing to their long-term impact on metabolic enzymes (e.g., carbamazepine). Some drug–drug interactions involving psychotropic medications are life-threatening, such as those involving the co-administration of MAOIs and drugs with potent serotoninergic (e.g., meperidine) or sympathomimetic (e.g., phenylpropanolamine) effects.[38] These combinations are therefore absolutely contraindicated.

However, most drug–drug interactions in psychopharmacology manifest in somewhat more subtle ways, often leading to poor medication tolerability and compliance due to adverse events (e.g., orthostatic hypotension, sedation, or irritability), diminished medication efficacy, or puzzling manifestations such as altered mental status or unexpectedly high or low drug levels. Drug combinations that can produce these often less-catastrophic drug–drug interactions are usually not absolutely contraindicated. Some of these combinations may, indeed, be valuable in the treatment of some patients though wreaking havoc for other patients. The capacity to anticipate and to recognize both the major, but rare, and the more subtle, but common, potential drug–drug interactions allows the practitioner to minimize the impact of these interactions as an obstacle to patient safety and to therapeutic success.

It is crucial to be familiar with the small number of drug–drug interactions in psychopharmacology that, though uncommon, are associated with potentially catastrophic consequences. These include drugs associated with ventricular arrhythmias, hypertensive crisis, serotonin syndrome, Stevens–Johnson syndrome, seizures, and severe bone marrow suppression. In addition, drug–drug interactions are important to consider when a patient's drugs include those with a low therapeutic index (e.g., lithium, digoxin, or warfarin) or a narrow therapeutic window (e.g., indinavir, nortriptyline, or cyclosporine) such that relatively small alterations in pharmacokinetic or pharmacodynamic behavior can jeopardize a patient's well-being. In addition, it is worthwhile to consider potential drug–drug interactions whenever evaluating a patient whose drug levels are unexpectedly variable or extreme or a patient with a confusing clinical picture (such as clinical deterioration) or with unexpected side effects. Finally, drug–drug interactions are likely to be clinically salient for a patient who is medically frail or elderly, owing to altered pharmacokinetics and vulnerability to side effects, as well as for a patient who is heavily using alcohol, cigarettes, or illicit drugs or who is being treated for a drug overdose.

Given the increasing acceptance of combined pharmacotherapeutic regimens for many difficult-to-treat disorders,[39] the vast literature of reported and potential drug–drug interactions, and the increasingly litigious society in which physicians practice, the physician today is faced with a dilemma when evaluating the potential significance of drug–drug interactions. Fortunately, an increasing range of resources are available, including prescribing software packages and regularly updated websites (such as www.drug-interactions.com) that allow the prevention and detection of potential interactions.

Numerous factors contribute to interindividual variability in drug response.[26,40] These factors include treatment adherence, age, gender, nutritional status, disease states, and genetic polymorphisms that can influence risk of adverse events and treatment resistance**.** Drug–drug interactions are an additional factor that influences how patients react to drugs. The importance of these interactions depends heavily on the clinical context. In many cases, the practical impact of drug–drug interactions is likely to be very small compared with other factors that affect treatment response, drug levels, and toxicity. It is reasonable therefore to focus special attention on commonly used classes of drugs and the contexts in which drug–drug interactions are most likely to be clinically problematic.

Antipsychotic Drugs

The antipsychotic or neuroleptic drugs, used in the treatment of schizophrenia, schizoaffective disorder, organic psychoses, mood disorders, and an increasingly broad range of other psychiatric conditions, include the phenothiazines (e.g., chlorpromazine, fluphenazine, perphenazine, thioridazine, and trifluoperazine), butyrophenones (haloperidol), thioxanthenes (thiothixene), indolones (molindone), diphenylbutylpiperidines (pimozide), dibenzodiazepines (loxapine), and the newer atypical agents (clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone). As a class, they are generally rapidly, if erratically, absorbed from the GI tract after oral administration (peak plasma concentrations ranging from 30 minutes to 6 hours). They are highly lipophilic and distribute rapidly to body tissues with a large apparent volume of distribution. Protein-binding in the circulation ranges from approximately 90% to 98%, except for molindone and quetiapine, which are only moderately protein-bound.

The antipsychotics generally undergo substantial first-pass hepatic metabolism (primarily oxidation and conjugation reactions), reducing their systemic bioavailability when given orally compared with intramuscular (IM) administration, the fractional absorption of which nearly approximates that of IV administration. Most of the individual antipsychotics have several pharmacologically active metabolites (e.g., paliperidone is 9-hydroxyrisperidone, the primary active metabolite of risperidone).[41]

Because of their propensity to sequester in body compartments, the elimination half-life of antipsychotics is quite variable, generally ranging from approximately 20 to 40 hours. For butyrophenones, however, elimination pharmacokinetics appears to be especially complex, and the disappearance of drug from the systemic circulation, and even more so from brain, can take much longer,[7,42] as it does for the newer agent, aripiprazole (and its active metabolite, dehydro-aripirazole),[41] whose half-life can exceed 90 hours.

The lower-potency antipsychotics (including chlorpromazine, mesoridazine, thioridazine, and clozapine) are generally the most sedating and have the greatest anticholinergic, antihistaminic, and α_1-adrenergic antagonistic effects, whereas the higher-potency antipsychotics (with the exception of the atypical agent, risperidone), including haloperidol, loxapine, molindone, and the piperazine phenothiazines, such as trifluoperazine, are more likely to be associated with an increased incidence of extrapyramidal symptoms (EPS), including akathisia, dystonia, and parkinsonism.

The atypical antipsychotics generally have multiple receptor affinities, including antagonism at dopamine D_1 to D_4 receptors, serotonin (5-HT) 5-HT_1 and 5-HT_2 receptors, α_1- and α_2-adrenergic receptors, histamine H_1 receptor, and cholinergic muscarinic receptors, with variations across agents. Thus, for example, clozapine and olanzapine have notably greater affinity at the muscarinic receptors than the other agents, and aripiprazole is actually a partial agonist at the D_2 receptor.

Although the more-complex pharmacologic profile of these newer atypical agents, as well as the older low-potency antipsychotics, has generally been associated with a lower risk of EPS, the same broad range of receptor activity also poses greater risk of *pharmacodynamic interactions*. Pharmacodynamic interactions refer to the pharmacologic effects that result from interactions at the same or interrelated biologically active (receptor) sites

Lower-potency drugs, as well as some atypical antipsychotics, can produce significant hypotension when combined with vasodilator or antihypertensive drugs related to α_1-adrenergic blockade (Table 34–3).[42,43] Hypotension can also occur when low-potency antipsychotics and atypical antidepressants are combined with TCA and MAOI antidepressants. Severe hypotension has been reported when chlorpromazine has been administered with the angiotensin-converting enzyme (ACE) inhibitor captopril. Hypotension can develop when epinephrine is administered with low-potency antipsychotics. In this setting, the α-adrenergic stimulant effect of epinephrine, resulting in vasodilation, is unopposed by its usual pressor effect because α_1-adrenergic receptors are occupied by the antipsychotic. A similar effect can result if a low-potency neuroleptic is administered to a patient with pheochromocytoma. Finally, hypotension can develop when low-potency antipsychotics are used in combination with a variety of anesthetics, such as halothane, enflurane, and isoflurane.

In addition, the low-potency antipsychotics (e.g., thioridazine) have quinidine-like effects on cardiac conduction and can prolong Q-T and P-R intervals. Ziprasidone may also cause Q-T prolongation, although clinically significant prolongation (QTc longer than 500 msec) appears to be rare when administered to otherwise healthy subjects.[44] Significant depression of cardiac conduction, heart block, and life-threatening ventricular dysrhythmias can result from co-administering low-potency antipsychotics or ziprasidone with class I antiarrhythmics (e.g., quinidine, procainamide, and disopyramide); it can also result from the TCAs, which have

TABLE 34–3 Selected Drug Interactions with Antipsychotic Medications

DRUG	POTENTIAL INTERACTION
Antacids (aluminum- and magnesium-containing)	Interference with absorption of antipsychotic agents; fruit juice
Carbamazepine	Decreased antipsychotic drug plasma levels; additive risk of myelosuppression with clozapine
Cigarettes	Decreased antipsychotic drug plasma levels; reduced extrapyramidal symptoms
Rifampin	Decreased antipsychotic drug plasma levels; reduced extrapyramidal symptoms
TCAs	Increased TCA and antipsychotic drug plasma levels; hypotension, depression of cardiac conduction (with low-potency antipsychotics)
SSRIs	Increased SSRI and antipsychotic drug plasma levels (see Table 34–7); arrhythmia risk with thioridazine and pimozide
Bupropion, duloxetine	Increased antipsychotic drug plasma levels (see Table 34–2); arrhythmia risk with thioridazine
Fluvoxamine, nefazodone	Increased antipsychotic drug plasma levels (see Table 34–2), arrhythmia risk with pimozide; seizure risk with clozapine
β-blockers (lipophilic)	Increased antipsychotic drug plasma levels; improved akathisia
Anticholinergic drugs	Additive anticholinergic toxicity; reduced extrapyramidal symptoms
Antihypertensive, vasodilator drugs	Hypotension (with low-potency antipsychotics and risperidone)
Guanethidine, clonidine	Blockade of antihypertensive effect
Epinephrine	Hypotension (with low-potency antipsychotics)
Class I antiarrhythmics	Depression of cardiac conduction; ventricular arrhythmias (with low-potency antipsychotics, ziprasidone)
Calcium channel blockers	Depression of cardiac conduction; ventricular arrhythmias (with pimozide)
Lithium	Idiosyncratic neurotoxicity

SSRI, Selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant.

quinidine-like activity on cardiac conduction, and when administered in the context of other aggravating factors including hypokalemia, hypomagnesemia, bradycardia, or congenital prolongation of the QTc. Pimozide also can depress cardiac conduction as a result of its calcium channel–blocking action, and the combination of pimozide with other calcium channel blockers (e.g., nifedipine, diltiazem, and verapamil) is contraindicated.

Another clinically significant pharmacodynamic interaction arises when low-potency antipsychotics, particularly clozapine or olanzapine, are administered with other drugs that have anticholinergic effects, including TCAs, benztropine, and diphenhydramine. When these drugs are combined, there is a greater risk of urinary retention, constipation, blurred vision, impaired memory and concentration, and, in the setting of narrow-angle glaucoma, increased intraocular pressure. With intentional or inadvertent overdoses, a severe anticholinergic syndrome can develop, including delirium, paralytic ileus, tachycardia, and dysrhythmias. With lower affinity for muscarinic cholinergic receptors, the high-potency agents and nonanticholinergic atypical agents (e.g., risperidone) are indicated when anticholinergic effects need to be minimized.

The sedative effects of low-potency agents and atypical antidepressants are also often additive to those of the sedative–hypnotic medications and alcohol. In patients for whom sedative effects may be especially dangerous, including the elderly, the cautious selection and dosing of antipsychotics should always take into account the overall burden of sedation from their concurrent medications. For these patients, starting with low, divided dosage is often an appropriate first step.

Because dopamine receptor blockade is a property common to all antipsychotics, they are all likely to interfere, although with varying degrees, with the efficacy of levodopa in the treatment of Parkinson's disease. When antipsychotic treatment is necessary in this setting, the low-potency antipsychotics clozapine and quetiapine have been preferred.[45] Reciprocally, antipsychotics are likely to be less effective in the treatment of psychosis in the setting of levodopa, stimulants (e.g., dextroamphetamine), and direct agonists (e.g., piribedil) that facilitate dopamine transmission. Nevertheless, these agents have been combined with antipsychotics in cautious, modestly successful efforts to treat the negative symptoms of schizophrenia (including blunted affect, paucity of thought and speech, and social withdrawal).

Elevated prolactin is common in patients on antipsychotics, particularly the higher-potency agents haloperidol, risperidone, and paliperidone. It often manifests with irregular menses, galactorrhea, diminished libido, or hirsutism. Antipsychotic-induced prolactin elevations associated with clinical symptoms can be abated by reducing the dosage of the offending agent, switching to a prolactin-sparing agent (e.g., aripiprazole, quetiapine, ziprasidone, or clozapine), or adding adjunctive amantadine (200 to 300 mg/day) or a dopamine agonist such as bromocriptine (7.5 to 15 mg/day) or cabergoline (0.5 to 4 mg/week).[46] At present, the management of sustained asymptomatic hyperprolactinemia—which is far more clinically common—is less well defined.

The risk of agranulocytosis, which occurs rarely with the low-potency antipsychotics, is much higher with clozapine, with an incidence as high as 1% to 3%. For this reason, the

combination of clozapine with other medications associated with a risk of myelosuppression (e.g., carbamazepine) should be avoided. Similarly, because clozapine lowers the seizure threshold to a greater extent than other antipsychotics, co-administration with other medications that significantly lower the seizure threshold (e.g., maprotiline) should be avoided or combined use with an anticonvulsant should be considered.

The co-administration of lithium with antipsychotic agents (most notably haloperidol) has been associated, very rarely, with potentially irreversible neurotoxicity, characterized by mental status changes, EPS, and, perhaps in some cases, cerebellar signs and hyperthermia.[47] Related to this concern is the unconfirmed suggestion that co-administering lithium with an antipsychotic can increase the risk of NMS. Other clinical variables, including dehydration and poor nutrition, are likely to be of greater significance as putative risk factors for NMS. At present, the evidence is not sufficient to warrant avoidance of the widely used combination of lithium and neuroleptics. Such a possibility, however, should be considered when a patient receiving these medications has neuropsychiatric toxicity of unclear origin.

Pharmacokinetic drug interactions are quite common among the antipsychotic drugs. Plasma levels of the antipsychotic drugs, however, can vary as much as 10-fold to 20-fold between patients even on monotherapy, and, as a class, they have a relatively wide therapeutic index.[43,48] Therefore, factors that alter antipsychotic drug metabolism might not have apparent clinical consequences. Exceptions include antipsychotics linked to risk of arrhythmia, most notably thioridazine and pimozide. Another exception has to do with patients who are maintained on antipsychotics carefully tapered to the lowest effective dosage. In these patients, a small decrease in antipsychotic levels, as can occur with the introduction of a metabolic inducer or an agent that interferes with absorption, can bring them below the threshold for efficacy.

Antipsychotic drug levels may be lowered by aluminum-containing or magnesium-containing antacids, which reduce their absorption and are best given separately. Mixing liquid preparations of phenothiazines with beverages, such as fruit juices, presents the risk of causing insoluble precipitates and inefficient GI absorption.

Carbamazepine, known to be a potent inducer of hepatic enzymes, has been associated with reduction of steady-state antipsychotic drug plasma levels by as much as 50%. This effect is especially important to bear in mind as a potential explanation when an antipsychotic-treated patient appears to deteriorate in the weeks following the introduction of carbamazepine. Oxcarbazepine can also induce antipsychotic drug metabolism, as can a variety of other anticonvulsants, including phenobarbital and phenytoin.

Cigarette smoking may also be associated with a reduction in antipsychotic drug through enzyme metabolism.[49] As inpatient units and community residential programs have widely become smoke-free, there are often substantial differences in smoking frequency between inpatient and outpatient settings. Among patients who smoke heavily, consideration should be given to the impact of these changes in smoking habits on antipsychotic dosage requirements.[48]

When an antipsychotic drug is given together with a TCA, the plasma level of each agent can rise, presumably because of mutual inhibition of microsomal enzymes. Reciprocally, when a patient with psychotic depression is tapered off an antipsychotic, the plasma level of TCAs might also decline.

SSRIs and other antidepressants with inhibitory effects on CYP isoenzymes can also produce an increase in the plasma levels of a concurrently administered antipsychotic agent (see Table 34–3). Thus, increases in clozapine, olanzapine, and haloperidol plasma levels can occur when these drugs are co-administered with fluvoxamine. Increases in risperidone, aripiprazole, and typical antipsychotic levels can follow initiation of fluoxetine, paroxetine, bupropion, duloxetine, and sertraline. Quetiapine and ziprasidone levels can rise following addition of nefazodone, fluvoxamine, or fluoxetine.

Phenothiazine drug levels may be increased when co-administered with propranolol, another inhibitor of hepatic microenzymes. Because propranolol is often an effective symptomatic treatment for neuroleptic-associated akathisia, the combined use of the β-blocker with an antipsychotic drug is common. When interactions present a problem, the use of a water-soluble β-blocker, such as atenolol, which is not likely to interfere with hepatic metabolism, provides a reasonable alternative.

Mood Stabilizers

Lithium

Lithium is absorbed completely from the GI tract; it achieves peak plasma concentrations after approximately 1.5 to 2 hours for standard preparations and 4 to 4.5 hours for slow-release preparations. It distributes throughout total body water and, in contrast to most psychotropic drugs, does not bind to plasma proteins and is not metabolized in the liver. It is filtered and reabsorbed by the kidneys, and 95% of it is excreted in the urine. Lithium elimination is highly dependent on total body sodium and fluid balance; it competes with sodium for reabsorption in the proximal tubules. To a lesser extent, lithium is reabsorbed also in the loop of Henle but, in contrast to sodium, is not reabsorbed in the distal tubules. Its elimination half-life is approximately 24 hours; clearance is generally 20% of creatinine clearance but is diminished in elderly patients and in patients with kidney disease. The risk of toxicity is increased in these patients as well as in patients with cardiovascular disease, dehydration, or hypokalemia. The most common drug–drug interactions involving lithium are pharmacokinetic. Because lithium has a low therapeutic index, such interactions are likely to be clinically significant and potentially serious (Table 34–4).[50]

Among the best-studied of these interactions are thiazide diuretics and drugs that are chemically distinct but share a similar mechanism of action (e.g., indapamide, metolazone, and quinethazone). These agents decrease lithium clearance and thereby steeply increase the risk of lithium toxicity. Thiazide diuretics block sodium reabsorption at the distal tubule, producing sodium depletion, which, in turn, results in increased lithium reabsorption in the proximal tubule. Loop diuretics (e.g., furosemide and bumetanide) appear to interact to a lesser degree with lithium excretion, presumably because they block lithium reabsorption in the loop of Henle, potentially offsetting possible compensatory increases in reabsorption more proximally.[51,52] The

TABLE 34–4 Selected Drug Interactions with Lithium

DRUG	POTENTIAL INTERACTION
Aminophylline, theophylline, acetazolamide, mannitol, sodium bicarbonate, sodium chloride load	Decreased lithium levels
Thiazide diuretics	Increased lithium levels; reduction of lithium-associated polyuria
Nonsteroidal antiinflammatory drugs, COX-2 inhibitors, tetracycline, spectinomycin, metronidazole, angiotensin II receptor antagonists, angiotensin-converting enzyme inhibitors	Increased lithium levels
Neuromuscular blocking drugs (succinylcholine, pancuronium, decamethonium)	Prolonged muscle paralysis
Antithyroid drugs (propylthiouracil, thioamide, methimazole)	Enhanced antithyroid efficacy
Antidepressants	Enhanced antidepressant efficacy
Calcium channel blockers (verapamil, diltiazem)	Idiosyncratic neurotoxicity
Antipsychotic drugs	Idiosyncratic neurotoxicity, neuroleptic malignant syndrome risk

COX-2, Cyclooxygenase-2.

potassium-sparing diuretics (e.g., amiloride, spironolactone, ethacrynic acid, and triamterene) also appear to be less likely to cause an increase in lithium levels, but close monitoring is indicated when these drugs are introduced.[53] The potential impact of thiazide diuretics on lithium levels does not contraindicate their combined use, which has been particularly valuable in the treatment of lithium-associated polyuria. Potassium-sparing diuretics have also been used for this purpose. When a thiazide diuretic is used, a lithium dosage reduction of 25% to 50% and close monitoring of lithium levels are required. Monitoring of serum electrolytes, particularly potassium, is also important when thiazides are introduced because hypokalemia enhances the toxicity of lithium. Although not contraindicated with lithium, ACE inhibitors (e.g., captopril) and angiotensin II receptor antagonists (e.g., losartan) can elevate lithium levels, and close monitoring of levels is required when these agents are introduced.

Many of the nonsteroidal antiinflammatory drugs (NSAIDs) (including ibuprofen, indomethacin, diclofenac, naproxen, mefenamic acid, ketoprofen, and piroxicam) have been reported to increase serum lithium levels, potentially by as much as 50% to 60% when used at full prescription strength. This can occur by inhibition of renal clearance of lithium by interference with a prostaglandin-dependent mechanism in the renal tubule. The cyclooxygenase (COX)-2 inhibitors (e.g., celecoxib and rofecoxib), can also raise lithium levels. Limited data available suggest that sulindac,[54] phenylbutazone,[55] and aspirin[56] are less likely to affect lithium levels. A number of antimicrobials are associated with increased lithium levels, including tetracycline, metronidazole, and parenteral spectinomycin. In the event that these agents are required, close monitoring of lithium levels and potential dosage adjustment are recommended.

Conversely, a variety of agents can produce decreases in lithium levels, thereby increasing risk of psychiatric symptom breakthrough and relapse. The methylxanthines (e.g., aminophylline and theophylline) can cause a significant decrease in lithium levels by increasing renal clearance; close blood level monitoring with co-administration is necessary. A reduction in lithium levels can also result from alkalinization of urine (e.g., with acetazolamide use or with sodium bicarbonate), osmotic diuretics (e.g., urea or mannitol), or from ingestion of a sodium chloride load, which also increases lithium excretion.

A likely pharmacodynamic interaction exists between lithium and agents used clinically to produce neuromuscular blockade (e.g., succinylcholine, pancuronium, and decamethonium) during anesthesia. Muscle paralysis can be significantly prolonged when these agents are administered to the lithium-treated patient.[57] Although the mechanism is unknown, the possible inhibition by lithium of acetylcholine synthesis and release at the neuromuscular junction is a potential basis for synergism.

Lithium interferes with the production of thyroid hormones through several mechanisms, including interference with iodine uptake, tyrosine iodination, and release of triiodothyronine (T_3) and thyroxine (T_4).[7] Lithium can therefore enhance the efficacy of antithyroid medications (e.g., propylthiouracil, thioamide, and methimazole) and has also been used preoperatively to help prevent thyroid storm in the surgical treatment of Graves' disease.[58]

There have been isolated reports of various forms of neurotoxicity, which is usually, but not always, reversible, when lithium has been combined with SSRIs and other serotoninergic agents, calcium channel blockers, antipsychotics, and anticonvulsants (e.g., carbamazepine).[59–61] In some cases, features of the serotonin syndrome or NMS have been present.[62] Although it is worthwhile to bear this in mind when evaluating unexplained mental status changes in a lithium-treated patient, the combination of lithium with these classes of medication is neither contraindicated nor unusual.

Valproic Acid

Valproic acid is a simple branched-chain carboxylic acid that, like several other anticonvulsants, has mood-stabilizing properties. Valproic acid is 80% to 95% protein-bound and is rapidly metabolized primarily by hepatic microsomal glucuronidation and oxidation. It has a short elimination half-life of approximately 8 hours.[7] Clearance is essentially unchanged in the elderly and in patients with kidney disease, whereas it is significantly reduced in patients with primary liver disease.[63]

In contrast to other major anticonvulsants (such as carbamazepine or phenobarbital), valproate does not induce hepatic microsomes. Rather, it tends to inhibit oxidation reactions, thereby potentially increasing levels of co-administered hepatically metabolized drugs (Table 34–5).[63–65] A complex pharmacokinetic interaction occurs when valproic acid and carbamazepine are administered concurrently. Valproic acid not only inhibits the metabolism of carbamazepine and its active metabolite, carbamazepine-10,11-epoxide (CBZ-E), but it also displaces both entities from protein-binding sites. Although the effect on plasma carbamazepine levels is variable, the levels of the unbound (active) epoxide metabolite are increased, with a concomitant increased risk of carbamazepine neurotoxicity.[66] Conversely, co-administration with carbamazepine results in a decrease in plasma valproic acid levels. Nevertheless, the combination of valproate and carbamazepine has been used successfully in the treatment of patients with bipolar disorder who were only partially responsive to either drug alone.[67]

Cimetidine, a potent inhibitor of hepatic microsomal enzymes, is associated with decreased clearance of valproic acid, resulting in increased levels. Dosage of valproic acid may need to be reduced in the patient starting cimetidine, but not other H_2-receptor antagonists.[68] Elevated levels of valproic acid have also been reported sporadically with fluoxetine[69] and other SSRIs. Aspirin and other salicylates can displace protein binding of valproic acid, thereby increasing the unbound (free) fraction,[65] which can increase risk of toxicity from valproate even though total serum levels are unchanged. Although absence seizures have been reported with the combination of clonazepam and valproate,[70] this is likely to be rare and limited to patients with neurologic disorders.

Lamotrigine

Lamotrigine is a phenyltriazine anticonvulsant that is moderately (50% to 60%) protein-bound and metabolized primarily by glucuronidation. Its most serious adverse effect is a life-threatening hypersensitivity reaction with rash, typically, but not always, occurring within the first 2 months of use.[46] The incidence among patients with bipolar disorder is estimated at 0.8 per 1000 among patients on lamotrigine monotherapy and 1.3 per 1000 among patients on lamotrigine in combination with other agents.

The risk of adverse effects including hypersensitivity reactions and tremor is increased when lamotrigine is combined with valproic acid. As much as a twofold to threefold increase in lamotrigine levels occurs when valproic acid is added, related to inhibition of glucuronidation of lamotrigine.[65,71] Accordingly, the *Physicians' Desk Reference* (PDR) provides guidelines for more gradual dosage titration of lamotrigine and lower target dosages when introduced in a patient already taking valproate. When valproate is added to lamotrigine, the dosage of lamotrigine should typically be reduced.

Conversely, lamotrigine levels can be decreased by as much as 50% when administered with metabolic inducers, particularly other anticonvulsants (including carbamazepine, primidone, and phenobarbital). Therefore, guidelines

TABLE 34–5 Selected Drug Interactions with Valproate and Carbamazepine

DRUG	INTERACTION WITH VALPROATE
Carbamazepine	Decreased valproate plasma levels; increased plasma levels of the epoxide metabolite of carbamazepine; variable effects on plasma levels of carbamazepine
Phenytoin	Decreased valproate plasma levels; variable effects on phenytoin plasma levels
Phenobarbital	Decreased valproate plasma levels; increased phenobarbital plasma levels
Lamotrigine	Increased lamotrigine levels; hypersensitivity reaction
Aspirin	Increased unbound (active) fraction of valproate
Cimetidine	Increased valproate plasma levels
Fluoxetine	Same as above
Clonazepam	Rare absence seizures

DRUG	INTERACTION WITH CARBAMAZEPINE
Phenytoin	Decreased carbamazepine plasma levels
Phenobarbital	Same as above
Primidone	Same as above
Macrolide antibiotics	Increased carbamazepine plasma levels
Isoniazid	Same as above

Furosemide	Same as above

TCA, Tricyclic antidepressants.

have been developed for dosing lamotrigine in the presence of these metabolic-inducing anticonvulsants. Similar-magnitude reductions in lamotrigine levels have been reported in patients on oral contraceptives, requiring an increase in the dosage of lamotrigine.[72] Lamotrigine levels and symptom status should be monitored closely when oral contraceptives or metabolic-inducing anticonvulsants are started.

Carbamazepine and Oxcarbazepine

Carbamazepine is an iminostilbene anticonvulsant structurally related to the TCA imipramine. Carbamazepine is slowly and inconsistently absorbed from the GI tract; peak serum concentrations are achieved approximately 4 to 8 hours after oral administration. It is only moderately (60% to 85%) protein-bound. Carbamazepine, a potent inducer of hepatic metabolism, can also induce its own metabolism, such that elimination half-life can fall from 18 to 55 hours to 5 to 20 hours over a matter of several weeks, generally reaching a plateau after 3 to 5 weeks.[7]

Most drug–drug interactions with carbamazepine occur by pharmacokinetic mechanisms. Drugs whose metabolism is increased by carbamazepine include valproic acid, phenytoin, ethosuximide, lamotrigine, alprazolam, clonazepam, TCAs, antipsychotics, doxycycline, tetracycline, thyroid hormone, corticosteroids, oral contraceptives, methadone, theophylline, warfarin, and cyclosporine.[65,73] The concurrent administration of carbamazepine with any of these drugs can cause significant reductions in plasma levels and can lead to therapeutic failure. Patients of child-bearing potential who are taking oral contraceptives must be advised to use an additional method of birth control.

Several drugs inhibit the metabolism of carbamazepine, including the macrolide antibiotics (e.g., erythromycin, clarithromycin, and triacetyloleandomycin), isoniazid, fluoxetine, valproic acid, danazol, propoxyphene, and the calcium channel blockers verapamil and diltiazem.[65,73] Because of its low therapeutic index, the risk of developing carbamazepine toxicity is significantly increased when these drugs are administered concurrently. Conversely, co-administration of phenytoin or phenobarbital, both microsomal enzyme inducers, can increase the metabolism of carbamazepine, potentially resulting in subtherapeutic plasma levels. Carbamazepine has also been associated with bone marrow suppression, and its combination with other agents that interfere with blood cell production (including clozapine) should generally be avoided.[48] The combination of carbamazepine with thiazide diuretics or furosemide has been associated with severe symptomatic hyponatremia,[74] suggesting the need for close monitoring of electrolytes when these medications are used concurrently.

Oxcarbazepine, a structural derivative of carbamazepine, appears to be a less-potent metabolic inducer than its parent compound, although it still can render certain important agents (particularly CYP 3A4 substrates) less effective because of similar pharmacokinetic interactions.[7] Women of childbearing potential should therefore receive guidance about supplementing oral contraceptives with a second effective form of birth control, as with carbamazepine. Like carbamazepine, oxcarbazepine is also associated with risk of hyponatremia.

Other Anticonvulsants

Several new anticonvulsants have become available that, as with valproate, carbamazepine, and lamotrigine, are now being explored in treating bipolar disorder and other psychiatric conditions. In contrast to older anticonvulsants with demonstrated effects on mood, much less is known about the potential pharmacokinetic interactions involving these newer agents, including topiramate, zonisamide, gabapentin, and pregabalin. At present, none of these anticonvulsants can be justified as a monotherapy for any phase of bipolar disorder, but they may have a role as an adjunct treatment in some bipolar patients.[46]

Topiramate

Topiramate is a sulfamate-substituted monosaccharide, related to fructose, a rather unusual chemical structure for an anticonvulsant. Topiramate remains under study for its putative mood-stabilizing[75] and weight-reducing effects[76,77] as well as its utility in substance-abusing populations.[78]

Topiramate is quickly absorbed after oral use. Most of the drug (70%) is later excreted in the urine unchanged; therefore, it requires dosage reduction in the setting of renal insufficiency. The remainder is extensively metabolized by hydroxylation, hydrolysis, and glucuronidation. Topiramate inhibits carbonic anhydrase; therefore, the concomitant use of other carbonic anhydrase inhibitors (e.g. acetazolamide) can lead to an increased risk of forming kidney stones. Patients adhering to a ketogenic diet can also be prone to nephrolithiasis with topiramate treatment and should be instructed to stay well hydrated.[46]

In the presence of hepatic enzyme inducers (e.g., carbamazepine), the elimination of topiramate may be increased by up to 50%. Based on its properties as a weak inhibitor of CYP 2C19 and an inducer of CYP 3A4, topiramate can increase plasma levels of phenytoin but decrease plasma concentrations of estrogens in women taking oral contraceptives.[7]

Topiramate is associated with the side effects of cognitive dysfunction and sedation, both of which are limiting factors in clinical use.

Zonisamide

Zonisamide is a sulfonamide anticonvulsant used in patients with partial seizures.[79] Like topiramate, zonisamide is under investigation in psychiatry to facilitate weight loss in bipolar patients, and it might have fewer adverse cognitive effects. The FDA has warned that zonisamide can cause metabolic acidosis in some patients. As a result, patients should have their serum bicarbonate levels assessed before starting treatment and periodically during treatment with zonisamide, even in the absence of symptoms. Zonisamide is metabolized mostly by the CYP 3A4 isoenzyme; its metabolism is inhibited by ketoconazole, cyclosporin, miconazole, fluconazole, and carbamazepine (in descending order).[80]

Gabapentin and Pregabalin

Gabapentin—used at present in psychiatry for patients with anxiety, mood instability, or pain—is not a salt, but it resembles lithium because it is not hepatically metabolized, is not appreciably protein-bound, and is excreted by the kidney largely as unchanged drug. As with lithium, therefore, it is essential to adjust dosage according to changes in renal function.

Like gabapentin, pregabalin is rapidly absorbed when administered on an empty stomach, undergoes negligible metabolism in humans, has very low protein-binding, and is eliminated from the systemic circulation primarily by renal excretion unchanged. Studies have shown that pregabalin has a role in treating chronic pain disorders, such as fibromyalgia[81] and spinal cord injuries. Although *in vivo* studies have shown no significant pharmacokinetic interactions for pregabalin, it might have potential interactions with opioids (pregabalin is synergistic with opioids in lower dosages), benzodiazepines, barbiturates, alcohol, and other drugs that depress the CNS.

Antidepressants

The antidepressant drugs include the TCAs, the MAOIs, the SSRIs, the atypical agents (bupropion, trazodone, nefazodone, and mirtazapine), and the serotonin–norepinephrine reuptake inhibitors (SNRIs) (venlafaxine, duloxetine, and desvenlafaxine). Although the TCAs and MAOIs are used infrequently, they continue to serve a valuable role in the treatment of more severe, treatment-resistant depressive and anxiety disorders despite the wide range of drug–drug interactions they entail.

SSRIs and Other Newer Antidepressants

The SSRIs (e.g., fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram) share similar pharmacologic actions, including minimal anticholinergic, antihistaminic, and α_1-adrenergic blocking effects and potent presynaptic inhibition of serotonin reuptake.[7,82] There are important pharmacokinetic differences that account for distinctions among them with respect to potential drug interactions (Table 34–6).

Nefazodone, similar to trazodone, is distinguished from classic SSRIs by its antagonism of the 5-HT_2 receptor and differs from trazodone in its lesser antagonism of the α_1-adrenergic receptor. Mirtazapine blocks the 5-HT_2 receptor, 5-HT_3 receptor, and the α_2 adrenergic receptors. Venlafaxine, similar to TCAs, inhibits serotonin and norepinephrine reuptake, but, in contrast to TCAs, it is relatively devoid of postsynaptic anticholinergic, antihistaminic, and α_1-adrenergic activity. Similarly, duloxetine is an inhibitor of serotonin and norepinephrine reuptake, although whereas venlafaxine is predominantly serotoninergic at low to moderate dosages, duloxetine is a potent inhibitor of both the norepinephrine and serotonin transporters across its clinical dosage range.

Although not an approved antidepressant, the SNRI atomoxetine, indicated for the treatment of ADHD, might have a role in depression pharmacotherapy as a single agent or adjunctive treatment. It is neither a significant inhibitor nor inducer of the CYP system, but owing to its adrenergic effects, the risk of palpitations or pressor effects is likely to be greater than with serotoninergic agents when combined with prescribed and OTC sympathomimetics, and its use with MAOIs is contraindicated.

All of the SSRIs (except for fluvoxamine [77%], citalopram [80%], and escitalopram [56%]) as well as nefazodone are highly protein-bound (95% to 99%). Venlafaxine is minimally protein-bound (20% to 30%), whereas duloxetine is highly protein-bound (90%). All of the antidepressants are hepatically metabolized, and all of them except paroxetine and duloxetine have active metabolites. The major metabolites of sertraline and citalopram, however, appear to be minimally active.

Elimination half-lives range from 5 hours for venlafaxine and 11 hours for its metabolite, *O*-desmethylvenlafaxine, to 2 to 3 days for fluoxetine and 7 to 14 days for its metabolite, norfluoxetine. Nefazodone, similar to venlafaxine, has a short half-life (2 to 5 hours), with fluvoxamine, sertraline, paroxetine, citalopram, and escitalopram in the intermediate range of 15 to 35 hours.[7] Food can have variable effects

TABLE 34–6 Potential Drug Interactions with the Selective Serotonin Reuptake Inhibitors and Other Newer Antidepressants

DRUG	POTENTIAL INTERACTION
MAOIs	Serotonin syndrome
Secondary amine TCAs	Increased TCA levels when co-administered with fluoxetine, paroxetine, sertraline, bupropion, duloxetine
Tertiary amine TCAs	Increased TCA levels with fluvoxamine, paroxetine, sertraline, bupropion, duloxetine
Antipsychotics (typical) and risperidone, aripiprazole	Increased antipsychotic levels with fluoxetine, sertraline, paroxetine, bupropion, duloxetine
Thioridazine	Arrhythmia risk with CYP 2D6–inhibitory antidepressants
Pimozide	Arrhythmia risk with CYP 3A4–inhibitory antidepressants (nefazodone, fluvoxamine)
Clozapine and olanzapine	Increased antipsychotic levels with fluvoxamine
Diazepam	Increased benzodiazepine levels with fluoxetine, fluvoxamine, sertraline
Triazolobenzodiazepines (midazolam, alprazolam, triazolam)	Increased fluvoxamine, nefazodone, sertraline
Carbamazepine	Increased carbamazepine levels with fluoxetine, fluvoxamine, nefazodone
Theophylline	Increased theophylline levels with fluvoxamine
Type 1C antiarrhythmics (ecainide, flecainide, propafenone)	Increased antiarrhythmic levels with fluoxetine, paroxetine, sertraline, bupropion, duloxetine
β-blockers (lipophilic)	Increased β-blocker levels with fluoxetine, paroxetine, sertraline, bupropion, duloxetine
Calcium channel blockers	Increased levels with fluoxetine, fluvoxamine, nefazodone

CYP, Cytochrome P450; *MAOI*, Monoamine oxidase inhibitor; *TCA*, tricyclic antidepressant.

on antidepressant bioavailability, including an increase for sertraline, a decrease for nefazodone, and no change for escitalopram.

The growing knowledge about the interaction of the newer antidepressants with the CYP isoenzymes has revealed differences among them in their pattern of enzyme inhibition that are likely to be critical to the understanding and prediction of drug–drug interactions.[4,31]

Cytochrome P450 2D6

Fluoxetine, norfluoxetine, paroxetine, bupropion, duloxetine,[83] sertraline (to a moderate degree), and citalopram and escitalopram (to a minimal degree)[4] all inhibit CYP 2D6, which accounts for their potential inhibitory effect on TCA clearance and the metabolism of other CYP 2D6 substrates. Other drugs metabolized by CYP 2D6—and whose levels can rise in the setting of CYP 2D6 inhibition—include the type 1C antiarrhythmics (e.g., encainide, flecainide, and propafenone) as well as β-blockers (e.g., propranolol, timolol, and metoprolol), antipsychotics (e.g., risperidone, haloperidol, aripiprazole, thioridazine, and perphenazine), TCAs, and trazodone. CYP 2D6 converts codeine into its active analgesic form.

These observations underscore the need to exercise care and to closely monitor when prescribing these SSRIs, bupropion, or duloxetine in the setting of complex medical regimens. Plasma TCA levels do not routinely include levels of active or potentially toxic metabolites, which may be altered by virtue of shunting to other metabolic routes when CYP 2D6 is inhibited. Therefore, particularly in the case of patients at risk for conduction delay, electrocardiography and blood level monitoring are recommended when combining TCAs with SSRIs, duloxetine, or bupropion.

Cytochrome P450 3A4

Fluoxetine's major metabolite (norfluoxetine), fluvoxamine, nefazodone, and, to a lesser extent, sertraline, desmethylsertraline, citalopram, and escitalopram inhibit CYP 3A4. All of these agents therefore have the potential for elevating levels of pimozide and cisapride (arrhythmia risks), calcium channel blockers, the statins, carbamazepine, midazolam, and many other important and commonly prescribed substrates of this widely recruited CYP enzyme.

Cytochrome P450 2C

Serum concentrations of drugs metabolized by this subfamily may be increased by fluoxetine, sertraline, and fluvoxamine. Reported interactions include decreased clearance of diazepam on all three SSRIs, a small reduction in tolbutamide clearance on sertraline, and increased plasma phenytoin concentrations reflecting decreased clearance on fluoxetine. Warfarin is also metabolized by this subfamily, and levels may be increased by the inhibition of these enzymes. SSRIs can interact with warfarin by still other, probably pharmacodynamic mechanisms (such as depletion of platelet serotonin). Although the combination is common, increased monitoring is recommended when SSRIs are prescribed with warfarin.

Cytochrome P450 1A

Among the SSRIs, only fluvoxamine appears to be a potent inhibitor of CYP 1A2. Accordingly, increased serum concentrations of theophylline, haloperidol, clozapine, olanzapine, and the tertiary amine TCAs including clomipramine, amitriptyline, and imipramine can occur.[4] Because theophylline and TCAs have a relatively narrow therapeutic index and because the degree of elevation of antipsychotic blood levels appears to be substantial (e.g., up to fourfold increases in haloperidol concentrations), additional monitoring and consideration of dosage reductions are necessary when fluvoxamine is co-administered with these agents.

Additional Interactions

Mirtazapine, although neither a potent inhibitor nor inducer of the CYP cytochrome isoenzymes, has numerous pharmacodynamic effects including antagonism of the histamine, α_2-adrenergic, 5-HT_2 and 5-HT_3, and muscarinic receptors, creating the possibility of myriad pharmacodynamic interactions (including blockade of clonidine's antihypertensive activity).[84] It also has the possible benefit of attenuated nausea and sexual dysfunction that can occur with SSRIs.[85]

The serotonin syndrome is a potentially life-threatening condition characterized by confusion, diaphoresis, hyperthermia, hyperreflexia, muscle rigidity, tachycardia, hypotension, and coma.[86,87] Although this can arise whenever an SSRI is combined with a serotoninergic drug (e.g., L-tryptophan, clomipramine, or venlafaxine) and drugs with serotoninergic properties (e.g., lithium, mirtazapine, dextromethorphan, tramadol, meperidine, and pentazocine), the greatest known risk is associated with the co-administration of an SSRI with an MAOI; this is absolutely contraindicated. In view of the long elimination half-life of fluoxetine and norfluoxetine, at least 5 weeks must elapse after fluoxetine discontinuation before an MAOI can be safely introduced. With the other SSRIs, an interval of 2 weeks appears to be adequate.

The weak, reversible MAOI antimicrobial linezolid, used for treatment of multidrug-resistant gram-positive infections, has been implicated in a small number of postmarketing cases of serotonin syndrome in patients on serotoninergic antidepressants, typically patients on SSRIs, as well as other medications, including narcotics.[88] Patients on serotoninergic antidepressants receiving linezolid should be monitored for the occurrence of symptoms suggesting serotonin syndrome. The co-administration of SSRIs with other serotoninergic agents is not contraindicated, but it should prompt immediate discontinuation in any patient on this combination of drugs who presents with mental status changes, fever, or hyperreflexia of unknown origin.

Tricyclic Antidepressants

TCAs are thought to exert their pharmacologic action by inhibiting the presynaptic neuronal reuptake of norepinephrine and serotonin in the CNS with subsequent modulation of both presynaptic and postsynaptic α-adrenergic receptors. TCAs also have significant anticholinergic, antihistaminic, and α-adrenergic activity as well as quinidine-like effects on cardiac condition, and in these respects they resemble the low-potency antipsychotic drugs, which are structurally similar.[82]

TCAs are well absorbed from the GI tract and subject to significant first-pass liver metabolism before entry into the systemic circulation, where they are largely protein-bound, ranging from 85% (trimipramine) to 95% (amitriptyline).

Peak plasma concentrations are reached approximately 2 to 6 hours after oral administration. They are highly lipophilic, with a large volume of distribution. TCAs are extensively metabolized by hepatic microsomal enzymes, and most have pharmacologically active metabolites.[89]

With two methyl groups on the terminal nitrogen of the TCA side-chain, imipramine, amitriptyline, trimipramine, doxepin, and clomipramine are called *tertiary amines*. The demethylation of imipramine, amitriptyline, and trimipramine yields the secondary amine TCAs, desipramine, nortriptyline, and protriptyline, which are generally less sedating and have less affinity for anticholinergic receptors. The demethylation of imipramine relies on cytochrome CYP isoenzymes 1A2, 3A3, and 3A4, whereas that of amitriptyline appears to rely primarily on 1A2. These tertiary amines as well as their secondary amine offspring are then hydroxylated via CYP 2D6, a step sensitive to inhibition by a wide variety of other drugs.[2] The hydroxymetabolites of the most commonly prescribed TCAs can be active. Furthermore, the hydroxymetabolite of nortriptyline can block the antidepressant effect of the parent drug,[90] and some hydroxymetabolites of the TCAs may be cardiotoxic.[91]

Additive anticholinergic effects can occur when the TCAs are co-administered with other drugs possessing anticholinergic properties (e.g., low-potency antipsychotics, antiparkinsonian drugs), potentially resulting in an anticholinergic syndrome. SSRIs, atypical antidepressants, and MAOIs are relatively devoid of anticholinergic activity, although the MAOIs can indirectly potentiate the anticholinergic properties of atropine and scopolamine. Additive sedative effects are not uncommon when TCAs are combined with sedative–hypnotics, anxiolytics, or narcotics or alcohol (Table 34–7).

TCAs possess class 1A antiarrhythmic activity and can lead to depression of cardiac conduction, potentially resulting in heart block or ventricular arrhythmias when combined with quinidine-like agents (including quinidine, procainamide, and disopyramide as well as the low-potency antipsychotics).[92–94] The antiarrhythmics quinidine and propafenone, inhibitors of CYP 2D6, can additionally produce clinically significant elevations of the TCAs, thus increasing the risk of cardiotoxicity through both pharmacodynamic and pharmacokinetic mechanisms.[95,96]

The arrhythmogenic risks of a TCA are enhanced in a patient with underlying coronary or valvular heart disease, a patient with a recent myocardial infarction or hypokalemia, and in a patient receiving sympathomimetic amines, such as amphetamine stimulants.[92,93]

TCAs also interact with several antihypertensive drugs. TCAs can antagonize the antihypertensive effects of guanethidine, bethanidine, debrisoquine, or clonidine via interference with neuronal reuptake by noradrenergic neurons. Conversely, TCAs can cause varying degrees of postural hypotension when co-administered with vasodilator drugs, antihypertensives, or low-potency neuroleptics.

Hypoglycemia has been observed with secondary and tertiary TCAs, particularly in the presence of sulfonylurea hypoglycemic agents,[2] suggesting the need for close monitoring.

Pharmacokinetic interactions involving the TCAs are often clinically important. The antipsychotic drugs (including haloperidol, chlorpromazine, thioridazine, and perphenazine) are known to increase TCA levels by 30% to 100%.[97,98] Cimetidine can also raise tertiary TCA levels as predicted by microsomal enzyme inhibition,[99] as can methylphenidate. The antifungals (e.g., ketoconazole), macrolide antibiotics (e.g., erythromycin), and calcium channel blockers (e.g., verapamil and diltiazem) as inhibitors of CYP 3A4 can also impair the clearance of tertiary amine TCAs, thereby requiring a reduction in TCA dosage. SSRIs have been associated with clinically significant increases in TCA plasma levels, believed to be the result of inhibition primarily, but not exclusively, of CYP 2D6.[25] Similar elevations of TCA levels would be expected with other potent CYP 2D6 inhibitor antidepressants (e.g., duloxetine and bupropion). Inducers of CYP enzymes can increase the metabolism of TCAs. Thus, plasma levels of TCAs may be significantly reduced when carbamazepine, phenobarbital, rifampin, or isoniazid are co-administered or in the setting of chronic alcohol or cigarette use.

TABLE 34–7 Selected Drug Interactions with Tricyclic Antidepressants

DRUG	POTENTIAL INTERACTION
Carbamazepine Phenobarbital Rifampin Isoniazid	Decreased TCA plasma levels
Antipsychotics Methylphenidate SSRIs Quinidine Propafenone Antifungals Macrolide antibiotics Verapamil Diltiazem Cimetidine	Increased TCA plasma levels
Class I antiarrhythmics	Depression of cardiac conduction; ventricular arrhythmias
Guanethidine Clonidine	Interference with antihypertensive effect
Sympathomimetic amines	Arrhythmias, hypertension (e.g., isoproterenol, epinephrine)
Antihypertensives Vasodilator drugs Low-potency antipsychotics	Hypotension
Anticholinergic drugs	Additive anticholinergic toxicity
MAOIs	Delirium, fever, convulsions
Sulfonylurea hypoglycemics	Hypoglycemia

MAOI, Monoamine oxidase inhibitor; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant.

Monoamine Oxidase Inhibitors

Monoamine oxidase is an enzyme located primarily on the outer mitochondrial membrane and is responsible for intracellular catabolism of the monoamines. It is found in

high concentrations in brain, liver, intestines, and lung. In presynaptic nerve terminals, MAO metabolizes cytoplasmic monoamines. In liver and gut, MAO catabolizes ingested bioactive amines, thus protecting against absorption into the systemic circulation of potentially vasoactive substances, particularly tyramine.

Two subtypes of MAO have been distinguished: Intestinal MAO is predominantly MAO_A, whereas brain MAO is predominantly MAO_B. MAO_A preferentially metabolizes norepinephrine and serotonin. Phenylethylamine and benzylamine are the prototypic substrates for MAO_B. Both MAO subtypes metabolize dopamine and tyramine. The currently available MAOIs—phenelzine, tranylcypromine, and isocarboxazid—are nonspecific inhibitors of both MAO_A and MAO_B. Selegiline, available in transdermal form, has been approved for the treatment of depression. At low dosages selegiline is primarily an inhibitor of MAO_B, though it is a mixed MAO_A and MAO_B inhibitor at higher dosages.

When patients are using MAOIs, dietary[100,101] and medication restrictions must be closely followed to avoid serious interactions. The MAOIs are, therefore, generally reserved for use in responsible or supervised patients when adequate trials of other classes of antidepressants have failed. The two major types of MAOI drug–drug interaction are the serotonin syndrome and the hypertensive (also called hyperadrenergic) crisis.[102]

Hypertensive Crisis

Hypertensive crisis is an emergency characterized by an abrupt elevation of blood pressure, severe headache, nausea, vomiting, and diaphoresis; intracranial hemorrhage or myocardial infarction can occur. Prompt intervention to reduce blood pressure with the α_1-adrenergic antagonist phentolamine or the calcium channel blocker nifedipine may be lifesaving.[38]

Potentially catastrophic hypertension appears to be due to release of bound intraneuronal stores of norepinephrine and dopamine by indirect vasopressor substances. The reaction can therefore be precipitated by the concurrent administration of vasopressor amines, stimulants, anorexiants, and many OTC cough and cold preparations; these include L-dopa, dopamine, amphetamine, methylphenidate, phenylpropanolamine, phentermine, mephentermine, metaraminol, ephedrine, and pseudoephedrine.[103,104] By contrast, direct sympathomimetic amines (e.g., norepinephrine, isoproterenol, and epinephrine), which rely for their cardiovascular effects on direct stimulation of postsynaptic receptors, rather than on presynaptic release of stored catecholamines, appear to be somewhat safer when administered to patients on MAOIs (although they are also contraindicated).[101]

Hypertensive crises may also be triggered by ingestion of naturally occurring sympathomimetic amines (particularly tyramine), which is present in various food products, including aged cheeses (e.g., stilton, cheddar, bleu cheese, or camembert, rather than cream cheese, ricotta cheese, or cottage cheese), yeast extracts (e.g., Marmite, brewer's yeast tablets), fava (broad) beans, overripe fruits (e.g., avocado), pickled herring, aged meats (e.g., salami, bologna, and many kinds of sausage), chicken liver, fermented bean curd, sauerkraut, many types of red wine and beer (particularly imported beer), and some white wines. Although gin, vodka, and whiskey appear to be free of tyramine, their use should be minimized during the course of MAOI treatment, as with other antidepressants, because of the risk of exaggerated side effects and reduced antidepressant efficacy. Other, less-stringent requirements include moderate intake of caffeine, chocolate, yogurt, and soy sauce. Because MAO activity can remain diminished for nearly 2 to 3 weeks following the discontinuation of MAOIs, a tyramine-free diet and appropriate medication restrictions should be continued for at least 14 days after an MAOI has been discontinued.[38]

The lowest dose available of transdermal selegiline has been shown to have minimal risks of hypertensive crisis on a normal diet and therefore does not require the same level of restriction; however, dosages of at least 9 mg in 24 hours carry the same dietary recommendations as oral MAOIs.[38,100] Reversible inhibitors of MAO_A, such as moclobemide and brofaromine (not approved in the United States), and novel delivery systems (e.g., transdermal selegiline) are being developed, offering some promise that MAOIs will be devised that provide antidepressant benefits with fewer dietary and medication restrictions.

Serotonin Syndrome

The serotonin syndrome, the other major drug–drug interaction involving the MAOIs, occurs when MAOIs and serotoninergic agents are co-administered.[105] Potentially fatal reactions most closely resembling the serotonin syndrome can also occur with other drugs with less-selective serotoninergic activity, most notably meperidine and dextromethorphan, a widely available cough suppressant. Both of these medications, similar to the SSRIs, SNRIs, and clomipramine, are absolutely contraindicated when MAOIs are used. Other serotoninergic medications (e.g., buspirone and trazodone) are not contraindicated but should be used with care.

The 5-HT_1 agonist triptans, used in the treatment of migraine, have been implicated in serotonin syndrome when administered to patients on MAOIs. Other narcotic analgesics (e.g., propoxyphene, codeine, oxycodone, morphine, alfentanil, or morphine) appear to be safer alternatives to meperidine, but, in conjunction with MAOIs, their analgesic and CNS-depressant effects may be potentiated and rare serotonin syndrome–like presentations have been reported.[30,44,106] If opioid agents are necessary, they should be started at one fifth to one half of the standard dosages and gradually titrated upward, with monitoring for untoward hemodynamic or mental status changes.

Extremely adverse, although reversible, symptoms of fever, delirium, convulsions, hypotension, and dyspnea were reported on the combination of imipramine and MAOIs.[107] This has contributed to avoidance of the once-popular TCA–MAOI combinations. Nevertheless, although incompletely studied, the regimen has been observed in some instances to be successful for exceptionally treatment-refractory patients.[46,107–110] When TCAs and MAOIs are combined, simultaneous initiation of a TCA–MAOI or initiation of the TCA before, but never after, the MAOI is recommended, as is avoidance of the more serotoninergic TCAs (including clomipramine, imipramine, and amitriptyline).[111,112]

The sedative effects of CNS depressants (including the benzodiazepines, barbiturates, and chloral hydrate) may be potentiated by MAOIs. MAOIs often cause postural hypotension, and severe additive effects have occurred when co-administered with vasodilator or antihypertensive medications or low-potency antipsychotics.[30] The MAOIs, similar to the TCAs, have also been observed to potentiate hypoglycemic agents, including insulin and sulfonylurea drugs, suggesting the need for more frequent glucose monitoring when MAOIs are co-administered with hypoglycemic medications.[30]

Phenelzine has been associated with lowered serum pseudocholinesterase levels and prolonged neuromuscular blockade.[113] When possible, phenelzine may be discontinued 10 to 14 days before elective procedures requiring succinylcholine.[30] Nevertheless, the concurrent use of MAOIs is not a contraindication to surgery or electroconvulsive therapy (ECT), although it requires a detailed pre-procedure consultation with the anesthesiologist.

St. John's Wort

Although the efficacy of St. John's wort for depression remains to be confirmed, it has emerged as the most carefully studied herbal preparation when it comes to drug–drug interactions. Initial concerns about the generally weak, though potentially variable, MAOI activity of this botanical and the associated risk of serotonin syndrome when combined with serotoninergic agents have only been weakly borne out, with few cases of serotonin syndrome reported despite widespread concurrent use of St. John's wort with serotoninergic antidepressants. However, case reports and clinical trials indicate that some critical medications may be rendered less effective in some patients concurrently taking St. John's wort.[114,115] These medications include immunosuppressants (such as cyclosporine and tacrolimus), coumarin anticoagulants, antiretrovirals, theophylline, digoxin, amitriptyline, and oral contraceptives. Although the precise mechanisms and herbal constituents responsible for these effects remain to be elucidated, the primary focus has been on CYP 3A4 and P-glycoprotein. A paucity of systematic information exists concerning potential drug interactions and adverse effects of other herbal products, including a possible risk of increased bleeding in patients on ginkgo biloba and warfarin and of hepatotoxicity in patients on certain kava preparations.[116]

Psychostimulants and Modafinil

Psychostimulants

Psychostimulants have provided an often rapidly effective treatment of depressive symptoms among elderly and medically frail patients, including those with heart disease or HIV infection, who would be at particular risk from anticholinergic, hypotensive, sedative, or quinidine-like effects of the TCAs.[117–120] Although the broader range of options presented by the newer antidepressants has limited the need for stimulants in these settings, stimulants continue to be recruited as antidepressants and antidepressant adjuncts to the SSRIs, TCAs, and bupropion in the management of treatment-refractory depression. In addition, the cautious combination of methylphenidate and dextroamphetamine with MAOIs has been found to be effective in a subset of treatment-refractory depressed patients[121,122] and in efforts to treat particularly severe postural hypotension from the MAOIs. In view of the high risk of hypertensive crises, the addition of stimulants to MAOIs for antidepressant augmentation should remain an option only in exceptional cases in which other options (e.g., ECT) have been carefully weighed.

Methylphenidate, one of the most commonly used stimulants in modern psychiatric practice, has low bioavailability (20% to 30%) in orally administered forms and undergoes extensive presystemic metabolism through hydrolysis or de-esterification with limited oxidation.[123,124] Carboxylesterase-1A1 (CES-1), located in the stomach and liver, is the primary enzyme involved with first-pass methylphenidate metabolism. Difference in an individual's hydrolyzing enzyme activity, linked to variants in human CES-1 gene,[125] can lead to wide variations in methylphenidate metabolism (and corresponding methylphenidate blood concentrations) in certain persons. Improved, long-acting forms of methylphenidate and amphetamine have become available, thereby circumventing the short duration of action of the older immediate-release stimulant preparations (e.g., 3 to 4 hours of effectiveness for ADHD symptoms with immediate-release methylphenidate). A transdermal preparation of methylphenidate, which avoids much of the first-pass metabolism through CES-1, is also available.

In combination with other drugs, psychostimulants such as methylphenidate have been linked to increased plasma levels of TCAs and possibly other antidepressants; increased plasma levels of phenobarbital, primidone, and phenytoin; increased prothrombin time on anticoagulants; attenuation or reversal of the guanethidine antihypertensive effect; and increased pressor responses to vasopressor drugs.[30] Methylphenidate has been implicated in putative drug interactions more often than dextroamphetamine or mixed amphetamine salts.[126] At present, methylphenidate and other psychostimulants have been insufficiently studied to draw firm conclusions about their comparative suitability for use among patients following more-complex medical regimens.

Modafinil

The relatively benign side-effect profile of modafinil, together with its stimulant-like properties but differing mechanism, have motivated efforts to define the potential role of this wakefulness-promoting agent currently approved for treatment of narcolepsy. Its success as a treatment for fatigue in neurologic conditions (e.g., multiple sclerosis) [127] suggests the possibility of usefulness as a treatment for drowsiness related to other causes, including medications (e.g., antipsychotic-induced sedation). In addition, it has shown some promise in initial studies as an agent, like the psychostimulants, useful for treating depression co-morbid with medical illness[128] and as an antidepressant adjunct in refractory depression.[129] Likewise, several studies have suggested efficacy for children[130,131] and adults[132] with ADHD, though the use of modafinil for this purpose remains an off-label practice.

Clinical and preclinical studies have suggested that modafinil may be less likely than methylphenidate or dextroamphetamine to generate euphoria[133]; nevertheless it is a Schedule IV drug and its abuse liability is not yet known

to be less than the psychostimulants in real-world clinical settings. In addition, the risks of exacerbating psychosis or unmasking motor tics in predisposed persons, as can occur on psychostimulants, is not well defined. Modafinil interacts with the CYP isoenzymes as a minimal to moderate inducer of 3A4 and as an inhibitor of the 2C isoforms.[134] Modafinil can thereby engage in drug–drug interactions with common substrates, including oral contraceptives (the levels of which can decrease) and β-blockers and warfarin (the levels of which can increase), which requires monitoring and patient education.

Benzodiazepines

The benzodiazepines are a class of widely prescribed psychotropic drugs that have anxiolytic, sedative, muscle-relaxant, and anticonvulsant properties. Their rate of onset of action, duration of action, presence of active metabolites, and tendency to accumulate in the body vary considerably and can influence both side effects and the success of treatment. Most benzodiazepines are well absorbed on an empty stomach, with peak plasma levels achieved generally between 1 and 3 hours, although with more rapid onset of some (e.g., diazepam and clorazepate) than others (e.g., oxazepam). Duration of action of a single dose of benzodiazepine generally depends more on distribution from systemic circulation to tissue than on subsequent elimination (e.g., more rapid for diazepam than lorazepam). With repeated doses, however, the volume of distribution is saturated, and elimination half-life becomes the more important parameter in determining duration of action (e.g., more rapid for lorazepam than diazepam). A benzodiazepine that is comparatively short-acting on acute administration can therefore become relatively long-acting on long-term dosing. Benzodiazepines are highly lipophilic and distribute readily to the CNS and to tissues. Plasma protein-binding ranges from approximately 70% (alprazolam) to 99% (diazepam).[7]

Of the benzodiazepines, only lorazepam, oxazepam, and temazepam are not subject to phase I metabolism. Because phase II metabolism (glucuronide conjugation) does not produce active metabolites and is less affected than phase I metabolism by primary liver disease, aging, and concurrently used inducers or inhibitors of hepatic microsomal enzymes, the 3-hydroxy substituted benzodiazepines are much preferred in older patients and patients with liver disease. Perhaps the most common and clinically significant interactions involving benzodiazepines are the additive CNS-depressant effects, which can occur when a benzodiazepine is administered concurrently with barbiturates, narcotics, or ethanol. These interactions can be serious because of their potential to cause excessive sedation, cognitive and psychomotor impairment, and, at higher dosages, potentially fatal respiratory depression. An interesting pharmacodynamic interaction exists between benzodiazepines and physostigmine, which can act as a competitive inhibitor at the benzodiazepine receptor, antagonizing benzodiazepine effects. The specific benzodiazepine antagonist, flumazenil, however, is now more commonly the treatment of choice in managing a severe benzodiazepine overdose.

Pharmacokinetic interactions include a decreased rate of absorption, but not extent of absorption, of benzodiazepines in the presence of antacids or food. This is more likely to be a factor in determining the subjective effects accompanying the onset of benzodiazepine action for single-dose rather than repeated-dose administration. Carbamazepine, phenobarbital, and rifampin can induce metabolism, lowering levels of benzodiazepines that are oxidatively metabolized. In contrast, potential inhibitors of CYP 3A4 (including macrolide antibiotics, antifungals such as ketoconazole and itraconazole, nefazodone, fluvoxamine, and cimetidine) have been associated with decreased clearance and therefore increased levels of the triazolobenzodiazepines. A similar reaction occurs with several nonbenzodiazepine sedative–hypnotics (e.g., zolpidem, zaleplon, and eszopliclone), which are also metabolized through this pathway. The metabolism of diazepam depends in part on CYP 2C19. Decreased diazepam clearance has been reported with concurrent administration of a variety of agents including fluoxetine, sertraline, propranolol, metoprolol, omeprazole, disulfiram, low-dose estrogen-containing oral contraceptives, and isoniazid.[30]

PSYCHIATRIC USES OF NONPSYCHIATRIC MEDICATIONS

In the general hospital, consideration of the psychiatric complications of nonpsychiatric medications[135] is an integral part of the evaluation of alterations in mood, behavior, or mental status. A selected array of nonpsychiatric medications that are associated with neuropsychiatric symptoms are listed in the text in the differential diagnosis of mood changes (see Chapter 9), delirium (see Chapter 10), psychosis (see Chapter 12), and anxiety (see Chapter 13) in the medical setting. Nevertheless, whether by extrapolation from known *in vitro* mechanisms or through serendipity, nonpsychiatric drugs have also been found to be useful in the treatment of psychiatric illness. These include medications that ameliorate the side effects of psychotropic drugs as well as the growing number of nonpsychiatric medications studied for the treatment of mood, anxiety, psychotic, substance abuse, attentional, and tic disorders.

Medications for Psychotropic Drug Side Effects

The importance of attentive management of psychotropic drug side effects for alleviating the patient's suffering, for developing a therapeutic alliance, and for increasing the likelihood of the patient's adherence to necessary treatment continues to fuel the search for effective pharmacologic strategies when more-conservative measures fail to reduce dangerous or difficult-to-tolerate side effects.[7] Anticholinergic agents (benztropine 1 to 2 mg twice a day, biperiden 1 to 3 mg twice a day, and trihexyphenidyl 1 to 3 mg twice a day) and, less often, anticholinergic antihistamines (diphenhydramine 25 to 50 mg twice a day) and amantadine (100 mg two to three times a day) are widely used for managing the parkinsonian side effects of antipsychotics. Benztropine 2 mg and diphenhydramine 50 mg are also used IM or IV for the acute management of dystonia. Anticholinergic side effects are not uncommon, however, and combination of these drugs with other highly anticholinergic agents (e.g., tertiary amine TCAs) invites the risk

of frank toxicity. In this regard, IV physostigmine has been used in the emergency management of the anticholinergic syndrome, which includes delirium and tachyarrhythmias. β-blockers (including propranolol starting at 10 to 20 mg one to two times a day or the less centrally active atenolol (approximately 50 mg/day) have been useful for akathisia from antipsychotics and antidepressants, for lithium-associated tremor, and, less commonly, for jitteriness on antidepressants. Although the risk of depression on β-blockers is likely to be quite small, it is still reasonable nevertheless to monitor for alterations in mood whenever moderate to high dosages of the more lipophilic CNS active agents are used (e.g., propranolol dosages greater than 80 mg/day).[135,136]

Diuretics, including amiloride 5 to 10 mg one to three times a day and hydrochlorothiazide 50 to 100 mg/day, have been successful in treating disruptive polyuria on lithium, albeit potentially requiring reduction of lithium dosage and close monitoring of lithium levels and serum potassium. Anticholinergic side effects, including urinary retention, constipation, blurred vision, and dry mouth, may be treated with bethanechol 10 to 25 mg one to three times a day; dry mouth and blurred vision can also be treated with 1% pilocarpine ophthalmic solution. Excessive sweating on antidepressants is infrequently treated with the α_1-adrenergic agents terazosin (1 mg for every hour of sleep) and doxazosin (1 to 2 mg for every hour of sleep) as well as with anticholinergic agents, such as benztropine (0.5 to 1.0 once or twice daily) or glycopyrrolate (1 to 2 mg once daily to three times a day).

Pharmacologic attempts to reduce orthostatic hypotension on antidepressants have included caffeine or cautious introduction of T_3 (25 to 50 µg/day), T_4 (50 to 200 µg/day), the mineralocorticoid fludrocortisone (0.05 to 0.5 mg/day), salt tablets (600 to 1800 mg/day), methylphenidate, or dextroamphetamine (5 to 20 mg/day). These measures tend to be used after other measures have failed, including efforts to maximize hydration and to improve venous return from the lower extremities by calf muscle exercises or surgical support stockings.

Nausea or indigestion that is not responsive to change in dosing strategy or a change in preparation has been successfully treated with nizatidine (150 to 300 mg/day), famotidine (20 to 40 mg/day), or metoclopramide (5 to 10 mg one to two times a day). Metoclopramide, a cholinergic agonist and dopamine antagonist, has been associated rarely with extrapyramidal and dyskinetic effects, akathisia, and a case of mania, and because it increases gastric motility, it can potentially affect the absorption of co-administered medications. With respect to the H_2 antagonists, although all are capable of producing mood and cognitive changes, including delirium, cimetidine, which has been most closely associated with these effects, is also a potent inhibitor of CYP metabolism, rendering it least preferable among these agents for use in patients on multiple psychotropic medications. Similarly, omeprazole, an inhibitor of the gastric proton pump, appears to be an inducer of CYP 1A2 and an inhibitor of CYP 2C,[4] and its potential impact on the metabolism of concurrent medications should therefore be considered when it is prescribed. Agents that block 5-HT_3 receptors also may be helpful in reducing nausea related to serotoninergic agents. Although odansetron is an option, a less-expensive, albeit less-selective, alternative for appropriate candidates is mirtazapine.

Diarrhea not responsive to changes in preparation or dosing is often responsive to standard agents, such as loperamide or diphenoxylate. Acidophilus (1 capsule/meal) and cyproheptadine (2 to 4 mg one to three times a day) have also been used as antidiarrheal strategies.

Weight gain on psychotropic medications is common, distressing, and associated with risk of diabetes and hyperlipidemia. In addition to behavioral strategies for weight reduction, attention has also been directed toward pharmacologic strategies. These have included exploratory use of the anticonvulsants topiramate (25 to 100 mg one to three times a day) and zonisamide (up to 600 mg once daily). Both agents have carbonic anhydrase inhibitory properties and have been linked to an increased risk of nephrolithiasis. The H_2 antagonists, including nizatidine (up to 300 mg/day) have also showed promise in curbing weight gain, as have dopaminergic agents and bupropion.

Sexual dysfunction has proved to be a particularly common and troublesome side effect of antidepressants, especially the SSRIs, including diminished libido, erectile dysfunction, ejaculatory delay, and anorgasmia. As an alternative to switching medications (e.g., to bupropion, nefazodone, or mirtazapine), a variety of partly effective strategies have been marshaled for when dosage reductions or drug holidays[137] have not been feasible. These include sildenafil (25 to 100 mg/day)[138–140]; yohimbine (2.5 mg as needed up to 5.4 mg three times a day), potentially complicated by jitteriness, dizziness, or irritability; cyproheptadine (4 to 16 mg/day), with the potential, although apparently quite small, risk of interfering with efficacy of serotoninergic antidepressants; bethanechol (10 to 25 mg one to three times a day); neostigmine (7.5 to 15 mg/day); and amantadine (100 mg two to three times a day). Psychotropic medications have also been used in an effort to treat sexual dysfunction, including bupropion (75 to 150 mg/day),[141] nefazodone (50 to 200 mg/day), methylphenidate (5 to 10 mg one to four times a day), trazodone (25 to 100 mg/day), and buspirone (5 to 20 mg two to three times a day), as have dopamine agonists, such as ropinirole.[142] Improvement may be limited not only by the lack of more-effective pharmacologic strategies but also by the impact of depressive illness on sexual interest and by the influence of relevant psychosocial factors (e.g., marital conflict) that can accompany the depression.

α_1-Adrenergic Antagonists

Prazosin, the α_1-adrenergic receptor antagonist used for many years to treat hypertension, has been demonstrated in several open-label trials, chart reviews, and two placebo-controlled trials[143] to offer possible benefit at dosages of up to 10 mg at bedtime in the treatment of core symptoms of posttraumatic stress disorder (PTSD), particularly nightmares, insomnia, and hyperarousal.[144] Side effects include orthostatic blood pressure changes and dizziness, and particular caution does need to be observed when administered concurrently with other agents with α_1-adrenergic blocking properties, including low-potency antipsychotics.

α_2-Adrenergic Agonists

The antihypertensive clonidine is highly lipophilic and readily crosses the blood–brain barrier, where it stimulates α_2-adrenergic receptors. In 1980 it was first reported to be

an effective pharmacotherapy for Gilles de la Tourette's syndrome of chronic multiple motor and phonic tics,[145] and, as such, an alternative to antipsychotic drugs (such as haloperidol and pimozide and, more recently, risperidone), which have been the mainstays of treatment for this disabling condition arising in childhood. Clonidine alone or with naltrexone has been useful in suppressing the signs and symptoms of autonomic hyperactivity associated with inpatient detoxification from narcotic substances, including heroin, methadone, narcotic analgesics, and propoxyphene.[145] Although generally more likely to cause sedation and hypotension than other treatments for akathisia (e.g., anticholinergic medications, β-blockers, and benzodiazepines), clonidine has also been used to reduce akathisia refractory to other agents.[146] Clonidine has been shown effective in the treatment of ADHD in children and adolescents,[147] particularly in cases in which there is a marked hyperactive or aggressive component.

Although controlled trials are generally lacking, guanfacine, another α_2-adrenergic receptor agonist antihypertensive drug, appears to be useful for many of the same indications as clonidine but with the potential advantages of a longer half-life and generally less sedation.[148,149]

β-blockers

In addition to their role in the treatment of akathisia and tremor, the nonselective β-adrenergic receptor antagonists, which block the β_1-adrenergic receptors in heart and brain and β_2-adrenergic receptors in lung, blood vessels, and brain (including glial cells), have been among the first-line treatments for organically based aggressive behavior.[150] Anti-aggression β-blockers include the lipid-soluble agents propranolol and pindolol and the water-soluble agent nadolol.[151] Dosages used are generally high (e.g., propranolol up to about 12 mg/kg per day), and there may be a response latency of as long as 6 to 8 weeks. High dosages of propranolol can have modest adjuvant antipsychotic properties[152] and anti-manic effects[153]; however, the need for dosages as high as 800 to 2000 mg or more has limited the utility of this treatment approach.

Much lower dosages of β-blockers (e.g., propranolol 10 to 40 mg or the equivalent) have been used widely to reduce symptoms associated with performance anxiety[154] and are not uncommonly used for this purpose by musicians and public speakers. β-blockers are less likely to be effective pharmacotherapy for more generalized forms of social phobia, however, when compared with benzodiazepines, MAOIs, or SSRIs. The β-blockers have also had limited use for treatment of autonomic arousal associated with other anxiety states, including PTSD, generalized anxiety disorder, and panic disorder.

The prescription of β-blockers is potentially hazardous in a variety of common clinical conditions, including bronchospastic pulmonary diseases, insulin-dependent diabetes, hyperthyroidism, significant peripheral vascular disease, and congestive heart failure. In addition, β-blockers entirely or primarily eliminated by liver (e.g., propranolol, metoprolol, and pindolol) may be inhibitors of, as well as substrates for, hepatic microsomal enzymes and are therefore more likely to be subject to pharmacokinetic drug interactions than β-blockers primarily cleared by kidney (e.g., atenolol, nadolol, and sotalol).[155]

Psychopharmacological Management of Children and Adolescents

35

Boris A. Lorberg, M.D.
Jefferson B. Prince, M.D.

Similar to adults, hospitalized children develop psychiatric illness as a result of psychosocial stresses of hospitalization (e.g., loss of control, threat of illness, separation from caregivers), effects of general medical conditions (e.g., infections), use of medications or substances (e.g., drug–drug interactions, drug withdrawal), and exacerbation of preexisting psychiatric vulnerabilities. The decision to use psychotropics in this population should be based on a careful diagnostic formulation and consideration of the strikingly limited database on the risks and benefits of using, as well as not using, psychotropics. Since the National Institute of Mental Health (NIMH) conference "Medication Safety Monitoring 2000: Developing Methodologies for Monitoring Long-Term Safety of Psychotropic Medications in Children," researchers on pediatric psychopharmacology have continued to emphasize the need for collecting safety data in children.[1,2] Despite increasing research efforts, expanding clinical experience, and a continued rise in prescriptions for psychoactive medications to pediatric patients, a large gap remains between empirical support and clinical practice.[3] General guidelines for the use of psychoactive medications in children and adolescents are provided in Table 35–1; they are consistent with the American Academy of Child and Adolescent Psychiatry's (AACAP) policy statement on prescribing psychotropic medications for children and adolescents (AACAP Policy Statement October 21, 2001).

ISSUES IN CLINICAL MANAGEMENT

Use of psychotropics in pediatric patients raises a variety of concerns. The first of these issues is the off-label use of medications. The Food and Drug Administration (FDA) approves the use of medications in specified clinical situations. However, the FDA allows practitioners to use medications in clinical situations not included in the official labeling—that is, practitioners may use a medication for clinical situations other than the approved use or use it in age groups in which it has not been formally studied. Medical advances are often made with use of drugs in conditions that are not yet approved by the FDA.

A second issue deals with obtaining consent to use medications. Except in emergency situations, consent must be obtained from the custodial parent or the legal guardian before any compounds can be used in pediatric patients. This consent process involves a discussion of the diagnosis being treated, the prognosis with or without treatment, the potential risks and benefits of the proposed intervention, and a discussion of treatment alternatives. The practitioner also needs to assess the reliability of the parents before initiation of outpatient treatment because it will be their responsibility to administer the drugs on an outpatient basis. If the parents cannot reliably administer the medication, this type of intervention may be precluded.

A third issue involves developmental factors. Both pharmacodynamic and pharmacokinetic factors may influence the safety, tolerability, and efficacy of medications in the pediatric population.[4] Pharmacodynamic factors, such as the ongoing development of neural networks, may affect response to medications. Similarly, pharmacokinetic factors may influence the absorption, distribution, metabolism, and excretion of medications. Pediatric patients often require higher doses of medication to achieve the same benefit as adults, perhaps as a result of more extensive or rapid metabolism by the liver or increased renal excretion (owing to a higher glomerular filtration rate). Furthermore, the pharmacokinetics in children and adolescents may be different for short- and long-term exposures. Clinicians must keep these factors in mind as they monitor the use of medications in children and adolescents.

MEDICAL PRECAUTIONS AND CONTRAINDICATIONS

In the presence of active pediatric illness, special precautions apply when using psychotropics (Table 35–2). For example, in the presence of preexisting cardiac disease that might impair cardiac conduction, tricyclic antidepressants (TCAs) either alone or in combination with antipsychotics should be used cautiously; a cardiac evaluation should be considered before initiating treatment. In 2008 the American Heart Association re-issued an official scientific statement regarding how to decide on cardiovascular monitoring of children and adolescents receiving psychotropics, specifically stimulants.[5,6] Clinicians should refer to these recommendations when selecting and monitoring psychotropics.

TABLE 35–1 General Guidelines for the Use of Psychoactive Medications in Children and Adolescents

1. The use of psychotropics should follow a careful evaluation of the child and the family (including psychiatric, medical, and social considerations).
2. Consideration should be given to the child's nonpsychiatric disorders, and an exclusionary differential diagnosis should be considered, particularly in an acute medical setting.
3. Children who manifest transient symptoms related to an adjustment to a medical illness or to a loss should be considered for nonpharmacologic treatment; pharmacologic care should be reserved for severe or refractory cases.
4. Pharmacotherapy should be considered as part of a comprehensive treatment plan that includes individual and family psychotherapy, educational and behavioral interventions, and careful medical management; it should not be presented as an alternative to these interventions. However, pharmacotherapy should be considered as an initial treatment when it is known to be superior to other modalities.
5. If a patient has a psychiatric disorder that may respond to a psychotropic, the clinician should decide which psychotropic to use and take into consideration the age and weight of the child and the severity and nature of the clinical picture. The diagnosis and target symptoms should be defined before the initiation of pharmacotherapy.
6. The family and the child should be familiarized with the risks and benefits of this intervention, the availability of alternative treatments, the possible adverse effects, the potential for interactions with other medications, the realization that unforeseeable adverse events may arise, and the prognosis with or without treatment. Permission to use medications should be obtained from the custodial parent or from the patient's legal guardian.
7. Ongoing assessment of pharmacologic interventions is necessary. When a medication is thought to be either ineffective or inappropriate to the current clinical situation, it should be tapered and discontinued under careful clinical observation. Appropriate alternatives should be reviewed with the family before initiation.
8. Pediatricians, family practitioners, other medical staff, mental health professionals, and child psychiatrists should work collaboratively in the pharmacologic management of children.

TABLE 35–2 Medical Precautions for and Contraindications to Use of Stimulants

MEDICATION	MECHANISM	PRECAUTIONS/ACTIVE MEDICAL CONDITIONS	RECOMMENDATIONS
Tricyclic antidepressants (TCAs); TCAs + antipsychotics	May impair cardiac function	Preexisting cardiac disease	If indicated, cardiac evaluation before the initiation of treatment; use with caution
β-blockers	Bradycardia	Congestive heart failure (CHF), sinus bradycardia, first-degree atrioventricular block, and Wolff–Parkinson–White syndrome	Contraindicated Note: Should not be used with β-adrenergic medications (Clonidine, Tenex) because of heart block risk.
β-blockers	Bronchoconstriction	Asthma	Contraindicated
β-blockers	Risk of masking the symptoms of hypoglycemic crisis	Diabetes mellitus	Use with caution
β-blockers	Risk of masking the symptoms of thyrotoxicosis	Hyperthyroidism	Use with caution
TCAs, bupropion, antipsychotics, stimulants	Risk of lowering the seizure threshold	Epilepsy	Use with caution
Stimulants	Risk of lowering the seizure threshold	Epilepsy	Use with caution
Antidepressants, antipsychotics, and antianxiety agents	Central nervous system (CNS) depression	Chronic respiratory disease.	Use with caution
Antidepressants, antipsychotics, and antianxiety agents	Anticholinergic properties	Acute narrow-angle glaucoma and untreated open-angle glaucoma	Contraindicated

Because β-blockers may cause severe bronchoconstriction and bradycardia, they are contraindicated in patients with asthma, congestive heart failure, sinus bradycardia, first-degree atrioventricular block, and Wolff–Parkinson–White syndrome. Similarly, β-blockers should not be used in conjunction with α-adrenergic medications because of concerns over heart block. β-blockers can mask the symptoms of hypoglycemic crisis and thyrotoxicosis and therefore should be used with caution in patients with diabetes and hyperthyroidism.

Atypical antidepressants (e.g., bupropion), antipsychotics, and TCAs have each been reported to lower the seizure threshold. Although the *Physicians' Desk Reference* (PDR)[7,8] notes that stimulants are associated with seizures, clinical experience and recent investigations do not support this assertion. Furthermore, stimulants do not appear to exacerbate well-controlled epilepsy. Recently published guidelines for the evaluation of attention-deficit/hyperactivity disorder (ADHD) do not recommend a baseline electroencephalogram (EEG) as part of the work-up, and recent data indicate that patients with ADHD and a normal EEG are at minimal risk for seizures. However, patients with ADHD and an epileptiform EEG do have an increased risk of seizures.[9]

Antidepressants, antipsychotics, and antianxiety agents can produce central nervous system (CNS) depression; therefore these agents should be used with caution in patients with a chronic respiratory disease.

Known drug interactions should also be considered. Psychostimulants generally do not generate significant interactions with other agents, with the exception of monoamine oxidase inhibitors (MAOIs); however, many antidepressants, antipsychotics, and anticonvulsants can interact with a wide array of drugs. Clinicians are encouraged to have ready access to databases that can provide up-to-date information about their metabolism and interactions with other medications. For instance, antidepressants, antipsychotics (particularly those with strong anticholinergic properties), and antianxiety agents are contraindicated in patients with acute narrow-angle glaucoma and in untreated patients with open-angle glaucoma.

Psychotropics should be used with caution in pediatric patients with renal or hepatic dysfunction. In these patients psychotropics with specific metabolic pathways (i.e., renal or hepatic) should be selected or the dose decreased and serum levels closely monitored.

EMERGENCY INTERVENTIONS: TREATMENT OF ACUTE AGITATION OR AGGRESSION

Typically, the request for the emergency use of psychotropics deals with the initial management of acutely assaultive or self-injurious behaviors. Use of emergency psychotropics should be conducted in concert with behavioral interventions and aimed at addressing the crisis situation, its causes, and its psychosocial impact.[10] If reduced stimulation and general calming measures are ineffective, pharmacotherapy should be considered. Low doses of a short-acting benzodiazepine (e.g., lorazepam 0.5 to 1 mg) or a sedating antihistamine (e.g., diphenhydramine 25 to 50 mg) can be used to reduce acute anxiety, agitation, and insomnia with few side effects. These agents can be administered orally, intravenously (IV), or intramuscularly (IM). Behavioral disinhibition can occur among children and should be monitored. In severe or agitated psychotic states, low doses of a sedating antipsychotic (e.g., chlorpromazine or thioridazine 25 to 50 mg, olanzapine 2.5 to 10 mg, or quetiapine 25 to 300 mg) may be very effective in reducing concomitant anxiety, agitation, or psychosis. For children with active hallucinations or severe disturbances of reality, a higher-potency antipsychotic (e.g., risperidone at 0.25 to 4 mg orally) may be necessary. Often a combination of a benzodiazepine and an antipsychotic may be necessary for severe agitation. Medications used for crisis management should not be continued indefinitely, unless they are indicated for the treatment of a co-existing psychiatric disorder.[10]

DELIRIUM

Delirium is a transient derangement of cerebral function with global impairment of cognition and attention. It is frequently accompanied by disturbances of the sleep–wake cycle and changes in psychomotor activity. Delirium may be an early warning of a deteriorating medical condition, a toxic insult, or a brain injury, and it may be accompanied by self-injurious behaviors, such as pulling out IV lines. In adolescents clinicians should consider substance intoxication and drug interactions (between prescribed medications and illicit substances, such as marijuana and TCAs) in the differential.[11]

Treatment is usually directed at both the cause and the symptoms. Correction of metabolic abnormalities, removal of agents that may be exacerbating the symptoms, or treatment of the underlying injury or infection is generally followed by reversal in the delirium. After attempting to re-orient and decrease the sensory input, the practitioner may need to implement pharmacologic intervention. Generally, antipsychotics are useful if hallucinations or delusions are present, whereas anxiolytics (i.e., benzodiazepines) help reduce anxiety and apprehension. As mentioned previously, antihistamines (e.g., diphenhydramine 25 to 50 mg orally or IM every 6 to 8 hours) or benzodiazepines (e.g., lorazepam 0.5 to 1 mg orally, IM, sublingually [SL], or IV every 4 to 6 hours) generally are considered to be the most benign choices for agitation and anxiety. In older children or adolescents who do not respond to these treatments or in those with psychosis, severe dyscontrol, or agitation, haloperidol can be used, with the dose repeated every 6 hours if needed. Psychotropic medications should be withdrawn with resolution of the delirium.

CHILDHOOD ANXIETY DISORDERS

Children tend to be anxious when receiving care in any medical setting. When the level of anxiety impairs the child (or practitioner) and is unremitting, a child should be assessed for an anxiety disorder. Anxiety problems may also manifest in children as multiple somatic complaints, such as headaches and stomachaches. Childhood anxiety disorders are relatively common and tend to persist into adult life.[12,13] The three most common childhood anxiety disorders seen in medical settings are separation anxiety disorder (SAD), generalized anxiety disorder (GAD) of childhood, and acute stress disorder (ASD). Other anxiety disorders, such as posttraumatic stress disorder (PTSD), obsessive–compulsive disorder (OCD), and tic disorders may be present in hospitalized children.

In SAD the predominant disturbance is a developmentally inappropriate excessive anxiety on separation from familial surroundings. It is called *separation anxiety* because it is assumed that the main disturbance is the child's inability to separate from the parent or major attachment figures. When separation occurs or is anticipated, the child may

experience severe anxiety to the point of panic. Although it may develop during the preschool age, it more commonly appears in older children.

Similar to GAD in the adult patient, the essential feature of childhood GAD is excessive worry and fears that are not focused on a specific situation or a result of psychosocial stressors. Affected children may manifest an exaggerated or unrealistic response to the comments or criticisms of others.

At this time no medication is FDA-approved for use in childhood anxiety disorders. Based on the efficacy and safety of multiple randomized controlled trials (RCTs), the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, sertraline, and fluvoxamine appear to be the first-line medications for the treatment of SAD and GAD in children.[14] The literature on benzodiazepines, TCAs, buspirone, and β-blockers is mixed at best.[15]

Acute stress disorder develops within 1 month of an acute traumatic event and lasts for a maximum of 1 month. It is manifested by anxiety, dissociative symptoms, persistent re-experiencing of the trauma, and avoidance of stimuli that evoke recollections of the trauma. The Screening Tool for Early Predictors of PTSD (STEPP) is a 12-item questionnaire that obtains information from the child, parents, and medical record. A score of 4 or greater from the child or 3 or greater from the parent demonstrates sensitivity in predicting PTSD of 0.88 for children and 0.96 for parents.[16] Because of its high sensitivity, brevity, and ease of scoring, STEPP offers a quick way to identify children and families at high risk of developing PTSD in the acute care setting. The nature, severity, duration, and proximity to the trauma are factors that influence the development of ASD. In a number of patients, ASD may continue beyond 1 month and develop into PTSD. Effective management is focused on ensuring safety and reducing pain, anxiety, and fear. Recent investigations of children with burns suggest that aggressive management of pain with morphine may reduce and secondarily prevent PTSD.[17] Pediatric patients with PTSD are likely to have co-morbidity with other psychiatric disorders, a history of neglect or abuse, or both.[18,19]

In adults with PTSD, SSRIs have been shown to be useful in reducing symptoms of anxiety, depressed mood, rage, and obsessional thinking.[20,21] In fact, both sertraline and paroxetine are approved for treatment of PTSD in adults and are often used in pediatric patients.[20]

β-blockers, in particular propranolol, have been studied as a means of reducing arousal symptoms of PTSD. Similarly, α_2-adrenergic agents, such as clonidine or guanfacine, may likewise reduce anxiety, hyperarousal, and impulsivity and improve attention.[20,21]

In patients with dissociation, medications that enhance gamma-aminobutyric acid (GABA), such as the benzodiazepines or gabapentin (Neurontin), may reduce the severity of anxiety. In patients with fear or terror, the short-term use of atypical antipsychotics in low doses may be useful. Long-term treatment of ASD and PTSD uses both pharmacologic and psychotherapeutic modalities.[22]

High-potency (e.g., alprazolam 0.25 to 1 mg three times per day or clonazepam 0.25 to 1 mg three times per day) or medium-potency (e.g., lorazepam 0.25 to 1 mg three times per day) benzodiazepines can be effective for short-term relief of anxiety. A short-acting compound (e.g., lorazepam) can be very effective in managing more acute situations (e.g., anxious or agitated reactions to psychosocial crises). Doses of 0.5 to 1 mg of lorazepam given orally or SL are often effective. Lorazepam may be administered IM in an emergency. Use of short-acting benzodiazepines requires multiple daily doses. Long-term use should be avoided whenever possible.

In general, the clinical toxicity of benzodiazepines is low, but higher rates of disinhibition are observed in the pediatric population than in adults. Children who become disinhibited on high-potency benzodiazepines may respond more favorably to the mid- or low-potency agents (e.g., clorazepate or diazepam). The most commonly encountered short-term adverse effects of benzodiazepines are sedation, disinhibition, and depression.

When long-term treatment in older adolescents is warranted, long-acting benzodiazepines (such as clonazepam) may be preferable. For clonazepam an initial dose of 0.25 to 0.5 mg can be given at bedtime. The dose may be increased by 0.5 mg every 5 to 7 days depending on the clinical response and the side effects. Typically, doses between 0.25 and 2 mg per day are effective. Potential benefits of the longer-acting compounds are single-daily dosage and a decreased risk of withdrawal symptoms on discontinuation of treatment.

Buspirone is a nonbenzodiazepine anxiolytic without anticonvulsant, sedative, or muscle-relaxant properties. Clinical experience with this drug suggests limited antianxiety efficacy.[14] The effective daily dose is estimated to range from 0.3 to 0.6 mg/kg.

One controlled study with high-dose imipramine demonstrated efficacy under controlled conditions.[23] However, TCAs have had only limited usefulness for management of anxiety disorders given their narrow therapeutic window.[14]

AKATHISIA

Akathisia is a movement disorder experienced as inability to sit still (the term is derived from the Greek and literally means "not to sit").[24] In children and adolescents, it is most often seen as a side effect of antipsychotics or antidepressants. Akathisia may be confused with ADHD or agitation. Historically, patients are free from akathisia before starting an antidepressant or antipsychotic or reducing an anticholinergic medication. Treatment of akathisia involves reducing the dose of the offending medication to the lowest effective dose and then adding either β-blockers or benzodiazepines (0.5 to 1 mg three times per day of lorazepam). Although all β-blockers are likely to be effective, propranolol has good CNS penetration and is typically used. Propranolol should be initiated at 10 mg two times per day and the dose increased every several days to effect.

Studies in adults have demonstrated the efficacy of the potent selective β-1 blocking agent betaxolol in reducing akathisia. Betaxolol is a selective and potent β-1 blocker with a long half-life (allowing a dose once daily) with minimal medication interactions. Betaxolol is generally initiated at 5 mg and can be titrated as tolerated to doses between 10 to 20 mg per day.

OBSESSIVE–COMPULSIVE DISORDER

The best studied of the juvenile anxiety conditions, OCD often develops early in life. Nearly one third of adults with obsessions report the onset of symptoms before the age of 15; cases of the disorder have been described as early as age 3. It is characterized by persistent ideas or impulses (obsessions) that are intrusive and irrational (e.g., thoughts of having caused violence, becoming contaminated, or severely doubting oneself) that may lead to persistent repetitive, purposeful behaviors (compulsions, e.g., handwashing, counting, checking, touching) in order to neutralize the obsessive worries.[25] In the medical setting, this disorder is often associated with an exaggerated, persistent, and impairing obsession with an organ, disease process, or treatment. This disorder has been estimated to affect 1% to 2% of the adult population; it has been shown to be familial and associated with Tourette's syndrome (TS) and ADHD.

The treatment of OCD with serotonergic medications has been promising. Studies suggest that children with OCD respond in a similar fashion to these agents as adults. Currently, the SSRIs, (e.g., sertraline [Zoloft, initiated at 12.5 to 25 mg daily and titrated to 50 to 200 mg daily], fluvoxamine [Luvox, a more sedating drug that is initiated at 25 mg at bedtime and increased to 25 to 150 mg twice per day], and fluoxetine [Prozac, initiated at 5 to 10 mg and increased to 60 mg per day]) are FDA-approved for OCD in the pediatric population.[26–30] The SSRIs paroxetine (Paxil), citalopram (Celexa), escitalopram (Lexapro), and the mixed agent venlafaxine (Effexor) may also be useful in the management of OCD.

In addition, the TCA clomipramine (Anafranil) has been shown under controlled conditions to be useful for this chronic disorder. These studies suggest a clomipramine dosage of up to 250 mg per day, a fluoxetine dose of approximately 10 to 40 mg per day, and a sertraline dose of 50 to 200 mg per day, although anecdotal information indicates that some children may require higher dosages. Treatment with these agents should be initiated at a low dose (e.g., 25 mg per day of clomipramine) and increased slowly according to clinical response and side effects.

Recently, researchers have shown increased interest in a syndrome that resembles both OCD and tic disorders: pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS). Investigators have studied plasma exchange, IV immunoglobulin, and penicillin to treat OCD and tics associated with PANDAS. Although many of these patients responded favorably to the treatments, the numbers studied remain small and the study designs were open.[31,32] These treatments appear effective only for those patients whose OCD and tics were associated with streptococcal infections.

TIC DISORDERS

The best-known tic disorder is TS, a childhood-onset neuropsychiatric disorder that often persists throughout the patient's lifetime; it is manifested by multiple motor and vocal tics and other behavioral and psychological symptoms. TS is commonly associated with OCD (in about 30% of cases) and ADHD (in about 50% of cases). It is noteworthy that in many cases it is not the tics but rather the co-morbid disorders that are the major source of distress and disability. Much interest has been expressed in the overlap of TS with ADHD. Some interesting associations include the findings that ADHD appears earlier in life than tics, and stimulants may exacerbate tics. For many patients with tics and ADHD, the symptoms of ADHD appear to be associated with the most severe impairment.

Several typical antipsychotics (e.g., haloperidol, pimozide) have been considered the drugs of choice in TS; however, antipsychotics have limited effects on the frequently associated co-morbid disorders of ADHD and OCD, and they are associated with short-term (e.g., extrapyramidal side effects [EPS]) and long-term adverse effects (e.g., tardive dyskinesia [TD]). Recently, pilot studies of the atypical antipsychotics, risperidone (Risperdal) and ziprasidone (Geodon), have been completed in the treatment of TS. These studies show that both ziprasidone (initially dosed at 20 mg per day and increased to a mean dose of approximately 60 mg per day) and risperidone (titrated to a maximum dose of 0.06 mg/kg per day in one study and a maximum of 3 mg per day in another) were effective and generally well tolerated.[33–36] Both these medications are potent blockers of D_2 and 5-HT_{2A} receptors, thereby reducing the theoretical risk of EPS and TD. Of note, dysphoria and depression are reported to occur in adolescents with TS who are treated with risperidone.[37]

Clonidine has been shown to be highly effective in reducing the severity and frequency of tics and is considered a first-line drug for tic disorder and TS. Clonidine is usually begun at very low doses (i.e., 0.025 mg per day) to reduce the initial adverse effect of sedation, and it is increased upward as necessary.

Comparison of clonidine and risperidone and risperidone and pimozide demonstrated similar improvements in tic severity.[34,38] In addition, clonidine alone and in combination with methylphenidate was recently studied for effects on tics and ADHD.[39] Compared with placebo, clonidine and methylphenidate, clonidine alone, and methylphenidate alone were associated with reductions in tic severity. Although some patients experience an exacerbation of tics during treatment with stimulants (and it is still listed as a contraindication in the PDR), many patients appear to benefit from treatment of their ADHD symptoms.

Recently, the TCAs have been found to be effective in some children with TS. There have been promising results in open and controlled investigations of TCAs (desipramine and nortriptyline) for ADHD and tic symptoms in juveniles with tic disorders and TS.[40]

Given concerns over cardiac safety with the TCAs, atomoxetine (ATMX) may be an effective treatment for patients with ADHD and TS, although this remains to be formally studied.

Additional recent reports suggest that a variety of medications may prove useful in patients with TS with or without ADHD, including the selective type B, irreversible MAOI, L-deprenyl, the mixed $D_1/D_2/D_3$ dopamine agonist pergolide,[41,42] the hypotensive agent mecamylamine,[43,44] and medications that enhance cholinergic neurotransmission (e.g., donepezil and nicotine).[45,46]

Cannabinoids have also been investigated as a potential treatment for TS, although their use is not currently recommended.[47] Patients with co-morbid OCD may need additional pharmacotherapy with serotonergic agents (e.g., clomipramine or the SSRIs).

UPDATES ON SAFETY OF MEDICATIONS USED TO TREAT ADHD

In 2006 the FDA's Pediatric Drugs Advisory Committee (PDAC) reviewed data regarding the cardiovascular (CV) effects of medications used to treat ADHD as well as concerns regarding psychosis, mania, and suicidal thinking. However, currently the only black box warning for stimulants concerns the potential for substance abuse.

Cardiovascular Safety of ADHD Treatments

The PDAC cited the baseline rate of sudden unexplained death in the pediatric population as 0.6 to 6 occurrences per 100,000 patient-years.[48] According to the PDAC's and FDA's research, the rates of sudden unexplained death in pediatric patients (between 1992 and 2005) treated with methylphenidate (MPH), amphetamine, or ATMX were 0.2, 0.3, and 0.5 cases per 100,000 patient-years, respectively. On the basis of these data, the PDAC *rejected* adding a black box warning but recommended that current labeling language (regarding the CV risks to patients with structural cardiac abnormalities) for amphetamine drugs should be extended to all medications approved for the treatment of ADHD.[49,50]

The American Heart Association noted that it is prudent to monitor symptoms referable to the CV system (e.g., syncope, palpitations, chest pain) and vital signs at baseline in young patients taking psychotropics[51]; despite the generally benign CV effects of these medications, caution is warranted in the presence of a compromised CV system (e.g., with untreated hypertension, arrhythmias, or known structural heart defects). For most pediatric patients, it is not necessary to check an electrocardiogram (ECG) at baseline or with treatment. In patients at risk for CV symptoms, collaboration with the patient's primary care physician (PCP) is recommended to ensure that hypertension is not problematic. Recent data from an open-label study of adults being treated for ADHD suggested that if hypertension is well controlled, stimulants may be used safely[52]; however, in each case the physician and patient must weigh the risks against the benefits of treatment.

Aggression During Treatment with ADHD Medications

According to the PDAC's and FDA's research, all ADHD medications have been associated with episodes of aggression during clinical trials and in postmarketing surveillance. However, aggression in patients with ADHD usually responds to stimulant treatment.[53] During clinical trials rates of aggression have been similar whether the subject receives active treatment or placebo. The PDAC noted that the decision as to whether therapy is continued after an act of aggression is complex and that the physician and the parents should evaluate whether the risks of treatment outweigh the benefits to the child.

Psychotic Symptoms with ADHD Agents

The FDA has received hundreds of reports of psychotic or manic symptoms, particularly hallucinations, associated with use of medications for ADHD in children and adolescents. FDA drug-safety analysts recommended the addition of warnings to ADHD medication labels advising that ADHD medications be stopped if a patient experiences signs and symptoms of psychosis or mania. A recent review of stimulant trials found that psychotic-like or manic-like symptoms occur in approximately 0.25% of children (or 1 in 400) treated with stimulants.[54]

In summary, the PDAC concluded that potential episodes of psychosis, aggression, suicidality, and cardiac events during treatment with ADHD medications in children do not warrant a black box warning.

ADHD DISORDER

A common psychiatric condition, ADHD is found in 3% to 10% of school-age children.[55] ADHD is characterized by the classic triad of impaired attention, increased impulsivity, and excessive motor activity, although many children manifest only inattentiveness.[56] With developmental variations, ADHD affects children of all ages (as early as age 3), and it persists into adulthood about half of the time.[57–59] Within the medical setting, ADHD needs to be differentiated from environmental stimulation, iatrogenic causes (e.g., use of β-agonists), or other psychiatric disorders (e.g., anxiety, depression, mania, or intoxication). Pharmacotherapy remains the cornerstone of ADHD treatment (Table 35–3).[60–76]

FDA-APPROVED TREATMENTS FOR ADHD

Stimulants

Since the 1940s, stimulants have been used safely and effectively in the treatment of ADHD. There are three main stimulant families (see Table 35–3): methylphenidate (MPH) (e.g., short-acting Ritalin and Metadate, long-acting Concerta and Metadate-CD), dextroamphetamine (DEX) (e.g., short-acting Dexedrine tablets and long-acting Dexedrine spansules), and a mixture of dextroamphetamine salts (DEX) plus mixed amphetamine salts (MAS) (e.g., short-acting Adderall and long-acting Adderall-XR).

Stimulants increase intrasynaptic (extracellular) brain concentrations of dopamine; norepinephrine; and, to a lesser extent, serotonin (5-HT).[77,78] After oral administration, stimulants are rapidly absorbed and preferentially taken up into the CNS. Stimulants bind poorly to plasma proteins; this partially explains their relative paucity of drug–drug interactions. MPH is metabolized primarily by plasma-based esterases to ritalinic acid that is excreted in the urine. The amphetamines are 80% excreted in the urine unchanged; 20% undergo hepatic metabolism. Acidification of the urine may enhance excretion of the amphetamines. MPH is not usually detected on routine drug screening.

Methylphenidate

Originally formulated in 1954, methylphenidate was produced as an equal optical isomer mixture of d, l-threo-MPH and d, l-erythro-MPH. Because the erythro form of MPH

TABLE 35–3 FDA-Approved Treatments for Attention-Deficit/Hyperactivity Disorder

GENERIC NAME (BRAND NAME)	FORMULATION AND MECHANISM	DURATION OF ACTIVITY	HOW SUPPLIED	USUAL AND FDA-APPROVED ABSOLUTE MAXIMUM DOSING RANGE
Dex-MPH (Focalin)*	Tablet, 100% d-threo-MPH	3-5 hr	2.5-, 5-, and 10-mg tablets; 2.5 mg Focalin equivalent to 5 mg Ritalin	(0.15-1 mg/kg per day) 20 mg per day
MPH (Ritalin)* (Methylin)*	Tablet, 50 : 50 racemic mixture d,l-threo-MPH (50:50 d,l-t-MPH)	3-4 hr	5-, 10-, and 20-mg tablets	(0.3-2 mg/kg per day) up to 60 mg per day
MPH-SR (Ritalin-SR)* MPH (Metadate ER)*	Wax-based matrix tablet, 50:50 d,l-t-MPH	3-8 hr	Variable 20-mg tablets (amount absorbed appears to vary)	
MPH (Methylin ER)*	Hydroxypropyl methylcellulose-based tablet, (50:50 d,l-t-MPH); no preservatives	8 hr	10- and 20-mg tablets; 2.5-, 5-, and 10-mg chewable tablets; 5 mg/5 mL and 10 mg/5 mL oral solution	
MPH (Ritalin LA)*	Two types of beads give bimodal delivery (50% immediate release and 50% delayed release) of 50:50 d, l-t-MPH		20-, 30-, and 40-mg capsules; can be sprinkled	
MPH (Metadate CD)*	Two types of beads give bimodal delivery (30% immediate release and 70% delayed release) of 50:50 d, l-t-MPH		20-mg capsule; can be sprinkled	
MPH (Daytrana)*	MPH transdermal system	12 hr (patch worn for 9 hr)	10-, 15-, 20-, and 30-mg patches	(0.3 to 2 mg/kg per day) 30 mg per day
MPH (Concerta)*	Osmotic pressure system delivers 50:50 d,l-t-MPH		18-, 27-, 36-, and 54-mg tablets	(0.3 to 2 mg/kg per day) 72 mg per day
AMPH† (Dexedrine tablets)	d-AMPH tablet	4-5 hr	5-mg tablets	(0.15-1 mg/kg per day) 40 mg per day
AMPH† (Dextrostat)			5- and 10-mg tablets	
Mixed salts of AMPH† (Adderall)	Tablet of d,l-AMPH isomers (75% d-AMPH and 25% l-AMPH): -d-amphetamine saccharate, -d,l-amphetamine asparate, -d-amphetamine sulfate, and -d,l-amphetamine sulfate	4-6 hr	5-, 7.5-, 10-, 12.5-, 15-, 20-, and 30-mg tablets	
AMPH† (Dexedrine spansules)	Two types of beads in a 50 : 50 mixture immediate and delayed absorption of d-AMPH	8 (6-9) hr	5-, 10-, and 15-mg capsules	
Mixed salts of AMPH*‡ (Adderall-XR)	Two types of beads give bimodal delivery (50% immediate release and 50% delayed release) of 75 : 25 racemic mixture d,l-AMPH	At least 8 hr (but appears to last up to 12 hr in certain patients)	5-, 10-, 15-, 20-, 25-, and 30-mg capsules; can be sprinkled	
Lisdexamfetamine (Vyvanase)*	Tablets of dextroamphetamine and L-lysine	12 hr	30-, 50-, and 70-mg tablets	(0.15-1 mg/kg per day) 30 mg per day in children; recommended dose is 20 mg per day in adults
Atomoxetine*‡ (Strattera)	Capsule of atomoxetine	5 hr plasma half-life, but CNS effects appear to last much longer	10-, 18-, 25-, 40-, 60-, and 80-mg capsules	70 mg per day 1.2 mg/kg per day to 1.4 mg/kg per day or 100 mg

*Approved to treat attention-deficit/hyperactivity disorder age 6 years and older.
†Approved to treat attention-deficit/hyperactivity disorder age 3 years and older.
‡Specifically approved for treatment of attention-deficit/hyperactivity disorder in adults.

was linked with CV side effects, MPH is now manufactured as an equal mixture of d, l-threo-MPH. Later studies found that the d-threo MPH isomer was twice as active as the l-threo one. The d-threo isomer or MPH called Focalin (d-threo-MPH or dex-MPH) has been a recent addition. With regard to conversion and potency, 10 mg of Ritalin is biologically equivalent to 5 mg of Focalin.

The time to peak plasma concentration with oral administration of immediate-release d, l-threo-MPH (e.g., generic MPH, Ritalin, Metadate, Methylin) is variable (1 to 2 hours); its half-life is 2 to 3 hours. Behavioral effects of immediate-release MPH peak 1 to 2 hours after administration and tend to dissipate in 3 to 5 hours. Although generic MPH has a similar pharmacokinetic profile to Ritalin, it is more rapidly absorbed and peaks sooner.[79]

Plasma levels of the sustained-release preparations of MPH (Ritalin-SR) peak in 1 to 4 hours and have a half-life of 2 to 6 hours.[80] Peak behavioral effects of this preparation are noted 2 hours after ingestion, and effects last up to 8 hours. Because of the wax-matrix preparation, absorption of the sustained release (SR) preparation is variable; it is less often used now that better alternative extended-delivery systems are available.

Recently, several novel methods of delivering MPH and amphetamine have become available; each is intended to extend the clinical effectiveness of stimulants. Although these medications all deliver a stimulant, their pharmacokinetic profiles differ. Concerta (OROS methylphenidate), the first of these novel delivery systems, has been available since August 2000. Concerta uses the OROS technology to deliver a 50:50 racemic mixture of d, l-threo-MPH. An 18-mg caplet of Concerta delivers the equivalent of 15 mg MPH (5 mg MPH three times per day) providing 12-hour coverage. Initially the 18-mg caplet provides 4 mg MPH and delivers the additional MPH in an ascending profile over 12 hours.[81] The recommended dose of Concerta is between 18 to 54 mg per day, although a trial in adolescents studied doses up to 72 mg per day.[82] If Concerta is cut or crushed, its delivery system is compromised.

Metadate-CD (MPH-MR) capsules (10, 20, and 30 mg; may be sprinkled) contain d, l-threo-MPH with 30% of immediate-release beads and 70% of extended-release beads.[83] Metadate-CD delivers 30% or 6 mg of d, l-threo-MPH initially and is designed for 8-hour coverage.

Ritalin-LA (MPH-ERC) capsules (10, 20, 30, and 40 mg; may be sprinkled) deliver 50% of its d, l-threo-MPH initially and another bolus approximately 3 to 4 hours later, thereby providing approximately 8 hours of coverage.

The primarily active form of MPH is the d-threo isomer,[84] which has become available in both immediate-release tablets (Focalin 2.5, 5, and 10 mg) and extended-delivery capsules (Focalin XR 5, 10, 15, and 20 mg). The efficacy of D-MPH is well established in children, adolescents, and adults under double-blind conditions.[85,86] D-MPH is approved to treat ADHD in children, adolescents, and adults in doses of up to 20 mg per day and has been labeled to provide 12 hours of coverage.[8] Although the research is not definitive, 10 mg of MPH appears to be approximately equivalent to 5 mg of D-MPH, and clinicians can reasonably use this estimate in clinical practice.[87]

For patients who have difficulty swallowing or tolerating an oral stimulant formulation or for patients who need flexibility in the duration of medication effect, there is a new treatment option. The MPH Matrix Transdermal System (MTS; Daytrana; 10-, 15-, 20-, and 30-mg patches[88,89]) delivers MPH through the skin. The patches are applied once daily and are intended to be worn for 9 hours, although in clinical practice they can be worn for shorter or longer periods. The MTS usually takes effect within 2 hours and provides coverage for 3 hours after removal of the patch. Because the MPH is absorbed through the skin, it does not undergo first-pass metabolism in the liver; therefore patients require lower doses with the patch compared with oral preparations (10 mg MTS is equivalent to 15 mg extended-release oral MPH).

Amphetamines

Mixed amphetamine salts (MAS; Adderall) are a racemic mixture of approximately 3:1 of d- to l-amphetamine.[8] The two isomers have different pharmacodynamic properties, and some patients with ADHD preferentially respond to one isomer over another. Recent data on children with ADHD suggest that, when compared with immediate-release MPH, the peak behavioral effects of Adderall occur later and are more sustained.[90]

The extended-delivery preparation of MAS is a capsule containing two types of Micotrol beads (MAS XR; Adderall XR). The beads are present in a 50:50 ratio, with immediate-release beads designed to release MAS in a fashion similar to that of MAS tablets, and delayed-release beads designed to release MAS 4 hours after dosing.[8] A single dose of MAS-XR 20 mg is bioequivalent to 10 mg of an MAS tablet dosed twice per day. The efficacy of MAS XR is well established in youth with ADHD.[90–92]

Dextroamphetamine (DEX; Dexedrine) tablets contain only the d-isomer of amphetamine. DEX tablets achieve peak plasma levels 2 to 3 hours after oral administration and have a half-life of 4 to 6 hours. Behavioral effects of DEX tablets peak 1 to 2 hours after administration and last 4 to 5 hours. When DEX spansules are used, behavioral effects last 6 to 9 hours.

Lisdexamphetamine dimesylate (LDX; Vyvanase), previously known as NRP-104, was recently approved by the FDA for treatment of ADHD in children between the ages of 6 and 12 years. LDX is an amphetamine prodrug in which L-lysine, a naturally occurring amino acid, is co-valently linked to d-amphetamine. After oral administration, the prodrug is hydrolyzed in the body to release d-amphetamine. Although lisdexamfetamine appears to have less abuse liability and overdose protection, the FDA has recommended a CII schedule. It is available in doses of 30, 50, and 70 mg that appear to be comparable to MAS XR doses of 10, 20, and 30 mg, respectively.[93]

Pemoline

Pemoline (Cylert) is a CNS stimulant that enhances central dopaminergic transmission, while being structurally different from MPH, DEX, and MAS. Since receiving FDA approval for the treatment of ADHD and narcolepsy in the 1970s, it has been linked with 21 cases of liver failure (13 of them fatal). In 2005 the FDA withdrew its approval for pemoline. Since our last edition, Abbott Laboratories has discontinued the production of Cylert for economic reasons (March 2005).

Guidelines on the Use of Stimulants in Children

The AACAP released guidelines on the use of stimulants in children and adolescents in 2007[60]; these included starting with a longer-acting preparation in most cases. Clinicians can initiate therapy at 18 mg Concerta or 20 mg Metadate-CD or Ritalin-LA for MPH products or 5 to 10 mg Adderall-XR or Dexedrine spansules. However, in the hospital setting, clinicians may prefer short-acting stimulants, starting with lower doses (2.5 to 5 mg per day for children and adolescents, 5 to 10 mg per day for adults), given in the morning with food. The dose is titrated upward every 3 to 5 days until a beneficial effect is noted or adverse effects emerge. Typically, the half-life of the short-acting stimulants necessitates at least twice-daily dosing, with the addition of similar or smaller afternoon doses, based on breakthrough symptoms. Although the PDR lists maximum dosages for amphetamine products at 40 mg per day and 60 mg per day for MPH, patients often benefit from suggested daily doses that range from 0.3 to 1.5 mg/kg per day for amphetamine products and from 0.5 to 2 mg/kg per day for MPH products. Thus an older adolescent may need immediate-release MPH up to 30 mg three to four times daily or amphetamine 15 to 20 mg three to four times a day.

Numerous short-term (less than 12 weeks) clinical trials show that approximately 70% of patients with ADHD respond to stimulants. A positive dose–response relationship of stimulants is present for both hyperactivity and inattention. Longer-term trials have demonstrated the tolerability and continued efficacy of stimulants in patients treated continuously over 2 years.

Despite the vast literature and excellent safety profile of stimulants, studies indicate that approximately one third of children and adolescents with ADHD either do not respond or manifest intolerable adverse effects; these outcomes necessitate alternative treatments. Fortunately, ATMX and other off-label treatments (including antidepressants and antihypertensives) are available.

Side Effects of Stimulants

Although generally well tolerated, stimulants can cause clinically significant side effects (e.g., anorexia, nausea, insomnia, nightmares, headaches, dizziness, dry mouth, anxiety, irritability, dysphoria, rebound phenomena).[62–64,94] Rates and types of stimulant-induced side effects appear to be similar in all ADHD patients, regardless of age. In patients with a current co-morbid mood or anxiety disorder, clinicians should consider whether a presenting complaint reflects the co-morbid disorder, a side effect of the treatment, or an exacerbation of the co-morbidity. Moreover, although stimulants can cause these side effects, many ADHD patients experience these problems before treatment; therefore it is important for clinicians to document these symptoms at baseline.[63] Although tolerance to the effects of stimulants has been debated, data from the NIMH Multimodal Treatment of ADHD study demonstrated the persistence of stimulant-associated medication effects. Recommendations about management of common side effects are listed in Table 35–2.

Appetite Suppression

Youth treated with stimulants often experience a dose-related reduction in appetite (in some cases, weight loss); thus it often is useful to administer stimulants during or after meals.[65] Although appetite suppression has been observed to decrease over time,[66] clinicians should give guidance on improving the patient's nutritional options with higher caloric intake to balance the consequences of decreased food intake.[62] Cyproheptadine, in doses of 4 to 8 mg, has recently been reported to improve appetite in ADHD patients with stimulant-associated appetite suppression.[67]

Sleep

Stimulant-induced sleep disturbances are common. Modifications in behavior and sleep hygiene (e.g., adjusting the timing of sleep or type of stimulant used) may be helpful.[68] Symptomatic treatments include use of melatonin (1 to 3 mg, while monitoring for over-the-counter [OTC]–related variability),[70] clonidine (0.05 to 0.2 mg, monitoring for hypotension),[69] diphenhydramine (25 to 50 mg, with the understanding that its effectiveness is often short-lived), trazodone (25 to 50 mg, monitoring for priapism), mirtazapine (3.75 to 15 mg, especially useful with co-morbid anorexia), imipramine (25 to 100 mg, especially useful with enuresis).[62] Although not yet studied, another consideration for insomnia is ramelteon, a synthetic melatonin receptor agonist.[71]

Mood, Anxiety, and Substance Abuse

A majority of patients with ADHD experience at least one additional co-morbid psychiatric disorder. ADHD is co-morbid with anxiety disorders (in approximately 40%), mood disorders (in approximately 33%), substance abuse disorders, oppositional defiant disorder (ODD; in up to 70%), and conduct disorder (CD) (in approximately 25%).[95] These co-morbid disorders may alter a stimulant's effectiveness. For instance, patients with ADHD and co-morbid mood or anxiety disorders may respond differently to a stimulant, depending on the clinical state of their co-occurring disorders. In addition, stimulants may exacerbate tics, obsessions, or compulsions, although they are frequently used in patients with these conditions. Irritability or dysphoria may occur 1 to 2 hours after administration of stimulants, which suggests an absorption peak phenomenon that may respond to lower and more frequent doses. Occasionally, they may elicit a depressive reaction or psychosis.

DEX, MAS, and MPH are all Schedule II controlled substances that have the potential for abuse. The order of addictive liability with available preparations from most to least addictive is MAS, DEX, then MPH. Although the rates of substance abuse in patients with ADHD are increased, the use of stimulants does not appear to increase the risk of substance abuse; recent data suggest that successful stimulant treatment of children with ADHD may delay or decrease the risk of substance abuse in adolescence. When administered orally in their intended dosages, stimulants do not appear to cause euphoria, nor do they appear to be addictive. The design of the extended-delivery preparations makes abuse of stimulants less likely. Recent meta-analytic data show that in patients with ADHD treated for years with stimulants, the risk of substance abuse is halved compared with patients who

have ADHD but are not treated with stimulants.[94] Although no physical withdrawal is associated with stimulants, patients who have used high doses for a prolonged period may experience fatigue, hypersomnia, hyperphagia, dysphoria, and depression when the drug is discontinued. Given the abuse potential of these medications, it is important to inquire about concomitant use of drugs and alcohol.

Medication Interactions with Stimulants

The interactions of stimulants with other prescription and OTC medications are generally mild and not a major source of concern.[78,96,97] Co-administration of stimulants with MAOIs is the only true contraindication to their use: It may result in a potentially life-threatening hypertensive crisis. Concomitant use of sympathomimetic agents (e.g., pseudoephedrine or caffeine) may potentiate the effects of both substances and exacerbate sleep difficulties. Stimulants are associated with small increases in heart rate and blood pressure that are usually insignificant. Although data on the co-administration of stimulants with TCAs suggest little interaction between these compounds,[98] careful monitoring is warranted when prescribing stimulants with either TCAs or anticonvulsants because of potential CV and CNS effects. Although administration of stimulants with ATMX is common in clinical practice and appears to be well tolerated and effective, to date only small samples have been studied; therefore patients who take this combination should be monitored closely.[99]

Growth

The long-term impact of stimulants on growth velocity remains a concern, and data are conflicting. The current consensus is that height and weight should be monitored prospectively because stimulants may have a mild negative impact on growth velocity (possibly related more to ADHD than to its treatment).[100] In the vast majority of patients, growth delay does not pose a significant problem. However, if a decrease in growth rate occurs while a child is taking a stimulant, consideration should be given to either a medication "holiday" or alternative treatments.

Some studies support significant growth delay. For instance, in the MTA study, ADHD youth treated with a stimulant continuously over 2 years experienced a deceleration of about 1 cm per year. Despite this slowing, the children remained within the normal curves, except for those subjects in the lowest percentile for height. Other studies have not detected a significant growth delay. In a study by Faraone and associates[72] of the growth deficit in girls with ADHD, deficits were modest, only evident in early adolescence, unrelated to weight deficits or stimulant treatment, and not significant after correction for age and parental height. The finding of small height differences in preadolescent girls was consistent with results from other long-term studies.[66,72]

Atomoxetine

A highly selective norepinephrine reuptake inhibitor, ATMX (Strattera) increases intrasynaptic norepinephrine. ATMX was initially developed as an antidepressant but became FDA-approved as a nonstimulant (hence, not a controlled agent) for the treatment of ADHD.

In the initial trials, ATMX was dosed twice a day (up to 2 mg/kg per day). However, its CNS effects appeared to last more than 24 hours, even though its plasma half-life appeared to be only 5 hours. As expected, later studies demonstrated its efficacy and tolerability when dosed once a day,[101] with its best tolerability occurring when dosed in the evening.[102] ATMX should be initiated at 0.5 mg/kg per day; after several days, it can be increased to 1.2 mg/kg per day. Current guidelines recommend a maximum once-daily dose of 1.4 mg/kg per day. It may take up to 10 weeks to see the full benefits of ATMX treatment (although some patients achieve an early response).[103–105]

To date, plasma levels of ATMX have not been used to guide dosing. However, Dunn and colleagues[106] found that patients with a plasma level of ATMX greater than 800 ng/mL had more robust responses, although those treated with higher doses also had more side effects. Laboratory monitoring aside from routine medical care has not been necessary. Recently, concerns have been raised that treatment with ATMX may increase the risk of hepatitis. During post-marketing surveillance, two patients (out of 3 million exposures) developed hepatitis during treatment with ATMX.[107] Patients should consult with their doctors if symptoms of hepatitis develop.

Although generally well tolerated, the most common side effects in children and adolescents taking ATMX include dyspepsia, dizziness, and reduced appetite.[108] Height and weight are unaffected by long-term use.[104] In older adolescents ATMX may be associated with dry mouth, insomnia, nausea, decreased appetite, constipation, decreased libido, dizziness, and sweating.[109] When patients experience nausea, the dose of ATMX should be divided and administered with food. Sedation is often transient, but it may be helped by either administering the dose at night or dividing the dose. If mood swings occur, patients should be evaluated and their diagnosis reassessed.

The impact of ATMX on the CV system appears to be minimal.[110] ATMX was associated with a mean increase in the heart rate of 6 beats per minute and an increase in both the systolic and diastolic blood pressure of 1.5 mm Hg. Extensive ECG monitoring indicates that ATMX has no apparent effect on QTc intervals, and ECG monitoring aside from routine medical care is not indicated.

Recently, the FDA issued a public health advisory, and the manufacturer later added a black box warning regarding the development of suicidal ideation in patients treated with ATMX.[8] As with the SSRIs, there was a slight increase in suicidal thinking in controlled trials of ATMX. Parents should monitor for any such occurrences and for unexpected changes in mood or behavior.

ATMX is metabolized primarily in the liver to 4-hydroxyatomoxetine by the cytochrome CYP P450 2D6 enzyme, and it is primarily excreted in the urine.[111,112] ATMX does not appear to inhibit 2D6. Although patients identified as poor metabolizers (i.e., having low 2D6 activity) appear to tolerate ATMX, they seem to have more side effects; a reduction in the dose may be necessary. Therefore in patients who are also on strong 2D6 inhibitors (e.g., fluoxetine, paroxetine, and quinidine), it may be necessary to reduce the dose of ATMX. Use of ATMX is contraindicated with MAOIs.

Alternative (Non-FDA-Approved) Treatments for ADHD

Bupropion Hydrochloride (Wellbutrin, Zyban)

Bupropion hydrochloride (Wellbutrin, Zyban) is a unicyclic aminoketone (unrelated to other antidepressants) that modulates both norepinephrine and dopamine. Bupropion is approved for the treatment of depression and as an aid for smoking cessation in adults,[8] and it has improved ADHD symptoms in children, adolescents,[113–117] and adults.[118–120] Although helpful, the magnitude of bupropion's effect is less than that seen with either stimulants or ATMX. Bupropion can be particularly useful in patients with ADHD and co-morbid conditions (e.g., ADHD and nicotine dependence,[121] substance use and mood disorders,[118] substance abuse and conduct disorder,[122] depression,[114] and bipolar disorder [BPD]).[123] In light of the high rates of marijuana use in patients with ADHD,[124] it is important for clinicians to note that adolescents treated with bupropion may experience increased irritability during marijuana withdrawal.[125]

Bupropion appears to be more stimulating than other antidepressants, and it may cause irritability, exacerbate tics,[126] and induce seizures (more often than do other antidepressants).[8] Seizures appear to be dose-related (above 450 mg per day) and are more likely to occur in patients with bulimia or a seizure disorder.

Treatment should be initiated at 37.5 mg per day of the immediate-release (IR, tid dosing), 100 mg sustained-release (SR, bid dosing), or 150 mg extended release (XL, once-daily dosing) and titrated gradually as indicated. Although dosage guidelines are not available for children, in one study doses of 3 to 6 mg/kg per day were given. As in adults, no single dose of the IR preparation should exceed 150 mg, SR 200 mg, or XL 450 mg. A recent open trial found the SR form of bupropion (mean dose 2.2 mg/kg in the morning and 1.7 mg/kg in the afternoon) was helpful for the reduction of symptoms of depression and ADHD in adults.[127]

Tricyclic Antidepressants

Although controlled trials in ADHD youth[128] and adults[129] demonstrate the efficacy of TCAs, their effects are less robust than are those of stimulants. On the other hand, possible advantages of TCAs over stimulants include once-daily dosing, the option of monitoring plasma drug levels, and a negligible abuse liability. TCAs may be particularly useful in patients with co-morbid anxiety; ODD[130]; tics[131]; and, theoretically, depression (in adults). However, given concerns about potential cardiotoxicity and the availability of ATMX, use of the TCAs has been significantly curtailed.

Desipramine (DMI) and nortriptyline are associated with lower risks of adverse effects (e.g., sedation, dry mouth, and impairment in cognition) than imipramine and other tertiary amine TCAs and therefore may be better tolerated.[129]

Dosing for ADHD appears to be similar to that for depression. ECGs should be obtained at baseline and as the dose is increased (as well as when there is a family history of early-onset or sudden cardiac arrhythmias).[5] Treatment with a TCA should be initiated with 10 mg or 25 mg depending on the size of the child (approximately 1 mg/kg per day) and increased slowly (every 4 or 5 days) by increments of 20% to 30%. For imipramine and DMI, an upper dose limit of 5 mg/kg per day has been suggested for children, and for nortriptyline 2 mg/kg per day is suggested. When a daily dose of 2 to 3 mg/kg per day (or a lower effective dose for imipramine and DMI or 1 mg/kg per day for nortriptyline) is reached, steady state serum levels and an ECG should be obtained. A steady state serum level obtained 10 to 14 hours after the last dose is usually achieved after at least 1 week on the same daily dose. Monitoring serum levels of TCAs is more helpful in preventing toxicity than it is in determining optimal levels for response.

Common short-term adverse consequences of the TCAs include anticholinergic effects (e.g., dry mouth, blurred vision, orthostasis, and constipation). To date, no known deleterious effects have been associated with chronic administration of these drugs. After the sudden death of a number of children receiving DMI, concerns were raised regarding the possible cardiac toxicity of TCAs in children.[132] However, epidemiologic evaluation of the association between DMI and sudden death in children has not supported a causal relationship.[133] TCAs predictably increase heart rate and are associated with conduction delays that generally affect the right bundle and thus require ECG monitoring.[134] However, these effects, when small, rarely seem to be pathophysiologically significant in patients with a normal baseline ECG. In children with documented congenital or acquired cardiac disease, pathologic rhythm disturbances (i.e., atrioventricular block, supraventricular tachycardia, ventricular tachycardia, and Wolff–Parkinson–White syndrome), family history of sudden cardiac death or cardiomyopathy, or diastolic hypertension (> 90 mm Hg) or when the cardiovascular status of the patient is unknown, a complete (noninvasive) cardiac evaluation is indicated before initiating treatment with a TCA to help determine the risk–benefit ratio of such an intervention. A serious adverse event associated with use of TCAs is overdose, either by the patient or by a sibling. Thus parents should closely supervise the storage and administration of these medications.

α-Adrenergic Agonists

Clonidine

Clonidine is an imidazoline derivative with α-adrenergic agonist properties; it has been primarily used in the treatment of hypertension.[135] At low doses it appears to stimulate inhibitory, presynaptic adrenergic autoreceptors in the CNS.[136] Clonidine has achieved an increasing prominence in pediatric psychopharmacology because of its wide range of uses and relative safety.[137] Although clonidine ameliorates symptoms of ADHD,[138] its overall effect is less than the stimulants[139] and likely smaller than ATMX, TCAs, and bupropion. Clonidine appears particularly helpful in patients with ADHD and co-morbid conduct disorder or ODD,[140,141] tic disorders,[142,143] and ADHD-associated sleep disturbances.[144,145] In addition, clonidine has been increasingly reported to be useful in developmentally disordered patients to control aggression toward self and others.[146] Furthermore, clonidine appears to reduce anxiety and hypervigilance in traumatized children.[20]

Clonidine is a relatively short-acting compound with a plasma half-life ranging from approximately 5.5 hours (in children) to 8.5 hours (in adults). Usual dose ranges from 3 to 10 µg/kg per day given generally in divided doses, once, twice, three, or four times per day; there is also a transdermal preparation.[147] Therapy is usually initiated at the lowest manufactured dose of a half (0.05 mg) or a quarter (0.025 mg) of a 0.1-mg tablet, depending on the size of the child (approximately 1 to 2 µg/kg per day) and increased depending on the clinical response and adverse effects. The initial dosage can more easily be given before bedtime because nocturnal sedation will not adversely affect daytime function.

The most common short-term adverse effect of clonidine is sedation, which tends to subside with continued treatment. It can also produce hypotension, dry mouth, vivid dreams, depression, and confusion. Overdoses of clonidine in children under the age of 5 may have life-threatening consequences.[148] Except in overdose, clonidine is not known to be associated with long-term serious adverse effects. Because abrupt withdrawal of clonidine has been associated with rebound hypertension, slow tapering is advised.[149,150] In addition, extreme caution should be exercised with the co-administration of clonidine with β-blockers or calcium channel blockers because adverse reactions, including complete heart block, have been reported.[151] After reports of several sudden deaths related to clonidine use, concerns about the safety of co-administration of clonidine with stimulants were raised.[152,153] However, these cases were thoroughly examined, and no causative link between use of the combination and sudden death was found. Additional discussion of these issues can be found in the work of Wilens and coworkers.[154] Current guidelines are to monitor blood pressure when initiating and tapering clonidine, but ECG monitoring is not usually necessary.[5]

Guanfacine (Tenex)

Recently, the clonidine-like but more selective, α_2-adrenergic agonist compound guanfacine (Tenex) has been used as an alternative to clonidine for the same indications.[155–157] Possible advantages of guanfacine over clonidine include less sedation and a longer duration of action. Anecdotal information suggests that guanfacine may be more useful in improving the cognitive (inattention) symptoms of ADHD (and less effective in reducing the behavioral symptoms of impulsivity, aggressiveness, and hyperactivity). In open pilot trials, school-age children with ADHD and co-morbid tic disorder treated with guanfacine (in doses ranging from 0.5 mg twice per day to 1 mg three times per day) showed reduction in both tics and ADHD.[158] Controlled data also demonstrated the benefit of guanfacine in reducing tic severity and ADHD symptomology.[159]

Guanfacine treatment is associated with minor, clinically insignificant decreases in blood pressure and pulse rate. The adverse effects of guanfacine include sedation, irritability, and depression. Several cases of apparent guanfacine-induced mania have been reported, but the impact of guanfacine on mood disorders remains unclear.[160] New guanfacine extended-release formulation at doses of 2, 3, and 4 mg per day was more effective than placebo and was generally well tolerated in a multicenter, 8-week, fixed-dose escalation study in children with ADHD who were 6 to 17 years of age.[157]

Novel Treatments for ADHD

Modafinil

Modafinil, a novel stimulant that is distinct from amphetamine, is approved for the treatment of narcolepsy.[161] Unlike the broad brain area activation observed with amphetamine, modafinil appears to activate specific hypothalamic regions.[162,163] Although initial trials in adults were negative, in three recent pediatric trials, modafinil demonstrated efficacy in the treatment of ADHD.[164–166] The FDA PDAC voted that modafinil is "not approvable" for pediatric ADHD owing to possible Stevens–Johnson syndrome in pediatric patients (see www.fda.gov). It may be reasonable to consider combining modafinil with stimulants,[167,168] but clinicians should be aware of the potential to exacerbate mania.[169]

Selegiline

Selegiline (l-deprenyl), an irreversible type B MAOI that is metabolized into amphetamine and methamphetamine, has been compared with MPH in two trials of ADHD youth[170,171] and in adults.[172] Previous work with selegiline in children with ADHD and TS suggested that it may reduce symptoms of ADHD.[173,174] Although to date its role in the treatment of ADHD has been limited by both the availability of alternative treatments and potential for the "cheese reaction," its recent formulation as a patch,[175] which may diminish this reaction, may increase interest in its use.

MOOD DISORDERS

Depression

Children and adolescents may develop a variety of depressive disorders (including major depressive disorder [MDD], dysthymia or mood disturbances that are primary or associated with medical conditions, substance use or abuse, and as a result of psychosocial problems).[176] In the medical setting, clinicians are challenged to differentiate transient symptoms of depression from true depressive disorders. Children often manifest worry, hopelessness, and sadness as primary symptoms related to their own illness, whereas adolescents typically display anxiety, anger, or withdrawal. If the symptoms are episodic and associated with limited impairment, they are generally considered an adjustment disorder with depressed or anxious mood. These patients usually respond to reassurance, environmental intervention, or interpersonal or cognitive-behavioral therapy (CBT). In the outpatient medical setting, children and adolescents with depression may present for evaluation for medical symptoms of unclear etiology. During routine examination these patients may appear sad, withdrawn, apathetic, anxious, angry, or irritable. Although an increasing number of families seek care from PCPs for depression, most family physicians and pediatricians believe they are inadequately trained to screen for, evaluate, and manage pediatric depression.[177,178]

The prevalence of MDD increases with advancing age. Epidemiologic studies from community and clinical samples estimate that the prevalence of MDD is approximately 0.3% in preschoolers, 2% in children, and between 1.5% to 9% in adolescents.[179–187] By the end of

adolescence, the cumulative incidence of MDD is estimated at 20%.[182,185,186,188,189] Although the gender ratio appears equal in children with MDD, by the age of 14, girls appear twice as likely to experience depression as boys.[190] However, additional data suggest that boys and girls who develop depression during prepubescence experience similar symptoms, rates of recovery, relapse, and co-morbidity.[191] Depressive disorders in older children and adolescents commonly co-occur with anxiety, ADHD, and conduct and substance use disorders.[192] The challenge to the clinician is to recognize the developmental progression of co-morbidity. Children initially may be evaluated and treated for ADHD, only to develop depression several years later during their treatment for ADHD.

Pediatric depressive disorders are recognized by their core symptoms (which are similar to those found in adults but with developmentally specific associated features, including sudden-onset school difficulties, school refusal, irritability, sad faces, low energy, isolation, withdrawal, negativism, and aggression or prolonged irritability).[193,194] Diagnostic criteria for MDD include at least a 2-week period of symptoms that represent a change from previous function, with at least one of the symptoms being either depressed mood (which may manifest as irritability in pediatric patients) or loss of interest or pleasure. Other symptoms include decreased or increased appetite, weight loss (or in children, failure to make expected weight gains), weight gain, insomnia or hypersomnia, psychomotor retardation or agitation, fatigue or loss of energy, feelings of worthlessness, inappropriate or excessive guilt (which may be manifest in children as extreme sensitivity to rejection or requests), diminished ability to concentrate (which may be manifested in children as indecisiveness), and recurrent thoughts of death or suicide with intent or a plan.[176] Assessing depression in preschoolers may require some adjustment from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) criteria, and it remains an area of active investigation.[195]

On average, the duration of pediatric depression appears to be approximately 7 months; in the course of a first episode, as many as 40% appear to recover without specific treatment.[193,196] However, patients who do not recover are at high risk for chronic depression, and those who do recover have high rates of recurrence and dysthymia.[197,198] Evidence suggests that children of parents who suffered from depression, especially before the age of 30, have a significantly increased risk for recurrent bouts of depressions.[199,200] Mood disorders in children tend to be chronic compared with the more episodic nature that is typical of adult mood disorders. Furthermore, children and adolescents with depression have a higher rate of conversion to BPD. In follow-up, almost half of the children who initially had single-episode, nonpsychotic MDD converted to BPD that lasted into their early 20s.[201,202] Similarly, as many as 20% of adolescents who had MDD converted to BPD during follow-up.[203] Risk factors for switching from MDD to BPD include history of BPD in parents and grandparents or a family history of antidepressant-induced mania. Other warning signs for conversion to mania include a rapid onset of depression associated with psychosis, psychomotor retardation, and hypersomnia.[204] Afflicted patients may be at increased risk for self-injurious behaviors or suicide.

Suicidal ideation, threats, and behaviors are commonly seen among children and adolescents with psychiatric disorders. These behaviors are of great concern to clinicians who need to ensure the safety of patients within the medical setting and identify patients at increased risk for self-injurious behaviors. The American Academy of Pediatrics (AAP) and the AACAP published reviews and guidelines for the evaluation and management of suicidal behaviors in children and adolescents.[205,206] Suicide remains a leading cause of death in adolescents 15 to 19 years of age; in fact, the number of adolescent suicides has increased dramatically in the past few decades. Overall, male subjects are at increased risk compared with female subjects; in particular, boys with previous suicide attempts, a mood disorder (MDD or BPD), and associated substance abuse are at higher risk. Female subjects at greatest risk also have mood disorders (MDD or BPD) and a history of suicidal behaviors. After a suicide attempt, patients at greatest risk to repeat an attempt have a history of suicidal behaviors; continue to think about suicide; are agitated, irritable, and socially isolated; and have associated MDD, BPD, or substance abuse. In addition to medical care, these patients require close monitoring (which may include restraint, seclusion, or observation by a sitter). Information should be obtained from outside sources (e.g., family, school, the patient's therapist), and the patient must be evaluated for an underlying psychiatric disorder and treated appropriately. In outpatient settings approximately half of children referred for depression are suicidal. Pharmacotherapy should be considered for children with malignant symptoms, significant impairment, suicidality, or lack of response to psychotherapy.

Similar to adults, children with subsyndromal depressive disorders, that are long-standing and often associated with anhedonia and negativity, may have dysthymic disorder. Dysthymia in children and adolescents is manifested by chronically depressed mood for at least 1 year, in association with a change in appetite (too little or too much), a sleep disturbance (insomnia or hypersomnia), low energy, easy fatigability, low self-esteem, indecisiveness, poor concentration, and feelings of hopelessness.[25] Juveniles with dysthymia are often self-critical and feel easily criticized or rejected. Although dysthymic disorder is a major risk factor for future episodes of MDD,[207] juveniles with dysthymia have fewer melancholic symptoms and thoughts of suicide. In contrast to adults, children and adolescents must manifest their symptoms for at least 1 year rather than 2 years.[176]

Updates on Antidepressant-Associated Suicidality

Patients with MDD, both adult and pediatric, may experience worsening of their depression, suicidal thoughts, and behavior, regardless of whether they are taking antidepressants. Antidepressants may also cause emergence of suicidality during initial treatment. The controversial issue of SSRIs causing suicidal behaviors is not new.[208] On the one hand, a 2003 analysis of a large FDA database (N = 48,277 patients) failed to show any increase in suicide rates for patients treated with SSRIs.[209] On the other hand, analysis of nine pooled studies (three for depression) of paroxetine treatment in pediatric patients showed that

1.5 to 3.2 times as many patients on paroxetine as on placebo described severe mood changes, including suicidal ideation (www.medicines.mhra. gov.uk). As a result, in June 2003 the FDA recommended that paroxetine not be used for the treatment of depression in patients younger than 18 years of age.

The next study analyzed more than 4100 pediatric patients pooled from 24 placebo-controlled trials for eight drugs (citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, and venlafaxine). It showed that about 2 out of every 100 pediatric patients became more suicidal on placebo. On antidepressants 4 out of every 100 pediatric patients became suicidal—an additional 2 per 100 patients. Although no one committed suicide in these studies, the FDA issued a black box warning[210] for all antidepressants in children to raise public awareness regarding the potential of increased suicidality based on this data in October 2004.

A more recent *Journal of the American Medical Association* analysis (Apr 18, 2007)[211] covered data on 5310 children and teenagers from 27 studies, including 7 that were part of an FDA review in 2004 that led to the black box warning. The researchers found that for every 100 children treated with antidepressants, only approximately 1 more child experienced worsening suicidal feelings above what would have happened without drug treatment in contrast to the FDA analysis that found an added risk affecting about 2 in 100 patients.

The FDA changed their black box label in 2007[212] on the basis of its pooled analysis of placebo-controlled trials in children and adolescents with MDD, OCD, or other psychiatric disorders (a total of 24 short-term trials of 9 antidepressant drugs in more than 4400 patients). This analysis showed that among youth younger than 18 years of age, antidepressant treatment led to 14 additional cases of suicidality per 1000 patients. Among 18- to 24-year-olds, antidepressant treatment led to 5 additional cases of suicidality per 1000 patients. Among 25- to 64-year-olds, antidepressant treatment led to 1 fewer case of suicidality per 1000 patients. Among those 65 years old, antidepressant treatment led to 6 fewer case of suicidality per 1000 patients.

The TADS 2004 Study (Treatment of Adolescents with Depression Study) sponsored by the NIMH compared the effectiveness of fluoxetine, CBT, and placebo in the treatment of adolescents with MDD.[213] It showed that although a number of adolescents started the study with suicidal thoughts, there was a significant reduction in the incidence of such thoughts with treatment. The reduction was most marked in the adolescents who received a combination of medication and therapy.

A study published in the *Archives of General Psychiatry* in October 2003[214] showed an inverse relationship between regional change in the use of antidepressants in individuals 10 to 19 years of age and the incidence of completed suicide. In other words, if the area showed an increase in the use of antidepressants, there was a decrease in the incidence of completed suicides.

Lastly, it is unknown whether the suicidality risk extends to longer-term use (i.e., beyond several months). However, there is substantial evidence from placebo-controlled maintenance trials in adults with depression that the use of antidepressants can delay the recurrence of depression.[210] All patients being treated with antidepressants for any indication should be monitored appropriately and observed for clinical worsening, suicidality, and unusual changes in behavior, especially during the initial 1 to 2 months of a course of drug therapy or whenever the dose is increased or decreased.

Pharmacotherapy

Prescription of antidepressants for children and adolescents has increased dramatically in recent years.[215–218] However, this increase must be put into the context of the prevalence of pharmacologically responsive depression in this population.[219] Fortunately, research investigating the safety, tolerability, and efficacy of antidepressants in juveniles has expanded significantly.

Tricyclic Antidepressants Versus Selective Serotonin Reuptake Inhibitors

Initial studies of the pharmacotherapy of pediatric depression focused on the use of TCAs.[220] Despite solid methodology, thorough assessment, diagnosis, and treatment-controlled trials of TCAs in children and adolescents with depression have demonstrated a minimal advantage of TCAs over placebo. Because pediatric depression appears refractory to treatment with TCAs, researchers have investigated the safety, tolerability, and efficacy of the SSRIs. Currently, SSRIs appear to be the medications of choice for the treatment of pediatric depression and dysthymia.[187,221,222]

FDA-Approved Treatments for Pediatric Major Depressive Disorder

Fluoxetine

As a result of two large, double-blind, placebo-controlled trials that demonstrated the short-term safety, tolerability, and efficacy of fluoxetine, it was the first FDA-approved medication for the treatment of MDD in children and adolescents between 7 and 17 years of age.[223–225] In the first trial (single site, NIMH-sponsored), 583 subjects with MDD were screened and 96 randomized to either placebo or fluoxetine (20 mg). With use of the primary outcome measures of reduction on Childhood Depression Rating Scale (CDRS) scores, by week 5 fluoxetine separated from placebo. By the end of the study period, 56% (N = 27) of the fluoxetine-treated patients and 33% (N = 16) of the placebo-treated patients were rated as "much" or "very much" improved on the Clinical Global Impression (CGI) scale. Response rates were similar in adolescents and latency-age children, as well as in males and females. Although patients responded well to the treatment, only 31% of the fluoxetine-treated patients achieved full remission, compared with 23% of placebo-treated patients. Lifetime co-morbidities with anxiety disorders (N = 54, 55%), dysthymia (N = 34, 35%), ADHD (N = 29, 30%), and ODD (N = 29, 30%) were common in this sample.

In the second trial (multisite, industry-sponsored), 420 pediatric subjects with MDD were screened and 219 randomized to either placebo (N = 110) or 20 mg of fluoxetine (N = 109). In this sample co-morbidity with ADHD (N = 31,

14%), oppositional defiant disorder (ODD) (N = 34, 16%), CD (N = 4, 2%), and anxiety disorders (none reported, and baseline HAM-A scores in clinically insignificant range) appeared relatively low. Compared with patients randomized to placebo, patients treated with fluoxetine showed significant reductions in CDRS scores as early as the first week of treatment and they were maintained on the treatment throughout the 9 weeks of the trial. Although significantly more fluoxetine-treated patients achieved remission (41.3% versus 19.8%; $p < 0.05$), based on the predefined definition of response (> 30% reduction in CDRS scores) the percentage of patients responding to fluoxetine was not significantly different than placebo (65.1% versus 53.5%; p = .093). Compared with placebo, fluoxetine treatment was associated with significantly greater improvements in CGI severity (52.3% vs. 36.8%; p = 0.028) scores. The most common side effect observed with fluoxetine treatment was headache, although difficulty paying attention and dizziness were also commonly reported.

Since our last edition, the TADS study (Treatment of Adolescents with Depression Study) compared the effectiveness of fluoxetine, CBT, and placebo in the treatment of adolescents with MDD.[213] It involved 439 adolescents with moderate to severe depression. The teens were randomly assigned to receive medication alone, placebo pills alone, CBT alone, or a combination of medication and CBT. The rates of improvement were 34.8% for placebo, 43.2% for therapy alone, 60.6% for medication alone, and 71% for the combination of medication and psychotherapy. Those on medication alone or psychotherapy alone did not do significantly better than those on placebo. However, the adolescents on medication alone did significantly better than those who received psychotherapy alone.

Escitalopram

In March 2009 escitalopram became the second antidepressant to be approved by the FDA for the acute and maintenance treatment of MDD in adolescents 12 to 17 years of age. Escitalopram was approved on the basis of data from two flexible-dose, placebo-controlled trials that each lasted 8 weeks. One trial was conducted in children and adolescents (6 to 17 years of age) and compared escitalopram with placebo.[226] Only in a *post hoc* analysis of adolescent (12 to 17 years of age) completers, but not in the primary (last observation carried forward) analysis of all participants, escitalopram significantly improved Childhood Depression Rating Scale-Revised (CDRS-R) scores compared with placebo.

The other trial was conducted in children and adolescents 7 to 17 years of age; the difference using CDRS-R was significant beginning at week 1 through week 8 between placebo (24%) and citalopram (36%) at week 8. The greatest benefit was observed in the adolescent group.

Two additional flexible-dose, placebo-controlled MDD studies—one with escitalopram in patients 7 to 17 years of age and one with citalopram in adolescents—failed to demonstrate a significant benefit in the primary end point.

Non-FDA-Approved Treatments for Pediatric MDD

On the basis of results of large controlled trials, other SSRIs appear to be efficacious in the treatment of pediatric depression.

Sertraline

Wagner and associates reported on pooled results of two 10-week (industry-sponsored multisite) double-blind, placebo-controlled trials of sertraline for pediatric depression.[227] In this protocol 377 outpatients (177 children 6 to 11 years of age and 189 adolescents 12 to 17 years of age) were randomized to treatment with placebo or sertraline. Based on a 40% decrease in the adjusted CDRS-R total score at study end point, 69% of sertraline-treated patients compared with 59% of placebo patients were considered responders ($P = .05$). Although generally well tolerated, sertraline treatment was associated with higher rates of diarrhea, vomiting, anorexia, and agitation. In an open trial of sertraline in depressed adolescents (N = 53), Ambrosini and associates[228] observed significant improvements in efficacy (measured using various rating scales) by ensuring adherence to the prescribed dose of sertraline between weeks 6 and 10. These results suggested that in clinical practice the acute phase of treatment for depression in adolescents should extend for at least 10 weeks.

Citalopram

Wagner and colleagues[229] also reported on the efficacy of citalopram in the treatment of MDD in children and adolescents. In this trial 174 pediatric patients (83 children 6 to 11 years of age and 91 adolescents 12 to 17 years of age) were randomized in a double-blind manner to treatment with either placebo or citalopram. Citalopram was initiated at 20 mg and increased to 40 mg after 4 weeks if clinically indicated. In patients treated with citalopram, significant reductions in mean CDRS-R scores were observed by week 1 ($p < 0.02$) and maintained thorough the end of the study (week 8, $p < 0.04$). By the end of the study, significantly more patients treated with citalopram responded compared with those taking placebo (36% vs. 24%; $p < 0.05$). Patients treated with citalopram more commonly reported nausea, influenza-like symptoms, and rhinitis.

Fluvoxamine

Although well studied in pediatric anxiety disorders,[230] we are not aware of any controlled trials that have investigated the efficacy of fluvoxamine in the treatment of pediatric depression.

Paroxetine

An early report compared the efficacy of paroxetine, imipramine (Tofranil), and placebo in the treatment of adolescent depression. In this 8-week, double-blind, placebo-controlled, parallel design trial, 425 adolescents (12 to 17 years of age) were screened and 275 randomized (93 to paroxetine, 95 to imipramine, and 87 to placebo). Co-morbidity with anxiety disorders (N = 73, 26.5%) and externalizing disorders (i.e., ADHD, ODD, and CD) (N = 71, 25.8%) commonly were observed in this cohort. Paroxetine was started at 20 mg per day, which could have been titrated up to 30 mg at week 5 and to 40 mg at weeks 6 to 8. Imipramine was initiated at 50 mg and titrated up weekly to a target dose of 200 mg per day (but which could have been increased to 250 mg at week 5 or 300 mg during weeks 6 to 8 as clinically indicated). Although paroxetine was associated with significant improvements in CGI scores, it did not separate from imipramine or placebo on

the total score of the primary outcome measure (Hamilton Rating Scale for Depression-17 item [HAM-D-17]). However, the HAM-D-17 was designed for adult patients, and it may not be the best way to measure change in adolescent depression. For this reason most current trials in pediatric depression use the CDRS-R to measure medication effect.[221] Nearly half of the paroxetine-treated patients were maintained on 20 mg per day. The most frequent side effects observed in the paroxetine-treated group included dry mouth, nausea, dizziness, insomnia, somnolence, and headache. Although 11 paroxetine-treated patients experienced serious adverse events, including emotional lability (N = 5), conduct problems or hostility (N = 2), worsening depression (N = 2), euphoria and expansive mood (N = 1), and headache during discontinuation (N = 1), investigators believe that only the discontinuation-related headache was directly related to paroxetine treatment.

Venlafaxine

Several other antidepressants are used in juvenile depression. Venlafaxine (Effexor) possesses both SSRI and noradrenergic properties. Venlafaxine is effective in refractory adult depression and may be useful in the treatment of juvenile mood disorders and children with ADHD that is co-morbid with their depression. The adverse effect profile of venlafaxine is similar to that of the SSRIs, except for significant nausea that can be reduced by using very low doses for the first 1 to 2 weeks. Venlafaxine also led to an increase in diastolic blood pressure, pulse, and skin problems.[231] Venlafaxine did not show benefit over placebo in one published trial, although low doses (75 mg per day) were used.[232]

Bupropion

Bupropion hydrochloride is a novel antidepressant with noradrenergic and dopaminergic properties. Bupropion may be helpful in children with prominent mood lability, dysthymia, and co-morbid ADHD.[114] Similar to the management of ADHD (discussed previously), bupropion should be started between 37.5 to 75 mg per day of the immediate-release preparation or 100 mg of the sustained-release preparation and titrated upward as necessary, eventually converting to the extended-release preparation for compliance and full-day coverage. The major side effects in children include insomnia, possible exacerbation of tics, and the theoretical risk of seizures with the short-acting preparation. Bupropion should not be used in patients with bulimia. No blood monitoring is required.

Mirtazapine

Results of a recent controlled trial of mirtazapine (Remeron) showed little difference in response between mirtazapine and placebo in a controlled study of juveniles with depression. Anecdotal reports and clinical experience suggest that mirtazapine may be helpful in patients with ADHD who benefit from treatment with a stimulant but who suffer from insomnia and anorexia.

Nefazodone

Although open trials[233] and a small case series[234] of nefazodone (Serzone) showed promise, results of a 15-site double-blind, placebo-controlled trial only approached statistical significance over placebo in adolescents with depression.[235] At this time, given concerns over hepatotoxicity and the availability of many alternative medications with demonstrated efficacy, the role of nefazodone in the treatment of pediatric depression is limited.

Pharmacokinetics of Antidepressants in Children and Adolescents

Although the main pharmacodynamic effects of SSRIs are similar, the SSRIs are structurally dissimilar to one another and vary in their pharmacokinetics and drug interactions. The SSRIs inhibit specific hepatic isoenzymes and thereby increase the serum levels of other compounds. In the medical setting, treatment with antidepressants may produce clinically significant medication interactions. Parents and clinicians should be aware that SSRIs may interact with antibiotics, especially the macrolide derivatives that are currently being used on pediatric patients. Clinicians need access to updated databases on medication interactions and current references.[236]

Fluoxetine is a racemic mixture that is metabolized to its active metabolite, norfluoxetine. Both fluoxetine and norfluoxetine are substrates of CYP 2C9, 2C19, 3A4, and 2D6. Both fluoxetine and norfluoxetine are potent inhibitors of 2D6 and therefore may increase the levels of medications that are metabolized through 2D6 (e.g., certain antidepressants, antipsychotics, analgesics, calcium channel blockers, β-blockers, dextromethorphan, and ATMX). Wilens and co-workers[237] recently reported on the pharmacokinetics of fluoxetine and its major metabolite, norfluoxetine, in 10 children (6 to 12 years of age) and 11 adolescents (12 to 17 years of age). In this open-label study, patients received fluoxetine 20 mg per day. Mean steady states of fluoxetine and norfluoxetine were achieved, on average, within 4 weeks, although high between-patient variability was observed. Furthermore, on average, children accumulated higher amounts of fluoxetine (twofold) and norfluoxetine (1.7-fold) compared with adolescents. Accumulation of fluoxetine and norfluoxetine in adolescents was similar to the profile for adult patients. The clinical implications of this finding are that most children should be started on fluoxetine 10 mg per day.

Sertraline, which is produced as the S-enantiomer and metabolized to its active metabolite desmethylsertraline, is both a substrate of 2B6, 2C9, 2C19, 2D6, and 3A4. Both sertraline and desmethylsertraline are modest inhibitors of 2C9, 2C19, and 3A4. Case reports have shown that sertraline increases the concentration of phenytoin, pimozide, warfarin, cyclosporine, and diazepam. Sertraline is known to inhibit glucuronidation, and it has been reported to cause toxic levels of lamotrigine. Levels of sertraline may be reduced by adjunctive analgesic agents, such as carbamazepine and phenytoin.[236] Axelson and associates recently studied the pharmacokinetics of sertraline in adolescents.[238] They observed that the mean steady state half-life of sertraline 50 mg per day was significantly shorter than the single-dose half-life (15.3 ± 3.5 hours versus 26.7 ± 5.2 hours; $p < 0.001$) and the mean steady state half-life of 100 to 150 mg per day of sertraline (20.4 ± 3.4 hours). These authors suggested that adolescents may need doses greater than 50 mg per day to achieve a therapeutic response for

depression. Similarly, Axelson and associates studied the pharmacokinetics of sertraline in 29 children (6 to 12 years of age) and 32 adolescents (13 to 17 years of age). These investigators found that during treatment with sertraline 200 mg per day, the T_{max} (14.6 ± 16.1 vs. 10.8 ± 8 hours) and half-lives of sertraline (26.2 ± 8.4 versus 27.1 ± 8.2 hours) and its main metabolite desmethylsertraline (78.5 ± 50.6 versus 75.4 ± 37.1 hours) were similar in children and adolescents, respectively. These results also demonstrated that a single dose of sertraline 50 mg and a steady state dose of sertraline 200 mg per day led to a significantly increased C_{max} and an area under the curve (AUC) in children, compared with adolescents or adults. However, when these pharmacokinetic parameters were normalized for body weight, no significant differences were observed. These results suggest linear pharmacokinetics of sertraline in pediatric patients across the dose range of 50 to 200 mg per day, and the authors concluded that sertraline can be safely used within the adult dosage schedule.

Paroxetine is an S-enantiomer that is a substrate of 2D6 and, to a lesser degree, 3A4. Paroxetine has no significant metabolites, is a potent inhibitor of 2B6 and 2D6, and is a mild inhibitor of 1A2, 2C9, 2C19, and 3A4. Co-administration of paroxetine with substrates of 2D6 (e.g., antidepressants, antipsychotics, analgesics, calcium channel blockers, β-blockers, antiarrhythmics), or 2B6 (e.g., bupropion, nicotine, sertraline, diazepam, tamoxifen) is likely to increase levels of the substrate.[236] Findling and colleagues[239] studied the pharmacokinetics of paroxetine in 30 children and adolescents with MDD. The mean steady state half-life of paroxetine was 11.1 ± 5.2 hours, with tremendous interindividual variation. Urinary excretion of paroxetine correlated with cytochrome 2D6 activity. These authors concluded that paroxetine is metabolized more rapidly in pediatric patients than in adults.

Citalopram (CIT), a racemic mixture of R and S-citalopram (S-CIT), is demethylated via 2C19, 2D6, and 3A4. It is a mild inhibitor of 2D6, but in general it has few medication interactions. Reis and co-workers,[240] using data from two trials, studied the pharmacokinetics of CIT in 44 patients younger than 21 years of age who were treated naturalistically with a mean dose of CIT 30 mg per day. As in adults, large interindividual variability in levels of serum CIT and its main metabolite desmethylcitalopram (DCIT) and didesmethylcitalopram (DDCIT) were observed in these adolescents. The mean serum half-life of CIT was 36 hours. These authors found that the pharmacokinetics of CIT was influenced by gender, smoking status, the menstrual period, and treatment with oral contraceptives. The active enantiomer S-CIT has recently become available as Lexapro. Like CIT, it has few medication interactions.

Fluvoxamine (Luvox) is a substrate of 2D6 and 1A2, which has no significant metabolites. It is described as a pan-inhibitor because it is a potent inhibitor of 2B6, 2C9, and 3A4 and a mild inhibitor of 2D6. When adding any medication to fluvoxamine, clinicians should be cautious.[236]

The profiles of the pK for novel antidepressants have been reported as well. Bupropion (Wellbutrin or Zyban) is mainly metabolized by 2B6 to its main metabolite hydroxybupropion. Bupropion acts as a modest inhibitor of 2D6. Although smoking does not affect the pK profile, co-administration with paroxetine, sertraline, or other 2B6 inhibitors may cause interactions. Stewart and associates[241] examined the single-dose pK profile of bupropion SR (150 mg) in 75 adolescents (13 to 18 years of age). These investigators found no differences in the pK profile between smokers and nonsmokers; however, girls in this sample had an increased C_{max}, $t_{1/2}$, and AUC for both bupropion and hydroxybupropion.

Findling and associates[233] studied the pK profile of nefazodone (NEF) in 28 patients (N = 15 children, 7 to 12 years of age, and N = 13 adolescents, 13 to 16 years of age) treated for MDD. NEF is metabolized primarily by CYP 3A4 to at least three active metabolites: hydroxynefazodone (OH-NEF), triazoledione, and metachlorophenylpiperazine (mCPP). Formation of mCPP is dependent on CYP 2D6 activity. Although the pK profile showed significant variability, the C_{max} and AUC in children was observed to be greater than in adolescents and the serum half-life increased with increased dosage ($t_{1/2}$ 1.9 hours after first dose, 2.7 hours after 1 week, and 4.1 hours after 1 week on 100 mg twice per day). The pK profile for adolescents approximated that seen in adults. Substantial increases in concentration of mCPP were observed in the five patients (two children and three adolescents) considered poor metabolizers of CYP 2D6. A recent case series (two adults and one adolescent) described liver failure in three patients treated with NEF.[242] All patients developed jaundice and encephalopathy and showed prominent necrosis in the centrolobular area. One patient recovered without transplantation, one died after transplantation, and one underwent successful transplantation. In response to these cases, the FDA added a black box warning to NEF's labeling. The FDA warning reported liver failure that resulted in death or transplant in 1 per 250,000 to 300,000 patient years of NEF treatment (see www.fda.gov/medwatch/SAFETY/2002/ Serzone_deardoc.PDF). The FDA warning recommended not starting NEF in patients with active liver disease or with elevated baseline serum transaminases. The FDA further advised that patients should be educated about the signs of liver dysfunction, and NEF should be discontinued in patients who develop an elevated serum AST or ALT level. In May 2004 Bristol-Myers Squibb discontinued the sale of Serzone in the United States and Canada. Several generic formulations of NEF are still available.

Clinical Use of SSRIs

Given the likelihood of relatively similar efficacy, selection of an SSRI should take into consideration tolerability (e.g., side-effect profile), anticipated medication interactions, half-life (e.g., potential for bipolar switching), and adherence.[194] Whereas paroxetine, fluoxetine, citalopram, escitalopram, and sertraline may be associated with agitation and increased energy, fluvoxamine appears to be more sedating and can be useful in children with sleep difficulties associated with mood symptoms. SSRIs should be initiated at low doses (e.g., 5 to 10 mg fluoxetine, 12.5 to 25 mg sertraline, 5 to 10 mg citalopram, 2.5 to 5 mg escitalopram, 5 to 10 mg paroxetine, 12.5 to 25 mg fluvoxamine, and 18.75 to 37.5 mg venlafaxine) and titrated upward slowly.[222] Like fluoxetine, sertraline, paroxetine, and citalopram, escitalopram is now available as an elixir. Contrary to previous beliefs, adolescents typically develop depression before the onset of heavy tobacco use (which is associated with the

development of depressive symptoms).[243] Clinicians should consider directing adolescents with MDD and tobacco use to appropriate anti-smoking programs. Once an antidepressant response is obtained, patients and their families often benefit from encouraging adherence to prevent relapse; however, the ideal length of treatment in pediatric patients requires further study. After treatment is completed (typically 6 to 12 months after remission), the SSRIs should be slowly tapered, to prevent both a discontinuation syndrome and recurrence of symptoms. Patients and their families need education regarding the monitoring of future depressive episodes.

Treatment Nonresponse

Only approximately 60% of adolescents with depression will show an adequate clinical response to an initial treatment trial with an SSRI. The latest study of options after nonresponse to an SSRI, TORDIA,[231] evaluated the relative efficacy of four treatment strategies in adolescents who continued to have depression despite adequate initial treatment with an SSRI. This randomized controlled trial of 334 patients 12 to 18 years of age with a primary diagnosis of MDD that had not responded to a 2-month initial treatment with an SSRI was conducted at six U.S. academic and community clinics from 2000 to 2006. For adolescents with depression not responding to an adequate initial treatment with an SSRI, the combination of CBT and a switch to another antidepressant resulted in a higher rate of clinical response (54.8%; 95% confidence interval [CI], 47%-62%) than did a medication switch alone (40.5%; 95% CI, 33%-48%; p = .009). However, a switch to another SSRI was just as efficacious as a switch to venlafaxine (47.0%; 95% CI, 40%-55% *versus* 48.2%; 95% CI, 41%-56%; p = .83) and resulted in fewer adverse effects (increase in diastolic blood pressure and pulse, skin problems).

Side Effects and Complications

In general, SSRIs are well tolerated and have fewer side effects than TCAs, especially when taken in overdose. Common adverse effects of SSRIs include manic activation, agitation, gastrointestinal symptoms, irritability, insomnia, sexual dysfunction, and weight loss.[222,244] Whereas paroxetine, fluoxetine, citalopram, and sertraline may be associated with agitation and increased energy, fluvoxamine appears to generate sedation and is useful in children with sleep difficulties associated with mood symptoms. In approving fluoxetine for the treatment of juvenile depression and OCD, the FDA expressed concern that fluoxetine-treated patients may grow more slowly than patients treated with placebo (1.1 cm in height and 2 lb in weight) over a 19-week interval. Similarly, a small case series described slowing of growth during treatment with either fluoxetine (20 to 80 mg per day) or fluvoxamine (50 to 100 mg per day) in four Middle Eastern patients with TS or OCD.[245] Although these agents have been used for almost 15 years in juveniles without detection of significant effects on growth, clinicians should consider alternative treatments if a patient's height or weight inexplicably decelerates. Given the lack of CV effects with SSRIs, monitoring of vital signs and ECG does not appear necessary unless there is an additional medical concern.[5,246] Similarly, no specific blood monitoring appears necessary in children receiving SSRIs. Although it has not been well studied, Walkup summarized clinically relevant complications of SSRI pharmacotherapy in children and adolescents.[247] Activation, which is distinguished from a change in mood or impulse control, may be related to either akathisia, hyperactivity, or disinhibition; it usually responds to lowering of the dose. Signs of mania (which may include impulse dyscontrol, mood swings, grandiosity, hypersexuality, and aggression) may be observed and accompany bipolar switching. Treatment of mania relies on pharmacologic approaches. Celebration may occur in SSRI-treated anxious children who experience relief of their anxiety; they may seem impulsive or uninhibited. Developmental issues may be observed as anxiety or depression lifts, after which additional co-morbidities become evident (e.g., ADHD or Asperger's syndrome). Frontal lobe–type symptoms may appear and be manifested primarily by apathy. Gastrointestinal symptoms are very common, as noted previously. Adolescents prescribed SSRIs may experience sexual side effects, although reports of these side effects are minimal in controlled studies in this population.

Like adults, children may experience a discontinuation syndrome as they are tapered off SSRIs or if they miss their scheduled dose. Typically, this syndrome occurs among those taking SSRIs with shorter half-lives (e.g., paroxetine or venlafaxine), although it can occur with any antidepressant.[248] As in adults, the discontinuation syndrome is typically characterized by physical symptoms (e.g., nausea, gastrointestinal disturbance, diarrhea, dizziness, insomnia, lightheadedness, headache, shakiness, and sensations of a mild electrical shock), cognitive symptoms (e.g., confusion, poor memory, cloudiness, and forgetfulness), and emotional symptoms (e.g., increased crying, mood lability, and anxiety).[249] Patients and parents should be educated about the discontinuation syndrome, and steps should be taken to prevent its occurrence (including the use of SSRIs when necessary, encouraging adherence, tapering SSRIs gradually, and ensuring that the manufacturer of the medication stays the same throughout treatment if a patient is taking a generic preparation).[250] When patients experience a discontinuation syndrome, reintroducing the medication usually provides relief, although some patients may need to be switched to an SSRI with a longer half-life. A discontinuation syndrome has also been described as leading to a more complicated course of illness. In their review of the literature, Ali and associates[251] noted that antidepressant withdrawal in general, and SSRI withdrawal in particular, appears to increase the risk of mania in adults with BPD. The authors postulated either noradrenergic hyperactivity or cholinergic overdrive as the possible underlying pathophysiology.

Bipolar Disorder

Pediatric BPD is a relatively recent phenomenon in the modern child psychiatry landscape. NIMH recognized pediatric mania in 1995, 20 years after pediatric depression. There has been a growing awareness of the existence of pediatric BPD, a childhood symptom complex reminiscent of adult BPD.[252–254] The AACAP and the NIMH have convened round-table meetings, and the AACAP has issued practice parameters regarding the evaluation, diagnosis,

management, and research of pediatric BPD.[255–257] It is common for many children and adolescents with BPD to seek medical attention in emergency departments or develop severe, out-of-control symptoms during medical hospitalizations. Children may also be referred to PCPs for unremitting temper tantrums. Prepubertal mania is usually co-morbid with ADHD, and these patients typically present with extreme hyperactivity, impulsivity, and aggression.[258,259] Children with BPD commonly present with an extremely irritable or explosive mood associated with poor psychosocial function; it is often devastating to the child and the family. These children often overreact to minor environmental stressors (mood reactivity). Additional symptoms consistent with mania include grandiosity, unmodulated high energy, decreased need for sleep, over-talkativeness, increased goal-directed and pleasurable activity (e.g., social, work, school, and sexual), and poor judgment (e.g., seeking out reckless activities). Although the juvenile symptom complex of mania should be differentiated from ADHD, conduct disorder, depression, trauma, substance use and abuse, and psychotic disorders, these disorders commonly co-occur with childhood mania.[260] The clinical course of juvenile mania is most frequently chronic and mixed with co-occurring manic and depressive features.[251–264]

Pharmacotherapy

Until recently, lithium was the only FDA-approved drug for the treatment of BPD in children 12 years of age and older. In 2007 the FDA approved the use of risperidone (Risperdal) for acute treatment of manic or mixed episodes of bipolar I disorder in children 10 to 17 years of age. In 2008 the FDA approved aripiprazole (Abilify) for acute treatment of manic or mixed episodes associated with BPD (type I) in pediatric patients between the ages of 10 and 17.

Unfortunately, early-onset BPD appears less responsive to lithium.[265,266] Therefore children and adolescents with BPD are often treated with combinations of lithium, anticonvulsants, and atypical antipsychotic mood stabilizers.[267,268] If the patient does not respond to an adequate trial (in dose and time) of a single agent or cannot tolerate the medication, subsequent trials with alternative medication(s) are recommended. In manic or mixed presentations, with psychotic symptoms, additional antipsychotic treatment is recommended. In BPD with prominent symptoms of depression, combined treatment with a mood stabilizer and an antidepressant is indicated. Clinicians must be wary of the potential destabilizing effects of SSRIs in the treatment of bipolar depression in children and adolescents.[268] Recent data indicate that the management of BPD with or without co-morbid disorders (depression and ADHD) may require an aggressive treatment approach that combines several therapeutic agents.

Lithium

The use of lithium carbonate in BPD and treatment-resistant unipolar depression appears helpful; surprisingly, it has not been studied under controlled conditions. The usual starting dose of lithium ranges from 150 to 300 mg per day in divided doses, two or three times per day. Weller and co-workers[269] published dosage guidelines for lithium in children 6 to 12 years of age, suggesting the initial total daily doses (administered three times per day) of 600 mg per day for patients weighing less than 25 kg, 900 mg for patients weighing 25 to 40 kg, 1200 mg per day for patients weighing 40 to 50 kg, and 1500 mg per day for patients weighing 50 to 60 kg. There is no known therapeutic serum lithium level in children. Based on the adult literature, serum levels of 0.8 to 1.5 mEq/L for acute episodes and levels of 0.4 to 0.8 mEq/L for maintenance therapy are suggested. Although lithium is commonly used in pediatric patients with BPD, only one prospective well-controlled study has been conducted. In this small but seminal study, Geller and colleagues[270] found that treatment with lithium both improved global functioning and reduced frequency of positive urine drug screens among adolescents with BPD co-morbid with substance abuse.

Common short-term adverse effects of lithium include gastrointestinal symptoms (e.g., nausea, vomiting), renal symptoms (e.g., polyuria, polydipsia), and CNS symptoms (e.g., tremor, sleepiness, memory impairment).[271] Short-term adverse effects associated with the use of lithium are generally dose-related. The incidence of toxicity increases directly with increased serum levels, and symptoms respond favorably to dose reduction. It is important to monitor a child's hydration status because lithium induces mild dehydration that, when more severe, may lead to toxic accumulation of lithium. It is therefore prudent to consider withholding or reducing lithium doses in children who are dehydrated or who have experienced prolonged vomiting. The chronic administration of lithium may be associated with metabolic (e.g., substantial weight gain and decreased calcium metabolism), endocrine (e.g., decreased thyroid functioning), dermatologic (e.g., acne), cardiac, and renal dysfunction. Thus it is necessary that children be screened for renal function (e.g., blood urea nitrogen, creatinine), thyroid function (e.g., thyroid-stimulating hormone), ECG, and calcium level before lithium treatment is started and that these tests be repeated every 6 months. Female patients should undergo a pregnancy test and be educated about the dangers of lithium exposure during pregnancy. Particular caution should be exercised when lithium is used in patients with neurologic, renal, or CV disorders.

Alternative antimanic medications for children and adolescents include anticonvulsants.

Carbamazepine

Carbamazepine, approved for treatment of pediatric seizures (e.g., psychomotor, grand mal) and trigeminal neuralgia, is structurally related to the TCAs. Carbamazepine is not FDA-approved for the treatment of pediatric mania; however, anecdotal reports and some studies support its consideration.[272–274] Although carbamazepine may be useful, worsening behavior during treatment has been reported.[275]

Carbamazepine induces its own metabolism, which is usually complete after 3 to 5 weeks on the medication. Carbamazepine has many medication interactions,[236] induces the metabolism of substrates of 3A4 (e.g., haloperidol, phenytoin), and may reduce levels of valproic acid and increase lithium levels by reducing lithium clearance. Inhibitors of 3A4 (e.g., erythromycin) may increase levels of carbamazepine. The plasma half-life after chronic administration is between 13 and 17 hours. The therapeutic plasma concentration is variably reported as 4 to 12 µg/mL,

and recommended daily doses in children range from 10 to 20 mg/kg, administered twice per day. Because the relationship between the dose and the plasma level is variable and uncertain with marked interindividual variability, plasma level monitoring is recommended. Common short-term side effects include dizziness, drowsiness, nausea, vomiting, and blurred vision. Idiosyncratic reactions (e.g., bone marrow suppression, liver toxicity, and skin disorders [including Stevens–Johnson syndrome]), have been reported but are rare. However, given the seriousness of these reactions, careful monitoring of blood counts and liver and renal function is warranted initially and during treatment.

Oxcarbazepine

Oxcarbazepine (Trileptal) appears to have fewer reports of medication interactions and adverse effects (e.g., less effect on bone marrow and skin). However, minimal data are currently available regarding its efficacy in pediatric BPD. Its only RCT in manic or mixed BPD (type I) children (7 to 18 years of age) was negative.[276] Clinicians who prescribe it should monitor for hyponatremia and be aware that it can induce the metabolism of ethinyl estradiol.

Valproic Acid

Valproic acid (VPA) is an anticonvulsant that is FDA-approved for the acute and maintenance treatment of BPD in adults; by extension, it may be useful in the treatment of juvenile BPD. However, the evidence for VPA in childhood BPD has been mixed at best.

In an 18-month double-blind, placebo-controlled study of youths 5 to 17 years of age with bipolar I or II disorder initially treated with lithium and divalproex until in remission for 4 weeks, divalproex alone was equal to lithium alone in survival time until emerging symptoms of relapse or survival time until discontinuation for any reason.[277] In a prospective 6- to 8-week randomized, open trial, Kowatch and colleagues[274] compared the efficacy of lithium, carbamazepine, and VPA in 42 children and adolescents with BPD I or II. Using improvements in scores on CGI and Young Mania Rating Scale (> 50% change from baseline), these investigators observed response rates of 38% with carbamazepine, 38% with lithium, and 53% with VPA ($\chi 2$ = 0.85, p = 0.60). In the initial open phase of another trial, Wagner and co-workers[278] reported that 22 of 40 patients with BPD (55%) experienced more than 50% improvement in the Mania Rating Scale (YMRS) during open treatment with VPA in doses of 15 to 17 mg/kg per day. Finally, in the double-blind, placebo-controlled trial of divalproex ER in 150 pediatric patients (manic or mixed episode, 10 to 17 years of age), there was no differences in efficacy on primary or secondary measures or incidence of adverse events.[279]

VPA is primarily metabolized by the liver; it has a plasma half-life of 8 to 16 hours and a therapeutic plasma concentration of 50 to 100 µg/ml. Recommended initial daily doses are 15 mg/kg per day that are gradually increased to a maximum of 60 mg/kg per day, administered three times a day. Common short-term side effects include sedation, thinning of hair, anorexia, nausea, and vomiting. Idiosyncratic reactions (e.g., bone marrow suppression and liver toxicity) have been reported but appear to be rare. Asymptomatic elevations of serum glutamic oxaloacetic transaminase usually resolve spontaneously. Although fatalities resulting from hepatic dysfunction have been reported in children younger than 10 years of age with monotherapy, these have occurred primarily in children younger than 2. The risk of serious hepatic involvement is increased by concomitant use of other anti-seizure medications and may be dose-related. Careful monitoring of blood counts and liver and renal function are warranted initially and during treatment. Hyperammonemia has been reported, and depending on clinical impression, monitoring ammonia levels may be appropriate.

Atypical Antipsychotics

Increasingly, the atypical antipsychotic medications (including clozapine [Clozaril], olanzapine [Zyprexa], quetiapine [Seroquel], risperidone [Risperdal], ziprasidone [Geodon], and aripiprazole [Abilify]) are being used in the management of pediatric BPD. These medications differ from "typical" antipsychotics (e.g., chlorpromazine and haloperidol) in their receptor profile (D_2 blockade and the fact that they affect multiple other receptors, including serotonin), reduced likelihood of causing EPS, reduced likelihood of causing hyperprolactinemia (the exception is risperidone), and a greater benefit on the negative symptoms of psychosis and on cognition.[280] Whenever these medications are used, patients and families should be informed about the potential for side effects, including EPS, akathisia, neuroleptic malignant syndrome, and TD and dystonias. Although the risk of developing TD is lower with the atypical medications, the rate of occurrence is unknown. Patients treated with antipsychotic medications should be monitored regularly with the Abnormal Involuntary Movement Scale (AIMS) examination.

Risperidone

Risperidone is FDA-approved to treat pediatric mania.[281] Risperidone is usually initiated at 0.25 mg once or twice per day and titrated up to 3 to 4 mg per day in most pediatric patients, although it appears to retain its atypical properties in doses up to 6 mg per day. Its common adverse effects include weight gain, sedation, drooling, and elevation of prolactin levels. Although EPS is not common, clinicians should be aware of this possibility and recognize it when it occurs. Like adults, children and adolescents with EPS can be treated with oral or IM diphenhydramine or benztropine. Although pK studies in children are lacking, data in adults indicates that risperidone reaches peak concentrations within 1 hour, is metabolized through CYP 2D6, and has a half-life of 3 hours in extensive metabolizers and 17 hours in poor metabolizers.[282] There are case reports of hepatotoxicity, tachycardia, prolongation of the QTc interval, and stroke (in elderly patients).

Aripiprazole

Aripiprazole (Abilify) was FDA-approved for manic and mixed states in pediatric BPD I in 2008. Aripiprazole appears to have mixed agonist–antagonist properties and is described as a "dopamine/serotonin stabilizer." It has a long half-life and does not appear to cause significant interactions with other medications that are metabolized through the P450 system. It can cause akathisia. It is usually started at 2.5 to 5 mg per day and titrated to 10 to 15 mg per day (up to 30 mg/day in adult trials).

Olanzapine

Olanzapine is currently FDA-approved for acute and maintenance treatment of BPD in adults.[283] Frazier and co-workers[284] openly treated 23 children with BPD (5 to 14 years of age) with olanzapine for 8 weeks.[284] Of the 23 patients who completed this study, 61% responded (defined as more than 30% reduction in YMRS). These patients also experienced significant reductions in depressive symptomatology. The major side effects of olanzapine were sedation and weight gain (mean = 5 kg), although EPSs were not observed. In some patients the weight gain outweighed clinical benefits and necessitated switching to an alternative treatment, although in some patients the weight gain remained stable. In adults on atypical antipsychotics, hyperglycemia, new-onset diabetes, and diabetic ketoacidosis (50% occurred in those without weight gain) have been observed during treatment.[285,286] Olanzapine is available in injectable, tablet, and Zydis (melts on the tongue) forms. Olanzapine is typically initiated at 2.5 to 5 mg and can be titrated up to 20 mg. Olanzapine is metabolized, by way of glucuronidation (primary) and oxidation via CYP 1A2.[236] Grothe and colleagues[287] studied the pK of olanzapine in adolescents, observing a mean serum half-life of 37.2 ± 5.1 hours; boys and smokers metabolized it more rapidly.

Quetiapine

DelBello and associates[288] published results of an open trial that added quetiapine to VPA in the treatment of 30 adolescents with BPD. In this trial patients were treated openly with VPA (20 mg/kg) and then randomized to adjunct therapy with either placebo or quetiapine (titrated up to 450 mg per day). The group receiving the combination treatment showed significantly greater response rate (reductions in YMRS scores) compared with the VPA and placebo group. The patients receiving VPA and quetiapine experienced greater sedation and weight gain.

The pK of quetiapine has not been formally studied in children and adolescents. Data from adult studies indicate that quetiapine is readily absorbed from the gastrointestinal tract and reaches peak concentrations 1.5 hours after ingestion. It is metabolized primarily in the liver by CYP 3A4 and does not appear to be affected by gender, smoking, or race.[282] Occurrence of EPS appears low, but quetiapine can cause dizziness, sedation, and weight gain.

Ziprasidone

The atypical antipsychotic ziprasidone (Geodon) may also be used in the treatment of pediatric BPD. As of this writing, however, there is limited data regarding its efficacy for BPD in this population. Ziprasidone may increase QTc intervals, and thus before use obtaining a baseline ECG and family history of cardiac problems (especially early-onset arrhythmia) is wise. Although ziprasidone is primarily metabolized through aldehyde oxidase, it is also metabolized in part via CYP 3A4. Co-administration of ziprasidone with medications that may also lengthen the QTc interval (e.g., thioridazine, pimozide, droperidol, class IA and III antiarrhythmics) is not recommended. In children and adolescents, ziprasidone is initiated at 10 to 20 mg per day or twice per day and can be increased upward to 40 to 60 mg twice per day.

Additional treatments in pediatric BPD that are reasonable to consider but have little data to support their use include use of alternative anticonvulsants.

Alternative Anticonvulsants

Gabapentin (Neurontin) is approved as an adjunct therapy for seizures. It is not significantly metabolized in humans and has few medication interactions.[289] Trials with gabapentin for BPD in adults have been negative; however, it has reduced anxiety.

Lamotrigine (Lamictal) is an anticonvulsant that was recently approved in the maintenance treatment of BPD type I in adults. Lamotrigine's labeling contains a boxed warning that serious rashes, including Stevens–Johnson syndrome, occur in approximately 1% of patients younger than 16 years of age. The risk for rash seems to increase if lamotrigine is increased too quickly, the initial dose is greater than recommended, or it is administered with VPA. Mandoki[290] reported on a case series of 10 pediatric patients with BPD treated with VPA (500 to 1500 mg per day) without an adequate response. Lamotrigine (50 to 200 mg per day) was added to VPA, with significant improvement. The role of lamotrigine in treatment of pediatric BPD remains unclear.

Topiramate (Topamax) is an antiepileptic that has shown promise in treatment of BPD in adults.[291] Its only RCT in children with mania or mixed state bipolar I disorder (N=56; ages 6 to 17) was negative.[290] In trials with epilepsy, topiramate was associated with weight loss; however, it also can cause word-finding difficulties, oligohidrosis, and renal stones.[289] Topiramate has a half-life of approximately 24 hours, is excreted unchanged in the urine, and inhibits carbonic anhydrase as well as CYP 2C19.

Investigations into the phenomenology, diagnosis, and pharmacotherapy of pediatric BPD continue. Current guidelines support using pharmacotherapy in the context of an overall multimodal treatment plan.

Developmental Disorders

The term *developmental disorders* includes mental retardation (MR), pervasive developmental disorders (PDDs) (e.g., autism, Asperger syndrome), and specific developmental disorders previously called *learning disabilities* (e.g., nonverbal learning disability).[292] MR diagnosis requires impairment in intellectual function (e.g., IQ below 70) and deficits in at least two adaptive skill areas with onset before age 18. At any given time, approximately 1% to 3% of the population meet the diagnostic criteria for MR.[293,294] PDD symptoms develop before the age of 30 months and involve unusually restricted behaviors with impaired development of social skills (e.g., reciprocal interactions), communication skills (e.g., idiosyncratic language), and sensory–motor skills (e.g., hyporeactivity and hyperreactivity to sensory stimulation).[292] Children who have normal language and cognitive development but impaired social development (e.g., problems with social cues, few friends, oddities), may have Asperger syndrome.[295] Individuals with developmental disorders are at an increased risk of seizure disorders, hearing loss, and other medical co-morbidities.

Mental Retardation

In general, the treatment of specific developmental disorders is largely remedial and supportive. Although psychotropics can temporarily control behavioral and psychiatric complications in some children with developmental disorders, they have not been shown to affect the cardinal symptoms and the basic course of the underlying disorders. For example, in a multicenter double-blind, placebo-controlled trial of children with MR and disruptive behaviors, Aman and associates[296] demonstrated that treatment with risperidone (6 weeks of 0.02 to 0.06 mg/kg per day) led to reduced aggression and irritability. Common side effects included somnolence, headache, and weight gain (mean = 2.2 kg).

If the child with a developmental disorder also meets diagnostic criteria for ADHD or a mood disorder, the guidelines described for the treatment of these disorders are applicable. For example, stimulants appear generally well tolerated and effective in reducing symptoms of hyperactivity and impulsivity in patients with MR.[295,297]

Pervasive Developmental Disorders

Children with PDD often have aggressive, hyperactive, repetitive, and self-injurious behaviors that may respond to pharmacologic treatment. In October 2006 the FDA approved the use of risperidone for the symptomatic treatment of irritability (including aggression, deliberate self-injury, and temper tantrums) in children and adolescents with autism.[298] To date, four RCTs of risperidone in children with PDD have demonstrated moderate and clinically significant benefits in behavioral control, including disruptive and repetitive behaviors, hyperactivity, and self-injury.[299–303] Social and language impairments were only slightly modified by treatment, although results differed among studies. Open trials with a variety of atypical antipsychotics, including olanzapine[304] and ziprasidone,[305] have similarly shown promise in modulating maladaptive behaviors in patients with developmental delay.

A number of alternative pharmacologic agents, in addition to antipsychotics, are being employed for complications or co-morbidities of developmental disorders. Considering the relatively low toxicologic profile of these drugs compared with the antipsychotics, they are the preferred treatment for the management of these children. β-blockers (e.g., propranolol) may improve self-regulation in patients with developmental disorders and thus reduce agitation, aggression, and self-abusive behaviors.[306,307] Propranolol is usually given in divided doses throughout the day. Treatment is typically initiated at 10 mg twice per day and increased as clinically indicated. The dose range is 2 to 8 mg/kg per day. Short-term adverse effects of propranolol are usually not serious and generally abate when the drug is decreased or stopped. Nausea, vomiting, constipation, and mild diarrhea have been reported. Psychiatric side effects appear to be relatively infrequent but can occur; symptoms include vivid dreams, depression, and hallucinations. Propranolol's capacity to induce β-adrenergic blockade can cause bradycardia, hypotension, and an increase in airway resistance. Thus it is contraindicated in patients with asthma and certain cardiac conditions. Because abrupt cessation of this drug may be associated with rebound hypertension, a gradual taper is recommended. In a similar manner, clonidine, lofexidine and buspirone have been used to diminish aggression in patients with developmental disorders.[308–311]

For children with prominent obsessive behavior, rigidity, or compulsive rituals, recent studies indicate that the SSRIs may be helpful. In many cases, the full antidepressant dosage (discussed later) is necessary; however, children should be started with the lowest possible dose to prevent adverse effects such as disinhibition or agitation. Controlled trials in adults treated with fluoxetine[312] and fluvoxamine[313] have shown positive results. However, studies in children have been less robust. The long-acting benzodiazepines may also be useful as single or adjunctive agents in children with prominent anxiety symptoms, although a major adverse effect, disinhibition, may result in restlessness and more disturbed behavior.

Antidepressants and mood-stabilizers may be effective in controlling affective disorders, and stimulants may improve symptoms of ADHD when these disorders co-exist.

In response to an initial positive report, great interest and study has focused on secretin.[314,315] However, of the 10 controlled studies that have been conducted, 8 demonstrated no benefit of secretin over placebo, regardless of the form of secretin (biological versus synthetic),[316] following single-dose[317] or ongoing administration of secretin.[318] Despite mostly negative data for secretin, many parents elected to continue its use. At this time the role of secretin appears limited at best.

PSYCHOTIC DISORDERS

The term *psychosis* is generally used to describe the abnormal behaviors of children with grossly impaired reality testing.[319] The diagnosis of psychosis requires the presence of either delusions (false implausible beliefs) or hallucinations (false perceptions that may be visual, auditory, or tactile). Often, psychosis in children is seen with MDD, BPD, or severe dissociative states, such as PTSD. Psychotic disorders in children, as in adults, can be functional or organic. Functional psychotic syndromes include schizophrenia and related disorders and the psychotic forms of mood disorders. Organic psychosis can develop secondary to CNS lesions as a consequence of medical illness, trauma, or drug use. Children may manifest psychosis for a substantial amount of time without indicating its presence to parents or caregivers. Therefore all children with major mood disorders or those who have manifested abnormal or bizarre behaviors should be queried for the presence of psychosis.

Currently, the atypical antipsychotics (e.g., risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole), are first-line agents in the pharmacotherapy of psychosis in children and adolescents. In 2007 the FDA approved risperidone for treatment of schizophrenia in children 10 to 17 years of age.

Typically, atypical antipsychotics are initiated at a low dose and gradually titrated up to achieve efficacy. Risperidone is started at 0.25 mg twice a day and can be increased every day or two with close observation.[320] In patients treated over the long term with risperidone, clinicians should monitor weight, vital signs, and laboratory results (e.g., triglyceride, cholesterol, prolactin).[321,322] Olanzapine and quetiapine are generally more sedating and

are initiated at 2.5 to 5 mg per day and 25 to 50 mg per day, respectively.[323] Olanzapine has recently been investigated in two open studies in pediatric patients with schizophrenia.[324,325] Significant improvements were observed in children and adolescents; however, these patients experienced significant weight gain and sedation.

If trials with two or three atypical antipsychotics are ineffective, a trial with a typical agent (e.g., chlorpromazine, haloperidol) should be considered. The usual oral dosage of antipsychotics ranges between 3 and 6 mg/kg per day for the low-potency phenothiazines (e.g., chlorpromazine) and between 0.1 and 0.5 (up to 1) mg/kg per day for the high-potency antipsychotics (e.g., haloperidol). Antipsychotic medications have a relatively long half-life and therefore should not be administered more than twice daily.

Common short-term adverse effects of antipsychotics are drowsiness, increased appetite, and weight gain. Anticholinergic effects (e.g., dry mouth, nasal congestion, blurred vision) are more commonly seen with the low-potency phenothiazines. Short-term adverse effects of antipsychotics are generally managed with adjustments of the dose and the timing of administration. Excessive sedation can be avoided by using less sedating agents and prescribing most of the daily dose at nighttime. Drowsiness should not be confused with impaired cognition; it can usually be corrected by adjusting the dose and the timing of administration. In fact, there is no evidence that antipsychotics adversely affect cognition when used in low doses. Anticholinergic adverse effects can be minimized by choosing a medium- or high-potency compound.

Acute dystonia, akathisia (motor restlessness), parkinsonism (bradykinesia, tremor, and lack of facial expressions), and other EPSs are more commonly seen with the high-potency compounds (butyrophenones and thioxanthenes) and have been reported to occur in up to 75% of children receiving these agents. The extent to which antiparkinsonian agents (e.g., anticholinergic drugs, benztropine, trihexyphenidyl, antihistamines, the antiviral agent amantidine) should be used prophylactically when antipsychotics are introduced is controversial. Whenever possible, antiparkinsonian agents should be used only when EPS emerge. Akathisia may be particularly problematic in young patients because it is often underrecognized. When a child or adolescent starts on an antipsychotic and becomes acutely agitated with an associated inability to sit still and with aggressive outbursts, the possibility of akathisia should be considered. If this condition is suspected, it may be necessary to lower the dose of the antipsychotic. The centrally acting β-adrenergic antagonist propranolol often is very helpful in treating this adverse effect.

A benign withdrawal dyskinesia and a syndrome of deteriorating behavior have been associated with the abrupt cessation of these drugs. As in adults, the long-term administration of antipsychotic drugs may be associated with TD. Although children appear generally less vulnerable than adults to developing TD, there is an emerging consensus that this potentially worrisome adverse effect may affect children and adolescents in 10% to 15% of cases. Prevention (appropriate use for a clear indication, clear target symptoms, periodic drug discontinuation to assess the need for drug use) and early detection (with regular monitoring) are the only effective treatments for TD.

Little is known about the potentially lethal neuroleptic malignant syndrome in juveniles; however, preliminary evidence indicates that its presentation is similar to that in adults. This syndrome may be difficult to distinguish from primary CNS pathology; concurrent infection; or other, more benign side effects of antipsychotics that include EPS or anticholinergic toxicity. Treatment appears similar to those strategies used in adults.

In patients who do not respond to trials with either first-line atypical or typical antipsychotics or who experience significant dyskinesia from these medications, consideration should be given to a trial with clozapine (Clozaril).[326,327] In the United States and Europe, there has been considerable experience with clozapine in adolescents. Established dose parameters are not yet available; however, in one open study of clozapine for schizophrenic youths, doses from 125 to 825 mg per day (mean = 375 mg per day) for up to 6 weeks were necessary for effectiveness. Although remarkably effective in chronic treatment-resistant schizophrenia and affective psychosis, there is a dose-related risk of seizures and an increased risk of leukopenia and agranulocytosis in adolescents that is similar to the risk in adults; it requires close monitoring.

COMBINED AGENTS

Increasingly, multiple agents have been used in both clinical practice and research settings for the treatment of child and adolescent psychiatric disorders. This need has arisen out of an emerging awareness of the high rates of co-morbidity described in clinical and epidemiologic studies of juvenile psychiatric disorders. Previously, the law of parsimony dictated a single cause for each symptom complex; this led to the use of large doses of individual agents for a given disorder, often resulting in intolerable adverse effects. In contrast, the use of combined pharmacotherapy has permitted more targeted treatment and greater efficacy, often achieved with lower doses and fewer adverse effects.

Fluoxetine and MPH, for instance, have been described as useful in the management of children with depression and ADHD.[328] In addition, controlled investigations of single agents have produced inconclusive findings in many disorders. Enhanced response rates have been reported when traditional agents are combined. For example, improved anti-ADHD efficacy has been shown with the combination of stimulants and TCAs. Interest is growing in trials combining ATMX and stimulant pharmacotherapy for ADHD.

On the other hand, growing use of combined pharmacotherapy in children has drawn intense attention from the media and regulatory agencies.[329,330] On balance, rational use of combined psychotropics may produce significant benefits in the hands of experienced clinicians. It has become imperative for future research to provide clinicians with the evidence base for combined-agent pharmacotherapy.

36 Behavioral Medicine

Brian A. Palmer, M.D., M.P.H.
Lisa Scharff, Ph.D.
Bruce J. Masek, Ph.D.

The field of behavioral medicine, now 30 years old, began when applied behavior analysis, behavior therapy, and psychophysiology emerged as clinical sciences. The field's inception drew inspiration from other sources, notably a vision of the limitations of the biomedical model, the value associated with the recognition that behavioral factors broaden our understanding of health and illness,[1] and dissatisfaction with the long-standing dominance of the psychoanalytic approach in psychosomatic medicine.[2]

Behavioral medicine was initially viewed in broad terms as an interdisciplinary field concerned with the development of knowledge in the behavioral sciences and techniques relevant to prevention, diagnosis, treatment, and rehabilitation of physical illness.[3] It grew rapidly in the 1980s. By the end of that decade, curricula in behavioral medicine were found in most medical schools and graduate programs in clinical psychology, and clinical units and research programs in behavioral medicine were operational in most major universities and medical centers. Even a few academic departments changed their names to incorporate *behavioral medicine* into their titles.[4] Thus, the stage was set in the 1990s for the pursuit of a scientific agenda that was ambitious and broad in scope to identify behavioral factors that influence the development and course of organic disease, to develop psychosocial interventions that reduce the effect of these behavioral factors, and to demonstrate that such psychosocial interventions improve clinical outcomes in organic disease through direct effects on the underlying pathology.[5]

Just how good is the clinical evidence from the past quarter century with respect to these propositions? Many believe that the evidence supports the notion that behavioral factors are involved in the development and course of most major diseases, and that psychosocial interventions effectively reduce the risk of illness, decrease morbidity and mortality, and improve health-related quality of life.[6–10] However, a minority views the same evidence as the product of seriously, if not fatally, flawed studies.[11–13] Both sides seem to agree that the mind can influence the body to the betterment or the detriment of one's health and that some of the evidence is worthy of further scrutiny in large-scale prospective, rigorously controlled clinical trials with hard biological end points.[14]

Currently, behavioral medicine still draws heavily on the theory and practice of applied behavioral analysis, behavioral therapy, and psychophysiology for interventions to modify the risk, course, and effect of organic disease. Stress, negative emotions, lifestyle, and quality of life among other factors are frequent targets for interventions. Clinical topics under the umbrella of behavioral medicine have expanded over the last 2 decades,[9] reflecting advances in biomedical science (e.g., organ transplantation), changing public health priorities (e.g., HIV/AIDS treatment and prevention), and innovative applications of existing technologies (e.g., aging). For those readers interested in a comprehensive review of the evolution of the field, a special issue of the *Journal of Consulting and Clinical Psychology*[15] is an excellent source.

The goals of this chapter are more modest. We present an overview of clinically important psychosocial factors that mediate both health and illness and discuss the most frequently employed interventions used in behavioral medicine to modify their impact. We conclude with an examination of behavioral medicine's role in the management of two very common clinical problems, irritable bowel syndrome and recurrent abdominal pain, to provide perspective on the practice of behavioral medicine in a hospital setting.

PSYCHOSOCIAL FACTORS AFFECTING HEALTH AND ILLNESS

Stress

Stress has been implicated directly or indirectly in the development and clinical course of a host of physical ailments, from the common cold[16] to coronary heart disease (CHD).[17] Stress is thought to play an important role in the development and maintenance of risk factors for organic disease, such as smoking, obesity, and physical inactivity.[18] The view that stress is ubiquitous and that it has harmful effects on the body's organ systems and defenses has infiltrated the public's consciousness. This view has been succinctly summed up as "a mania for pop psychosomatics, which writes off to stress everything from athlete's foot to cancer" (p. 739).[19]

From a clinical perspective the pathologic effects of stress are of concern. In susceptible individuals, chronic and persistent exposure to stressors, be they real (physical) or perceived (psychological), lead to a dampening of homeostatic mechanisms that restore internal stability and defend against disease.[20] As homeostatic mechanisms become less effective or break down completely under

the pressure of chronic stress, susceptible individuals are subject to exacerbations of existing illnesses or are predisposed to new diseases. The outcome of pathological stress depends on a variety of factors (including the type of stressor, the length of exposure, one's genetic predisposition, preexisting coping strategies, and the presence of social and environmental supports).[21] Behavioral medicine's answer to stress is a collection of techniques known as stress management. These techniques teach patients to lower levels of stress arousal, particularly in stressful social environments, and to enhance the relaxation response.

Negative Emotions

Interest in how emotional states affect health and illness is probably as old as medicine itself. Negative emotional states may be precursors to organic disease as suggested by recent studies of CHD[15] and essential hypertension.[22] Moreover, morbidity and a decreased quality of life are often seen in association with chronic pain disorders[23] and with cancer.[24]

Negative emotions (such as anger, sadness, and pessimism) are part of the human condition and are not necessarily harmful to health. The damaging effects are thought to occur when these emotions are expressed in their chronic forms: hostility, depression, and helplessness, respectively. Interventions used in behavioral medicine for negative emotional states have focused on the development of cognitive coping skills to replace the maladaptive thoughts, feelings, and behaviors that are the basis of negative emotional states.

The Relaxation Response

One strategy to counter the physiologic effects of stress is to employ the relaxation response. The relaxation response is induced by various forms of meditation, yoga, tai chi, breathing exercises, and guided imagery, to name a few,[25] and is associated with a number of physiologic changes (from decreased pulse and respiratory rate, to specific gene expression changes in short- and long-term practitioners).[26] Functional magnetic resonance imaging (fMRI) studies indicate that the practice of meditation induces the relaxation response and activates neural structures involved in attention and the control of the autonomic nervous system.[27] Instruction in the relaxation response combined with cognitive restructuring, exercise, and enhanced nutrition has been shown to reduce both physical and psychological symptoms in somatizing patients.[28]

Mindfulness meditation reduces anxiety and increases positive affect.[29–31] During an 8-week training program, mindfulness meditation was associated with an increase in antibody titers to flu vaccine and an increase in left frontal activation on electroencephalogram (EEG) as compared with wait-listed controls.[32]

RISK FACTORS

Nonadherence with Medical Therapy

Nonadherence with medical therapy occurs throughout the life span, and there is little doubt that low rates of adherence to established medical therapies contribute to increased morbidity, increased health care costs, and adverse consequences for public health.[33,34] A meta-analysis of 63 studies examining adherence and treatment outcome suggests that adherence is most strongly related to outcome in nonmedication regimens for treating chronic disease.[35] Many theories explain why some patients are nonadherent with diagnostic maneuvers and treatment. Belief in the efficacy of treatment, complexity of medical regimens, passive self-care decision-making, and problems with doctor–patient communication are some of the reasons put forth to explain why some patients fail to follow through with prescribed medical therapy.[36] Behavioral medicine interventions are based on the premise that nonadherence is a behavioral problem that is particularly suited to applied behavioral analysis methods that aim to modify overt behavior. The patient's beliefs about health and illness and the doctor–patient relationship are not considered relevant targets for intervention. The behavioral procedures of reinforcement and stimulus control have proven to be effective for the improvement of adherence from simple to complex medical regimens.[37] For example, in a study of refractory hypertension, one third of the sample achieved normalization of blood pressure simply through electronic monitoring.[38]

BEHAVIORAL MEDICINE INTERVENTIONS

Stress Management

The goal of stress management is to teach patients skills that relieve them from the harmful effects of stress. First, patients must learn to identify thought patterns and social situations that produce stress. Second, patients are taught relaxation techniques that cultivate low states of arousal. A host of relaxation techniques exist; none has been proven to be more therapeutic than any other for stress reduction. Some of the most commonly taught techniques are progressive muscle relaxation, deep breathing, imagery, and meditation. To become skilled in relaxation, patients must practice these techniques daily for 3 to 4 weeks. It is most helpful to provide patients with a CD version of the relaxation instructions that facilitates adherence with practice at home. Children as young as 7 years old can learn relaxation techniques.[39] The final step to prevention involves guiding patients in the use of relaxation techniques in their natural environment, replete with stressful stimuli.

Biofeedback is sometimes used to help patients learn about relaxation techniques. Immediate feedback about muscle tension, heart rate, surface skin temperature, and respiration can facilitate the learning process, particularly for patients who present with high levels of arousal, who harbor skepticism about the approach, or who doubt their ability to learn relaxation.

Cognitive Coping

Cognitive coping involves teaching a patient to identify negative thoughts and behaviors that increase their stress burden and the situations where stress occurs. Cognitive distortions (e.g., all-or-none thinking, overgeneralization, discounting the positives, jumping to conclusions, "should" statements, and personalization) are identified for and with the patient, and (negative) automatic thoughts and

core beliefs ("I am incompetent") are evaluated in light of evidence that supports and refutes them. Then, positive coping strategies (e.g., positive reappraisal, diverting attention, problem-solving, coping self-statements, disengagement, and relaxation techniques) are taught to replace negative patterns. Rehearsal of coping strategies during therapy sessions is critical for the successful application in the natural environment. Patients are encouraged to start using coping strategies at the first opportunity. Self-monitoring tools (such as diaries and checklists) are used first to assess maladaptive coping and then to monitor progress and to refine coping strategies as needed.

Behavioral Procedures

One of the most effective techniques to improve adherence is to provide feedback to patients on their adherence early in the course of therapy when they are most at risk for developing patterns of nonadherence. Objective measures of adherence (e.g., serum drug levels, urine metabolites, or physiological markers [e.g., blood glucose level or measures of pulmonary function]), when feasible, are the feedback methods of choice in this regard.[40] Positive and negative reinforcement are often employed to promote adherence with treatment regimens that extend over long periods. Positive reinforcement is the process by which rewards (e.g., parking vouchers, gift certificates, and negotiated privileges) are provided to the patient contingent on observed or objectively measured adherence at specified intervals. Negative reinforcement is the converse process by which patients lose the opportunity to earn money or privileges if they are nonadherent; they must remain adherent to avoid this possibility. Stimulus–control techniques include teaching patients to self-monitor adherence behaviors, to structure their medical therapy to have it occur while performing daily routines, and to enlist the social environment to generate external cues for adherence (e.g., a telephone call, e-mail, or postcard reminder).

Motivational Interviewing

Motivational interviewing is an empirically-supported intervention to improve outcome by strengthening patient commitment for behavior change.[41] The approach combines patient-directed and patient-centered methods to selectively reinforce the patient's self-motivational statements to take action.[42,43]

CLINICAL APPLICATIONS

Irritable Bowel Syndrome and Recurrent Abdominal Pain

A strong, documented relationship exists between stress and abdominal pain. Most people are familiar with the sensation of "butterflies" in the stomach when facing stress, and when bad news is delivered it can be referred to as "a kick in the stomach." Individuals with irritable bowel syndrome (IBS) or its childhood counterpart, recurrent abdominal pain, almost unanimously endorse stress as a trigger of their symptoms. Abundant and growing research evidence reveals that IBS and recurrent abdominal pain may be related to autonomic nervous system function and to an increased sensitivity to physiologic changes in the gut that are also highly responsive to stress.

Behavioral medicine treatments have been highly effective for IBS and recurrent abdominal pain[44,45]; they usually involve relaxation training to activate the parasympathetic nervous system and cognitive techniques to decrease the effects of stress on the body. Education is crucial to the process, because a patient needs to understand the rationale for treatment to be invested in it. Biofeedback training can also be a useful strategy; patients can receive immediate feedback and learn that they can have a significant amount of control over their own bodies. Finally, self-hypnosis has also been used successfully as a pain management strategy that can be integrated into a pain management program.

EDUCATION

Patients with IBS or recurrent abdominal pain frequently report that they have gotten the message from health care providers that their pain is "in their head." Often the explanation for pain provided by a family physician or gastroenterologist is designed to comfort a patient and to emphasize that no organic cause for the pain can be found; therefore, there is no disease process to worry about. What the patient often hears instead is a dismissal of the pain as not being real or as a statement that the doctor cannot be of help with their suffering. One of the significant contributions that behavioral medicine has made in the treatment of stress-related disorders is to focus on the importance of communicating with patients. Simply validating the pain, providing education about the physical effect of stress, and explaining that there are skills that can be learned to manage stress and pain can be extremely beneficial. A shift in perception from being a victim to having options (i.e., to take more control) can be an important first step in the management of chronic pain.

Of course, patients must believe in the efficacy of treatment and in their ability to do what it takes to be successful in the treatment (self-efficacy); one must be motivated to participate. Moreover, the extent to which individuals believe that what they do influences their health (internal locus of control) versus the extent to which they believe health care professionals or others influence their health (external locus of control) varies greatly. For a behavioral medicine intervention to work well, the individual needs to be invested in the work and involved in the treatment program.

RELAXATION TRAINING

Stress triggers of IBS or recurrent abdominal pain initiate activity in the sympathetic nervous system and affect multiple physiologic activities (including digestion, breathing, and heart rate). The cultivation of a state of low arousal by activating the parasympathetic nervous system is antithetical to this aroused state: one simply cannot be stressed and relaxed at the same time. Relaxation training is designed to teach parasympathetic arousal during times of stress, so symptoms of pain and resultant bowel function can be reduced or even eliminated. As reviewed earlier in this chapter, many types of relaxation training are available.

COGNITIVE COPING SKILLS

Cognitive treatments for IBS and recurrent abdominal pain tend to focus on the identification of stressful situations that may lead to symptoms, on examination of the thoughts or "internal dialogue" that takes place in these situations, and appreciation of how to change the stressful situation itself, the reaction to the situation, or both. Usually the focus is specifically aimed at stressful situations that can lead to episodes of pain. The symptoms themselves or worries about them can also be significant stressors. Individuals with diarrhea-predominant IBS, for example, often state that concerns about being far from a bathroom and worries about being able to access a bathroom when needed can trigger an episode of pain and diarrhea.

BIOFEEDBACK

Biofeedback can aid relaxation training and allow patients to gain insight into their own ability to control different aspects of their bodies. Many individuals who suffer from pain can become distanced from their bodies and lack insight as to what relaxation feels like. They can be taught, however, what relaxation looks like on a monitor, and learn through this method what they need to do in order to achieve that state.

Several types of biofeedback have been used with IBS patients. Thermal biofeedback is often used because it assesses a generalized relaxation response. A thermal sensor is applied to the finger, and relaxation techniques are employed to relax the muscles and activate the parasympathetic nervous system, thereby allowing an increase in blood flow to the hand with a resultant increase in temperature. Electromyographic biofeedback can also be used to teach relaxation of specific muscle groups. Another type of biofeedback that has been used specifically with IBS patients is bowel sound feedback, during which a stethoscope is used to teach patients to change their bowel sounds. No studies have investigated the efficacy of thermal or electromyographic biofeedback alone for IBS or recurrent abdominal pain, and most treatments incorporate elements of other behavioral medicine strategies. Evidence in support of bowel sound feedback as a treatment for IBS has been mixed.

Hypnosis

Hypnosis can be a very powerful and useful technique when put to use by a trained and experienced clinician. Because the use of hypnotic trance and suggestion tends to focus on changing perceptions and directed attention, it is particularly useful when working with patients who have chronic or episodic pain (Table 36–1).

After the induction is taught, specific images and suggestions can be used to induce a state of relaxation. Often "ego-strengthening" suggestions are used to help deepen the trance and allow the patient to focus. Several different types of images and metaphors can then be used to help the patient gain control of his or her symptoms. Images of flowing water in streams or waterfalls can be used as a metaphor for the gastrointestinal tract that is working smoothly, or suggestions of having possession of a switchboard that can be used to manipulate different parts of the body are often used to allow the patient to gain a sense of control over symptoms. As in relaxation training, an audiotape or CD can be made for the patient to practice at home.

TABLE 36–1 Review of Current Evidence from Controlled and Partially Controlled Trials for Medical Applications of Hypnosis[46]

Evidence of Efficacy (Supported by Multiple Randomized Clinical Trials)
Control of cancer pain
Control of labor and childbirth pain
Control of medical procedure–related pain and distress
Reduction of symptoms of irritable bowel syndrome
Improved postoperative outcome in wound healing, anxiety, and vomiting
Obesity (although effects are small)
Possible Evidence of Efficacy (Supported by Poorly Controlled Trials or Mixed Results)
Control of burn pain
Control of pain in terminally ill cancer patients
Reduction of symptoms of asthma
Smoking cessation
Reduction of symptoms of nonulcer dyspepsia
Reduction of symptoms of posttraumatic stress disorder
Reduction of symptoms of tinnitus
Reduction of symptoms of conversion disorder
No Evidence of Efficacy (Negative Controlled Trials)
Schizophrenia
Hay fever
Delayed-type hypersensitivity response

Complementary Medicine and Natural Medications

37

Felicia A. Smith, M.D.
David Mischoulon, M.D., Ph.D.

Complementary and alternative medical (CAM) therapies constitute a diverse spectrum of practices and beliefs in current medical practice. The National Institutes of Health defines CAM as "healthcare practices outside the realm of conventional medicine, which are yet to be validated using scientific methods."[1] The term *natural medications* refers to medications derived from natural products that are not approved by the U.S. Food and Drug Administration (FDA) for their proposed indication.[2] Natural medications fall under the category of CAM and may include hormones, vitamins, plants, herbs, fatty acids, amino acid derivatives, and homeopathic preparations, among others. Although natural medications have been used for thousands of years, their use in the United States has increased dramatically over the past 10 to 15 years. In fact, a recent study found that in an American ambulatory adult population, 40% of patients routinely used one or more vitamin or mineral supplements.[3] Moreover, between 1990 and 1997, the prevalence of herbal remedy use increased by 380%, and high-dose vitamin use increased by 130%.[4] The consultation psychiatrist must therefore be informed about these medications to provide comprehensive patient care. This chapter provides an overview of the use of natural medications in psychiatry. Issues pertaining to general safety and effectiveness are discussed first, followed by a more specific look at some of the remedies used for mood disorders, anxiety and sleep disorders, menstrual disorders, and dementia. The final section is devoted to a description of two nonmedication alternative therapies: acupuncture and hypnosis.

EFFICACY AND SAFETY

Although there has been a recent increase in both government and industry sponsorship of clinical research involving natural medications, data regarding efficacy still lag behind. The true benefits of natural remedies are often unclear, and few systematic studies have addressed the question of effectiveness.[5] Because the FDA does not routinely regulate natural medications, issues of safety remain unresolved. One concern flows from the belief that if a remedy is "natural," it is therefore safe. Reports of toxicity may not reach the populations using the remedies, because they are often purchased over the counter. Moreover, data are limited regarding the safety and efficacy of combining natural medications, and about their use with more conventional medications.[5] This situation is very important to the consultation psychiatrist because of the prevalence of polypharmacy often seen in inpatient medical settings. It is also noteworthy that patients frequently do not disclose their use of CAM therapies to their physicians. In one study, fewer than 40% of CAM therapies used were disclosed to a physician,[4] thereby making it essential to ask patients specific questions about their use of prescribed and over-the-counter medications. Finally, significant variability exists between different preparations of natural medications. Preparations often vary in purity, quality, and potency, and efficacy and side effects may vary accordingly. As mentioned earlier, government- and industry-sponsored studies are increasingly being undertaken to further elucidate the potential uses, safety, and efficacy of these medications. The remainder of this chapter outlines what is currently known in this regard for a few such natural medications.

MOOD DISORDERS

Omega-3 fatty acids, St. John's wort (SJW), *S*-adenosylmethionine (SAMe), folic acid, vitamin B_{12}, and inositol have all been used for mood disorders. Here we describe the efficacy, possible mechanisms of action, dosing, adverse effects, and drug interactions of each of these medications. Because of the nature of consultation psychiatry, a particular emphasis is placed on the interface between their psychiatric and other medical uses, as well as on drug interactions.

Omega-3 fatty acids are polyunsaturated lipids derived from fish oil that have been shown to have benefits in a variety of health domains including rheumatoid arthritis, Crohn's disease, ulcerative colitis, psoriasis, and systemic lupus erythematosus.[6] Cardioprotective effects have been demonstrated, as have several neuropsychiatric benefits. Eicosapentaenoic acid and docosahexaenoic acid are thought to be psychotropically active omega-3 fatty acids.[2] Lower rates of depression and bipolar disorder have been detected in countries where more fish is consumed, suggesting that omega-3 fatty acids may play a protective role in these disorders.[7] Omega-3 fatty acids also may have a role in the treatment of both bipolar disorder and unipolar depression. Close to 20, mostly positive, studies on patients with unipolar depression have been reported.[8] Though efficacy studies of bipolar illness have been more mixed,[9–12] most of the benefit in bipolar illness may be related to alleviating or preventing depression rather than mania.[13] In fact, there have been reports of cycling in bipolar patients who take omega-3 preparations without concomitant mood stabilizers,[14] so caution is warranted when treating bipolar patients. Mixed results have also been shown in the areas of postpartum depression[15–17] and schizophrenia.[18–21]

Although their mechanism of action is not completely clear, omega-3 fatty acids may function the way mood stabilizers do, by inhibiting G-protein signal transduction via reduced hydrolysis of phosphatidylinositol and other membrane phospholipids.[22] Other proposed mechanisms include neuronal membrane stabilization and antiinflammatory effects.[22] Commercially available preparations of omega-3 fatty acids vary in composition, and the optimal ratio of eicosapentaenoic acid to docosahexaenoic acid has yet to be determined. Psychotropically active dosages are generally thought to be in the range of 1 to 2 g/day, with the major side effect being dosage-related gastrointestinal (GI) distress.[8] There is a theoretical risk of increased bleeding, so concomitant use of high-dose nonsteroidal antiinflammatory drugs or anticoagulants is not recommended.[8] In sum, the use of omega-3 fatty acids is promising, particularly given the range of potential benefits and the relatively low toxicity seen thus far. However, larger studies are still needed.

St. John's wort (*Hypericum perforatum* L.) has been shown to be more effective than placebo in the treatment of mild to moderate depression.[14,23] Studies have suggested that SJW is as effective as low-dose tricyclic antidepressants (TCAs) (e.g., imipramine 75 mg, maprotiline 75 mg, or amitriptyline 75 mg).[2,14,23] Data comparing SJW and selective serotonin reuptake inhibitors (SSRIs) are more mixed, although in at least two cases SJW was shown to be as effective as sertraline and fluoxetine in the treatment of mild to moderate depression.[24,25] SJW has not shown a significant advantage over placebo in other studies[26–28]; however, some believe that a more severely depressed study population may have contributed to at least some of these outcomes.[2,5,14] Although hypericin is thought to be the main antidepressant ingredient in SJW, polycyclic phenols, pseudohypericin, and hyperforin are also thought to be active ingredients. Possible mechanisms of action include the inhibition of cytokines, a decrease in serotonin receptor density, a decrease in reuptake of neurotransmitters, and monoamine oxidase inhibitor (MAOI) activity.[2,5] Of note is that SJW should not be combined with SSRIs because of its MAOI activity and the possible development of serotonin syndrome, but no special diet is required for the patient on SJW.[14] The metabolism of SJW is not well understood, but it is thought to be hepatic. Suggested dosages range from 900 to 1800 mg three times per day depending on the preparation, and adverse effects include dry mouth, dizziness, constipation, and phototoxicity. A switch to mania in patients with bipolar disorder may also occur.[14,29] Finally, a number of drug–drug interactions with SJW are particularly noteworthy for the consultation psychiatrist. Because hyperforin induces cytochrome P450 (CYP) 3A4 expression, therapeutic activity of the following medications may be reduced: warfarin, cyclosporine, oral contraceptives, theophylline, digoxin, and indinavir.[2,5,14] Transplant rejections have been reported as a result of interactions between SJW and cyclosporine[14]; therefore, transplant recipients should not use SJW. Individuals with human immunodeficiency virus infection and on protease inhibitors should also avoid SJW because of drug interactions. In conclusion, SJW appears to be better than placebo and equivalent to low-dose TCAs for the treatment of mild depression. It may also perform comparably to SSRIs, but more data are needed. It may not be as effective for more severe forms of depression. Care should be taken because of the drug–drug interactions mentioned earlier.

In dosages of up to 1600 mg/day, SAMe has been shown to elevate mood in depressed patients. Meta-analyses and comprehensive reviews support antidepressant efficacy of SAMe when compared with placebo and TCAs.[30–32] However, many studies have used IM and IV preparations, as well as oral SAMe; early oral preparations of SAMe were unstable and rapid decomposition may have resulted in less robust efficacy findings.[31] Current oral preparations, although tosylated for improved shelf life, may nonetheless require high dosages for adequate bioavailability—in some instances, as much as 2000 to 3000 mg/day; the medication is relatively expensive, and the out-of-pocket cost may be prohibitive to some.[14,31,32]

S-adenosyl-methionine is the principal methyl donor in the one-carbon cycle, and SAMe levels depend on availability of the vitamins folate and B_{12}. SAMe donates methyl groups to hormones, neurotransmitters, nucleic acids, proteins, and phospholipids. Thus, SAMe has been proposed to work as an antidepressant by providing methyl groups in the reactions that result in the synthesis of acetylcholine, serotonin, and dopamine.[33] Potential adverse effects are relatively minor and include anxiety, agitation, a switch to mania, insomnia, dry mouth, bowel changes, and anorexia.[31–33] Sweating, dizziness, palpitations, and headaches have also been reported.[31–33] At least one case has been reported of suspected serotonin syndrome when SAMe was combined with clomipramine in an elderly woman.[34] No significant drug–drug interactions have been reported, and there is no apparent hepatotoxicity.[31–33] SAMe, therefore, is a natural medication that shows promise as an antidepressant. It appears to be relatively safe and is without significant interactions thus far, making it a particularly good candidate for augmentation therapy. One open study thus far has demonstrated benefit from open SAMe augmentation in SSRI partial responders.[35] Further study will help clarify issues of efficacy and safety.

Folate and B_{12}, vitamins obtained in the diet, play important roles in the synthesis of central nervous system (CNS) neurotransmitters (e.g., serotonin, dopamine, and norepinephrine). Sequelae of folate and vitamin B_{12} deficiencies include a variety of neuropsychiatric and general medical conditions (e.g., macrocytic anemia, neuropathy, cognitive dysfunction or dementia, and depression). Folate deficiency may result from inadequate dietary intake, malabsorption, inborn errors of metabolism, or an increased demand (e.g., as seen with pregnancy, infancy, bacterial overgrowth, and rapid cellular turnover).[33,36]

Certain drugs may also cause folate deficiency. These include anticonvulsants, oral contraceptives, sulfasalazine, methotrexate, triamterene, trimethoprim, pyrimethamine, and alcohol.[37] Vitamin B_{12} deficiency states may also result from inadequate dietary intake, malabsorption, impaired utilization, and interactions with other drugs. Included in such drugs are colchicine, H_2 blockers, metformin, nicotine, oral contraceptive pills, cholestyramine, K-Dur, and zidovudine.[37] Folate deficiency may also hinder antidepressant

response,[38] and folate supplementation may be a beneficial adjunct to SSRI-refractory depression.[39] Vitamin B_{12} deficiency, in turn, may cause an earlier age of onset of depression.[2] The recommended daily dosage of vitamin B_{12} is 6 µg, and that of folate is 400 µg. Because both vitamins are involved in the synthesis of CNS neurotransmitters, adequate levels provide optimal neurotransmitter synthesis that may aid in reversing depression. Finally, folate may mask vitamin B_{12} deficiency by correcting macrocytic anemia while neuropathy continues, so vitamin B_{12} levels should be routinely measured when high dosages of folate are given. Folate may also reduce the efficacy of phenytoin, methotrexate, and phenobarbital.[40] In summary, correction of folate and B_{12} deficiencies may improve depression or augment other antidepressant therapy. The recent FDA approval of 5-methyltetrahydrofolate (5-MTHF; Deplin) may present a desirable treatment option for depressed patients; 5-MTHF is thought to penetrate the blood–brain barrier more readily than other folate forms, and it may, in theory, deliver more of the active product to its site of action.[36] Psychiatrists should be mindful of potential deficiency states (as outlined here) and should check serum levels in patients at risk for deficiencies (such as elderly patients, the medically ill, or those who have not responded to antidepressant treatment).

Inositol, a natural isomer of glucose, is present in common foods. It has been found in small studies to be effective in the treatment of depression, panic disorder, obsessive–compulsive disorder, bulimia, binge-eating disorder, and possibly bipolar depression.[41–45] Effective dosages range from 12 to 18 g/day. Negative monotherapy trials with inositol have been run with patients with schizophrenia, dementia, attention deficit hyperactivity disorder, premenstrual dysphoric disorder, autism, and electroconvulsive therapy–induced cognitive impairment.[5,46] Augmentation studies of inositol with SSRIs in patients with depression and obsessive–compulsive disorder have been mostly negative.[47–49] One crossover comparison of inositol against fluvoxamine for panic disorder suggested similar efficacy for both agents.[43] Inositol is a polyol precursor in brain second-messenger systems that may reverse desensitization of serotonin receptors.[2,5] Mild adverse effects include GI upset, headache, dizziness, sedation, and insomnia. There is no apparent toxicity or known drug interactions at this time.[2,5] Treatment with inositol for the indications mentioned here currently appears safe and remains promising.

ANXIOLYTICS AND HYPNOTICS

Three natural agents are often used for their anxiolytic and hypnotic properties: valerian, melatonin, and kava. Valerian *(Valeriana officinalis)* is a sedating plant extract that has been used for over 2000 years. It is thought to promote natural sleep after several weeks of use by decreasing sleep latency and by improving overall sleep quality. The effects on slow-wave sleep increase with time. Valerian is thought to work by decreasing gamma-aminobutyric acid (GABA) breakdown.[2,5] Sedative effects are dosage related, with usual dosages in the range of 450 to 600 mg about 2 hours before bedtime. Dependence has not been an issue, nor has daytime drowsiness. Adverse effects, thought to be uncommon, include blurry vision, GI symptoms, headache, and dystonia. Because of potential hepatotoxicity, valerian should be avoided in patients with liver dysfunction. Major drug interactions have not been reported. Although valerian has been used as a hypnotic for many years (in pediatric and elderly populations as well as adults) with relatively few reported adverse effects, more trials are needed to further quantify efficacy and safety.

Melatonin is a hormone made in the pineal gland that has gained popularity for its use by travelers to avoid jet lag. It is derived from serotonin and is thought to play a role in the organization of circadian rhythms via interaction with the suprachiasmatic nucleus.[50] Melatonin generally facilitates falling asleep within 1 hour, no matter what time of day it is taken. Optimal dosages, although this is controversial, are thought to be in the range of 0.25 to 0.30 mg/day. Some preparations, however, contain as much as 5 mg of melatonin.[2,5] Daytime sleepiness and confusion have been noted with high dosages. Other reported adverse effects include decreased sex drive, retinal damage, hypothermia, and fertility problems. Moreover, melatonin is contraindicated in pregnancy and in immunocompromised patients.[2,5] There are few reports of drug–drug interactions. In conclusion, melatonin is a promising and relatively safe hypnotic, probably best used in people with insomnia secondary to circadian disturbances, and potentially useful in children with sleep difficulties. Caution should be taken in patients at risk, as noted.

Kava *(Piper methysticum)* is derived from a root originating in the Polynesian Islands. Although it is believed to have a mild anxiolytic effect, study results have been mixed. The mechanism of action is attributed to kavapyrones, which are central muscle relaxants involved in GABA receptor binding and norepinephrine uptake inhibition.[2,5] The suggested dosage is 60 to 120 mg/day, with GI upset, headaches, and dizziness being the major adverse effects. Toxic reactions, however, have been seen at high dosages or with prolonged use and include ataxia, hair loss, respiratory problems, yellowing of the skin, and vision problems. Even more worrisome are reports of severe, sometimes fatal, hepatotoxicity, including some requiring liver transplantation.[2,5] For this reason, the FDA has been investigating the safety of kava and has recommended that the duration of use not exceed 3 months. Although kava appears to be somewhat efficacious in the treatment of mild anxiety, current concerns about safety make cautious use essential. It should be used only under a physician's supervision and should be avoided by people who are taking other potentially hepatotoxic drugs or who have a history of recent alcohol abuse or liver disease of any sort.

PREMENSTRUAL AND MENOPAUSAL SYMPTOMS

Black cohosh *(Cimicifuga racemosa)* at a dosage of 40 mg/day has been shown to reduce physical and psychological menopausal symptoms.[51] Active ingredients are thought to be triterpenoids, isoflavones, and aglycones, which may participate in suppression of luteinizing hormone in the pituitary gland.[2,5] Mild side effects include headache, dizziness, GI upset, and weight gain. In the past few years, a few reports have emerged of possible liver toxicity,

convulsions, and cardiovascular problems, although some have argued that these toxicities could not be conclusively linked to black cohosh.[52] Black cohosh is not recommended for individuals who are pregnant or who have heart disease or hypertension. More data are needed to further specify beneficial effects as well as safety profiles.

COGNITION AND DEMENTIA

Ginkgo biloba comes from the seed of the ginkgo tree and has been a part of Chinese medicine for thousands of years. It has generally been used for the treatment of impaired cognition and affective symptoms in dementing illnesses; however, a possible new role has emerged in the management of antidepressant-induced sexual dysfunction.[53] Diminished memory and abstract thinking are target symptoms when used for individuals with dementia. Studies have shown modest but significant improvements, with a dosage of 120 mg/day, in both cognitive performance and social function.[54] Progression of disease may be delayed by 6 to 12 months. Further evidence suggests greater improvement for those with mild dementia and stabilization at most with more severe disease.[55] *Ginkgo biloba* has been proposed to enhance learning capacity, as evidenced by one study of healthy young volunteers who made significant improvements in speed of information processing, executive processing, and working memory when on the medication.[56] The body of evidence as a whole has been mixed,[57–59] however, and a recent systematic review suggests a lack of convincing evidence for acute or long-term benefits in young and healthy people.[60] The active components of ginkgo, flavonoids and terpene lactones, stimulate nerve cells that are still functional,[2,5] which seems to provide protection from pathologic effects such as hypoxia, ischemia, seizures, and peripheral damage. Because ginkgo has been shown to inhibit platelet-activating factor, it should be avoided in those at high risk of bleeding. Other side effects include headache, GI distress, seizures in epileptics, and dizziness. The suggested dosage of *Ginkgo biloba* is 120 to 240 mg/day with at least an 8-week course of treatment. However, full benefit may not be seen for a year. Comparisons between ginkgo and FDA-approved nootropics, based on a few meta-analyses[61] and one head-to-head study of ginkgo versus donepezil in patients with Alzheimer's disease,[62] suggest better tolerability for ginkgo, but somewhat more modest efficacy than cholinesterase inhibitors. In conclusion, *Ginkgo biloba* appears to be a safe and efficacious cognition-enhancing medication. It may also have a role in reducing antidepressant-induced sexual dysfunction, although this evidence is mixed and must be regarded as preliminary.[63] Further studies are needed to fully understand its complete and long-term effects.

Dehydroepiandrosterone (DHEA) is an androgenic hormone synthesized primarily in the adrenal glands, which is converted to testosterone and estrogen.[30] Although study results have been somewhat mixed, DHEA is thought to play a role in enhancing memory and in improving depressive symptoms.[30,64–66] Mechanisms of action may include modulation of *N*-methyl-D-aspartate receptors and $GABA_A$ receptor antagonism.[30] Synthetic DHEA is available in an oral formulation and as an intraoral spray, with dosages ranging from 5 to 100 mg/day. As in many other natural remedies, strength and purity are not regulated. In women, there is a risk for weight gain, hirsutism, menstrual irregularity, voice changes, and headache. Men may experience gynecomastia and prostatic hypertrophy, and the effects on hormone-sensitive tumors are not known.[30] Although early data are promising for DHEA, larger studies must be undertaken to clarify risks versus benefits before it may be safely recommended.

NONMEDICATION THERAPIES

Acupuncture has been used in Eastern countries for several millennia for the treatment of neuropsychiatric disorders, especially pain. Acupuncture is quite safe, with no major adverse events reported in a recent review of over 65,000 treatments.[67] Although some data support its use to treat a wide range of psychiatric disorders, including schizophrenia, bipolar disorder, substance abuse, and mood and anxiety disorders, the lack of an ideal placebo has been a major barrier in establishing its efficacy in Western studies. However, recent findings in the arena of functional neuroimaging may provide a deeper understanding of the role of acupuncture in mediating pain perception.[68] Further study will help elucidate potential neuropsychiatric benefits of this ancient Eastern treatment.

Hypnosis can be defined as "an event or ritual between a hypnotist and an hypnotic subject in which both agree to use suggestion to bring about a change in perception or behavior."[69] Hypnosis is thought to depend on the dissociative and imaginative abilities of the subject, on the motivation of the subject, and on the relationship between the hypnotist and the subject.[69] Mechanisms are unclear, but levels to which a patient can be hypnotized tend to fall on a bell-shaped curve. Although hypnosis may be used for a wide variety of medical and psychiatric conditions, the following disorders often respond better than others: anxiety, pain, asthma, phobias, nausea, vomiting, and bulimia.[69] Contraindications include unwillingness to be hypnotized, a history of paranoia, and an inexperienced hypnotist. Clinicians should exercise caution in patients with posttraumatic stress disorder or dissociative disorders, as hypnosis may precipitate intrusive (or false) memories in a patient who is not ready to confront them.[70] Because hypnosis may be employed at the bedside, it is particularly attractive to the consultation psychiatrist. Finally, hypnosis is a powerful tool when administered by properly trained individuals, and it may be used alone or as an adjunct in the treatment of a wide array of medical disorders.

CONCLUSION

The spectrum of CAM therapies is quite diverse in current medical practice and is gaining significant popularity in the United States. Historical lack of scientific research in this area has contributed to deficiencies in knowledge with respect to safety and efficacy of many of the natural remedies on the market today. A recent surge in funding by government and industry sources should help in this regard. Current knowledge about a few such therapies has been outlined in this chapter, including proposed treatments for mood disorders, anxiety and sleep disorders, menstrual disorders, and dementia. Many of these therapies may

prove to be a valuable addition to the armamentarium of treatments available to psychiatrists in the future. A particular emphasis was placed on potential adverse effects and drug–drug interactions, given the nature of consultation psychiatry. A general knowledge of these therapies and routine questioning about their use is an essential part of comprehensive care by the consultation psychiatrist.

38 Difficult Patients

Daniel J. Zimmerman, M.D.
James E. Groves, M.D.

The medical equivalent of war is the care of the difficult patient. Doctors soldier steadily on through all kinds of clinical chores, arduous schedules, and "administrivia," but when they get to the types of patients variously called "obnoxious,"[1] "needy," "crocky,"[2] "malignant," and even "hateful,"[3] they fight the worst battles of their careers, become prone to clinical blunders, mess up their personal lives, violate boundaries, and get sued. The good news is that—almost without exception—the "difficult patient" situation makes the consulting psychiatrist more useful to treating physician and patient alike than in any other medical encounter. Harrowing though such situations may temporarily be, it is just this kind of consultation that earns the trust and respect of the physician consultee and generates more consultation requests later on. (And, really, there are few better ways for a psychiatrist starting out to build a practice than by becoming a specialist on care of the difficult patient.) Before turning to management strategies, it is worth reviewing the presentations of difficult patients.

TYPES OF DIFFICULT PATIENTS

Delirious patients may be assaultive. Guilty, bereaved spouses can be litigious. Temporal lobe epileptic patients are often clingy and viscous. Manic patients are emotional cyclones. Celebrities at times generate anxiety in their caregivers. Schizophrenics can be noncompliant. Anyone when ill can become angry, dependent, and hypochondriacal. Somehow none of these difficult situations necessarily produces "difficult patient" scenarios.

Difficult patients are almost always persons with personality disorders—with one exception: Only patients with addictions seem to contradict the difficult-patient-equals-personality-disorder rule (if one includes persons with eating disorders—thinness addicts). There has been a state-versus-trait debate about whether substances elicit a "true" or "underlying" personality *("in vino veritas")* as opposed to the idea of substances sickening or "poisoning" the true self (intoxication, dipsomania). Personality disorders lie closer to trait because they so seldom change much, and addictions and eating disorders lie closer to state because when they do change, the change can be rather dramatic. Every experienced physician can think of a patient with an addiction who was not typically difficult, and occasionally some "really bad actor" goes to Alcoholics Anonymous, gets sober, and a year or two later looks and acts like a real *mensch*. In the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, (DSM-IV),[4] personality disorders are defined by clusters of traits, and addictions are states that the substance gives rise to. (For the purposes of management later on in this chapter, however, we will tend to think of excess alcohol as a personality disorder in a bottle.)

Not all patients with personality disorders are difficult patients. Looking at pure types through the lens of DSM-IV, those not necessarily belonging to the difficult patient paradigm are paranoid, schizoid, and schizotypal personality disorders (cluster A); likewise, avoidant, dependent, and obsessive–compulsive personality disorders (cluster C) do not necessarily belong to the difficult patient paradigm. It is not impossible to find the patient with schizotypal or paranoid personality who gets along well with the treating physician. Even the patient with dependent personality—if not angry but merely clinging—can be someone the physician enjoys working with. Although some of these may be difficult patients, it is really when we look into DSM-IV cluster B disorders that a pit of despair opens: antisocial, borderline, and narcissistic. (For the sake of this discussion, histrionic patients are grouped with borderline patients because, as difficult patients, they are almost indistinguishable.)

With these three diagnoses, there is almost a complete overlap between difficult patients and personality disorders. It is not Axis I or Axis III conditions that make for typically difficult patients, but the cluster B subset of Axis II disorders, the dramatic–emotional–erratic cluster. DSM-IV defines them as the following[4]:

- Antisocial personality disorder involves a pattern of disregard for, and violation of, the rights of others.
- Borderline personality disorder is characterized by a pattern of instability in interpersonal relationships, poor self-image, dysphoric affects, and marked impulsivity.
- Narcissistic personality disorder is embodied by a pattern of grandiosity, a need for admiration, and a lack of empathy.

The key word here is *pattern*. Personality traits lead to personality disorder "only when they are inflexible, maladaptive, and persisting and cause significant functional impairment or subjective distress."[4] These traits are enduring for most of the life span; they are pervasive (i.e., they color most of the patient's personal and social interactions). They deviate markedly from the expectations of the patient's culture. Finally, they do not result from another mental or physical disorder, such as depression or head trauma.

Antisocial and Narcissistic Personality Disorders

Patients with antisocial personality disorder display the defining trait of disregard for the rights of others. The disorder satisfies the general criteria for the other personality disorders and consistently manifests at least three of the following traits[4]: rule-breaking, lying, impulsivity or poor planning, belligerence, recklessness, irresponsibility or faithlessness, and a lack of conscience or empathy.

Narcissistic personality disorder[4] defines itself in the grandiosity and lack of empathy shown by at least five of the following traits: arrogance; a lust for power through beauty, love, brilliance, or money; convictions of "specialness"; a hunger for admiration; entitlement; exploitation and manipulativeness; stunted empathy (an inability to "feel into" the other person); envy; and displays of contemptuousness.

Antisocial personality disorder and narcissistic personality disorder are similar in terms of selfishness but different in terms of social destructiveness. One could think of the difference as that between criminality and shabby ethics. Whether these two entities differ more in degree or in kind is a question perhaps better left to religion or philosophy, yet in psychiatry one view has been that the personality disorders have similar ego defects (except in degree) and similar underlying psychic organizations[5–7] or even a common one called *borderline personality organization*.[8] If it is true that a change in social context (e.g., incarceration) brings out borderline personality in persons who otherwise look antisocial, as some have claimed,[9] there may be some utility to the notion of a core personality disorder called *borderline with several variant presentations*. At any rate, the management strategies discussed subsequently work for borderline and for other personality disorders alike, given a rigorous application and a sufficiently strong social structure.

The concept of an underlying or core borderline personality organization is a metaphor that has considerable utility in the discussion of the difficult patient. In the medical setting, antisocial and narcissistic patients are difficult only when they are acting like borderlines. The idea is that the underlying good–bad split or fragmented borderline personality organization is held together by the self-promoting program of the antisocial person and the grandiosity of the narcissist. Antisocial and narcissistic patients who believe their physicians' interests parallel their own are unctuous and undifficult ("prison sincerity"). When the psychopathy and grandiosity are punctured by illness or injury and thwarted by medical treatment, the underlying fragmented, rageful, splitting, attacking borderline comes out. In the discussion that follows, therefore, *borderline personality* is the referent paradigm of difficulty, to be discussed more at length and used interchangeably with *difficult patient*.

Borderline Personality Disorder

Borderline personality is so named[10] because it seemed to psychoanalysts to lie between the psychoses and the neuroses. Borderline patients are dreaded for their impulsivity, swings from love to hate, and maddening irrationality. They split the world into exaggerated dichotomies of good and evil. An interpersonal middle ground does not exist. These patients, by some combination of innate rage and inept parenting, cannot find a moderate position in any aspect of mental life.[11]

Borderline patients have a multifaceted personality disorder, "without a particular behavioral specialty."[12] Subtypes range from bordering on psychosis, in which the patient is chaotic or irrational, to bordering on neurosis, in which the patient desperately clings to others to feel real.[8,13] A few borderline patients cope with an inadequate sense of self by adapting like chameleons to the environment of the moment (the as-if personality).[14] The core borderline patient has the characteristics shown in Table 38–1, the current official diagnostic criteria.[4]

In the past, borderline personality was sometimes held to be a subset of biological depressive illness[15–17] or a variant of traditional diagnoses, such as hysteria, sociopathy, or alcoholism.[18,19] Because up to 90% of some samples of borderline patients have co-morbid conditions, some researchers questioned the construct validity of the borderline diagnosis, whereas others defended it[20–26]: As many as half of some borderline populations suffer a major depressive episode on Axis I; conversely, some 13% of Axis I alcoholics have co-morbid borderline personality. On Axis II, at least 20% of borderline patients receive an additional personality disorder diagnosis. Of these Axis I–plus–Axis II patients, some have remission of borderline symptoms

TABLE 38–1 DSM-IV Criteria for Borderline Personality Disorder

Borderline personality disorder is a pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment; note: do not include suicidal or self-mutilating behavior covered in criterion 5
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
3. Identity disturbance: markedly and persistently unstable self-image or sense of self
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating); note: do not include suicidal or self-mutilating behavior covered in criterion 5
5. Recurrent suicidal behavior, gestures, or threats or self-mutilating behavior
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

Adapted from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders,* ed 4, Washington, DC, 1994, American Psychiatric Association.

when their affective disorder is treated or when active alcohol abuse stops, again confusing the validity of the diagnosis. (Because it is more closely related to management, differential diagnosis is discussed in a later section.)

Regardless of subtype or co-morbid diagnosis, however, borderline patients can abruptly flee treatment or develop psychotic transference and delusions about their caregivers.[27–29] Short, circumscribed episodes of delusional thinking in unstructured situations and when under stress are almost pathognomonic.[13,29–31] Borderlines display a signature trait, poor observing ego,[32] which is a dense denial of vital aspects of reality and irrationality to a degree that almost has to be seen to be believed. Although the relation of borderline personality to schizophrenia has long been debated,[14,33–35] it is likely that if there is a border with a biological illness, it is closer to affective illness[36–39] without being completely tangential to it.[40]

Heredity plays a crucial role in the cause of borderline personality. Innate intolerance to anxiety and a constitutional tendency toward rage are accepted even by psychoanalytic theorists regarding borderline personality.[41] The disorder resembles aspects of traits long thought to run in families, and evidence suggests that borderlines cluster in families with affective disorders—38% of borderline patients have first-degree relatives with some affective disorder[42]—and impulsivity and affective instability generally cluster in some families with borderline members even when depression does not.[43]

Theories of the nonbiological component also focus on the family of origin.[44,45] Psychoanalysts view borderline personality as arising from failure by the patient's mother to foster coherent differentiation between self and object in the first 18 months of life,[46,47] leading to the development of pathologic ego defenses (see Table 38–3). The patient does not learn to tolerate negative affects associated with separation[48,49]; this continues the child's clinging into adulthood, as if others were desperately needed parts of the self.[8,50,51] The borderline's adult relationships are called *transitional* after the transitional object.[52–54] The patient's mother (probably borderline herself[55]) apparently feared fusion with (and destruction of or by) the child. She could not let the child separate because of her own fears of being alone. On rapprochement, she tended to reject the child for "deserting" her.[52–58] She mostly saw the child as her own transitional object and—used as the imaginary playmate of the mother—the child never grew into an emotionally separate human being.

In borderline personality, the boundaries between the self and others are blurred, so that closeness seems to threaten fusion. Sexuality and dependency are confused with aggression. Needs are experienced as rage. Long-term relationships disintegrate because of an inability to find optimal interpersonal distance. Because of inadequate ego mechanisms of defense, there is little ability to master painful feelings or to channel needs or aggression into creative outlets. Ambivalence is poorly tolerated. Impulse control is dismal. The patient has a fragmented mental picture of the self and views others as all bad and simultaneously all potent, a chaotic mixture of shameful and grandiose images.[11]

In addition to the literature on inadequate parenting, there has been an avalanche of reports linking borderline personality with parental abuse, particularly sexual abuse.[59] The line of reasoning often put forth is that the child victim of sexual abuse (especially of chronic abuse[60]) used dissociation[61] as a defense against massive psychic trauma, and the dissociation became habitual, undermining ego integration. This association with sexual abuse is seen as variously explaining phenomena ranging from a propensity toward dissociative psychotic-like episodes, rage, sexual disorders, psychotic–erotic transferences in psychotherapy, and self-mutilation all the way to the co-morbidity of borderline personality with multiple personality and with eating disorders. The literature on abuse does have the important effect of spotlighting the relationship between borderline phenomena and dissociation, something the older literature underemphasized. Although the linkage to childhood sexual abuse is still being worked out, it is clear that a significant number of borderline patients, when asked to give a history of such abuse, do so (up to 33% of nonclinical populations and 57% of borderline psychiatric inpatients[59]); this has to be taken into account in management.[62]

Borderline personality is relatively rare; it occurs in perhaps 1% to 5% of the population.[63] Despite its small size, the borderline cohort stands out in the general hospital because of its florid presentation and poor prognosis[64,65] and because of the feelings of anger and helplessness stirred up in the caregivers.[66] These patients make themselves medical outcasts because they ruthlessly destroy the care they crave.

DIFFICULT BEHAVIOR AND THE CONSULTEE

The previous discussion about the DSM-IV diagnoses of difficult patients must be leavened with a simple fact: It is not the diagnosis of these patients that make them difficult for the consultee—it is their behavior. The relationship of the behavior to other aspects of mental life is schematized in Figure 38–1 and pharmacotherapy is presented in Figure 38–2.

Such patients have abnormally intense affects, poorer than average neutralizers of affect, or both. In any case, raw rage, naked dependency, and ontologic shame are present and are often found on the surface. The cognitive structures that ordinarily temper intense affects are distorted and primitive. The ego weakness of the patient is shown by the absence of higher-level defenses and by the primitive nature of the ones that are present.

Under pressure of intense affect (rage, terror, shame), the patient uses dissociation to a greater or lesser extent and enters the dream-like state that persons ordinarily enter only in extreme emergencies. In this dissociated state (which is probably present much of the time to some degree), the patient is distracted, numb, and difficult to reach. The pervasiveness of dissociation is one feature of borderline personality that is insufficiently discussed in the literature; however, it can contribute drastically to the pathologic cognitions of borderline patients and place a distorting lens of unreality between them and the real world.

Besides dissociation, the borderline patient uses denial of major aspects of reality to cope. This mythification of the external, threatening world is displayed in defenses called *primitive idealization*, *omnipotence*, and *devaluation*. As the

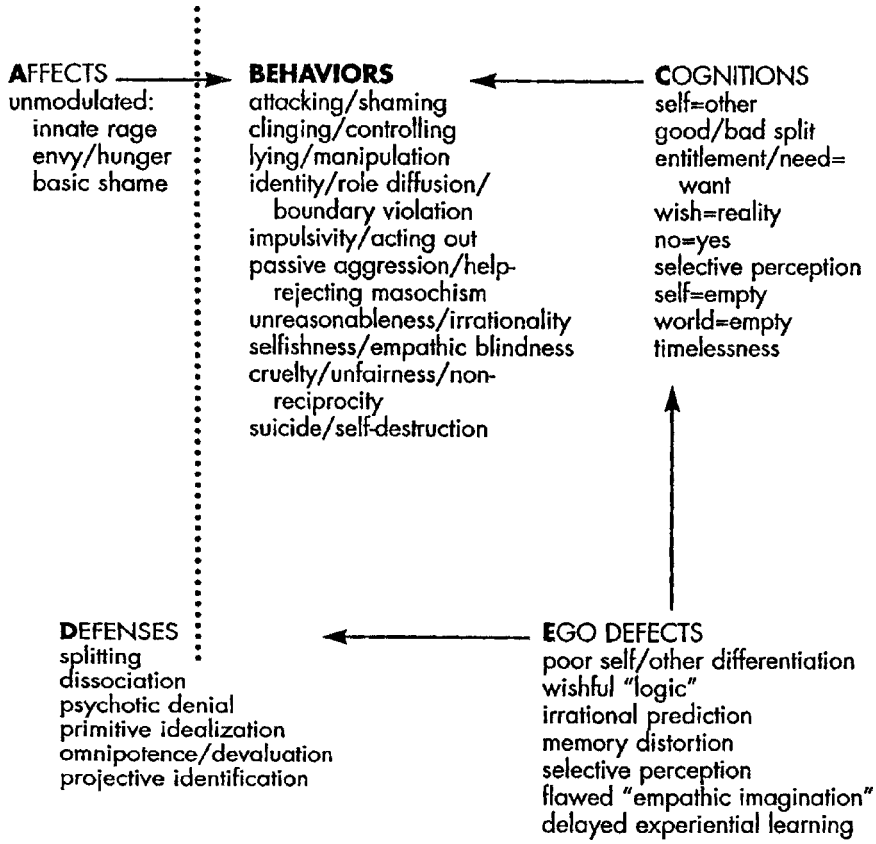

Figure 38–1. The difficult patient's types of problem behavior.

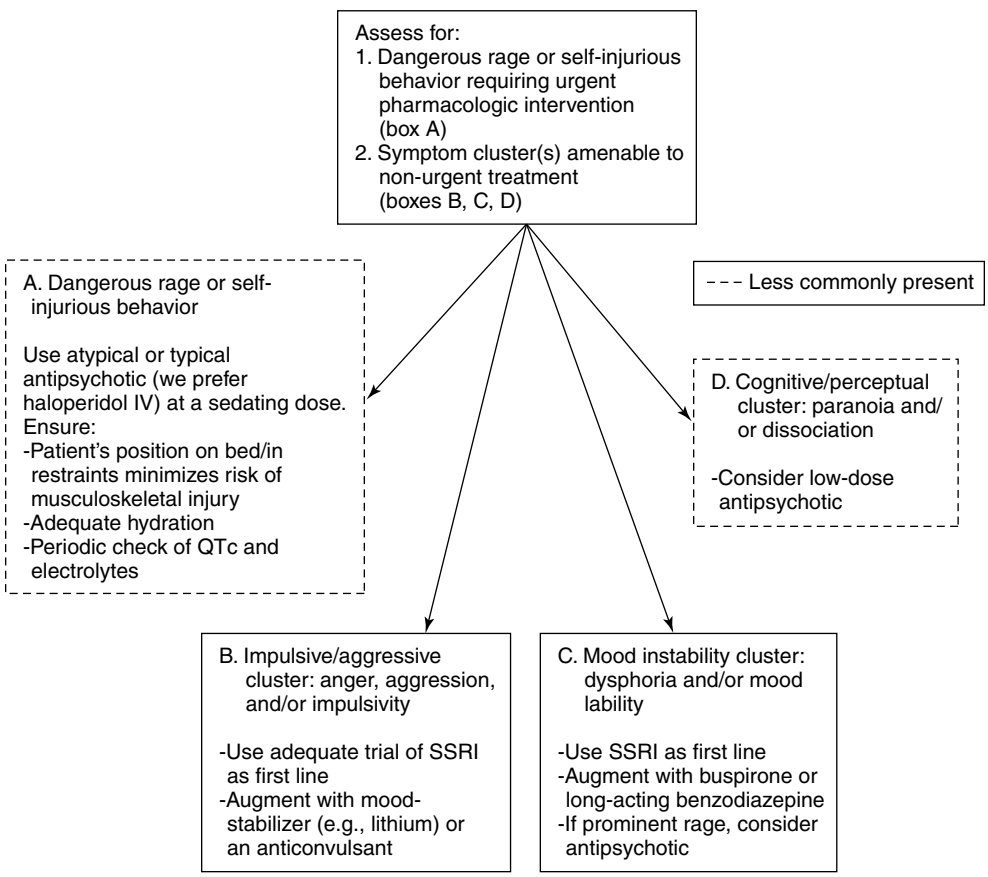

Figure 38–2. Psychopharmacologic treatment of the difficult patient.

names imply, these are metaphors for the dreamy, wishful, mythified world the difficult patient inhabits, a world of black and white and good and evil. These maladaptive defenses may be all too visible in the medical setting, but even more troubling are two others with which such patients unsuccessfully try to manage their extreme negative affects: splitting and projective identification.

Splitting is by definition a rigid separation of positive and negative thoughts or feelings. Normal persons are ambivalent and can experience two contradictory feeling states at one time; the borderline personality characteristically shifts back and forth, entirely unaware of one feeling state while in another. Sometimes one state is rigidly held while its opposite is projected onto the environment. The cause of splitting is unknown; it is said to protect the patient from the anxiety of reconciling contradictory extremes (at the expense of the already unstable personality). In social systems,[67–71] borderline patients can split the staff into warring "good" and "bad" factions that unwittingly act out the patient's internal world.

Projective identification[72–76] is said to consist of taking an unwanted aspect of the self, such as cruelty or envy, and wholly ascribing it to ("projecting it into") another. The patient then unconsciously pressures that person to own the projected attribute. Unaware that a self-fulfilling prophecy is being set up, the recipient complies with the projection and acts it out. These two mechanisms can complement each other, with projective identification being used to "confirm" one side of a polarized, split view of the world.[11]

Although the long-term psychotherapy of the borderline patient can involve therapeutic undoing of these defenses,[8,77] it is dangerous to confront such defenses in brief encounters in the medical setting. It is crucial, however, to be aware of their presence. For example, awareness of borderline splitting prepares the consultant to deal with the division of the medical staff into "good ones" and "bad ones." Recognition of the patient's primitive idealization, of a physician for instance, can help the consultant prepare for the furious devaluing that is to follow.

Helping the Consultee

The medical setting is a social system with its own history, boundaries, hierarchy, customs, and taboos. The introduction of a difficult patient into this culture sometimes places such stress on the system as to cause malfunctions in caregiving or outright extrusion of the patient, a situation that active psychiatric consultation can prevent.[78–80] Difficult patients are exquisitely vulnerable to caregivers' ordinary imperfections in communication and consistency, and they are often remarkably attuned to their caregivers' normal negative feelings of anxiety, shame, anger, and depression. Such patients are especially vulnerable to feelings of rejection by caregivers,[81] and their shaky defenses are even more compromised than usual by the stresses of illness and treatment.

After initial diagnosis and treatment of the patient, the consultant's next priority should be to gauge the amount of distress the staff is under. A psychologically naive medical staff can regress to a helpless or vengeful position in response to the patient's ingratitude, intractability, impulsivity, manipulativeness, dependency, entitlement, and rage. Regression in any social system can emerge as disagreement among staff; it can take the form of inappropriate confrontation of the patient, or it can manifest itself as a deterioration in the patient's behavior.[11] Regression seems to occur when there exists a large disparity between what is expected and what is found.[82] Troublesome dissonance of this sort between patient and staff generally occurs in any or all of three dimensions: perception of reality, values governing control and aggression, and rules about interpersonal closeness (Table 38–2).

The earliest clue to the nature of the dissonance lies in the consultation request.[83] Its tone, covert messages, intensity, timing, and route by which it reaches the consultant all can reflect the dissonance between patient and staff expectations. (In this sense, the consultation request resembles the chief complaint in the history, often the first, best clue to the problem.) Consultation is sought when the patient is out of touch with the staff's reality. Such dissonance can range

TABLE 38–2 Consultation Management of Staff and Difficult Patient Dissonance in the Medical Setting

TYPE OF DISSONANCE: CONSULTATION REQUEST	PATIENT'S PROBLEM BEHAVIORS	CONSULTANT'S WORK WITH THE CONSULTEE	CONSULTANT'S WORK WITH THE PATIENT
Dissonant reality: vague, confusing request for help; puzzled tone	Inappropriate to realities of illness or hospital; denial and demandingness	Explains patient's reality to staff; models "reality testing"	Diagnosis of any cognitive disorders; gives medication and reality-testing request
Aggressive dissonance: request to control or remove patient; fearful or angry tone	Menacing, self-destructive, or suicidal	Recommends social, chemical, or physical restraints necessary for safety	Evaluates potential violence; searches for source of patient's panic
Staff and patient dissonance regarding interpersonal distance: request consultant to take over care of patient; depressed, guilty tone to consultation request	Dependent	Gives permission to say "no" to patient's unrealistic, excessive demands	Clarifies for patient that some, but not all, needs can be realistically met
	Rejecting	Diminishes guilt and depression by stating impossibility of entirely satisfying patient	Allows patient some distance; repeatedly appeals to patient's "entitlement" and autonomous side
	Manipulative (dependent and rejecting)	Serves as forum for hatred toward patient; voices hateful feelings but behaves nonsadistically	Bargains; sets firm, noninterpretive limits on manipulation; clarifies patient's self-interest

from mild (when the patient is from a different culture) to severe (when the patient is psychotic). When the patient is docile, the request is matter-of-fact; when the patient manifests grotesquely sexual or aggressive behavior, the consultant might receive a shrill, disorganized call for help.

Consultation is sought when the patient's aggression violates staff expectations. The staff expects to be in control of the patient, who is expected to be grateful, compliant, and nondestructive. Dissonance in this dimension can range from mild, when the patient sulks, to severe, when the patient is violent or self-destructive. The tone of such a consultation request ranges from irritation to anger or outright fear, depending on the kind of aggression the patient displays.

Consultation is sought when the patient's need for closeness is different from what the staff deems appropriate. The staff expects the patient to be involved with the caregivers but to keep a certain distance. When the patient asks for repeated reassurances or when the patient makes inexhaustible or contradictory demands, a depressed, guilty request often ensues. Arrogant, peremptory consultation requests often herald a hostile, dependent, manipulative patient; depressed, tired requests can foretell an empty, clinging patient.

The primitive defenses[8,41,72–76,84] of the difficult patient can stimulate staff disagreement (Table 38–3). To cope with deep feelings of self-loathing, the patient might see the staff as loathsome—otherwise why would they care (projective identification)? Or the patient may see the staff as magically all good, to keep all the badness in the world away (primitive idealization). To make sense of a world in which people are both good and bad, such a patient might choose some people on the staff to be "all good" and some to be "all bad" (splitting). This "explains" for the patient "why" things always go wrong: The patient is caught between good and bad forces outside the self and therefore they are not the fault of the self. When the patient views the staff through the defense of splitting, the staff might eventually behave as if it were so. The patient will tell an "all good" staff member what terrible things an "all bad" staff member has done, said, or thought and then swear the "good" one to secrecy. As less and less communication takes place and as the patient escalates demands, the "good" staff and "bad" staff begin to disagree about the care of the patient because the borderline patient may be "good" with "good" staff and vice versa. The remedy for this depends on re-establishing open staff communication, even if it is hostile, to enable staff to get a well-rounded view of the patient. Firm, nonpunitive limit setting[67,69] (Table 38–4) is crucial for inpatient treatment because it must be made clear that the patient cannot destroy the caregiving system or be destroyed by it, no matter how intense the wishes or fears may be.

It is a natural human instinct to confront such patients angrily, but caregivers should exercise precautions during confrontations. Avoiding a confrontation of narcissistic entitlement is as important as it is difficult.[85] Such patients exude an offensive sense of deservedness that is always tempting for an overworked staff to confront angrily and suddenly. Often the difficult patient has only this sense of entitlement to keep a fragmented personality together during the stresses of hospitalization. Entitlement for the narcissist is what hope and faith are to normal persons. Preserving it requires a deliberate effort. Taken together, what Tables 38–2 to 38–4 show is that such behavior of the difficult patient (e.g., manipulativeness and entitled demanding)—obnoxious though they may be—sometimes function as defenses at a relatively high level for that patient. Stripping them away makes the patient fall back on even lower-level defenses, such as psychotic denial and dissociation, or—worse—to be defenseless, panic, or explode.

TABLE 38–3 Manifestations of Primitive Ego Defenses: The Difficult Patient in the Medical Setting

Splitting: Keeping completely apart two opposite ideas and their associated feelings. Staff are divided into "good ones" and "bad ones," reflecting the patient's incapacity to achieve ambivalence enough to see that caregivers have human limits, with "good" and "bad" qualities at the same time.
Projective identification: The tendency to see some staff as "bad" as the patient feels. This gets translated into behavior based on the following kind of "logic": "I'm bad and you take care of me, which means you're as rotten as I am, otherwise you wouldn't care for me." This perception is so powerfully held that the staff receiving it tend to act it out unconsciously.
Primitive denial: The alternating expungement from consciousness of first one and then another perception of opposite quality (in which it is called *splitting*) or a wish so powerful that it obliterates crucial aspects of reality contradicting that wish. For instance, fear might cause the patient to deny a serious condition and flee the hospital where it could be treated.
Primitive idealization: The tendency to see some staff as totally "good" to protect the patient from "bad" staff or from the patient's medical condition.
Omnipotence and devaluation: A shift (splitting) between the need to establish a relationship with a magical, powerful staff (primitive idealization) versus the conviction of omnipotence in the self that makes all others impotent by comparison (primitive idealization of the self). Omnipotent caregivers are supposed to deliver to the patient perfect care to protect against disease, and when this does not happen, the staff is seen as impotent and hateful. (Splitting makes the perception shift dramatically, whereas projective identification causes the staff to buy into the patient's primitive projections, making them come true).

Adapted from Groves JE: Management of the borderline patient on a medical or surgical ward: the psychiatric consultant's role, *Int J Psychiatry Med* 6:337–348, 1975.

TABLE 38–4 Rules for Confronting the Difficult Patient

Acknowledge the real stresses in the patient's situation.
Avoid breaking down needed defenses.
Avoid overstimulating the patient's wish for closeness.
Avoid overstimulating the patient's rage.
Avoid confronting narcissistic entitlement.

Adapted from Adler G, Buie DH: The misuses of confrontation with borderline patients, *Int J Psychoanal Psychother* 1:109–120, 1972.

Setting limits, avoiding confrontation, and avoiding overstimulation of the desire for closeness and rage are difficult to arrange in the fast-paced medical milieu.[85] Prevention of staff splitting is especially difficult because of the various subcultures in medicine. If, for instance, the patient chooses the nurses to be "all bad" and the physicians to be "all good," the nurses may displace anger to the physicians but be unable to express it directly because of role-induced sanctions, and the physicians may see the nurses as incompetent and unable to comprehend their treatment plan for the patient. Such situations are fertile ground for the splitter and require concerted effort toward open communication.

Pathologic dependency manifests in one of its extremes as manipulativeness: an intense, covert, contradictory, self-defeating attempt to get needs met.[3,84] It is the behavioral manifestation of a need by the patient to get close but at the same time maintain a safe distance from sources of emotional support. Some patients feel so empty that, paradoxically, getting their needs met threatens them with engulfment; they are so famished that closeness can actually make them feel merged with someone else and therefore not really alive. Such patients seem to have a deathly fear of what they most crave.

In limit-setting confrontations with manipulative, entitled patients, the consultant might have to model for the staff firmness, repetition, and an appeal to the patient's sense of entitlement (rather than an assault on it): "You deserve the best medical care we can give, and that's why we're recommending X, Y, and Z." The consultant has to keep uppermost in mind the appeal to the entitlement and not get drawn into logical or illogical arguments. Moreover, it is important to avoid interpreting the resistance to cooperation as a fear of dependency, a tactic that would at best leave the patient somewhat bewildered. Repetition is crucial. Encounters to engage compliance often have to be repeated two or three times at varying intervals before the patient agrees, for instance, to take medication.

Dependent, manipulative patients stir up sadism in the caregivers, which inhibits the setting of effective limits. The consultant supports the staff's self-esteem and performance by reinforcing strengths rather than by pointing out weaknesses, by teaching, by lending a conceptual framework to mitigate anxiety, by modeling interactions, and, most of all, by matter-of-factly stating that such patients stir up hatred even in the best of caregivers. Whenever the staff brings even a hint of negative reference to the patient, the consultant can say something like, "Yeah, these patients are manipulative and irritating as hell!" Or, "Everybody hates this kind of patient—I know I do." This personalization, juxtaposed with the consultant's own nonsadistic behavior toward the patient, legitimizes hostility toward the patient, but shares it among staff rather than inflicting it on the patient.

In general, the earlier in the hospitalization the consultant is called, the more overt is the reason for the consultation and the more effective will be the intervention because the difficult patient has had less time to project into the staff the intense, seemingly inborn shame such patients possess in great abundance. Late in the hospitalization, the consultant may be urgently called in to see the patient for vague reasons and arrive to find the situation in a shambles, the patient in restraints, the staff ashamed and in bitter conflict—and nobody either willing or able to say what has been going on.

Consultant's Role

The consultant's role in the management of the difficult patient consists of a specialized type of consultee-oriented approach in which countertransference hatred and fear are drawn away from the patient and strategically metabolized within the relationship between staff and consultant. The consultant should actively promote a behavioral management practicum[84] placed in the medical chart for reference and as a symbol of the psychiatrist's helping presence. This "recipe" discusses communicating clearly with the patient and among staff; understanding the patient's need for constant interaction with personnel; dealing with entitlement without confronting needed defenses; and setting firm limits on dependency, manipulativeness, rage, and self-destructive behavior.

Generally the consultant's approach should first lead directly to the consultee. The request should be elicited in person or at least on the phone because the written record never reveals all of the problems in the management of the difficult patient. Then the consultant goes to the head nurse to get a history of the patient's response to hospital routine. Next, the consultant reads the chart and compares medication orders with records of medication actually administered. The consultant will have generated some hypotheses and is now ready to test them in the examination of the patient. As the consultant proceeds through these steps, an orderly plan emerges (Table 38–5).

TABLE 38–5 Order of Priorities for the Difficult-Patient Consultation in the Medical Setting

1. Rapidly evaluate the most pressing psychiatric problems, beginning with physical or social restraints if the patient appears about to lose control of violent or self-destructive impulses.
2. Create a differential diagnosis of the difficult patient, with an explicit biopsychosocial formulation of the predominant conflicts and stressors.
3. Identify dissonance between staff and patient and formulate a plan of action to reduce it (see Table 38–2).
4. Provide treatment recommendations—psychological and pharmacologic (see Figure 38–2 and Table 38–2), short-term and long-term— taking into account the ongoing medical regimen and implicitly addressing dissonance between staff and patient while explicitly addressing the patient's conflicts.
5. Educate the consultee and staff to reduce dissonance and to lend a conceptual framework for dealing with future difficult patients.
6. Actively participate without grandstanding or actually taking over the total psychological care of the patient.
7. Follow up and be involved in disposition planning for the medical and psychiatric needs of the patient.

Adapted from personal communications with TP Hackett, AD Weisman, NH Cassem, AW Alonso, TD Stewart, K Nobel, JA Renner, OS Surman, and many others.

One helpful approach is the consultee-oriented model of consultation,[86] which involves thinking of the patient and staff as a single entity and dealing as much as possible with the strong, healthy part. The entity consists of two parts. One part, the difficult patient, has problems with object relations, pathologic behavior exacerbated under stress, and several self-defeating and infuriating defenses, especially splitting. To prevent being split, the consultant should try to deal mainly with the healthy part, the staff. Because the staff is often closely linked in an unwilling, hateful, and guilty alliance with the patient and its collective self-esteem is already damaged by encounters with the patient, the consultant should not damage it further by interpreting the staff's pathology.

The attempt to ally with staff rather than the patient is destined to encounter several kinds of resistance at the outset. First, the patient is eager to engage the consultant to find out whether the consultant is "all good" or "all bad." Second, the staff, needing distance from its sense of failure, wants the consultant to take over the care of the patient completely. Third, neither the staff nor the patient has the energy to understand what is going on; they are in pain and want relief now, preferably by removal of the patient.

The alliance with the staff depends to a large extent on previous experience with the consultant, how long it takes to answer the consultation request, and how much sense the advice makes. The alliance with the difficult patient is dramatically less important in terms of outcome than the alliance with the staff. Such patients are incapable of forming a real alliance, and their "alliances" are mostly primitive idealization. Ideally, the patient should be seen only briefly if there are enough data from other sources, and the staff is told that the consultant will work mainly with staff and see the patient infrequently.

Visiting the patient should be reserved in the early stages for the specific purpose of the consultant's alliance with the staff. Following the initial patient interview, the consultant goes to see the patient when a magical gesture of "taking over" is needed to comfort a desperate staff, when staff members feel that the consultant does not know how much they are suffering, and when the staff needs a specific model for carrying out recommendations on limit-setting or reality testing.

The consultation note, by its tone, specific information, and description of the patient in a way the staff can immediately recognize, remains in a medical record day and night as a tangible symbol of the consultant's helping presence. It outlines the request, history, mental status at the hour of the examination, and the psychiatric history. It is explicit about medications, and the potential for suicide and for violence. It includes specific, concrete management recommendations.

CASE 1

This was the conclusion of a consultation note for a difficult patient who had been spitting in her hyperalimentation line.

Impression: Ms. B is thought to have a chronic, severe personality disorder sometimes called borderline, meaning that she lies on the border of psychosis diagnostically and has only marginal social adjustment.

Recommendations: Continue haloperidol 2 to 10 mg IV twice a day as needed. Have brief, daily staff conferences to compare notes and reach a consensus about her surgical treatment plan. Try to have the same staff members work with Ms. B each day; bear in mind that she tends to panic at each change of shift. Set firm limits on her multiple and contradictory demands. She is quick to rage when her demands are not met and may threaten suicide. Do not imply that Ms. B does not deserve the things she demands, but rather say over and over again that you understand what she is asking, but because you feel she deserves the best possible care, you are going to continue to recommend the course dictated by your experience and judgment. If she continues spitting in her hyperalimentation line, assure her that physical restraint will ensue. (These limits do not mean that she should not be allowed to complain, but you need not tolerate more than twice as much as you would from the average patient.) Initiate suicide precautions (and search her luggage).

The consultant addresses dissonance arising from the patient's version of reality; tendency to act out; and demandingness, neediness, and rage. The consultant gives a mandate for open communication and daily staff conferences to prevent staff splitting and to provide a supportive environment. Firm limits, without challenging the patient's sense of entitlement, are set forth explicitly. The task now becomes one of seeing that recommendations are effected. There is nothing more frustrating than laboring to devise a treatment plan only to find that it is not carried out. When this happens, the consultant often finds that the source of resistance is still-unresolved dissonance between staff and patient (see Table 38–2).

Nowhere in the previous discussion is the unconscious motivation of the patient or of the staff brought to the attention of either. This is what is meant by *noninterpretive intervention*. Psychoanalytic interpretations foster a temporary regression and have no place in the consultation with the disruptive medical–surgical patient.[84,87] Instead, the consultant analyzes and reduces dissonance by speaking of its behavioral roots and consequences while resisting the temptation to illuminate interesting unconscious processes.

Medication

The psychopharmacologic management of difficult patients is quite complex and uncertain, again suggesting that borderline personality disorder (the referent paradigm of difficulty) is not simply a "border on" depressive disease. Based on the neuropsychiatric and psychopharmacologic literature, four clusters of personality disorder symptoms have been proposed as targets for pharmacotherapy.[88] The four clusters reflect difficulty with cognition or perceptual organization, impulsive and aggressive behavior, mood stability and dysphoria, and suppression of anxiety (see Figure 38–2). The personality disorder symptoms within each cluster might have a common neurobiological substrate that can serve as a rationale for treatment selection.

The impulsive–aggressive dimension and the mood-instability dimension are the two most relevant to cluster B personality disorders and, hence, the difficult patient.

Anger, aggression, and behavioral disinhibition constitute primary impairments in this domain, and they are thought to reflect dysfunction in the serotoninergic neurotransmitter system. Selective serotonin reuptake inhibitors (SSRIs) should be considered first-line agents for treating impulsivity and aggression in personality-disordered patients. However, if these patients do not respond well to adequate trials of SSRIs, augmentation with a mood stabilizer or an anticonvulsant can be considered, because there is empirical support for the use of divalproex sodium in this patient population.

The mood-instability dimension also appears to be most closely tied to the cluster B disorders and consists of mood dysregluation, depression, dysphoria, and emotional lability. These behaviors may have broad neurotransmitter underpinnings, possibly related to dysfunction in serotoninergic, cholinergic, or noradrenergic systems. SSRIs should be considered first-line agents for treating these symptoms. If augmentation is needed, buspirone or a long-acting benzodiazepine, such as clonazepam, can be considered. If rage is a prominent component of the mood dysregulation, antipsychotic agents should be considered.

When using the four-personality symptom clusters as a guide to pharmacotherapy for the difficult—personality-disordered—patient, the clinican should be mindful that the heterogeneity of DSM personality disorders results in patients having symptoms from several symptom clusters. For example, patients with borderline personality disorder tend to demonstrate behaviors from the impulsive–aggressive and mood-instability clusters, but some also exhibit symptoms within the cognitive–perceptual cluster. This reinforces the concept of selecting pharmacotherapy based on specific target symptoms rather than on a given personality disorder diagnosis. Experienced clinicians tend to use the symptom clusters as medication targets to avoid "chasing" single symptoms (to prevent situations in which a patient is prescribed four or more medications without a clear rationale). Clinical experience also suggests following guidelines (for dose and duration) for all medications to minimize treatment adjustments.

In terms of specific recommendations to the consultee, a trial of medication can be quite helpful in particular instances (see Figure 38–2). With patients exhibiting dangerous rage or other dangerous behavior, such as self-injury, antipsychotic medication titrated to a sedating dose may be life-saving.

Miscellaneous medications, ranging from methylphenidate to levodopa, have been reported to help difficult patients,[11] and there seem to exist single case reports touting almost any conceivable drug.[89] Given the present state of knowledge, it seems appropriate for the consultant to remember that mind and body are not separate, and that many seemingly insoluble problems respond to a search for, and aggressive treatment of, co-morbid psychiatric conditions, especially affective disorders and substance abuse. Common and uncommon medical conditions mimic personality disorders (just for illustration, three random instances in the literature are narcolepsy, Wolfram's syndrome, and Addison's disease[90–92]). Also, over the lifetime of any given patient, the relationship with a supportive physician is as healing as any drug.

PSYCHIATRIST'S WORK WITH THE PATIENT

Although design and promotion of the behavior management protocol and consultation with the staff are the initial work of the consultant, the psychiatrist performs the following tasks with the patient directly:

- The psychiatric mental status examination, differential diagnosis, and formulation (including the use of observations of transference and countertransference)
- Assessment of suicide potential
- Assessment of present need for control of violence (as opposed to making a prediction of dangerousness)
- Assessment of, and recommendations around, substance abuse and other "dysfunctional," addicted, or "co-dependent" patterns (e.g., inept parenting, eating disorders, spousal abuse, or obsessive–compulsive disorder)
- Rarely a highly focused, brief (one- or two-session) tactical psychotherapeutic intervention

Differential Diagnosis

If the consulting psychiatrist does not do it, there will not be a good mental status examination, psychiatric history, or biopsychosocial formulation in the medical record. However skilled or willing other specialists may be, only the psychiatrist has an understanding of the minute-to-minute fluctuations of transference and countertransference that occur early, even in a single interview. (Countertransference is so important as to be almost a diagnostic discriminator of borderline personality.[93]) Also, there is a kind of rigor and discipline that the experienced psychodiagnostician brings to these situations: No one else in the medical setting is, for instance, going to perform a Mini-Mental State Examination, ask about earliest memories, a history of sexual abuse, the content of dreams and fantasies, sexual worries, religious and spiritual concerns, disordered thoughts, and suicidal ideation—all in one interview—and then put them together into a differential diagnosis and formulation.

Differential diagnosis is crucial because co-morbidity is almost a hallmark of the difficult patient, and it is surprising (if not impossible) to encounter a cluster B patient who does not also have at least one of the following diagnoses: another personality disorder, substance-abuse disorders, affective disorders, anxiety disorders (especially panic and phobias), eating disorders, obsessive–compulsive disorder, posttraumatic stress disorder, adult attention-deficit/hyperactivity disorder, impulse-control disorder, or other disorders.

Suicide Assessment

The gravest predictors of a suicide attempt[94–99] by the difficult patient are the following:

- History of previous attempts, especially with high risk or a low chance of being rescued, and other violence
- Standard demographic predictors (advanced age, being single, and the like; see also Chapter 40 on suicide)
- Co-morbidity, especially with substance abuse and affective disorders
- Marginalized socioeconomic and cultural status

These predictors are the same whether the patient is in the medical setting or out of it, but there are other predictors specific to the medical setting: Recent worsening in the medical condition along with perceived rejection by caregivers[81] adds considerably to the risk of suicide. Suicide attempts in medical and surgical settings correlate not so much with depression in serious illness, such as cancer, but rather with anger over the loss of social supports. The large majority of suicide attempts occur in a clinical setting in which the patient's experience is of being abandoned: during failing treatment, at times of imminent discharge, in conjunction with disputes with the staff, or during staff holidays.

Some factors are poor predictors, notoriously the psychiatrist's countertransference.[99,100] Also, it is false to think that patients with antisocial personality or without clinical depression never kill themselves. Depression and the type of personality disorder are much less predictive of suicide than are punctured defenses and a "no-exit" situation, one the patient deems totally hopeless and inescapable. A good short mnemonic for immediate risk is the "3 H rule": hate, humiliation, and hopelessness. Strongly predictive are self-hate fused with hatred of another (often a spouse who has left), loss of face with extreme shame, and being trapped in a bad situation with no apparent prospect of escape.

Assessment of Potential for Violence

Problems arising when the patient has difficulty controlling aggression are helped when the consultant defines for the staff the range of responses, from supporting the sulking patient or even giving in to a mildly overcontrolling patient, to absolute limits on violence. The medical staff fear overreacting, and the consultant reduces anxiety by defining the management of varying degrees of aggression. Disruptions are mostly born of self-protective or fearful impulses in the confused or delirious patient. Rarely, however, a patient becomes dangerous. In those instances, the most common warning is fear; someone becomes scared of the patient. Staff almost never fear delirious behavior, controllable anger, or senile pique, but they do tend to become wary, then edgy, then frightened. This intuition in the caregivers is often the only warning the consultant gets before an explosion. Ominous signs in the patient are rapidly increasing demandingness; more frequent and intense anger, especially with abusive language; and mounting agitation and paranoia. The general feeling in the medical setting of an implacable crescendo of menace surrounding the patient is another ominous sign.

Before any decision about physical restraint of the patient is made, hospital security guards should be standing by on the ward. This is a first step in the decision-making process. Security can always be dismissed with thanks after standing by, but to delay summoning help until after such a decision is made risks panicking the patient, who may have an uncanny ability to sense an impending confrontation.

Such ideas refer to control of violent behavior in the immediate situation. Occasionally, however, the consultant is asked about the long-range "dangerousness" of the patient. This is an opinion that involves extrapolating from present behavior in a known, observed situation to a guess about the patient's interaction with a different milieu, one that might contain drugs, weapons, and situations beyond the psychiatrist's ken. Medicine is about healing, not social control. Dangerous persons (e.g., the man with schizophrenia and a gun, the person with an antisocial personality who commits rape) may in some sense be "difficult patients," but in these situations, they are not patients at all, but criminals.

Psychiatric opinions outside the medical purview violate an important boundary and feed the fallacy that all bad behavior is somehow psychiatric and that mentally ill persons have no personal responsibility for their behavior. What the psychiatrist can do, however, is document medical history from the consenting patient about drugs, access to weapons, felony convictions, and the like. Surprisingly often, such a patient discloses useful information in the context of a skillfully elicited childhood history of enuresis, fire-setting, and cruelty to animals. ("Were you ever accused of setting fires? Did anybody ever say you were mean to the neighbor's pets?") Such patients can be oddly eager to resurrect old denials and often are still indignant about them. They then sometimes go on to give themselves away and provide information needed to protect caregivers and other patients in the medical setting.

Substance Abuse

Substance abuse is the area in which the consultant can be most useful to patients with primitive personality problems. Substance abuse is such an issue for a significant proportion of difficult patients that excess alcohol can be thought of as a personality disorder in a bottle. More than half of some samples of borderline patients—two thirds in one study—abuse substances. Of these, perhaps up to a fourth have such a good response to abstinence that they no longer meet diagnostic criteria for the disorder.[22]

If one adds to the number of patients with substance abuse various other addictive, co-dependent, or dysfunctional problems (e.g., eating disorders, "sex and love addicts," or incest survivors), it is not implausible that almost any difficult patient would qualify for some sort of 12-step or "recovery" program. Such self-help groups have not excited much interest or research in psychiatry (and have even occasionally inspired disdain because of their focus on spirituality), but there are several conceptual reasons (based on Figure 38–1) why 12-step programs are ideal for difficult patients: Tenets of the "recovery" movement are essentially anti-psychological in their nature, and given the lack of observing ego of borderline patients, this is a benefit, not a deficit. Many borderline patients have such dramatic regressions when involved in psychological treatments that observers have suggested that much of their pathologic behavior is iatrogenic,[101,102] a reaction to too much empathy and psychoanalytic interpretation. Furthermore, such programs have two ingredients well known to help primitive character pathology: an emphasis on taking responsibility for oneself (as opposed to cultivating the victim role) and a highly structured series of steps and methods. Not least in importance, there are myriads of such groups meeting at almost any hour of the day or night in every location in the urban United States.

Not surprisingly, it requires great skill to persuade a difficult patient to identify with one of the 12-step programs. First, there is almost always dense denial of the abuse problem, along with a need to see the self as powerless and

victimized. Splitting patients and narcissists see themselves as "better than" persons in Alcoholics Anonymous, for example, and are so vulnerable to shame that they hesitate to take on another attribute they see as shameful. Also, the general culture outside such programs has little real information about what they can accomplish, so the patient is not only ashamed, but also usually ignorant of these resources.

There is an art to getting a difficult patient to consider that a problem with addiction, co-dependency, or the like may be the root of much of the suffering the patient endures. Practicing this art involves accumulating knowledge about such programs and having familiarity with some persons helped by them. It involves the ability to discern when the patient might be receptive, first to acknowledging an addictive problem and second to considering such a program. It involves knowing how to elicit information in a nonshaming way ("Do you find yourself drinking more than you really want to be drinking?"), presenting the condition as a disease and "not the person's fault," and introducing the ideas gradually in a nonthreatening way. ("Did your mom ever turn to Al-Anon for help with your father's drinking?" "Did you ever get help from the Adult Children of Alcoholics program or something like that?")

No difficult patient is ever educated easily, and it usually requires multiple inputs from numerous sources over many months even to begin to get some of these options accepted by the patient. The consulting psychiatrist is ideal to introduce such ideas and, given the relapse rate of difficult patients, might get another opportunity with the same patient in the future. The consultant can at least start the educational process without making the patient feel ashamed.

Brief Tactical Psychotherapy

Psychotherapy is a risky proposition, and the consultant is wise to resist the temptation to do much. Rarely, however, the crisis of an illness provides a unique chance for insight and growth for the patient with a primitive personality. This lucid interval is incidentally produced when an illness and treatment cut through the veils of dissociation surrounding such patients, their maladaptive projective defenses, and their habitual externalization of responsibility. In this context, sometimes the patient asks not only the superficial "why me," but also the deeper question, "Who am I that this is happening to?" In a certain sense, catastrophe throws the primitive individual into a developmental crisis in which there may be the potential for recouping a bit of the developmental lack of progress in the first 2 years of life—the maturation from the paranoid position to the depressive position—along with a capacity for grieving and the developing empathy for others that such maturational steps entail.

A study[103] of changes in pathologic narcissism in a cohort of subjects followed for several years found that a majority of them had improved significantly and that the improvement related to life achievements, new durable relationships, and disillusionment. These subjects displayed decreased grandiosity and deeper empathy for others as evidenced by better relationships. The disillusionment related to these improvements, moreover, had occurred at a critical juncture in the person's development and was of a certain type—challenging but not devastating. Rather than questioning the construct validity of narcissistic personality disorder (as was done in this study), the findings plausibly support the idea that certain painful, constructive real-life experiences help people change their primitive pathology. (That brief therapeutic interventions can further this process, even in primitive patients, is shown in some of the therapies detailed by Malan, Budman, Strupp, Bloom, Horowitz, and especially Winnicott.[104])

This is the rationale for a certain brief, tactical intervention by the psychiatric consultant who encounters the difficult patient during a medical or surgical crisis: how to keep the disillusionment from being completely devastating and help the patient make sense of it in terms of personal identity. (As Figure 38–1 shows, a vague sense of personal identity underlies much of the pathology of the difficult patient.) The patient is in a process of trying to adapt to the illness or injury, to work it through, to grieve losses, and to contain fears. In this context, the psychiatrist's aim is not merely to help further this grieving or adjusting process, but to accomplish a deeper, more lasting goal: using the illness or injury process as a template or map for other life changes, using the crisis of the moment to help the patient learn new ways of thinking about the self, and coping with rage, terror, and shame.

The tactical brief therapy of the difficult patient falls into two types of maneuvers: containment and intervention. Containment involves control of uncontrolled affect, distorted cognition, and destructive behavior. Intervention consists of correcting the misdirection of the patient's trajectory, previously determined by pathologic affect, distorted cognition, and self-defeating behavior. Containment and intervention roughly correspond to the two parts of traditional psychotherapy, the frame (scheduling, vacations, fee, phone calls, limits on acting out, confidentiality) and the content (symptoms, history, development, associations, discourse, dreams, fantasies, defenses, adaptation, transference, countertransference, and other nonframework components of therapy). This "moment" of brief tactical psychotherapy assumes the patient in the medical situation is temporarily contained and already in a dialogue with the psychiatrist about the illness or injury that brought the patient to this place at this time.

The therapist's first task—and therapist is what the consultant becomes at this moment—is to listen to see whether the patient is asking for intervention. The patient signals such readiness not only by addressing the impact of the illness or injury but also by mentioning the overall meaning of the patient's life, the patient's "story," the overarching narrative that helps any human being make sense of the world. If the tactical intervention is to be helpful, the patient must be the one to push for it. The therapist's experience at this point is of being passively drawn into the patient's turbulent material, yet actively steering the discussion away from affects too intense on the one side and cognitions that are psychotically distorted on the other.

So up to this point, the therapist's job has been careful listening and containment. If the patient is ready, the patient will introduce these two themes: the overall story of the patient's life and its meaning, and the meaning of the illness or injury that is serving as the focus of the tactical psychotherapeutic moment. The patient will tend to see the medical crisis as thematically pertinent to the meaningful life story—for instance, just another in a long series of

persecutions, a punishment for something bad the patient has done or is. The life story is generally a standard narrative of a search for perfect safety and love, a quest for power so the patient will never again be scared; there are seldom any major surprises at this point.

The therapist's first active step in the tactical intervention occurs now: labeling the life story; labeling the symbolic, adding metaphoric meaning of the illness or injury; and labeling the pain that is at the interface of the two. This is almost like offering a "title" for the story. ("All your life you've been a survivor; now you wonder if you can survive this terror.") The idea here is that, to survive, individuals have to construct a meaningful narrative of the crisis. Under pressure of converting experience into symbols and then into meaning, the primitive person may be forced to construct a more realistic life narrative (and hence a more coherent sense of personal identity).

If the patient continues to be receptive to tactical intervention, two things happen at this point: first, production of deeper material in symbolic form (mention of a fantasy or recurrent dream, some external, cultural symbol or icon, a movie or a television character) and, second, a rather pointed question for the therapist about what to do (an acceptance by the patient of the therapist as a relatively separate, helpful person). This turning point requires careful listening because the key organizing theme of the patient's life (as the patient sees it) is presented in this one moment of symbol formation along with the rather concrete question that follows directly after.

Here the therapist does not answer the patient's question about what to do with the illness assaulting the meaning in the patient's life. The therapist labels the assault, points out the crisis in meaning, and thematically throws the question back to the patient. ("In a way you're asking how to cope with this thing, but in a deeper way you're saying that you're Scarlett O'Hara, since you just mentioned her. How would Scarlett handle what you're going through?")

What the patient says next reveals whether the tactical linking of the two meanings and two stories seemed useful to the patient. If so, the patient produces more details of the life story, again asking the therapist what to do about the illness or injury. Again the therapist throws responsibility back to the patient, labeling meaningfulness issues and the importance of the illness or injury to it. ("You just mentioned losing your husband—like Scarlett O'Hara—and now you're asking how to cope with your boyfriend's reaction to your mastectomy. Scarlett fell back on Tara and her own resources. What resources do you have to draw on?")

This working-through cycle of question and deflection continues as long as the therapist has time and the patient has strength to bear the rage, terror, or shame of the moment. Usually the patient soon fatigues and moves the subject back to some specific entitled demand, such as getting more pain medication. This signals that the therapy part of the encounter is now over and that the consultant is once again back to management of the difficult patient.

Although the brief tactical psychotherapy just described is probably the most useful first-line approach, other psychotherapeutic methods have been designed for the treatment of borderline personality disorder and also can be applied to the difficult patient. Dialectical behavioral therapy (DBT),[105] transference focused psychotherapy (TFP),[106] mentalization-based therapy (MBT),[107] and schema focused therapy (SFT)[108] each have a somewhat different theoretical perspective; transference focused psychotherapy and mentalization-based therapy have shown efficacy in randomized, controlled trials for improving outcomes for those with borderline personality disorder. Although full implementation of these therapies is obviously not possible during a few consultation visits, familiarity with the theory and techniques they rely upon can enhance the consultant's ability to make sense of, and employ a therapeutic tool, in diverse situations. Table 38–6 summarizes these treatments and provides examples of how they can be adapted to encounters with the difficult patient.

TABLE 38–6 Psychotherapies for Borderline Personality Disorder and Their Relevance to the Difficult Patient

THERAPY	DEVELOPER	RELEVANT THEORY*	RELEVANT TECHNIQUES	EXAMPLE WITH THE DIFFICULT PATIENT
Dialectical behavioral therapy	Marsha Linehan	The patient is more emotionally vulnerable and reactive and is therefore ill-suited to a normal social environment	Acknowledge and validate the patient's difference while also encouraging change	Consultant: "This ward is a difficult place for you. Everyone's too busy to give you the help you need, and this illness is one of the most distressing things that's ever happened to you. Your rage and fear make sense. That being said, the doctors and nurses here really are trying their best. They're at least meeting you a third of the way. Do you think you could cut them a little more slack? Do you want me to communicate anything to them for you?"

Continued

TABLE 38–6 Psychotherapies for Borderline Personality Disorder and their Relevance to the Difficult Patient—*cont'd*

THERAPY	DEVELOPER	RELEVANT THEORY*	RELEVANT TECHNIQUES	EXAMPLE WITH THE DIFFICULT PATIENT
Transference focused psychotherapy	Otto Kernberg, John Clarkin	The patient is frozen in a state of immature emotional development where self is split into multiple negative and positive parts experienced successively in time, each infused with maladaptively powerful affects. Personality therefore lacks consistency and cohesion	Interpret the patient's successive self states to enhance the patient's awareness of the multiple roles she or he plays, which fosters a more integrated self	Consultant: "You say the doctors here are the best ever, but the nurses are all bitches. And at first you told me I understood you like no one else. But now that I'm trying to enforce the rules to protect your safety, you're ready to throw me on the trash heap. So it's almost like I experienced two different people: First you were so warm and tender and the next minute you were like a warrior ready to cleave me in two. Aside from letting you take off your heart monitor leads, which you know is too dangerous right now, how can we help you feel better heard and cared for?"
Mentalization-based therapy	Peter Fonagy, Anthony Bateman	The patient cannot make sense of the actions of self and others on the basis of intentional mental states, such as desires, feelings, and beliefs	Point out the patient's actions to help the patient draw a link between actions and what the patient is thinking and feeling; identify the patient's reactions to the therapist's words or actions and help them guess what you're feeling and thinking	Consultant: "Can you tell me what you were feeling and thinking while you were cutting yourself with that razor you brought in? Were you scared? Were you angry because we did something wrong?" Patient: "I told you to get the f*** out of here!!" Consultant: "I'm concerned about you and terrified when you scream like that. I know that scares other staff too. We'll need those restraints to keep you safe until we can understand you better and help you cope with this more safely."
Schema focused therapy	Jeffrey Young; influenced by the work of Aaron Beck	The patient's inner world is characterized by five modes, or aspects of self, that interact in destructive ways: the abandoned and abused child, the angry and impulsive child, the detached protector, the punitive parent, and the healthy adult	Develop the "healthy adult" by "limited reparenting," emotion-focused work (e.g., imagery and dialogues), cognitive restructuring and education, and breaking behavioral patterns	Patient: "I don't take my heart pills or my insulin usually for the simple reason that I'm a drop out and a druggie and what's the point of someone like me continuing to take up space on this earth." Consultant: (who has already established that the patient is not depressed but rather personality-disordered) "Multiple times already I've heard you be extremely hard on yourself. It would be useful to give that particular voice of yours a name. How about 'My Abusive Step-father'? When you hear yourself talking like that, try to remember that name. With outpatient therapy, you can learn how to tell that part of yourself to leave the rest of you alone and gradually he'll go away for good."

* With minor differences in emphasis all of these theories assume the same etiologic factors: innate temperamental difficulties, or an abusive or neglectful (or poorly matched in terms of temperament) relationship with a caregiver in early life.

Note: The patient = the borderline personality–disordered or difficult patient.

TERMINATION

Preparation of the difficult patient for discharge from the hospital is fraught with hazard. The patient not only might intensify disruptive behavior to prolong the hospital stay but also might simultaneously try to leave prematurely. The patient might secretly infect dressings or IV lines with saliva or feces and develop a fever while threatening to leave the hospital against medical advice. Or the patient might increase suicidal gestures, such as wrist slashing, to manipulate (get close to/stay distant from) the staff. Firm limits on sabotage and elopement should be discussed with the staff. Around termination, they should be more observant of the patient and more visible and firm. A specific discharge date should be firmly adhered to[109] despite a predictable worsening in the patient's psychological status.

After the patient has left, it is good for the consultant to touch base with the staff and the consultee once more to review the treatment and to share some of the consultant's own feelings. In this way, the consultant not only "terminates" with the staff but also paves the way for future work with the next difficult patient who comes to the general hospital.

39 Emergency Psychiatry

Jennifer M. Park, M.D.
Abigail L. Donovan, M.D.
Lawrence Park, M.A., M.D.
Laura M. Prager, M.D.

Over the past 20 years, emergency psychiatry has developed into an independent subspecialty practice within psychiatry. Although formal board certification requirements are lacking, all accredited U.S. psychiatric residency–training programs follow minimum training guidelines for emergency psychiatry.[1] The emergence of emergency psychiatry as a specialized practice parallels the dramatic increase in patient volume in urgent and emergency care settings over the past decade. In 2001 there were more than 2 million visits to U.S. emergency departments (EDs) for mental health–related chief complaints, accounting for more than 6% of all ED visits and representing an increase in the percentage of all visits by 28% over the previous decade.[2] Among emergency mental health visits, substance-related disorders (30%), mood disorders (23%), anxiety disorders (21%), psychosis (10%), and suicide attempts (7%) are the most common.[2]

Psychiatric emergencies encompass a range of clinical presentations and diagnoses. Typically, such patients seek treatment in a state of crisis, unable to be contained by local support systems. Crises may be understood and addressed from a variety of perspectives, including medical, psychological, interpersonal, and social. Symptoms often consist of an overwhelming mental state that puts the patient and others in danger. Patients may have suicidal or homicidal ideation, overwhelming depression or anxiety, psychosis, mania, or acute cognitive or behavioral changes. More recently, emergency services have also been used for nonemergent conditions.[2] Increasing numbers of patients seek treatment at EDs for urgent conditions, routine conditions, or outpatient referrals because of lack of coverage for routine outpatient care, lack of community health care resources, or an inability to access health care. This has led to longer lengths of stay for some psychiatric patients in the ED, especially for those who demonstrate acute safety issues (suicidal or homicidal ideation) but lack insurance.[3]

The scope of emergency psychiatry includes core skills for psychiatric practice, as well as more specialized skill sets. In addition to the evaluation and treatment of severe psychiatric conditions, practitioners of emergency psychiatry are called on to evaluate and manage suicidal behavior, homicidal (or violent) behavior, agitation, delirium, and substance intoxication or withdrawal states. Because clinical practice lies at the interface of medicine and psychiatry, having knowledge concerning the assessment and treatment of medical conditions that involve psychiatric symptomatology is critical. Recently, emergency psychiatrists have also played important roles in an organized response to disasters.

The aim of this chapter is to provide a foundation for the clinical aspects of psychiatric emergency care. First, the general psychiatric emergency evaluation will be reviewed, with a particular focus on common initial symptoms. Then, special topics and the emergency treatment of children will be examined.

DEMOGRAPHICS

As of 1991, the United States had approximately 3000 dedicated psychiatric emergency services (PESs).[4] By 2007 a survey revealed that roughly 86% of general hospitals provided some type of emergency psychiatric care, with 45% having either a psychiatric emergency service or an in-house consultation service and 41% contracting with an outside source to provide emergency psychiatric care.[5] Among the patients treated at these specialized services, approximately 29% are diagnosed with psychosis, 25% with substance abuse, 23% with major depression, 13% with bipolar disorder, and 22% with personality disorders[6]; co-morbidity is common. Suicidal ideation is present among approximately one third to one half of the patients.[4]

Though some patients may self-refer to a PES while in crisis, patients may also be referred by family; friends; general practitioners; medical specialists; mental health treaters in the community; and employees of local, state, and public agencies. Since the occurrence of several school shootings by students, schools in the United States have become a major source of emergency referrals for violence and suicide assessments.[7] Police officers and representatives of the legal system are also a source of referrals, insofar as the PES serves as a conduit between the psychiatric system and the legal system.[8] The role of the PES is to help the police identify those patients with psychiatric illness and to re-route them to appropriate care, whereas those without acute psychiatric illness are returned to the legal system.

TYPES OF DELIVERY MODELS

Two general models are used to deliver emergency psychiatric services. In the first the PES exists as an independent service, co-located with a general emergency medical service or located separately in a stand-alone facility. In the second model, the PES functions as a consultation service that provides recommendations to primary emergency medical services. The model of services offered is determined by the volume of patients and the financial resources available.[9]

Delivery of emergency psychiatric care through an independent service offers several benefits. The first is safety: A PES physically separated from the chaos of a busy ED provides a secure environment for the assessment of patients (with limited access to sharp or dangerous objects, with quiet surroundings to decrease stimulation, and with the ability to observe and rapidly initiate psychiatric treatment). The unit may also have security staff who are trained to understand mental health issues and who can help maintain a safe environment. Many units also have specialized rooms for restraint and seclusion.[9] In addition, an independent PES is more likely to have individual rooms for private interviews, thus protecting the patient's privacy and dignity.

Another benefit of a dedicated psychiatric unit is the opportunity to staff the unit with specialized personnel who are trained in emergency psychiatric care.[4,9] An interdisciplinary staff of psychiatric residents and attending physicians, nurses, social workers, and case managers can enhance the care of patients with acute illness, for example, by coordinating medical care with colleagues in the ED. Psychiatric nurses also play an important role in the triage of mentally ill patients within the psychiatric unit and the ED. Their ability to manage the milieu in an emergency unit, provide individual support to patients, dispense psychiatric medications, and recognize situations that require immediate nursing and physician intervention is invaluable.

Some PESs also have access to "crisis beds" or facilities that are able to provide 24- to 72-hour observation. The ability to observe a patient whose mental state may change significantly after the initiation of antipsychotics or with a period of sobriety may decrease the need for inpatient hospitalization.[4,9,10]

A PES may also have a mobile crisis team, whose role is to evaluate patients in the community, defuse a crisis before a patient is treated at the ED, and decrease rates of hospitalization. As early as 1980, mobile initial response teams were described as a component of California community mental health centers and as an alternative to ED care.[11] One report from 1990 demonstrated similar hospitalization rates among hospital-based and mobile team emergency interventions,[12] whereas more recent reports have demonstrated decreased hospitalization rates associated with use of mobile teams.[13-15]

THE PSYCHIATRIC INTERVIEW

The psychiatric emergency evaluation is a concise, focused evaluation with the goals of diagnostic assessment, management of acute symptoms, and disposition to the appropriate level of care. Just as a visit to an ED for a medical complaint involves an initial triage (a brief evaluation of the severity of the problem), many emergency psychiatry models also depend on an initial assessment of the dangerousness of the psychiatric complaint itself, as well as in the context of co-morbid medical conditions. This initial, brief determination of acuity should screen for active medical issues that cause a change in mental status, as well as substance intoxication or withdrawal, suicidal or homicidal ideation, and other types of psychiatric symptomatology.

Many patients are willing to participate in a psychiatric interview, but some are not. Most states have enacted legislation that allows for holding individuals against their will if they are unable to care for themselves or if they present a danger to themselves or others. In the PES, if there is reason to believe that a person presents a substantial risk of physical harm to himself or herself or to other persons, or presents a very substantial risk of physical impairment or injury (because of an inability to care for oneself), the person may be held or sequestered in the PES or ED for further evaluation. The cornerstone of the initial psychiatric evaluation is a careful history that focuses on the temporal relationship among symptoms that have led to the emergency visit, on associated signs and symptoms, and on possible precipitants and causes. For patients with chronic mental health issues, it is also important to understand what triggered the emergency visit on that day in particular. In addition, a past history of medical illnesses, psychiatric illnesses, medication usage, allergies, adverse reactions to medications, patterns of substance use, a family history of psychiatric illness, and a psychosocial history serve as important aspects of the initial evaluation. Table 39–1 describes the components of the evaluation, and Table 39–2 describes the special features of a substance abuse evaluation.

TABLE 39–1 The Emergency Psychiatric Interview and Evaluation

- Chief complaint
- History of present illness, with a focus on symptoms and the context for these symptoms; include a safety evaluation, with assessment of suicidal and homicidal ideation, plan or intent, and any associated risk factors
- Past medical history, with a focus on current problems
- Past psychiatric history, particularly symptoms or events similar to the current presentation; include diagnoses, previous hospitalizations, and suicide attempts
- Allergies and adverse reactions to medications
- Current medications, including an assessment of compliance
- Social history, particularly how it contributes to the context for the emergency visit
- Substance use and abuse history
- Family history, including symptoms or diagnoses similar to the patient's presentation and a family history of suicide
- Mental status examination
- Review of medical symptoms, particularly any medical symptoms that may account for the patient's presentation
- Vital signs
- Physical examination, if indicated
- Laboratory studies and other tests, if indicated
- Assessment, including a summary statement, a statement about the patient's level of safety, and a rationale for disposition recommendations
- Axes I through V according to DSM-IV criteria
- Plan and disposition
- Documentation of any significant interventions (e.g., medication administration) and the outcome

TABLE 39–2 The Substance Abuse Interview

For each substance used, assess the following:
- Age of first use
- Amount and frequency of use
- Method of use (e.g., drinking, smoking, intranasal, IV)
- Time of last use and amount used
- Medical sequelae of use
- Social sequelae (relationship problems, school or work absences, legal problems)
- Longest period of sobriety
- Previous treatment (detoxification programs, outpatient programs, partial hospitalization)
- Method of maintaining sobriety
- Participation in self-help substance abuse programs (e.g., Alcoholics Anonymous, Narcotics Anonymous)
- Risk for withdrawal syndrome
- Patient's motivation to cut down or stop substance use
- Patient's need for assistance meeting goals to cut down or stop substance use

It is important to be aware of all potential information that may be included in an emergency psychiatric evaluation and then choose to elaborate on areas that are most relevant to the patient at hand. The interview should be a fact-gathering mission, and the elements of the history should both tell a story about the current symptoms and provide support for the disposition that the psychiatrist chooses. For example, though the developmental history may not be an important part of the evaluation for an otherwise healthy-appearing adult patient with depression, it may be very important in the assessment of a young patient with obvious cognitive deficits.

The emergency evaluation always includes an assessment of the patient's living situation and social supports, as well as a brief understanding of how he or she spends the day (e.g., at work, at school, or in a day program). This assessment defines the patient's baseline level of function. In addition, a review of the patient's health insurance is necessary because this often dictates the types of treatment programs that are available as disposition options.

Often, presentations to the PES are complicated, and patients may be unable, or unwilling, to provide an accurate history. For this reason an important feature of the evaluation is the collection of history from multiple sources (including family, friends, treaters, police, or emergency personnel who transported the patient). When several informants can be interviewed, data can be corroborated from the various sources, which can help the psychiatrist make informed disposition decisions.

THE MEDICAL EVALUATION

For any patient treated at an ED with an altered mental status (be it a change in cognition, emotional state, or behavior), it is crucial to rule out an underlying medical condition that causes or contributes to the problem. A change in mental state may indicate a primary psychiatric condition, a primary medical condition with psychiatric symptoms, delirium (an acute and reversible condition secondary to a medical illness), or dementia (a chronic condition associated with long-term, irreversible brain pathology). It is important to consider medical etiologies for any condition that appears psychiatric in nature because many psychiatric hospitals have limited resources to diagnose and treat medical conditions. The ED medical evaluation may be the most comprehensive that the patient receives. A missed medical diagnosis because of an assumed psychiatric diagnosis could result in dire consequences for the patient.

A medical work-up should be considered for any new onset of psychiatric symptomatology or any significant change or exacerbation of symptoms. This initial medical work-up is often referred to as *medical clearance*, a term that generally refers to a medical evaluation aimed at ruling out underlying medical conditions that cause or contribute to a psychiatric presentation. Although much attention has been paid to defining a standard for medical clearance, there is no clear consensus regarding the required elements of the medical evaluation.[16,17]

One retrospective study of 212 consecutive patients who underwent a psychiatric evaluation at an ED demonstrated that among patients with a known psychiatric history and no medical complaints (38%), screening laboratories and radiographic results yielded no additional information; those patients could have been referred for further psychiatric evaluation with the history, the physical examination, and stable vital signs alone. Among the patients deemed to require further medical evaluation (62%), all had either reported medical complaints or their medical histories suggested that further evaluation would be necessary before psychiatric referral.[18] Another study of the medical evaluation of ED patients with new-onset psychiatric symptoms demonstrated that two thirds had an organic cause for their psychiatric symptoms.[19] These studies suggest that careful screening is important among patients with new-onset symptoms, but additional medical tests may be of little benefit among patients with known psychiatric disorders and without physical complaints or active medical issues.

The medical evaluation should involve a thorough medical history, a general review of systems, and the assessment of vital signs, followed by a physical examination or laboratory tests (or both) as indicated. Practitioners should be vigilant of characteristics (e.g., homelessness or IV drug abuse), which may put a patient at risk for additional medical conditions. The medical tests to consider are listed in Table 39–3.

THE SAFETY EVALUATION

The safety evaluation is a mandatory component of every emergency evaluation and assesses the likelihood that an individual will attempt to harm himself or herself or someone else. Suicide is the eighth leading cause of death in the United States, and more than 90% of patients who commit suicide have at least one psychiatric diagnosis.[20] Patients 15 to 24 years of age and those over 60 are in the highest-risk groups for suicide.

The psychiatrist must ask about thoughts, plans, and intent of suicide and homicide. These questions should be followed up with more specific questions about access to the means for harm. If a patient has a plan or the intent to commit suicide, the lethality of the plan, as well as the patient's perception of the risk, must be assessed. A medically low-risk plan may still coincide with a strong intent to die if the patient believes that the lethality of the attempt is

TABLE 39–3 Tests to Consider in the Medical Evaluation of Patients with Psychiatric Symptoms

- Complete blood count ([CBC] to monitor for infection, blood loss)
- Electrolytes, blood urea nitrogen (BUN), creatinine (metabolic changes, hyponatremia or hypernatremia, abnormal kidney function, dehydration)
- Glucose (hypoglycemia or hyperglycemia)
- Liver function tests and ammonia (e.g., liver dysfunction due to hepatitis or alcohol abuse)
- Pregnancy test
- Serum toxicology screen (ingestion, intoxication, poisoning)
- Medication levels (ingestion of medications, e.g., lithium and tricyclic antidepressants)
- Urine toxicology screen (to identify or confirm substance abuse)
- Calcium, magnesium, and phosphorus (hypoparathyroidism or hyperparathyroidism, eating disorders, poor nutrition)
- Folate, thiamine (alcohol dependence, poor nutrition, depression)
- Vitamin B_{12} (megaloblastic anemia, dementia)
- Thyroid-stimulating hormone; this result may not be available immediately, but it may be available during an extended observation period (hypothyroidism or hyperthyroidism)

The following tests and imaging studies may also be considered in the medical work-up:

- Lumbar puncture (infection, hemorrhage)
- Electroencephalogram (seizure, changes due to ingestion of medications, dementia)
- Computed tomography (CT) (acute hemorrhage or trauma)
- Magnetic resonance imaging (MRI) (higher resolution than CT for potential brain masses or lesions, posterior fossa pathology, or when radiation exposure is contraindicated)

Adapted from Alpay M, Park L: Laboratory tests and diagnostic procedures. In Stern TA, Herman JB, editors: *Psychiatry update and board preparation,* New York, 2000, McGraw-Hill.

high. Similarly, the possibility that the patient could have been rescued if he or she had followed through on the plan should be evaluated; an impulsive ingestion of pills in front of a family member after an argument conveys less risk than a similar attempt in a remote location. If a patient has attempted suicide previously, details of that attempt may facilitate an understanding of the current risk. In addition, the clinician should assess other risk factors for suicide, which include the presence of a major mental illness, substance abuse, impulsivity, family history of suicide, recent loss (social, occupational, or financial), chronic illness, and access to lethal means.

The assessment of violence is similar to the assessment of suicide risk. Every patient should be asked about thoughts to harm others, as well as the patient's potential plans and intent. Observation of the patient's mental status, behavior, and impulsivity during the interview provides important information. Because previous behavior is the best predictor of future behavior, if there is any suspicion of impending violence, it is important to establish previous violent thoughts and behaviors, triggers leading to those events, and their relationship to substance abuse. Questions about legal issues related to violence are also appropriate. In addition, the target of violence should be assessed. Violence may lack a specific target or be directed toward a specific individual. If there is a likelihood of directed violence toward an identified person or persons, there will be a duty to warn the identified target.

The safety evaluation should include contact with others who know the patient. Although civil commitment laws differ from state to state, most states have provisions for the containment of a patient who is deemed at risk for harm to self or others; however, in many cases a patient with suicidal or homicidal ideation will choose voluntary hospitalization. In cases in which the patient has acknowledged suicidal or homicidal ideation, but it has resolved during the course of the emergency visit, care must be taken to create a clear plan for steps that the patient should take if the feelings or thoughts return. Most often, these involve contact with family members and treaters and a return to a psychiatric evaluation center or ED.

PSYCHIATRIC SYMPTOMS AND PRESENTATIONS

Diagnosis using *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) criteria[21] can be difficult in the PES because patients are seen at a single point in time, often in the worst crisis of their lives. Although patients will not necessarily fit the criteria exactly, a search for the most common disorders (e.g., mood disorders, psychosis, anxiety disorders, substance abuse, and a change in mental status caused by a medical etiology [such as delirium]) will facilitate assessment. The following pages will outline some of the most common psychiatric presentations and patient characteristics in the ED.

The Depressed Patient

Depression is a common reason for seeking treatment at a PES. The severity of the depression may vary from mild to extremely severe; it may occur with or without psychosis or suicidal thinking. Anhedonia and other neurovegetative symptoms of depression are common complaints. Anxiety or anger attacks are often co-morbid with depression, and a history of mania must be assessed in every depressed patient to screen for bipolar disorder. Other medical conditions, especially hypothyroidism, must be considered. The severity of symptoms and the ability to participate in work and other routines may contribute to a diagnosis; however, the assessment of safety is essential in treatment planning.

The Anxious Patient

Although symptoms of anxiety may reflect a primary anxiety disorder, anxiety often heralds other disorders. Patients with psychosis may first describe anxiety about people who might try to harm them; patients with depression may have anxiety about financial or relationship difficulties. Psychomotor agitation, fidgeting, and pacing co-occur with anxiety but may also correlate with psychosis, alcohol withdrawal, or cocaine intoxication. Medical problems (e.g., hyperthyroidism, delirium) and medication side

effects (e.g., akathisia) may also be confused with anxiety. Chest pain and shortness of breath resulting from a panic attack are also common presentations to the ED that will require thorough medical evaluation in concert with a psychiatric evaluation.

The Psychotic Patient

Patients with psychosis suffer from disorganized thinking, hallucinations, delusions, or other forms of disordered thought (e.g., ideas of reference, thought broadcasting, or thought insertion). Patients with psychosis vary greatly in the severity of their symptoms; they may be affected by paranoia that has undermined their work or relationships or suffer from loose associations, delusions, or aggressive behavior. Because some patients have lost touch with reality and may be at risk for agitation or dangerousness, awareness for the safety of staff and other patients must be maintained. Among patients with new-onset psychosis, severe anxiety is common, and it may be difficult to differentiate from paranoia.

It is also important to rule out medical causes for symptoms, particularly among patients who lack a history of psychosis and whose age falls outside the usual range for the onset of psychosis (late teens to mid-20s). Auditory hallucinations are more common with psychiatric disorders, whereas visual hallucinations are more common in medical disorders, delirium, and substance abuse. Seizure disorders, delirium, metabolic changes, infections, ingestion, and withdrawal from alcohol or benzodiazepines should be considered in the differential for new-onset psychosis. Among the elderly with new-onset hallucinations, delirium and dementia should be strongly considered.

The Manic Patient

Manic patients can often be disruptive and provocative, with pressured speech, grandiosity, irritability, and flight of ideas. Such patients may be dressed or behave in an odd or seductive manner and may have impulsively traveled long distances. In mania with psychosis, paranoid thoughts and delusions or hallucinations often arise, leading to a lack of insight. It is important to assess for medical causes of mania, as well as for acute intoxication with cocaine or phencyclidine (PCP). Steroids can also contribute to manic symptoms, as can antidepressant medications.

The Patient with Intoxication or Withdrawal

Patients with substance intoxication or withdrawal often come to the attention of emergency personnel because of acute medical symptoms (e.g., unconsciousness, difficulty breathing, confusion). However, they may also come to the ED requesting referral for detoxification services or other substance abuse treatment. Substance abuse is frequently co-morbid with other psychiatric conditions. The following will outline the substances of abuse seen in the PES and key concepts in the assessment of substance abuse.

Alcohol

Alcohol intoxication can cause disorientation, ataxia, and slurring of speech; when high blood alcohol levels (BALs) are present, respiratory depression, coma, and death may follow. Chronic alcohol use leads to tolerance and a higher BAL without severe symptoms. For alcohol intoxication, treatment typically consists of observation, maintenance of the airway, and administration of IV fluids.

Alcohol withdrawal is medically dangerous and can be life-threatening. In its mildest form, alcohol withdrawal leads to irritability, tremor, autonomic instability (associated with an elevated blood pressure, pulse, and temperature), and sometimes seizures. Patients with a high tolerance for alcohol may be in alcohol withdrawal despite the presence of alcohol in their blood because of a relative withdrawal from the substance compared with their usual (intoxicated) state. Treatment of alcohol withdrawal generally involves use of oral or IV benzodiazepines (initially titrated to normalize vital signs and then tapered over several days), thiamine (to prevent Wernicke's encephalopathy), folic acid, and fluid repletion. A high-potency neuroleptic (e.g., haloperidol) can decrease psychomotor agitation associated with withdrawal. Prophylactic treatment with benzodiazepines and thiamine for patients at high risk of alcohol withdrawal is beneficial.

In more severe cases, alcohol withdrawal can lead to delirium tremens, which consists of a change in mental status, disorientation, visual hallucinations, and severe autonomic instability. Delirium tremens is a medical emergency with a mortality rate of 5% to 10%; it requires immediate medical care and treatment with IV benzodiazepines, thiamine, and fluids.[22]

Benzodiazepines and Barbiturates

Intoxication with benzodiazepines and barbiturates appears similar to intoxication with alcohol; it involves the presence of slurred speech, confusion, ataxia, and respiratory depression. Withdrawal is also dangerous and life-threatening; management is similar to that of alcohol withdrawal, including oral or IV benzodiazepines or barbiturates.

Opiates

Abused opiates seen in the PES include heroin, oxycodone, methadone, hydrocodone, and fentanyl. Intoxication can be identified by drowsiness and pupillary constriction; in addition, patients describe a sense of euphoria or calm. The greatest risk of opiate overdose is respiratory depression. Frequently, accidental overdoses occur when patients either miscalculate their dose after a period of abstinence (because of decreased tolerance) or when the drug is of a higher purity than expected. Opiate intoxication can be treated in the emergency setting with naloxone, an opioid antagonist, although drowsiness and respiratory depression may return as the naloxone wears off. In addition, the naloxone will cause an acute and uncomfortable withdrawal syndrome that often leads to agitation on awakening.

Opiate withdrawal is not life-threatening. Early symptoms include anxiety, yawning, diaphoresis, rhinorrhea, dilated pupils, abdominal and leg cramping, and chills. Elevated blood pressure, pulse, and temperature, as well as nausea and vomiting, will follow. A urine drug screen can usually confirm recent opiate use. In the emergency setting, symptomatic treatment consists of the use of clonidine for autonomic instability (monitor for hypotension), dicyclomine for abdominal cramps, and quinine sulfate for

leg cramps (limit to once per day on account of cardiovascular or renal toxicity). The patient can be referred to a licensed detoxification facility for methadone or buprenorphine detoxification.

Cocaine

Patients with cocaine abuse most often are treated at the ED suffering from medical symptoms (e.g., chest pain) or psychotic symptoms. The symptoms of cocaine intoxication include euphoria and grandiosity, irritability or agitation, lack of sleep, dilated pupils, and psychomotor restlessness (e.g., pacing, hand wringing, foot tapping, or choreiform-like movements). Patients may experience elevated blood pressure and temperature, tachycardia, palpitations, chest pain, and shortness of breath. Some patients experience hallucinations, paranoia, or agitation; antipsychotic medications are a useful treatment. With very high doses of cocaine, a patient can experience decreased responsiveness, seizures, and severe autonomic changes followed by coma and risk of cardiac arrest or ventricular fibrillation; treatment is supportive. Serum toxicology screens for cocaine, if available, may confirm very recent use of cocaine (within hours), whereas urine toxicology may confirm use up to 24 hours previously.

Although there is no clearly described withdrawal syndrome for cocaine, patients often experience a very strong urge to sleep once cocaine has left their system. They also describe feeling weak and tired, with cravings for days to weeks after use has ended.

Crystal Methamphetamine

Intoxication with crystal methamphetamine and other amphetamines may be recognized by mood lability or irritability, psychomotor agitation, confusion, and sweating. More severe cases may include paranoia, hallucinations, seizures, and fever. Treatment is supportive. Psychotic symptoms can be treated with antipsychotics.[23] Withdrawal from amphetamines leads to agitation, irritability, sleep disturbance, psychomotor agitation, and depressed mood.

Phencyclidine

Phencyclidine (PCP; also known as "angel dust") intoxication is usually heralded in the emergency setting by agitation, paranoia, hallucinations, and violent or bizarre behavior. Intoxication can cause nystagmus, ataxia, and slurred speech; at higher doses it may lead to seizures, hypertensive crisis, coma, and death. Treatment is supportive and should include management in a contained and quiet setting (because of the risk of violence). Antipsychotics, particularly high-potency neuroleptics (e.g., haloperidol), may be useful. PCP-induced psychosis can last from days to weeks; these patients may require hospitalization if symptoms do not improve within several hours.[23] There is no withdrawal syndrome from PCP.

Marijuana

Marijuana is a common drug of abuse among patients treated at the PES. Symptoms of intoxication include relaxed or elevated mood, alteration in the perception of time, tachycardia, and conjunctival injection.[23] Patients may report paranoia or hallucinations, although in these cases it is important to assess for other drugs of abuse and for underlying psychiatric disorders as well.

The Patient with a Change in Mental Status

When treating a patient who displays a significant change in mental state, the emergency psychiatrist must identify the underlying etiology. In general, changes in mental state represent delirium, dementia, or psychiatric conditions. Because psychiatric conditions are often a diagnosis of exclusion in the acute presentation, delirium and dementia must be ruled out. The Folstein Mini-Mental State Examination[24] can be useful to screen for cognitive changes. Dementia, a chronic and progressive condition characterized by memory and other cognitive impairments, is discussed elsewhere in this textbook (see Chapter 11).

Delirium, as defined by DSM-IV,[21] is a fluctuating state of consciousness and cognition that is caused by a variety of medical conditions. Delirium, also known as acute confusional state or encephalopathy, typically has an acute onset (over hours to days), has a fluctuating course, and is reversible. Disturbance in consciousness, reduced awareness of the environment, attentional difficulties, disorientation, and an inability to think or speak coherently are common symptoms of delirium. Psychomotor agitation is also common, though psychomotor retardation is possible. Symptoms typically associated with psychiatric diagnoses (e.g., auditory and visual hallucinations, acute changes in mood, psychotic or disorganized thoughts) may also be seen in delirious states. In general, it can be said that any medical condition has the potential to cause any type of alteration in mental state. Although certain underlying medical conditions are commonly associated with certain symptoms (e.g., anxiety or agitation with pheochromocytoma, mania with use of corticosteroids, and depression with interferon treatment), the underlying medical condition cannot be diagnosed by its presentation alone; all possible medical conditions must be considered.

Delirium may represent a serious or life-threatening condition. These conditions include Wernicke's encephalopathy, hypoxia, hypoglycemia, hypertensive encephalopathy, intracerebral hemorrhage, meningitis/encephalitis, poisoning (exogenous or iatrogenic), and seizures. Their assessment and treatment are outlined in Table 39–4. Other, less urgent conditions (including subdural hematoma, septicemia, subacute bacterial endocarditis, hepatic or renal failure, thyrotoxicosis or myxedema, delirium tremens, anticholinergic psychosis, and complex partial status epilepticus) may require acute interventions.[25] Once acute causes of delirium have been ruled out, other potential causes of delirium should be considered (see Chapter 10 for a more detailed discussion of delirium). When a medical diagnosis has been made, the primary objective is to address the underlying etiology. Nonetheless, symptomatic treatment of confusion or agitation associated with delirium should be administered.

If medical causes of delirium have been ruled out, a primary psychiatric diagnosis should be considered. A diagnosis of an Axis I primary mood or thought disorder often can be made on the basis of symptomatology. If the patient does not meet diagnostic criteria for an Axis I disorder, an Axis II personality disorder or personality traits should be considered. Agitation or threatening behavior may not be due to either an Axis I or an Axis II condition but may be

TABLE 39–4 Potentially Life-Threatening Causes of Delirium

CONDITION	DIAGNOSTICS	TREATMENT
Wernicke's encephalopathy	Clinical triad: change in mental status, gait instability, ophthalmoplegia	Thiamine 100 mg IM (may see improvement over the course of hours) status, gait instability, ophthalmoplegia
Hypoxia	Oxygen saturation/ABGs	Treat etiology
Hypoglycemia	Blood glucose	PO/IV administration of glucose, dextrose, sucrose, or fructose
Hypertensive encephalopathy	Blood pressure	Antihypertensive medication
Hyperthermia/hypothermia	Temperature	Cooling or warming interventions
Infectious process (e.g., sepsis, bacteremia, subacute bacterial endocarditis)	Infectious disease work-up	Treat infectious agent or site
Intracerebral hemorrhage	MRI/CT	Per hemorrhage type or location
Meningitis/encephalitis	LP, MRI	Antibiotic medication
Metabolic (e.g., chemical derangements, renal failure, hepatic failure, thyroid dysfunction)	Laboratory investigations	Per derangement
Poisoning/toxic reaction (e.g., environmental exposures, medications, alcohol, illicit substances)	Toxicology panel	Per toxin
Status epilepticus	EEG	Anticonvulsants and/or IV benzodiazepines

ABGs, Arterial blood gases; *CT,* computed tomography; *EEG,* electroencephalogram; *IM,* intramuscular; *IV,* intravenous; *LP,* lumbar puncture; *MRI,* magnetic resonance imaging; *PO,* oral *(per os)*.

representative of longer-standing problems with behavior regulation and thus may not be amenable to acute psychiatric treatment.

The Agitated Patient

In the emergency setting, evaluation and treatment may be complicated by *agitation*, defined as the physical manifestation of internal distress. Agitation may be a sign of psychiatric distress or be related to an underlying medical etiology. Early signs include pacing, tapping of the fingers and feet, sighing, moaning, breathing heavily, fidgeting, staring intensely, and appearing distracted by internal stimuli. Physical signs (e.g., elevations in blood pressure, pulse, or respiratory rate) may be noted. Pressured or loud speech, invasion of others' personal space, clenching of the jaw, or tension of other muscles often indicates escalating agitation. Agitation can herald a psychiatric emergency; it jeopardizes the safety of the patient as well as others in the treatment environment, and it impedes optimal evaluation and treatment.

Agitation is best managed by attempting to prevent or treat it as early as possible. The agitated patient should be enlisted in this task (i.e., to monitor his or her own internal state, report increases in anxiety or distress, and consider effective means for the reduction of distress in order to avert any behavioral dyscontrol). Modulation of the environment (by decreasing interpersonal interactions and auditory or visual stimulation) is an important initial step in management. A safe environment (free from the risk of harm) should be created to reduce agitation for some patients. Staff or family members should be available to communicate with the patient. Offers of food and drink may also be helpful.

Rapid movements, yelling, slamming doors, and throwing objects are important signals that the patient is out of control. Threats or attempts to harm oneself or others signal that more must be done to keep the patient and the staff safe. If there is a risk of harm to the patient or others, a physically safe environment, without allowing the patient access to objects that could be used as weapons and using the least-restrictive means possible, should be arranged. Pharmacologic interventions to reduce agitation should also be considered. Further discussion of management of agitation, including medications and restraint and seclusion, is provided later in this chapter.

Drug or alcohol intoxication or withdrawal (including nicotine withdrawal), delirium, injury, pain, dementia, psychosis, mania, anxiety, and borderline and antisocial personality disorders are just a few of the diagnoses that lead to agitation in the PES.

MANAGEMENT OF ACUTE SYMPTOMS

The primary goal in the PES is to manage acute crises. The intervention chosen will depend on the patient's needs, the severity of illness, and the time and resources available. For some patients the intervention consists of the opportunity to speak to an understanding clinician, who can form an alliance, demonstrate empathy, and provide reassurance. Other patients require IM medication or restraint for agitation. Between those extremes are various therapeutic interventions designed to decrease the acuity of the patient's situation, provide education about mental illness and treatment, and help the patient and family members make informed decisions about treatment. The interventions provided in the PES can be broken down into four categories: the environmental intervention,

the psychological intervention, the medication intervention, and use of restraint and seclusion (the option of last resort).

Environmental Intervention

Although resources and space may be limited, the environmental intervention is of critical importance for a patient in crisis. The environment will determine if the patient will sit, stand, or lie on a stretcher; if he or she will wear street clothes or a hospital gown; and if the clinician will be alone with the patient or be accompanied by family members or other emergency staff. If possible, the interview should occur in a quiet, clean setting, where the patient and clinician can both sit comfortably and not be overheard by strangers in the ED. This, of course, depends on the patient's behavior; the presence of other staff or security in the ED is paramount for safety when working with a patient who appears agitated or impulsive. Attention to the patient's basic needs (e.g., offering a blanket in a cold room, being sure that the patient has access to a restroom, and offering the patient something to drink or eat) will assist in forming an alliance.

Psychological Intervention

Forming an alliance during a brief interview in an emergency setting can be a challenge. PESs are often busy, with long waits for evaluation and treatment; clinicians who work there are often pulled in different directions. A sympathetic comment after a patient has experienced an extended wait can facilitate an alliance.

The psychiatrist should allow the patient a few minutes at the beginning of the interview to describe the situation. Beginning the interview with several open-ended questions will help the patient feel heard, allow a brief assessment of the patient's mental status, and give the psychiatrist time to formulate a plan to guide the course of the interview. Because of time constraints, the PES evaluation often involves more closed-ended screening questions (to rule out major symptoms or diagnoses) than occur in other psychiatric arenas. Empathic comments demonstrate concern and allow the clinician to interject with appropriate questions to guide the interview.

In the PES the psychological intervention is often pragmatic. It may consist of formation of an empathic connection and education about psychiatric symptoms, treatments, or the mental health system. The clinician may help the patient gain insight into the problem at hand and brainstorm about alternative solutions. Some dependent patients will want help in making a decision about treatment, whereas the clinician may want to lead narcissistic patients to create solutions themselves. The psychiatrist may offer reassurance that a problem is not as overwhelming as it seems or that help is available. The simple act of validating a patient's feelings of being overwhelmed can often be a therapeutic intervention. The patient's and the family's unstated wishes or concerns should be identified and managed.

Questions or techniques that allow the patient to regress are rarely helpful in the PES; instead, the patient should be encouraged to identify coping skills that have been helpful at other times. Though the patient should be allowed to describe difficult feelings and release tension, there should be an expectation that the patient behave within the boundaries of what is safe and appropriate in that environment (e.g., it is not appropriate to punch walls to demonstrate anger). There will be times when a patient is too ill to participate within these boundaries, and accommodations can be made, but this circumstance usually indicates a need for referral to a higher level of care.

Another key to providing therapeutic care in the emergency setting is to understand potential countertransference reactions. Amid the stress of overcrowded and chaotic EDs and PESs, staff members at every level can become cynical and angry. Although these reactions are understandable, care must be taken to separate these frustrations from the health and welfare of patients. Acting on countertransference reactions can lead to unprofessional behavior and can compromise clinical care and safety. For many years at Massachusetts General Hospital, psychiatric residents have participated in a weekly supervision session that focuses on recognizing countertransference reactions and enhancing resilience after long nights in the PES.[26] Awareness of stress levels and scheduled breaks (to eat meals and relax during long shifts) are necessary to the provision of good care on an emergency service.

Intervention with Medication

Never underestimate the power of medication in a psychiatric emergency. For some patients, particularly those who are psychotic or acutely agitated, administering medication may be the primary intervention. Medication can decrease anxiety and paranoia, improve disorganization, and help a manic patient to sleep. Benzodiazepines decrease symptoms of alcohol withdrawal. Some patients who are initially overwhelmed are able to participate in the interview and psychological intervention only after medication has been administered. Medication should be considered early and often in the process of an evaluation. If the patient uses a medication at home on an as-needed basis for similar symptoms or has tried a medication before, the same medication can be offered to minimize potential side effects of new medications. If the patient has not tried medications, consideration of the symptoms, differential diagnosis, intended means of administration of the medication, and potential side effects will help narrow down the options.[27,28]

Potential medication regimens in the PES include benzodiazepines (particularly lorazepam [0.5 to 1 mg] PO or IM; a benzodiazepine should always be the first choice if alcohol withdrawal is suspected); atypical neuroleptics (e.g., risperidone [0.5 to 1 mg] in oral tablet, liquid, or rapidly dissolving form or olanzapine [2.5 to 5 mg] in oral tablet or rapidly dissolving form); and high-potency neuroleptics (e.g., haloperidol) combined with a benzodiazepine and an anticholinergic agent (diphenhydramine or benztropine) for more severe agitation. A commonly used combination that can be administered PO or IM is haloperidol 5 mg and lorazepam 2 mg, plus diphenhydramine 25 to 50 mg (for prophylaxis of dystonia). Newer parenteral formulations of atypical neuroleptics for the management of acute agitation are also available; options include olanzapine 10 mg IM, ziprasidone 10 to 20 mg IM, and aripiprazole 9.75 mg IM. Table 39–5 lists a range of medications that are used for adult patients in the PES.

TABLE 39–5 Medications Frequently Used in the Psychiatric Emergency Service for Adult Patients

MEDICATION	STARTING* DOSE	FORMULATION AVAILABLE
Benzodiazepines		
chlordiazepoxide (Librium)	25-50 mg	PO/IM/IV
clonazepam (Klonopin)	0.5 mg	PO
diazepam (Valium)	5-10 mg	PO/IM/IV (oral solution available)
lorazepam (Ativan)	0.5-1 mg	PO/IM/IV (oral solution available)
oxazepam (Serax)	15-30 mg	PO
Typical Antipsychotics		
chlorpromazine (Thorazine)	25-50 mg	PO/IM (oral solution available)
fluphenazine (Prolixin)	5-10 mg	PO/IM (oral solution available)
haloperidol (Haldol)	5-10 mg	PO/IM/IV (oral solution available)
perphenazine (Trilafon)	4-8 mg	PO (oral solution available)
Atypical Antipsychotics		
olanzapine (Zyprexa)	5-10 mg	PO/IM†
quetiapine (Seroquel)	25-50 mg	PO
risperidone (Risperdal)	1-2 mg	PO† (oral solution available)
ziprasidone (Geodon)	20 mg (10-20 mg IM)	PO/IM
Other Agents		
benztropine (Cogentin)	0.5-1 mg	PO/IM/IV
buspirone (BuSpar)	5-10 mg	PO
clonidine (Catapres)	0.1 mg	PO
diphenhydramine (Benadryl)	25-50 mg	PO/IM/IV (oral solution available)
gabapentin (Neurontin)	100-200 mg	PO
propranolol (Inderal)	20 mg	PO (oral solution available)
trazodone (Desyrel)	25-50 mg	PO

*Starting doses are for healthy adult patients. Consider lower doses in patients who are elderly or have a history of head injury or mental retardation.

†Also available in an orally disintegrating tablet.

IM, Intramuscular; *IV,* intravenous; *PO,* oral *(per os).*

Elderly patients, patients with mental retardation, and patients with a history of head injuries can be particularly sensitive to anticholinergic side effects or to paradoxical reactions of medications such as benzodiazepines. Smaller initial doses of medication should be used, with increases made slowly in these populations.

Restraint and Seclusion

In general, use of the least restrictive means of restraint is the standard of care in psychiatry. However, this principle must be balanced with the risk of imminent danger as determined by the clinical assessment.

Restraint and seclusion are treatments of last resort when the patient is at imminent risk of harming himself or herself or someone else. Unfortunately, controlled studies comparing the impact of methods of restraint and seclusion are lacking.[29] Recent efforts have focused most on methods for reducing the need for restraint and seclusion in psychiatric settings.

All staff involved in restraint and seclusion should be well trained in the techniques for the safe management of aggressive behavior. Such management begins with the use of verbal de-escalation techniques and environmental interventions (e.g., placing the patient in a private room to decrease outside stimulation). Medication should be offered early in the course of agitation and aggression. If these interventions are not successful, and the patient remains at risk for harm to self or others, seclusion (placing the patient in a locked room alone) becomes an alternative for management. For patients who remain aggressive or at serious risk for harm, physical restraint may be the last resort to maintain their safety and the safety of those around them. Generally, it is the physician who orders restraint or seclusion, but the entire team should be clear about the reason for the restraint and the procedures involved. Each member of the team should feel responsible for maintaining the safety of the patient and the other staff.

The patient in seclusion or restraint should also be monitored at all times. In most facilities there is a limit to the time that the patient may remain in restraint; however, attempts should always be made to remove the restraints as soon as possible. Almost every patient who requires restraint or seclusion can benefit from medication to decrease the symptoms that have led to agitation.

Treatment After the Acute Crisis

The availability of outpatient treatment varies greatly by location and accessible resources in the hospital or the community. Some PESs offer prescriptions for medications on discharge and even provide follow-up while patients are awaiting referral to outpatient facilities. Other programs treat only acute problems and do not prescribe but may have access to urgent appointments or an outpatient program with a short wait list. Either way, after the management of the acute problem, treatment planning is part of every disposition.

The emergency psychiatrist must have a thorough knowledge of the local mental health resources. Inpatient units, crisis stabilization units, residential treatment services, partial hospitalization programs, detoxification units, and outpatient programs serve as alternative levels of care after the PES evaluation. Admission criteria vary, and many programs depend on prior approval by insurance companies. The acuity of the patient's symptoms, the insurance coverage, and the psychosocial support system must all be weighed to determine the appropriate level of care. Decisions made with the patient, the family, and other treaters should be coordinated.

SPECIAL POPULATIONS

The Personality-Disordered Patient

Patients with borderline or antisocial personalities usually require a significant amount of time from PES staff to coordinate their care. Such patients may request special services or favors that are outside of the normal routine of the unit. They may file complaints or even threaten to harm or kill themselves or others if the clinician is unwilling to provide the treatment that the patient prefers. These threats often are statements of desperation, though each statement must be evaluated with the patient's history and current situation in mind.

Problems often occur because of splits between staff members who disagree about how the patient should be managed. The most important aspect of the treatment of these patients is for the PES team to provide clear boundaries regarding the scope of care available, the role of individual staff members, and the goal of the emergency intervention. Outside contacts who know the patient may be able to provide insight for the purposes of the safety assessment.

The Grieving Patient

Management of acute grief (e.g., after a traumatic event or a death within the ED, the loss of a relationship, or the anniversary of a loss) is a common reason for referral to the PES. Grief is the normal response to loss and can manifest in many ways, including feelings of shock, sadness, anxiety, anger, and guilt.[30] The most common symptoms are outlined in Table 39–6, and any of these may be exhibited during the emergency evaluation. Brief periods of hearing the voice of a deceased spouse or feeling unable to participate in the routines of daily life are normal; they allow the patient time to come to terms with the loss. However, extended periods of depressed mood, anhedonia, and other neurovegetative symptoms may indicate an episode of major depression and require more immediate treatment.

The role of the psychiatrist in working with a grieving patient is to provide a supportive environment. Some patients will want to sit quietly, others will want to talk, and others will cry. If the situation is ongoing (e.g., a family member's injury is being treated in the ED), accurate information should be provided and false hope should not be given. Clinicians should help patients recognize how they have handled losses in the past and support similar coping skills.

TABLE 39–6 Symptoms of Grief

Somatic distress
- Throat tightness
- Shortness of breath and sighing
- Muscular weakness
- Loss of appetite and abdominal discomfort or emptiness

Preoccupation with the image of the deceased
- Visualizing the deceased or hearing the voice of the deceased
- Imagining conversations with the deceased

Guilt about things done or not done

Hostility toward others

Changes in behavior
- Pacing or moving aimlessly
- Difficulty initiating the normal routine

Adapted from Lindemann E: Symptomatology and management of acute grief, *Am J Psychiatry* 151(6 suppl):155–160, 1994.

Victims of Domestic Violence and Trauma

Domestic violence (i.e., an individual's use of force to inflict emotional or physical injury on another person with whom the individual has a relationship) affects spouses, partners, children, grandparents, and siblings of all races and genders. Between 2 and 4 million women are abused each year in the United States, and domestic violence has become the leading cause of injury among women between 15 and 44 years of age.[31] Men can also be victims of domestic violence.

Patients in the PES should be asked whether they have been a victim of violence or trauma, whether this contributes to their presenting symptoms, and whether they are safe in their current living environment. Symptoms of posttraumatic stress disorder should be screened for and included in treatment planning. Patients need not be asked to describe explicit details about past traumas. Instead, the patient can be helped to understand that the process of working through trauma should occur with a therapist who can provide long-term support, and then the clinician can provide an appropriate referral.

The Homeless Patient

It is estimated that approximately 20%[6] to 30%[32] of the patients who are treated at PESs are homeless,[6] and this characteristic adds complexity to the psychiatric evaluation. When a patient has insomnia or the fear of being harmed by others, it may be difficult to determine whether the symptoms are due to a psychiatric disturbance or the inherent risks of homelessness. Homeless patients are at greater risk for substance abuse, tuberculosis, skin conditions, and other serious chronic medical conditions (e.g., diabetes, acquired immunodeficiency syndrome [AIDS], and cancer); it is especially important to provide good medical screening during the assessment. The clinician must also account for the patient's housing situation and access to meals and medical care in the course of disposition planning. A treatment plan adapted to these realities is much more likely to succeed[33]; however, despite careful disposition planning, homeless patients are more likely than other patients to have repeat visits to the PES.[32]

EMERGENCY ASSESSMENT OF CHILDREN

Demographics

There are very few studies of emergency psychiatric presentations among children. It is estimated that there are about 434,000 annual pediatric visits for mental health conditions in the United States, which constitutes about 1.6% of ED visits in this age group (younger than age 19). Adolescents between 13 and 17 years of age account for more than two

thirds of the visits, and suicide attempts account for 13% of the visits. The most common diagnoses include substance-related disorders (24%), anxiety disorders (16%), attention-deficit and disruptive disorders (11%), and psychosis (10%). Nineteen percent of ED mental health visits result in inpatient admission, compared with only 9% of non–mental health visits in the same age group.[34] A study that analyzed data about young people (ages 7 to 24 years) treated at EDs for deliberate self-harm reported an annual rate of 225 per 100,000.[35] Among those patients, 56% were diagnosed with a mental disorder (including 15% with depression and 7% with substance use disorders), and 56% were referred for inpatient admission. Frequent precipitants for ED visits include family crises (e.g., death, divorce, financial stress, domestic abuse), disturbed or truncated peer relationships, and recent change of school.[36-38]

Basic Principles

Few child psychiatric emergencies are life-threatening; all result from the complex interaction of psychosocial, biological, and systems issues.

The primary goal is the safety of the child, and this principle must guide all subsequent plans for treatment or disposition. The clinician must always consider the possibility of abuse or neglect as the precipitant for the visit to the ED.

The evaluation itself is based on a developmental approach. The clinician must choose age-appropriate techniques with which to conduct the examination, and the assessment must be based on a solid understanding of normative behavior within each developmental stage.

The emergency psychiatric assessment of a child is often more complicated and time-consuming than the evaluation of an adult. The clinician must be familiar with resources for children and families within the community mental health system. Thorough evaluation often requires phone calls to outside providers (including pediatricians, school administrators, guidance counselors, and outpatient mental health professionals).

The Evaluation

The initial step in the assessment of a child in the PES is identification of the child's legal guardian(s). In routine cases the legal guardians are the biological parents who accompany the child to the hospital. In complex cases the child's legal guardian may be court-ordered to be only one parent, another relative, a foster parent, or a representative of the state agency responsible for the care and protection of children. Custody can be split into several parts, and one guardian can have legal (or decision-making) custody while another guardian retains physical custody. Sometimes a child remains in the home of the biological parent, but a state agency assumes responsibility for decisions regarding medical care. The clinician should never assume that the adult who accompanies the child is the legal guardian or that a friend or neighbor can offer consent for the assessment. Except in very rare, extenuating circumstances, the legal guardian must come to the assessment center and participate in the evaluation because that person will be a key factor in disposition.

The clinician who evaluates children in an ED should base the method of assessment on the age of the child, although the interview may also include many standard elements of the psychiatric history as listed in Table 39–1. The *style* and *process* of the interview and mental status examination depend on the age of the child.

Preschoolers (1 to 5 years), many of whom may be preverbal, are unable to provide a coherent narrative of the events leading up to the ED visit. The clinician must interview the parent or guardian to obtain the details of the history but should also pay careful and close attention to the interaction between the child and the caregiver as well as to the child's hygiene. Mental status assessment should focus on the child's behavior, level of agitation, mood, affect, and ability to take direction and accept reassurance from the caregiver. Common precipitants for ED visits in this age group include impulsive or dangerous behaviors (e.g., running away from home or from a caregiver in a public place, fire setting, or hitting a younger sibling).

Latency-age children (5 to 11 years) can often provide a clear description of the event that brought them to the ED but usually lack the ability to place the specific event within a larger context. It is often helpful for the clinician to interview the parent or caregiver before meeting with the child. Assessment of the mental status includes observations of the child's interaction with the caregiver; attention to speech and language; and direct questions about mood, affect, and risk for self-injurious behavior. Children who are younger than 6 years of age might retain their magical thinking and thus not yet be able to distinguish fantasy from reality.

Adolescents (12 to 18 years) should ideally be interviewed before the clinician speaks with caregivers or other concerned adults. This approach reinforces and supports the adolescent's desire for autonomy and control. Mental status assessment involves assessment of mood, affect, thought process and content, cognition, insight, and judgment, as well as suicidal and homicidal ideation.

Finally, the evaluation must include an assessment of the social situation. Being familiar with the local communities and school systems around the hospital will help the clinician better understand the social context of the PES visit. An inner-city school with few resources is very different from a wealthy suburban school with counselors and school nurses who can identify new problems and monitor medications; knowing these details will help the clinician make appropriate decisions about the treatment plan. It is also important to know the types of treatments that the child has accessed before. A child whose severe depression has failed to improve after several medication trials and participation in months of residential treatment programs is very different from one who seeks treatment for the first time with anxiety symptoms. The previous treatment history will inform the disposition decision.

As with adult patients, the options available for disposition vary widely by location and accessible resources through the hospital and community programs. The clinician must have an accurate working knowledge of the available resources and how to access them in order to facilitate appropriate disposition planning for the child in crisis.

Management

The agitated or aggressive child requires rapid diagnostic assessment and management. The differential diagnosis should focus first on organic (medical) causes of the behavior (including elevated lead levels [particularly for children under 5 years]), seizure disorders, metabolic abnormalities, medication (prescription or over-the-counter) ingestion or overdose, withdrawal from medication or recreational drugs, hypoxia, infection, and intoxication.

If an organic etiology is suspected, vital signs and laboratory studies should be obtained immediately. Laboratory studies might include a complete blood count (CBC); serum electrolytes (including blood glucose); serum and urine toxic screens;[39] and, in young women, a pregnancy test. It is usually helpful to control the environment and decrease stimulation by placing the child in a private room, sometimes with one family member who can be soothing and reassuring. With very young children, it can be helpful to offer food and drink.

Sometimes it is necessary to administer medication to control agitated or acutely intoxicated children, particularly if they are in danger of harming themselves or others. It is best to ask the parent or guardian which medications the child usually takes and administer either an additional dose of a standing medication or an existing as-needed medication. Administration of an oral medication is always preferable to an IM injection, but it is not always possible if the child is unable to respond to verbal direction or limit setting.

The choice of medication and route of administration depend on the severity of the agitation and the age of the child. Medications to consider include diphenhydramine (1.25 mg/kg per dose PO or IM if the child has no history of paradoxical excitation); clonidine (at a dose of 0.05 to 0.1 mg PO); an atypical neuroleptic (e.g., risperidone [0.5 to 1 mg] in oral tablet, liquid, or rapidly dissolving form or olanzapine [2.5 to 5 mg] in oral tablet or rapidly dissolving form or IM preparation); benzodiazepines (particularly lorazepam [0.5 to 1 mg] PO or IM can be helpful but can also cause paradoxical excitation and disinhibition); and for an older, acutely agitated adolescent, it is appropriate to use a high-potency neuroleptic (e.g., haloperidol) combined with a benzodiazepine and an anticholinergic agent (diphenhydramine or benztropine).

Physical restraints (e.g., locked leather restraints) are sometimes necessary and should be placed only by trained security personnel according to guidelines established by the appropriate state Department of Mental Health. Family members should leave the room during any form of restraint and be debriefed later about the course of events and reasons for particular interventions.

LEGAL RESPONSIBILITIES OF THE EMERGENCY PSYCHIATRIST

The emergency psychiatrist is responsible for knowing the legal regulations and local standards of care related to capacity evaluations, confidentiality, release of information, commitment standards, and mandatory reporting for patients with psychiatric symptoms who are treated at the PES. Although specific standards may differ, the following features may assist with understanding these general responsibilities. In all cases it is important to document carefully all steps involved in the decision-making process and to consult with a forensic psychiatrist or legal counsel trained in mental health law in difficult cases.

Capacity Evaluation

The capacity evaluation is often requested by other medical providers to determine whether a patient has the ability to make an informed decision about a particular medical procedure or treatment course. The determination of capacity is not based on legally determined criteria but rather on widely accepted clinical standards. In addition, a capacity evaluation applies to a single decision at a single moment in time; when in question, the patient's ability to make global medical decisions is determined through a court-based competency hearing and is outside the purview of the hospital psychiatrist. A patient is presumed to have capacity to make medical decisions until proven otherwise. The key components of this evaluation include the assessment of whether the patient can express a choice that is stable over time, understand the relevant information, appreciate the consequences of the decision, and manipulate all of the data in a logical fashion. In addition, capacity exists on a sliding scale that incorporates a risk:benefit analysis of the particular treatment in question; a patient may have capacity to decline a treatment with low benefit and high risks and at the same time not have the capacity to decline a treatment with high benefit and low risks. In many cases the psychiatrist will find that the patient's ability to make a clear and rational decision depends on an opportunity to learn more about the specific medical procedure. If the psychiatrist can coordinate further communication between the medical or surgical team and the patient, the capacity evaluation may become unnecessary.

Confidentiality and Release of Information

The care of psychiatric patients requires a strong commitment to confidentiality; in the emergency setting, all attempts are made to gain permission for any collateral contact regarding the patient's condition. However, for patients who present a risk of harm to themselves or others, it is sometimes necessary to consult with treaters or family members without the patient's consent. It is important to document clearly why the contact was made and to use the contact to gain information that will assist in the safety assessment. Although it is reasonable for the clinician to receive information necessary to maintain the safety of the patient, the clinician should limit the confidential information provided to the other party.

Another situation in which a breach in confidentiality may be justified is when a clinician learns that a patient is at imminent risk to harm another individual. The standards for the clinician's duty to protect the potential victim are different in every state, but most are based on the original Tarasoff case in California in 1976.[40]

Civil Commitment

Civil commitment refers to the state's ability to hospitalize an individual involuntarily because of risk of harm due to mental illness.[40] The commitment regulations and

processes vary by state. Most regulations incorporate risk of harm to self, risk of harm to others, and inability to care for self, all owing to psychiatric pathology, as the basis for civil commitment. The safety evaluation described in this chapter provides the clinician with a basic outline of an assessment to determine risk and is an important component of the assessment that may lead to civil commitment.

Mandatory Reporting

Most states have regulations regarding mandatory reporting for suspected child abuse,[41] elder abuse,[42] and abuse of individuals with mental retardation. In most cases mandatory reporters are obligated to report situations in which they suspect abuse, whether or not they have clear evidence; they are protected against claims of a breach of confidentiality under these conditions.[40] Mental health clinicians should be aware of whether they are considered mandatory reporters in their state and how to contact the appropriate agencies.

ROLE OF THE PSYCHIATRIST IN DISASTER PREPARATION

In the face of recent catastrophic events such as terrorist attacks and large-scale natural disasters, efforts have been undertaken to prepare medical teams to manage disasters. The role of psychiatry in this response is often overlooked until the actual event occurs. In the midst of a disaster response, the psychiatrist's ability to tolerate extreme affect becomes immediately useful. The psychiatrist can offer aid in at least four different arenas: organizational aid and planning for disaster response; treatment of psychological reactions to stress (using pharmacologic, psychotherapeutic, and interpersonal interventions), acutely and over the long term; provision of support to family members and friends of victims of the disaster; and support of medical staff who participate in disaster response (including emergency personnel, hospital staff, administrative staff, and other support personnel).[43,44]

Emergency psychiatrists are particularly well adapted to assist with disaster response. They are familiar with the medical and psychological effects of trauma, adept at working with grieving family members, and familiar with the resources in the community that can assist with long-term treatment. Disaster psychiatry is a growing field, and emergency psychiatrists will likely play an important role in the future of disaster-response planning.

Care of the Suicidal Patient

Theodore A. Stern, M.D.

Suicide, or intentional self-harm with the intent of causing death, is the eleventh leading cause of death in the United States, accounting for more than 30,000 deaths each year.[1] Nonlethal self-inflicted injuries are even more prevalent, accounting for nearly 600,000 emergency department (ED) visits per year[2] and reflecting the high ratio of suicide attempts to completed suicides. Psychiatric disorders, as the most powerful risk factor for both completed and attempted suicide, are associated with more than 90% of completed suicides[3,4] and with the majority of attempted suicides.[5–7] In addition, medical illness, especially chronic illness, is also associated with an increased risk of suicide.

Psychosomatic medicine psychiatrists must be familiar with the evaluation and treatment of patients who contemplate, threaten, or attempt suicide not only because of the risk of suicide associated with psychiatric and medical illness, but also because they are likely to be asked to evaluate patients who are medically or surgically hospitalized following a suicide attempt. Although guided by knowledge of epidemiological risk factors for suicide (Table 40–1), the clinician must rely on a detailed examination and on clinical judgment in the evaluation of current suicide risk.

EPIDEMIOLOGY AND RISK FACTORS

Epidemiology

Suicide accounts for 1.3% of the total number of deaths in the United States each year.[1,8] For every person who completes suicide, approximately 8 to 10 people attempt suicide.[9,10] Although no nationwide data on annual attempted suicides are available, research indicates that for every completed suicide, approximately 8 to 25 attempts are made[11–13]; that is, some individuals make more than one unsuccessful attempt. Each year, EDs treat nearly 600,000 self-inflicted injuries or suicide attempters.[2,14,15] These visits represent approximately 0.5% of all annual ED visits.[2,14]

Use of firearms is the most common method of committing suicide for both men and women in the United States, accounting for between 50% and 60% of annual suicides.[12,13] Suffocation, including hanging, is the second most common cause of suicide overall in the United States, and the second most common cause in men, accounting for approximately 6500 suicide deaths per year.[15,16] Poisoning, including drug ingestion, is the third most common cause of completed suicide in the United States and the second most common cause in women, accounting for approximately 5500 deaths per year.[15,16] Historically, drug ingestion has accounted for the majority of unsuccessful suicide attempts.[17,18]

Suicide rates differ by age, gender, and race. Rates generally increase with age; people older than 65 years are 1.5 times more likely to commit suicide than are younger individuals, whereas white men over age 85 years have an even higher rate of suicide.[14,19,20] The number of suicides in the elderly is disproportionately high; the elderly appear to make more serious attempts on their lives and are less apt to survive when medical complications from an attempt ensue—one out of four attempts in this group results in a completed suicide.[19–21] Although the elderly have the highest suicide rates, suicide in young adults (between the ages of 15 and 24) rose threefold between 1950 and 1990, becoming the third leading cause of death following unintentional injuries and homicide.[12,22,23] From 1990 to 2003, the suicide rate declined in the 10- to 24-year-old age group.[23,24] However, in 2004, for the first time in a decade and a half, the suicide rate in this age group increased by 8%.[24] In addition, hanging/suffocation became the most common method of suicide among girls in this age group.[24] Whether this rise in suicide in young people is a sporadic event or evidence of a trend remains to be seen as data for subsequent years become available.

Men are more likely to complete suicide than are women, although women are more likely to attempt suicide than are men. Four times more men than women complete suicide,[8,25] although women are three to four times more likely than men to attempt suicide.[25,26] The reasons for these disparities have not been established clearly. Whites and Native Americans attempt and commit suicide more than nonwhites.[5,12,25] African Americans and Hispanics have approximately half the suicide rate of whites.[25,27,28]

Psychiatric Risk Factors

Psychiatric illness is the most powerful risk factor for both completed and attempted suicide. Psychiatric disorders are associated with more than 90% of completed suicides[3,4,25,29] and with the vast majority of attempted suicides.[5–7] Mood disorders, including major depressive disorder (MDD) and bipolar disorder, are responsible for approximately 50% of

TABLE 40–1 Risk Factors for Suicide

Psychiatric illness
- Major depression
- Bipolar disorder
- Alcoholism and drug dependence
- Schizophrenia
- Character disorders
- Organic brain syndrome
- Panic disorder

Race
Marital status (widowed, divorced, or separated)
Living alone
Recent personal loss
Unemployment
Financial/legal difficulties
Co-morbid medical illness (having chronic illness, pain, or terminal illness)
History of suicide attempts or threats
Male gender
Advancing age
Family history of suicide
Recent hospital discharge
Firearms in the household
Hopelessness

completed suicides, alcohol and drug abuse for 25%, psychosis for 10%, and personality disorders for 5% (Table 40–2).[30,31]

Up to 15% of patients with MDD or bipolar disorder complete suicide, almost always during depressive episodes[32]; this represents a suicide risk 30 times greater than that of the general population.[33,34] True lifetime risk may be somewhat lower, because these estimates (and those for the other diagnoses discussed later) typically are derived from hospitalized patient samples.[30] The risk appears to be greater early in the course of a lifetime disorder, early on in a depressive episode,[11,35] in the first week following psychiatric hospitalization,[36] in the first month following hospital discharge,[36] and in the early stages of recovery.[36] The risk may[37] or may not[38] be elevated by co-morbid psychosis. A 10-year follow-up study of almost 1000 patients found that those who committed suicide within the first year of follow-up were more likely to be suffering from global insomnia, severe anhedonia, impaired concentration, psychomotor agitation, alcohol abuse, anxiety, and panic attacks, whereas those who committed suicide after the first year of follow-up were more likely to be suffering from suicidal ideation, severe hopelessness, and a history of suicide attempts.[37] A study of 667 patients with MDD found that patients who reported prior suicide attempts had more current general medical conditions, more current alcohol or other substance abuse, more work hours missed in the past week than nonattempters, and also reported more current suicidal ideation.[39]

TABLE 40–2 Percentage of Suicides with a Given Psychiatric Disorder

CONDITION	PERCENTAGE OF SUICIDES
Affective illness	50
Drug or alcohol abuse	25
Schizophrenia	10
Character disorders	5
Secondary depression	5
Organic brain syndromes	2
None apparent	2

Approximately 15% to 25% of patients with alcohol or drug dependence complete suicide,[35,40] of which up to 84% suffer from both alcohol and drug dependence.[40] The suicide risk appears to be greatest approximately 9 years after the commencement of alcohol and drug addiction.[3,41] The majority of patients with alcohol dependence who commit suicide suffer from co-morbid depressive disorders,[35,42,43] and as many as one third have experienced the recent loss of a close relationship through separation or death.[44]

Nearly 20% of people who complete suicide are legally intoxicated at the time of their death.[45] Alcohol and drug abuse are associated with more pervasive suicidal ideation, more serious suicidal intent, more lethal suicide attempts, and a greater number of suicide attempts.[46] Use of alcohol and drugs may impair judgment and foster impulsivity.[36,47]

Approximately 10% of patients with schizophrenia complete suicide, mostly during periods of improvement after relapse or during periods of depression.[43,48,49] The risk for suicide appears to be greater among young men who are newly diagnosed,[49–51] who have a chronic course and numerous exacerbations, who are discharged from hospitals with significant psychopathology and functional impairment, and who have a realistic awareness and fear of further mental decline.[49,51] The risk may also be increased with akathisia and with abrupt discontinuation of neuroleptics.[35] Patients who experience hallucinations (that instruct them to harm themselves) in association with schizophrenia, mania, or depression with psychotic features are probably at greater risk for self-harm, and they should be protected.[52]

Between 4% and 10% of patients with borderline personality disorder and 5% of patients with antisocial personality disorder commit suicide.[53] The risk appears to be greater for those with co-morbid unipolar depression or alcohol abuse.[54,55] Patients with personality disorders often make impulsive suicidal gestures or attempts; these attempts may become more lethal if they are not taken seriously. Even manipulative gestures can turn fatal.[52] A prospective cohort study of 7968 patients examined suicide rates up to 4 years after a deliberate self-harm episode and found an approximately 30-fold increase in risk of suicide compared to the general population.[56]

As many as 15% to 20% of patients with anxiety disorders complete suicide,[57] and up to 20% of patients with panic disorder attempt suicide.[58] Although the risk of suicide in patients with anxiety and panic disorders may be elevated secondary to co-morbid conditions (e.g., MDD and alcohol or drug abuse), the suicide risk remains almost as high as that of major depression, even after co-existing conditions are taken into account.[59] The risk for suicide attempts may be elevated for women with an early onset and with co-morbid alcohol or drug abuse.[58] Patients with obsessive–compulsive disorder (OCD) have also been found to be at high risk for suicidal behavior, with a history of suicide attempt reported in 27% of subjects in one study.[60]

The first prospective study of body dysmorphic disorder (BDD) found that patients with BDD have rates of suicidal ideation that are approximately 10 to 25 times higher than those in the general population and that their suicide attempt rate was 3 to 12 times higher. The completed suicide rate of patients with BDD is still being studied.[61]

One study of 754 inpatients and 1100 patients assessed following discharge from a psychiatric inpatient unit found that nearly a quarter of the inpatient suicides occurred within the first 7 days of admission—the majority died by hanging. Postdischarge suicide was most frequent in the first 2 weeks after leaving the hospital, with the highest number of deaths occurring on the first day following discharge.[62]

Medical Risk Factors

Medical illness, especially of a severe or chronic nature, is associated with an increased risk of suicide and is thus considered a risk factor for completed suicide (even though there is most likely a multifactorial relationship between medical illness and suicide).[16,63,64] Medical disorders are associated with as many as 35% to 40% of suicides[65] and with as many as 70% of suicides in those older than 60 years.[66] Acquired immunodeficiency syndrome (AIDS), cancer, head trauma, epilepsy, multiple sclerosis, Huntington's chorea, organic brain syndromes, spinal cord injuries, hypertension, cardiopulmonary disease, peptic ulcer disease, chronic renal failure, Cushing's disease, rheumatoid arthritis, and porphyria have each been reported to increase the risk of suicide. Notably, however, few investigations concerning the increased risk for suicide in these populations have controlled for the effects of age, gender, race, psychiatric disorders, other medical disorders, or use of medications. Studies of patients who commit suicide on general hospital medical or surgical units have also not been well-studied. A recent review of these rare cases suggests that agitation and a readily available lethal means of suicide are potent risk factors (as are past psychiatric illness, substance abuse, suicidal ideation, and depression).[67]

Patients with AIDS appear to have a suicide risk that is greater than that of the general population, and estimates of the increased risk range from 7 to 66 times greater than the general population.[30,68,69] It is generally accepted that the risk of suicide in human immunodeficiency virus (HIV) infection is increased approximately sevenfold.[16,68] Testing for antibodies associated with HIV-infection has resulted in an immediate and substantial decrease in suicidal ideation in those who turned out to be seronegative; no increase in suicidal ideation was detected in those who were seropositive.[70] Sexual orientation among men, in and of itself, has not been identified as an independent risk factor for completed suicide.[12,71]

Cancer patients have a suicide rate that is almost twice as great as that found in the general population and the risk appears to be higher in the first 5 years after diagnosis.[68,72,73] A large retrospective cohort study of patients diagnosed with cancer in the United States from 1973 to 2002 found that suicide rates varied among patients with cancers of different anatomic sites, with the highest risks observed in the following order: the lung and bronchus, stomach, oral cavity and pharynx, and larynx.[73] Head and neck malignancies have been associated with a risk of suicide 11 times greater than that of the general population (possibly due to increased rates of tobacco and alcohol use and the resultant facial disfigurement and loss of voice).[68] In men, gastrointestinal cancers are associated with a greater risk of suicide.[61] Other factors that may place cancer patients at greater risk include poor prognosis, poor pain control, fatigue, depression, hopelessness, delirium, disinhibition, prior suicide attempts, recent losses, and a paucity of social supports.[74,75]

Like cancer patients, individuals with head trauma, multiple sclerosis, and peptic ulcer disease have approximately twice the risk of suicide as those in the general population.[68,76,77] In patients with head injuries, the risk appears to be greater in those who suffer severe injuries and in those who develop dementia, psychosis, character changes, or epilepsy.[76–78] In patients with multiple sclerosis, the risk may be higher for those diagnosed before age 40 years and within the first 5 years after a diagnosis has been made.[79] In patients with peptic ulcer disease, the increased risk is thought to be due to co-morbid psychiatric and substance use (especially alcohol) disorders.[68,78]

Between the increased risk of suicide of approximately twofold for cancer, head trauma, multiple sclerosis, and peptic ulcer disease, and the increased risk in HIV-infected/AIDS patients (estimated to be at least nearly sevenfold), there are a number of medical illnesses associated with intermediate increases in suicide risk. These illnesses and conditions include epilepsy, systemic lupus erythematosus, spinal cord injuries, Huntington's disease, organic brain syndromes, and chronic renal disease. Patients with end-stage renal failure treated with hemodialysis may have the highest risk of all subgroups.[68,80] As many as 5% of patients with chronic renal failure on hemodialysis die from suicide; those who travel to medical centers for dialysis have a higher suicide rate than those who are dialyzed at home.[10] The risk for suicide among these patients may be as high as 400 times that of the general population.[81]

Patients with epilepsy are five times more likely than those in the general population to complete or to attempt suicide.[68,82–84] Sufferers of temporal lobe epilepsy, with concomitant psychosis or personality changes, may also be at greater risk.[68,82,83,85]

Delirious and confused patients may suffer from agitation and destructive impulses and be unable to protect themselves from harm.[74] In victims of spinal cord injury, the risk is actually greater for those with less severe injuries.[86,87]

Hypertensive patients[78] and those with cardiopulmonary disease[52] may also have a higher risk for suicide than those in the general population. Although previous reports suggested that β-blockers could contribute to increased risk by promoting depression,[78] recent studies suggest that β-blockers do not increase the risk of developing depression.[88] Patients with diabetes have more hopelessness and thoughts of suicide than internal medicine outpatients, although fatal and nonfatal suicidal behavior has not been well-studied in this population.[89] Finally, an association between suicide and very low cholesterol levels has been reported, but the connection is still under investigation.[16,30]

Suicidal ideation in pregnancy has been associated with unplanned pregnancy, current major depression, and a co-morbid anxiety disorder.[90] Completed suicide and suicide attempts are less frequent during pregnancy and the postpartum period than they are in the general population of women. However, suicides account for almost 20% of postpartum deaths.[91]

Surgical procedures have also been associated with a higher risk of suicide. Six epidemiological studies have concluded that the suicide rate in women who received cosmetic breast implants was approximately twice the expected rate based on estimates in the general population.[92–97]

Bariatric surgery is associated with an increased risk of death from non–disease related causes, including suicide, compared to other severely obese individuals. More research is necessary to determine whether these high rates of suicide are due to preexisting psychiatric illness in cohorts of surgery patients or to the postsurgical complications of the surgery or its impact on quality of life.[98]

Suicide has been distinguished from life-ending acts and end-of life decisions in the literature, based on patients with chronic kidney disease and dialysis.[99] Discussion of physician-assisted suicide is addressed in the end-of-life chapter (Chapter 41). Among patients with advanced AIDS, the desire for hastened death has been found to be 4.6% to 8.3%, significantly lower than the rate found in studies of patients with advanced or terminal cancer.[100]

Familial and Genetic Risk Factors

A family history of suicide, a family history of psychiatric illness, and a tumultuous early family environment have each been found to have an important impact on the risk for suicide.[12,65] As many as 7% to 14% of persons who attempt suicide have a family history of suicide.[101] A family history of suicide confers approximately a twofold increase in the risk for suicide after family psychiatric history is controlled for.[102] This increased suicide risk may be mediated through a shared genetic predisposition for suicide, psychiatric disorders, or impulsive behavior,[35,50,103] or through a shared family environment in which modeling and imitation are prominent.[104]

Genetic factors are supported by evidence that monozygotic twins have a higher concordance rate for suicide and suicide attempts than do dizygotic twins, and by evidence that biological parents of adoptees who commit suicide have a higher rate of suicide than do biological parents of nonsuicidal adoptees.[30,103,105] However, little is known about the specific genetic factors that confer this risk.[30] Studies have largely focused on serotonin neurotransmission, including genetic mutations in the rate-limiting enzyme in serotonin synthesis, L-tryptophan hydroxylase, serotonin receptors, and the serotonin transporter; however, this investigation is still preliminary.[102,106–108] Overall, it is estimated that one third to one half the risk of suicide is genetically mediated.[102]

Numerous familial environmental factors may also contribute to suicide risk. A tumultuous early family environment (including early parental death, parental separation, frequent moves, and emotional, physical, or sexual abuse) increases the risk for suicide.[109] A child's risk of future suicide attempts or completion may also be increased through modelling of suicidal behavior in important family members.[30]

Social Risk Factors

Widowed, divorced, or separated adults are at greater risk for suicide than are single adults, who are at greater risk than married adults.[110,111] Married adults with young children appear to carry the lowest risk.[36,52,65] Living alone substantially increases the risk for suicide, especially among adults who are widowed, divorced, or separated.[36] Social isolation from family, relatives, friends, neighbors, and co-workers also increases the chance of suicide.[50,65] Conversely, the presence of social supports is protective against suicide.[102]

Significant personal losses (including diminution of self-esteem or status[65,66]) and conflicts also place individuals, particularly young adults and adolescents, at greater risk for suicide.[3,112] Bereavement following the death of a loved one increases the risk for suicide over the next 4 or 5 years, particularly among people with a psychiatric history (including suicide attempts) and in those who receive little family support.[35,113] Unemployment, which may produce or exacerbate psychiatric illness or may result from psychiatric illness,[35] increases the likelihood of suicide and accounts for as many as one third to one half of completed suicides.[45,65] This risk may be particularly elevated among men.[35] Financial and legal difficulties also increase the risk for suicide.[12,36,114]

The annual number of suicides among soldiers on active duty in the Army, Army Reserve, and Army National Guard has reached a 28-year high, having risen steadily between the years 2004 and 2008.[115] One study of suicide risk among veterans of Operations Iraqi Freedom and Enduring Freedom showed that the overall risk was not significantly elevated compared to that in the general population, but suicide risk was increased for former active-duty veterans and for veterans diagnosed with a selected mental disorder.[116] However, a study of patients in the Veterans Health Administration in fiscal year 2001 found that the suicide rates were significantly higher than in the general population.[117]

The presence of one or more firearms in the home appears to increase the risk of suicide independently for both genders and all age groups, even when other risk factors, such as depression and alcohol abuse, are taken into account.[6,112,118] For example, adolescents with a gun in the household have suicide rates between 4 and 10 times higher than other adolescents.[23,119]

Past and Present Suicidality

A history of suicide attempts is one of the most powerful risk factors for completed and attempted suicide.[12,120] As many as 10% to 20% of people with prior suicide attempts complete suicide.[10,17,121] The risk for completed suicide following an attempted suicide is almost 100 times that of the general population in the year following the attempt; it then declines but remains elevated throughout the next 8 years.[35] People with prior suicide attempts are also at greater risk for subsequent attempts and have been found to account for approximately 50% of serious overdoses.[122] The clinical use of past suicide attempts as a predictive risk factor may be limited in the elderly because the elderly make fewer attempts for each completed suicide.[19–21,65]

The lethality of past suicide attempts slightly increases the risk for completed suicide,[35] especially among women with psychiatric illness.[42] The dangerousness of an attempt,

however, may be more predictive of the risk for suicide in those individuals with significant intent to suicide and a realization of the potential lethality of their actions.[123]

The communication of present suicidal ideation and intent must be carefully evaluated as a risk factor for completed and attempted suicide. As many as 80% of people who complete suicide communicate their intent either directly or indirectly.[65] Death or suicide may be discussed, new wills or life insurance policies may be written, valued possessions may be given away, or uncharacteristic and destructive behaviors may arise.[65]

People who intend to commit suicide may, however, be less likely to communicate their intent to their health care providers than they are to close family and friends.[48] Although 50% of people who commit suicide have consulted a physician in the month before their death, only 60% of them communicated some degree of suicidal ideation or intent to their physician.[3,48] In a study of 571 cases of completed suicide who had met with their health care professional within 4 weeks of their suicide,[124] only 22% discussed their suicidal intent. Many investigators believe that ideation and intent may be more readily discussed with psychiatrists than with other physicians.[124,125]

Hopelessness, or negative expectations about the future, is a stronger predictor of suicide than is depression or suicidal ideation,[126,127] and may be both a short-term and long-term predictor of completed suicide in patients with major depression.[48]

Contact with Physicians

Nearly half of the people who commit suicide have had contact with their primary care provider (PCP) within 1 month of committing suicide.[36,48,128] Approximately three quarters of people who commit suicide have seen a PCP in the year before the suicide.[128] Many of these individuals have sought treatment from their PCP for somatic rather than for psychiatric complaints.[129] Rates of psychiatric encounters in the period before completed suicides are lower than those for primary care contacts.[128] In the month before a completed suicide, approximately one fifth of suicide-completers obtained mental health services, and in the year before a completed suicide, approximately one in three suicide completers had contact with a mental health professional.[128]

PATHOPHYSIOLOGY

Suicide is a behavioral outcome with a large number of contributing factors, rather than a disease entity in itself. Therefore, in order to understand the pathophysiology of suicidality, it is necessary to examine the differences between individuals with a given set of predisposing factors who do not attempt or complete suicide and those who do. Research has focused on a wide array of neurobiological and psychological topics in an attempt to better understand the pathophysiology of suicide. Neurobiological inquiries have included neurotransmitter analyses, genetic studies, neuroendocrine studies, biological markers, and imaging studies.[16]

Of all the neurotransmitters, the relationship of serotonin to suicidality has been most widely studied.[16] Specifically, an association between reduced serotonergic activity, as indicated by lower levels of cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA), and serotonin dysfunction and suicidality has emerged since the 1970s.[30,102,130–141] This finding is independent of underlying psychiatric diagnoses.[131,132] Changes in norepinephrine transmission in suicide have also been investigated, but although there may be some association between a decreased number of noradrenergic neurons and suicidality,[142] overall, CSF studies have shown no significant difference in norepinephrine metabolites in those with suicidal behavior.[102,143] Data regarding the role of dopamine in suicide are inconclusive.[102,141,143,144] Lastly, heightened hypothalamic–pituitary–adrenal (HPA) axis activity has been implicated in the pathophysiology of suicide, although not all studies of the relationship between the HPA axis abnormalities and suicidal behavior have reached the same conclusions.[16,30,102,132,141]

Psychological aspects of suicide typically focus on psychodynamic and cognitive perspectives, and they have contributed to a vast literature on the topic. Suicide can be conceptualized as anger turned on oneself or anger toward others directed at the self.[145–147] Suicide has also been seen as being motivated by three driving forces: the wish to die, the wish to kill, and the wish to be killed.[147] Deficits in ego function have also been postulated to predispose to suicide,[145] as have poor object relations.[147] Hopelessness is a central psychological correlate of suicide, and extensive study on it has suggested that hopelessness may be the best overall predictor of suicide.[102] Shame, worthlessness, poor self-esteem, early traumatic relationships, and intense psychological pain are also key concepts in the understanding of suicide.[147,148] In addition, poor coping skills, antisocial traits, hostility, dependency or over-dependency, self-consciousness, and high intropunitiveness have also been associated with suicide.[147,149] Finally, research has postulated correlations between observed neuroanatomical, neurotransmitter, and neuroendocrine findings in suicide and attendant cognitive traits of loser status, no escape, and no rescue as central to understanding suicidal behavior.[132]

CLINICAL FEATURES AND DIAGNOSIS

The patient at risk for suicide varies along a continuum (from an individual with private thoughts of wanting to be dead or to commit suicide, to a gravely ill individual who requires emergent medical attention as the result of a self-inflicted injury aimed to end his or her life). There is no characteristic presentation for a suicidal patient. As a result, suicide risk must be assessed in all patients, and it depends on a thorough clinical assessment; the patient who has contemplated, threatened, or attempted suicide requires special consideration. The thoughts and feelings of the individual must be elicited and placed in the context of known risk factors for suicide.

Although useful as a guide to populations who may be more likely to commit or to attempt suicide, risk factors alone are neither sensitive nor specific in the prediction of suicide. Their pervasive prevalence in comparison with the relatively low incidence of suicide in the general population may also lead to high false-positive rates. A multiple logistic regression model that used risk factors (e.g., age, gender, psychiatric diagnoses, medical diagnoses, marital status,

family psychiatric history, prior suicide attempts, and suicidal ideation) failed to identify any of the 46 patients who committed suicide over a 14-year period from a group of 1906 people with mood disorders.[150] Similarly, a multiple regression analysis aimed at predicting risk classification by treatment disposition of individuals after a suicide attempt had only slightly more than a two-thirds concordance with the decisions made by the treating clinician.[151]

An evaluation for suicide risk is indicated for all patients who have made a suicide attempt, who have voiced suicidal ideation or intent, who have admitted suicidal ideation or intent on questioning, or whose actions have suggested suicidal intent despite their protests to the contrary. All suicide attempts and thoughts of suicide should be taken seriously, regardless of whether the actions or thoughts appear manipulative in nature. The work group on suicidal behaviors of the American Psychiatric Association has outlined the four critical features of a comprehensive assessment of patients with suicidal behaviors in its 2003 practice guideline: a thorough psychiatric evaluation, specific inquiry about suicidality, establishment of a multiaxial diagnosis, and estimation of suicide risk.[147] The key facets of each of these components are detailed in Table 40–3.

The approach to the patient at risk for suicide should be nonjudgmental, supportive, and empathic. The initial establishment of rapport may include an introduction, an effort to create some degree of privacy in the interview setting, and an attempt to maximize the physical comfort of the patient during the interview.[52] The patient who senses interest, concern, and compassion is more likely to trust the examiner and to provide a detailed and accurate history. Often ambivalent about their thoughts and plans, suicidal patients may derive significant relief and benefit from a thoughtful and caring evaluation.[50,52]

The patient should be questioned about suicidal ideation and intent in an open and direct manner. Patients with thoughts of and plans for suicide are often relieved when they find someone with whom they can speak about the unspeakable. Patients without suicidal ideation do not have the thoughts planted in their mind and do not develop a greater risk for suicide.[50,52,152] General questions concerning thoughts about suicide can be introduced in a gradual manner while obtaining the history of present illness. Questions such as "Has it ever seemed like things just aren't worth it?"[52] or "Have you had thoughts that life is not worth living?"[50] may lead to a further discussion of depression and hopelessness. "Have you gotten so depressed that you've considered killing yourself?"[52] or "Have you had thoughts of killing yourself?"[49] may open the door to a further evaluation of suicidal thoughts and plans.

Specific questions concerning potential suicide plans and preparations must follow any admission of suicidal ideation or intent. The patient should be asked when, where, and how an attempt would be made, and any potential means should be evaluated for feasibility and lethality. An organized and detailed plan involving an accessible and lethal method may place the patient at higher risk for suicide.[45] The seriousness of the wish or the intent to die must also be assessed. The patient who has begun to carry out the initial steps of a suicide plan, who wishes to be dead, and who has no hopes or plans for the future may be at greater risk. The last-mentioned domain (plans for the future) may be assessed by asking questions such as, "What do you see yourself doing 5 years from now?" or "What things are you still looking forward to doing or seeing?"[52]

Many clinicians have addressed the issues of lethality and intent by means of the risk/rescue ratio.[147,153] The greater the relative risk or lethality and the lesser the likelihood of rescue of a planned attempt, the more serious is the potential for a completed suicide. Although often useful, the risk/rescue ratio cannot be applied as a simple formula; instead, one must examine and interpret the particular beliefs of a given patient. For example, a patient may plan an attempt with a low risk of potential harm but may sincerely wish to die and believe that the plan will be fatal; the patient may thus have a higher risk for suicide. Conversely a patient may plan an attempt that carries a high probability of death, such as an acetaminophen overdose, but may have little desire to die and little understanding of the severity of the attempt; the patient may thus have a lower risk.[45,147]

The clinician must attempt to identify any possible precipitants for the present crisis in an effort to understand why the patient is suicidal. The patient who must face the same problems and stressors following the evaluation or who cannot or will not discuss potential precipitants may be at greater risk for suicide.[45] The clinician must also assess the social support in place for a given patient. A lack of outpatient care providers, family, or friends may elevate a patient's risk.[50,65]

The examiner who interviews a patient after a suicide attempt needs to evaluate the details, seriousness, risk/rescue ratio, and precipitants of the attempt. The patient who carries out a detailed plan, who perceives the attempt as lethal, who thinks that death will be certain, who is disappointed to be alive, and who must face unchanged stressors will be at a continued high risk for suicide. The patient who makes a calculated, premeditated attempt may also be at a higher risk for a repeat attempt than the patient who makes a hasty, impulsive attempt (out of anger, a desire for revenge, or a desire for attention), or the patient who is intoxicated.[52]

TABLE 40–3 Components of the Suicide Evaluation

Conduct a thorough psychiatric examination
• Establish initial rapport
• Combine open-ended and direct questions
• Gather data from family, friends, and co-workers
• Conduct a mental status examination
Suicide assessment
• Ask specifically about thoughts of suicide and plans to commit suicide
• Examine the details of the suicide plan
• Determine the risk/rescue ratio
• Assess the level of planning and preparation
• Evaluate the degree of hopelessness
• Identify precipitants
Establish a multiaxial diagnosis
• Obtain history
• Use data from a psychiatric examination
• Incorporate data from prior or current treaters
Estimate suicide risk
• Evaluate risk factors
• Evaluate available social supports

A thorough psychiatric, medical, social, and family history of the patient who may be at risk for suicide should be completed to evaluate the presence and significance of potential risk factors. Particular attention should be paid to the presence of MDD, alcohol or drug abuse, psychotic disorders, personality disorders, and anxiety disorders. The presence of multiple significant risk factors may confer an additive risk.

A careful mental status examination allows the clinician to detect psychiatric difficulties and to assess cognitive capacities. Important aspects to evaluate in the examination include level of consciousness, appearance, behavior, attention, mood, affect, language, orientation, memory, thought form, thought content, perception, insight, and judgment.[153,154] A psychiatric review of systems aids in the detection of psychiatric disease.

The clinician should interview the family and friends of the patient at risk to corroborate gathered information and to obtain new and pertinent data. The family may provide information that a patient is hesitant to provide and that may be essential to his or her care.[45,50,52] A patient who refuses to discuss an attempt or who insists that the entire event was a mistake may speak in an open and honest manner only when confronted with reports from his or her family. The evaluation of suicidal risk and the protection of the patient at risk are emergent procedures, which may take precedence over the desire of the patient for privacy and the maintenance of confidentiality in the physician–patient relationship. Concern over a life-or-death situation may obviate obtaining formal consent from the patient before speaking to family and friends.[52]

TREATMENT OF SUICIDE RISK

The treatment of suicide risk begins with stabilization of medical sequelae of suicidal behaviors. Attention to current or potential medical conditions must be prompt, and medical evaluations must be complete. The severity of the psychiatric presentation should not distract a clinician from his or her obligation to provide good medical care.[45] Once the patient is medically stable, or if the patient is suicidal but has not acted on suicidal impulses, the focus of treatment can shift to initiation of treatment for the underlying causes of the desire for death. Components of the treatment of suicide risk include providing a safe environment for the patient, determining an appropriate treatment setting, developing a treatment plan that involves appropriate somatic and psychotherapeutic interventions, and reassessing safety, suicide risk, psychiatric status, and treatment response in an ongoing fashion (Table 40–4).[147]

Throughout the evaluation and treatment of the suicidal patient, safety must be ensured until the patient is no longer at imminent risk for suicide. Appropriate intervention and the passage of time may aid in the resolution of suicidal ideation and intent.[45,52] A patient who is at potential risk for suicide and who threatens to leave before an adequate evaluation is completed must be detained, in accordance with statutes in most states that permit the detention of individuals deemed dangerous to themselves or others.[155] Patients who attempt to leave nonetheless should be contained by locked environments or restraints.[45]

TABLE 40–4 Treatment of Suicide Risk

Stabilize the medical situation
Create a safe environment
• Remove potential means for self-harm
• Provide frequent supervision
• Use restraints as needed
• Detain involuntarily if necessary
Identify and treat underlying mental illness
Identify and modify other contributing factors

Potential means for self-harm should be removed from the reach of a patient at risk. Sharp objects (such as scissors, sutures, needles, glass bottles, and metal eating utensils) should be removed from the immediate area. Open windows, stairwells, and structures to which a noose could be attached must be blocked. Medications or other dangerous substances that patients may have in their possession must be secured by staff in a location out of the patient's access.[45] Appropriate supervision and restraint must be provided at all times for a patient at risk for suicide. Frequent supervision, constant one-to-one supervision, physical restraints, and medications may be used alone or in combination in an effort to protect a patient at risk. The least restrictive means that ensures the safety of the patient should be used.

A decision about the appropriate level of care and treatment setting for the suicidal patient is critical. The patient's safety is paramount, and decisions about level of care—from discharge home with outpatient follow-up to involuntary hospitalization—should be based on risk determinations and methods most likely to protect the patient from self-harm, even when the patient disagrees. Those who are at high risk for suicide, or who cannot control their suicidal urges, should be admitted to a locked psychiatric facility. A patient who is at high risk but who refuses hospitalization should be committed involuntarily.

A patient who requires psychiatric hospitalization should be informed of the disposition decision in a clear, direct manner. Possible transfers should proceed as quickly and efficiently as possible because a patient may become quite tense and ambivalent about the decision to hospitalize. Those who agree to voluntary hospitalization and who cooperate with caregivers may have the highest likelihood of successful treatment.[52] A 3-year study of patients at a university ED in Zurich found that older patients were more likely to be hospitalized after a suicide attempt and that nearly half of patients admitted for psychiatric treatment were voluntary.[151] In a regression analysis of the same sample, more aggressive methods of suicide attempt (defined as not overdose or cutting), a history of previous inpatient treatment, and a current diagnosis of psychosis or schizophrenia were associated with inpatient admission.[151]

The clinician should always take a conservative approach to the treatment of suicidal risk and the maintenance of patient safety, and err, if necessary, on the side of excess restraint or hospitalization. From a forensic standpoint, the clinician sued for battery secondary to the use of restraints or to involuntary commitment would be easier to defend than the clinician sued for negligence secondary to a completed suicide. Acting in accordance with good clinical judgment in the best interest of the patient brings little danger of liability.[52] Adequate documentation should include the thought processes behind decisions to supervise, restrain, discharge, or hospitalize.[52]

Although managed care may place pressure on a clinician to avoid hospitalization through the use of less costly alternatives, there is no substitute for sound clinical judgment.[147] In particular, safety contracts or suicide prevention contracts, while intended to manage risk, are generally overvalued and of limited utility.[147,156] Specifically, suicide contracts depend on the subjective beliefs of the psychiatrist and the patient and not on objective data; they have never been shown to be clinically efficacious.[147,156] In addition, many suicide attempters and completers had suicide contracts in place at the time of the suicidal act.[147,157,158] Finally, a suicide contract is not a legal contract and it has limited utility, if any, if litigation should ensue from a completed suicide.[147,159,160]

Somatic therapies to target underlying psychiatric illness are a mainstay of the management of the suicidal patient. However, though psychiatric illness is a significant risk factor for suicide and treatment of underlying psychopathology is associated with decreased suicide risk, with few exceptions psychiatric medications have not independently been associated with a decrease in suicide. The two notable exceptions are long-term treatment with lithium (in affective illness)[161,162] and clozapine (in schizophrenia).[163,164]

Because depression is the psychiatric diagnosis most associated with suicide, psychopharmacologic treatment of depression is a central facet of management of suicide risk. However, antidepressants have not been shown to decrease suicide risk.[147,165] Although one recent study found a higher rate of suicide after discontinuation of antidepressants compared with ongoing antidepressant treatment, the study was small and further investigation is required.[166]

Controversy regarding the relationship of selective serotonin reuptake inhibitor (SSRI) antidepressants and suicide has now spanned more than a decade. In the early 1990s, reports of a possible increase in suicidal ideation and suicidal behavior in both adults and children on SSRIs emerged.[167,168] In 2004, the Food and Drug Administration (FDA) issued a black box warning for all antidepressants related to the risk of suicide in pediatric patients.[169] In 2007, the FDA proposed that makers of all antidepressants update the existing black box warning to include warnings of increased suicidal ideation and behavior for adults ages 18 to 24 years during the first 2 months of treatment.[170] Nonetheless, controversy about SSRIs and suicide persists in both adults and children. For example, in 2004, before the FDA advisory opinion, the American College of Neuropsychopharmacology's Task Force on SSRIs and Suicidal Behavior in Youth failed to find an association between SSRIs and increased suicidality in children; this was confirmed and extended in their final report.[171,172] Another study also showed an improvement in depression and a reduction in suicidal thinking when fluoxetine was combined with cognitive-behavioral a therapy (CBT), compared with placebo and CBT.[173]

The controversy has extended to the issue of whether the publicity surrounding the black box warning has had a significant effect in decreasing physician prescription of antidepressants for children and adolescents[174] and whether there are spillover effects on community treatment for adults with depression. One study found a spillover effect into community treatment for adults with depression, including a lower rate of diagnosis of depression than would have been expected by historical trends and a reduction in antidepressant prescription rates for adults with depression.[175] However, others have argued that the black box warnings had modest and targeted effects limited to the pediatric population.[176] One study that examined the U.S. data on prescription rates for SSRIs from 2003 to 2005 in children and adolescents found an association between decreased prescription rates and increases in suicide rates in children and adolescents.[177] However, making such an association has been heavily cautioned against and contested.[178] A meta-analysis of randomized controlled trials emphasized that the risks of suicidal ideation and suicidal attempts must be weighed in the context of the benefits of antidepressants for pediatric MDD, OCD, and non-OCD anxiety disorders.[179]

In adults, there has been similar controversy about a possible relationship among use of SSRIs and increased suicidality and self-harm. Multiple large studies that assessed the risk of suicide and self-harm have been completed; they largely concluded that SSRIs were not associated with a greater risk of suicide or violence.[147,180–183] However, debate has continued.[184] Most recently (in 2005), three papers published in the *British Medical Journal* reached varying conclusions and raised some questions about the data used in a previous analysis.[185–187] One analysis of 477 randomized control trials of more than 40,000 patients found no evidence that SSRIs increased the risk of suicide, but found weak evidence of an increased risk of self-harm.[185] A second review of randomized controlled trials with a total of 87,650 patients reached the opposite conclusion, finding an association between suicide attempts and the use of SSRIs.[186]

A case-control study of 146,095 individuals with a first prescription for depression found no greater risk of suicide or nonfatal self-harm in adults prescribed SSRIs as opposed to those prescribed tricyclic antidepressants (TCAs), although there was some weak evidence for increased nonfatal self-harm with use of SSRIs in patients under age 18 years.[187] A case-control study of Medicaid beneficiaries aged 19 to 64 years who had been hospitalized for depression found no association for suicide and suicide attempts with antidepressant drug use.[188] An observational study of over 225,000 U.S. veterans with a new diagnosis of depression found patients who received monotherapy with SSRI had approximately one third the risk of suicide attempts compared to those who received no medication.[189] A study of 1,264,686 people over 66 years of age, which matched 1138 suicide cases with four comparison subjects for each case, found that the use of SSRIs compared to other antidepressants was associated with an increased risk of completed suicide only for the first month of use.[190]

What is clear from review of the data on SSRIs is that more study is needed. Because SSRIs are prescribed for treatment of an underlying illness characterized by anxiety, agitation, and suicidality, it is difficult to separate out drug effect from illness effect.[147] Whether the medication might affect the patient's threshold for reporting ideation, rather than the actual occurrence of suicidal ideation itself, has also been raised.[191] Notwithstanding the continuing controversy, SSRIs do have the obvious advantage over TCAs and monoamine oxidase inhibitor (MAOI) antidepressants of being relatively safe in overdose.

Finally, because pharmacotherapy for depression typically requires several weeks for onset of efficacy, electroconvulsive therapy (ECT) may be indicated in cases in which suicide risk remains high or antidepressants are contraindicated.[147,192] ECT is associated with a decrease in short-term suicidal ideation.[147] Its use is best established for depression, and it may also be recommended for pregnant patients and for patients who have not responded to pharmacological interventions.[147]

Psychotherapeutic interventions are widely used to manage suicide risk, although few studies have addressed psychotherapy outcomes in the reduction of suicidality. Nonetheless, clinical practice and consensus supports the use of psychotherapy and other psychosocial interventions, despite the need for further study.[147] There is emerging evidence of the efficacy of multiple psychotherapeutic modalities in the treatment of depression, borderline personality disorder, and suicide risk *per se*, including psychodynamic psychotherapy, CBT, dialectical behavioral therapy, and interpersonal psychotherapy.[147]

DIFFICULTIES IN THE ASSESSMENT OF SUICIDE RISK

Clinicians may encounter obstacles with certain patients, or within themselves, during the evaluation of suicide risk. They must be adept in the examination of patients who are intoxicated, who threaten, or who are uncooperative, and they must be aware of personal feelings and attitudes (e.g., anxiety, anger, denial, intellectualization, or overidentification) to allow for better assessment and management of the patient at risk (Table 40–5). A survey study found that only 25% of patients who had self-disclosed suicidal ideation on a computer survey had suicidal ideation or other mental health issues documented in the chart; a majority of these patients were discharged to their home.[193]

A patient who is intoxicated may voice suicidal ideation or intent but retract such statements (frequently) when sober. A brief initial evaluation while the patient is intoxicated, and when his or her psychological defenses are impaired, may reveal the depth of suicidal ideation or the reasons behind a suicide attempt.[52] A more thorough final examination when the patient is sober must also be completed and documented.[45,52]

A patient who threatens should be evaluated in the presence of security officers and should be placed in restraints as necessary to protect both the individual and the staff.[52] Those who are uncooperative may refuse to answer questions despite all attempts to establish rapport and to create a supportive and empathic connection. Stating "I'd like to figure out how to be of help, but I can't do that without some information from you" in a calm but firm manner might be helpful. Patients should be informed that safety precautions will not be discontinued until the evaluation can be completed and that they will not be able to sign out against medical advice. Their capacity to refuse medical treatments should be carefully questioned.[52] A patient who refuses to cooperate until restraints are removed should be reminded of the importance of the evaluation and should be enlisted to cooperate with the goal of removing the restraints. Statements such as "We both agree that the restraints should come off if you don't need them. I am very concerned about your safety, and I need you to answer some questions before I can decide if it's safe to remove the restraints" might be helpful.[52]

TABLE 40–5 Common Reactions of Clinicians to Suicide

Anger
Anxiety
Denial
Depression
Helplessness
Indifference
Intellectualization
Overidentification
Rejection

A clinician may experience personal feelings and attitudes toward a patient at risk for suicide, which must be recognized and which must not be allowed to interfere with appropriate patient care.[145] Clinicians may feel anxious because of the awareness that an error in judgment might have fatal consequences. They may feel angry at a patient with a history of multiple gestures or at a patient who has used trivial methods, often resulting in poor evaluations and punitive interventions. Angry examiners may inappropriately transfer a patient with a low risk for suicide to a psychiatric facility or may discharge a patient with a high risk to home.[52] Attitudes of ED staff toward patients who have attempted suicide may vary based on gender, age, and hospital site.[194]

Some clinicians are prone to experience denial as they evaluate and treat patients at risk for suicide. They may conspire with the patient or family in the stance that voiced suicidal ideation was "just talk" or that an attempt was "just an accident." Others may practice intellectualization and choose to believe that suicide is "an act of free will" and that patients should have the personal and legal right to kill themselves.[45]

Clinicians commonly overidentify with patients with whom they share personal characteristics. The thought "I would never commit suicide" may become translated into the thought "This patient would never commit suicide," and serious risk may be missed.[52] The examiner may try to assure patients that they will be fine or may try to convince them that they do not feel suicidal. Patients may thus be unable to express themselves fully and may not receive proper evaluation and treatment.

A clinician who performs evaluations for patients who have made suicide attempts and who have been admitted to general hospital floors has to be aware of his or her own reactions to the patient, as well as to those of the staff. In addition, medical and surgical staff often develop strong feelings toward patients who have attempted suicide, and at times they wish that these patients were dead. The clinician must diffuse such charged situations, perhaps by holding group meetings for those involved to make them more aware of their negative feelings so that they are not acted out.[195] Such intervention may prevent mismanagement and premature discharge. Institutions should be aware of the need for guidelines for and management of immediate, short-term and long-term responses in the event of an in-hospital suicide.[196]

41 Care at the End of Life

Rebecca W. Brendel, M.D., J.D.
Marlynn Wei, M.D., J.D.
Lucy A. Epstein, M.D.
Ned H. Cassem, M.A., Ph.L., M.D., S.J., B.D.

With more than 2 million deaths each year in the United States,[1] providing both competent and compassionate care for patients at the end of life is a crucial task for physicians. The Institute of Medicine has identified end-of-life care as one of the priority areas for improvement of quality of care, and it has specifically identified pain control in advanced cancer and care of patients with advanced organ failure as areas of focus.[2] In addition, professional organizations including the American College of Physicians have issued guidelines for improving end-of-life care, including recommendations for clinicians to regularly assess patients for pain, dyspnea, and depression.[3,4]

Caring for patients at the end of life occurs amid an often complex background of medical, psychiatric, ethical, and legal concerns. Psychiatric issues (such as depression, anxiety, delirium, substance dependence, and coping difficulties) are common conditions encountered in the treatment of dying medically ill patients. This chapter provides an overview of the central principles of care, diagnosis, and treatment of patients at the end of life from the psychiatric perspective. It also examines current concepts in ethics and legal precedents that surround this evolving area of medicine, where advances in medical technology and practice have extended the human life span and led to the emergence of both opportunities and conflicts at the end of life.

GOALS OF TREATMENT

Psychiatrists face multiple challenges when caring for a dying patient, encompassing issues of diagnosis and treatment as well as larger ethical and legal considerations. Psychiatrists may be uniquely effective in helping a dying patient by ensuring optimization of palliative care and by assisting the patient and the family in the dying process. An important first step in the treatment of the dying patient is for the psychiatrist and the patient to define treatment goals. According to Saunders,[5] the primary aim of care is to help patients "feel like themselves" for as long as possible. Care at the end of life also offers an important opportunity, according to Kübler-Ross, to address and to complete "unfinished business."[6] Common themes in this category include reconciliation with estranged friends or family, resolution of conflicts with loved ones, and the pursuit of remaining hopes. Additionally, according to Kübler-Ross,[6] patients who are dying go through a transformational process (which includes stages of denial, anger, bargaining, guilt/depression, and eventual acceptance). These stages may occur in a unique order, may occur simultaneously, and may last variable amounts of time. Psychiatrists and other physicians may assist the dying patient in the transition through these often difficult stages toward acceptance.

Hackett and Weisman[7] also developed five goals for "appropriate death" that may focus therapeutic efforts for the treatment of a dying patient. These goals include freedom from pain, optimal function within the constraints of disability, satisfaction of remaining wishes, recognition and resolution of residual conflict, and yielding of control to trusted individuals. Perhaps the most important principle in the treatment of the dying patient is that the treatment be individualized. That is, within these general goals and paradigms, each patient's unique characteristics will necessitate careful tailoring of clinical interventions. This case-by-case approach can be accomplished only by getting to know the patient, by responding to his or her needs and interests, by proceeding at his or her pace, and by allowing him or her to shape the manner in which those in attendance behave. There is no one best way to die.

Hospice can provide an important function for the dying patient by incorporating spiritual and family support, pain management, respite services, and a multidisciplinary approach to medical and nursing care. When St. Christopher's Hospice opened in 1967 with Saunders as medical director, it was dedicated to enabling a patient, according to Saunders, "to live to the limit of his or her potential in physical strength, mental and emotional capacity, and social relationships."[5] Saunders viewed hospice as the "alternative to the negative and socially dangerous suggestion that a patient with an incurable disease likely to cause suffering should have the legal option of actively hastened death, that is, euthanasia."[5]

Currently, hospice provides home nursing, family support, spiritual counseling, pain treatment, medication, medical care, and some inpatient care for the terminally ill. In 1994,[8] this numbered approximately 340,000 dying persons, and by 2007, approximately 1.4 million patients received services from hospice.[8] A decade ago, the average patient was enrolled roughly 1 month before his or her death, and the vast majority of patients had cancer.[9–11] According to 2007 data, cancer diagnoses now account for less than 50% of hospice admissions, and growth in these admissions has been attributable to dementia, stroke or coma, and lung diseases.[8] The average length of hospice enrollment in 2007 was 67 days, with a median length of

service of 20 days.[5] Women were found to use hospice services more than men, whites more than blacks, and, overall, close to one in three older Americans used hospice services.[8] Higher hospice utilization rates were found for diseases that impose higher burden on caregivers or diseases with more prognostic accuracy.[8] The three causes of death with highest hospice utilization rates were malignancies, nephritis or kidney disease, and Alzheimer's disease.[8] Medicare pays for the vast majority of hospice services; in 2007 more than 80% of hospice patients received services through their Medicare benefits.[8] To qualify for hospice benefits, potential recipients of hospice care must have their physician and the hospice medical director certify that they are terminally ill and that they will live 6 or fewer months if their illness runs its normal course.[12]

THE ROLE OF THE PSYCHIATRIST

Psychiatrists can play a crucial role in the effective management of patients at the end of life because of their abilities to appreciate the medical aspects of disease, to understand the highly subjective and individual factors that contribute to the personal significance of illness, to understand personality styles and traits, and to engage with patients to modulate maladaptive responses to illness.[13,14] To this end, the psychiatrist may serve many functions, including facilitating medical treatment, augmenting communication between the patient and the caregivers, and modeling those qualities that may be helpful for the patient. Above all, the psychiatrist's primary goals are the diagnosis and management of psychiatric symptoms and illnesses. As for all other patients, a consideration of all factors that contribute to psychiatric suffering, including biological illnesses (Axis I and III), psychological style (Axis II), psychosocial factors (Axis IV), and functional capacity (Axis V), is essential. Studies indicate that psychiatric morbidity in the setting of terminal illness is very high.[15] The most common issues that lead to psychiatric interventions for the dying patient include major depression, anxiety, personality disorders, delirium and other organic brain syndromes, refractory pain, substance abuse, and difficulties surrounding bereavement.[16,17]

Depression

The more seriously ill a person becomes, the more likely the person is to develop major depression.[18] The prevalence rates of clinically significant depression in the terminally ill range from 20% to 50%.[15,19] Studies of terminally ill cancer patients have suggested rates of adjustment disorders of from 9% to 35% and rates of major depression of from 8% to 26%.[20–26] Depression has also been associated with poor quality of life in amyotrophic lateral sclerosis.[27,28] Careful vigilance for depression is necessary, as both symptoms of depression and the impact of depression on other aspects of the patient's life and medical care are challenging. For example, Weisman formulated the wish to die as an existential signal of the person's conviction "that his potential for being someone who matters has been exhausted."[29] Ganzini and colleagues[30] documented that severely depressed patients made more restricted advance directives when depressed, and they changed them after their depression remitted. At Memorial Sloan-Kettering Cancer Center, Breitbart and Holland[31] studied terminally ill patients with cancer and acquired immunodeficiency syndrome (AIDS) who had suicidal ideation and compared them to similar patients *without* suicidal ideation. The primary difference was the presence of depression in the patients with suicidal thoughts.[31] Thus, aggressive treatment of depression is a cornerstone of care, as it dramatically decreases suffering and improves quality of life. In terms of specific treatments, psychiatrists may consider the use of rapidly acting treatments that target specific symptoms. In addition to antidepressants, stimulants are another useful class of agents; their advantages include the rapid onset of improved mood and potentiation of coadministered narcotics (with less accompanying sedation). Suicidal ideation, if it appears, should not be thought of as an "understandable" response but rather as a condition that warrants immediate investigation and treatment.[17]

Desire to Hasten Death

It is also important to differentiate suicidal ideation from a stated desire to hasten death. In one study, suicide was distinguished from life-ending acts and end-of-life decisions in the literature based on patients with chronic kidney disease and dialysis.[32] The desire to hasten death has been identified consistently among a minority of terminally ill patients.[33–36] Among patients with advanced AIDS, the desire for hastened death has been found to be 4.6% to 8.3%, significantly lower than the rate found in studies of patients with advanced or terminal cancer.[37] Although the desire to hasten death is frequently associated with depression, other factors (such as pain, existential concerns, loss of function, and social circumstances) also play critical roles.[33,38–44] The psychiatric consultant needs to listen carefully to the patient who desires hastened death, to treat any underlying psychiatric or physical problem, and to take steps to lessen distress.[41,45]

Anxiety

Anxiety frequently occurs at the end of life and requires psychiatric attention.[17,19] Impending death can generate severe anxiety not only in those who face death themselves but also in their family members, friends, and caregivers. The patient who experiences anxiety surrounding death may not necessarily be able to articulate his or her fears, although anxiety may be related to prior losses or experiences that involve the death of others. Common fears associated with death include helplessness or loss of control, ideas of guilt and punishment, physical pain or injury, and abandonment.[16–18,46,47] The psychiatrist can be helpful by addressing these fears and by exploring issues of isolation, abandonment, and suffering. Appropriate attention should also be directed toward psychopharmacologic management of anxiety symptoms.

Personality Considerations

The terminally ill patient who has a personality disorder (such as narcissistic or borderline personality disorder) or other coping difficulties can present a particular challenge for care providers. For such a patient, help is hard if not impossible to accept and trust, which can interfere with his or her ability to take the comfort that is offered.[13,16,17]

For such a patient, much of the situation is out of his or her immediate control; this elicits regression and the use of more primitive defenses (such as splitting). This may manifest as poor communication with treaters, inadequate pain control, and difficulty in the resolution of interpersonal conflicts.[17] Psychiatrists may find it useful to call on psychodynamic diagnostic and treatment skills to assist such a person in accepting palliative care.[17] Treaters can help to transform the negative countertransference (on the part of caretakers) into an understanding of how best to help the patient undergo the dying process.[16,17] Working closely with family and friends of the patient, as well as the medical team, is important in these situations.[16,17]

Delirium and Cognitive Changes

As terminal illness progresses, medical complications (such as delirium and other cognitive changes) can occur.[48–52] These complications can manifest as confusion, psychosis, agitation, or a multitude of other symptoms and can be caused by the medical illness, its treatment, or both. Palliative care interventions should also be considered earlier in the course of deterioration from dementia, and goals of care for patients with dementia should include quality of life, dignity, and comfort.[48,53] Effective management of changes in affect, behavior, and cognition resulting from delirium or dementia is critical, as it can indicate worsening of medical illness and can greatly affect the quality of time spent with friends, family, and caretakers.[16,17,54]

Pain

Pain management can be a complex challenge requiring extensive expertise. Freedom from pain is basic to every care plan, and it should be achievable in most cases,[16] but management of breakthrough pain requires detailed assessments and management.[55–57] For a multitude of reasons, pain is often undertreated by medical staff.[58–62] Pain management may be particularly challenging for a patient with a history of substance dependence; patients with a history of addiction are more likely to receive inadequate pain management than patients without a history of substance abuse or dependence.[14,63,64] The reasons for this can include concerns about higher-than-expected (and escalating) dosages of opiates, potential misuse or diversion, and fears of legal consequences of prescribing narcotics to a patient with substance dependence.[63,65] Evidence of abuse may include unexpectedly positive results on toxicology screens, frequent requests for higher dosages, recurrent reports of lost prescriptions, and multiple visits to various providers or emergency departments for prescription refills.[66]

Physicians who prescribe to such patients may have divergent opinions about the treatment of substance dependence in the terminally ill. Some physicians feel that carefully monitoring a terminally ill patient on an opiate or actively treating the patient's substance dependence deprives the patient; however, optimal relief of suffering mandates acknowledgement and treatment of active substance abuse issues.[67] The goal of care requires the physician to separate the management of the patient's pain from the management of addiction, and to treat both.[14,68] Careful monitoring of a patient's narcotic use, use of a multidisciplinary team, encouragement of substance abuse treatment, limitation of prescribing power to a single provider, and use of screening tests (e.g., urine toxicology) may all be useful in the management of the terminally ill person with substance dependence.[69] Complementary therapies as part of end-of-life care for improvement of quality of life or moderation of pain distress are also being studied.[70]

Psychosocial Considerations

Optimal end-of-life care includes an understanding of the major areas of psychosocial concern (such as family, work, religion, faith, ethnicity, and culture). The presence of the family is crucial to help a patient resolve long-standing conflicts (if possible) and to provide a context for honoring and remembering the patient.[16] Psychiatrists can aid the family by encouraging the sharing of feelings among family members and by helping to create specific plans for the family (such as the compilation of commemorative items).[17] At the same time, an understanding of the complexities of family interactions (both positive and negative) helps prevent harm to a potentially fragile family system. For example, a recent randomized clinical trial of family-focused grief therapy found that it could help prevent pathologic grief in family members; however, it also had the potential to increase conflict in families where the level of hostility was high.[71]

As with family relationships, a sense of vocational identity can help create meaning for a patient at the end of life.[16] For some, work can be critical for self-esteem. As a patient can begin to feel less valuable when work ceases or retirement arrives, the presence of former and current colleagues can be quite supportive.

Similarly, thoughtful discussion about a patient's beliefs and faith can provide an opportunity for a patient to further his or her sense of meaning and thoughts about an afterlife.[17] Many patients are grateful for the chance to express thoughts about their faith. The patient's own clergyperson, if available, can often provide valuable information and insights about the patient and family and help smooth the course before death. Writers such as Allport[72] and Feifel[73] have contrasted an extrinsic religious orientation (in which religion is mainly a means to social status, security, or relief from guilt) with an intrinsic religious orientation (in which the values appear to be internalized and subscribed to as ends in themselves). Experimental work[74] and clinical experience[16] indicate that an extrinsic value system, without internalization, seems to offer less assistance in coping with a fatal illness than an intrinsic religious commitment (which can offer considerable stability and strength).

Last, patients from underserved communities or minority populations in the United States may have needs that are not served by the current health care system. Unfortunately, the same institutional, cultural, and individual factors that generate disparities in care for minority populations in general also affect care at the end of life.[75] These factors include lack of access to care, undertreatment of pain, and mistrust of the health care system.[75–77] Furthermore, important differences between ethnic groups and cultures can be found at all segments of end-of-life care. For example, several studies have shown that African American patients, as well as older individuals from other ethnic backgrounds (such as Latino, Asian, or Native

American), are somewhat less likely to have arranged for an advance directive as compared with Caucasion patients.[78] There are also important differences in terms of preferences for life-sustaining treatment. For example, in a study involving multiple ethnic groups, African Americans had the highest rate of preferring life-sustaining treatment, and European Americans had the lowest rates.[79] Multiple other studies have demonstrated a preference by African Americans to choose more life-sustaining treatment and cardiopulmonary resuscitation in the face of terminal illness.[75,80–83]

Additionally, culture may influence the decision-making process.[84] For example, family-centered (rather than individual) decision-making is common in certain ethnic groups in the United States, which challenges the traditional Western model of the importance of individual autonomy. Studies have found a higher use of family-centered decision-making among Latino and Asian groups in the United States, which may include the decision to disclose (or not to disclose) the diagnosis of a terminal illness to an individual patient.[78] Thus, attention to cultural competency by psychiatrists plays a significant role in mediating end-of-life care for patients from all ethnicities and cultures.

CHALLENGES FOR CARE PROVIDERS

The emotional intensity associated with providing empathy and support for the dying patient during a time of need may challenge and tire caregivers (such as family and professional staff). A critical skill in end-of-life care is being able to hold end-of-life discussions[85] and to listen to the patient and families, asking open-ended questions.[86–89] End-of-life discussions with physicians have been associated with fewer aggressive interventions, which, in turn, is associated with improved quality of life and caregiver bereavement adjustment.[90] Structured, proactive, multidisciplinary communication systems that include an ethics consultation and palliative care teams have also been shown to improve communication during critical care and end-of-life care for patients and their families.[91–95] Barriers to patient–physician communication about end-of-life care include physicians' own perception that the patient is not ill enough or is not ready to have the conversation.[96] Special considerations should be given to pediatric populations.[97]

Caregivers may also experience helplessness and despair in the face of their powerlessness over a patient's approaching death.[98] If left unaddressed, these feelings in caregivers can cause the caregiver to avoid the patient, to retreat, or even to convey to him or her how burdensome he or she is to caregivers. This could be devastating to the helpless patient who looks to the caregiver for hope. Hence, among the greatest psychological requirements for caregivers is to learn to live with negative feelings and to resist the urge to avoid the patient—actions that convey to the patient that he or she no longer matters. Certain traits make these empathic difficulties hazardous for some caregivers. Dependent persons who expect patients to appreciate, to thank, to love, and to nurture them are unconsciously prone to exhaust themselves regularly because they "can never do enough." This creates a pattern that may be sustainable for a patient with the capacity to nurture the caregiver, but it could have a disastrous outcome if the patient is depleted or intractably hostile. The harder the caregiver strives, the less rewarding the work becomes. Exhaustion and demoralization follow. Some caregivers want to please every physician they consult, and they come to a similar state of exhaustion because many of these patients cannot improve.

ETHICS AND END-OF-LIFE CARE

Principles

End-of-life care carries, inherently, a host of ethical questions that the psychiatrist is likely to encounter. A brief discussion of principles is not intended to supplant the need for concrete individualized judgments for every patient. Principles provide anchor points from which clinical reasoning can proceed—specifically, when limitation of life-supporting treatment is proposed.

The primary obligation of the physician to the patient in traditional medical ethics has been expressed in both positive and negative terms. The negative goal, always referred to first, is not to harm the patient *(primum non nocere)*. The positive obligation is to restore health, to relieve suffering, or both. Our contemporary dilemma, as Slater[99] has pointed out, arose because we now have many situations in which these two aims come into conflict (i.e., the more aggressive the efforts to reverse an incurable illness, the more suffering is inflicted on the patient). For example, if a 70-year-old man with large cell cancer of the lung is found to have metastatic spread of the disease to the other lung and to his liver, any treatment of the cancer is likely to make him feel worse and would be unlikely to prolong his survival.

A related problem is the difficulty in distinguishing treatments administered to relieve pain and suffering from those intended to hasten death.[100] The principle of double effect is commonly used to allow the administration of narcotics and sedatives with the intent to relieve suffering of dying patients, even though such administration may hasten death, but it is a principle that remains widely debated.[101–103]

Second, modern medicine respects patients' right to autonomy. This principle guarantees any competent patient the right to refuse any treatment, even a lifesaving one. This was the emphasis of the medical ethics of the 1970s and 1980s and it focused on refusing life-prolonging treatment, such as mechanical ventilation, and more recently, nutrition and hydration. Honoring such refusals presupposes that the patient is competent. It is important to remember that competent patients may make decisions that providers may view as irrational.[104] However, a patient cannot insist that the physician provide treatment that is considered futile.[105–109] Defining futility continues to be a goal of medical ethics as a balance is forged between the autonomy interest of patients to opt for aggressive treatment and concern by physicians that there is a duty not to offer or provide treatments that are ineffective.[110–112]

Another area of debate concerns the right for terminally ill patients with cancer to have access to investigational drugs.[113] A case was brought against the U.S. Food and Drug Administration by an alliance named after Abigail Burroughs, a young woman who had been diagnosed with

squamous-cell carcinoma of the head and neck at age 19 and had unsuccessfully attempted to obtain investigational drugs on a compassionate-use basis. In 2006, the U.S. Court of Appeals for the District of Columbia Circuit initially held that patients with cancer have a constitutional right of access to investigational cancer drugs.[114] On a rehearing, however, the Court of Appeals reversed the decision and found that there is no fundamental right of access to experimental drugs for the terminally ill.

Limitation of Life-Sustaining Treatment

One salient concept for psychiatrists to understand is the limitation of life-sustaining treatment. Whenever the risks or burdens of a treatment appear to outweigh the benefits, use of that treatment should be questioned by both physician and patient. Limitation of life-prolonging treatment is generally reserved for three categories of patients. First, patients whose illness is judged to be irreversible, who are moribund, and who need to be protected from needlessly burdensome treatments may refuse life-sustaining treatment. This is widely accepted for patients who will die with or without treatment (such as the patient with advanced metastatic cancer). Second, because of the right to refuse treatment, competent patients who are not moribund but who have an irreversible illness have also been allowed to have life-sustaining treatments stopped. Last, competent patients with a reversible illness have the right to refuse any treatment, including life-saving treatments.

However, complications emerge when a patient is not able to make or voice a decision regarding his or her wishes. In these situations, the state has a recognized legal interest in preserving life, and it may be difficult to ascertain whether the patient had a countervailing autonomy interest. One historical example is the case of Karen Ann Quinlan, a 21-year-old woman who in 1976 fell into an irreversible coma while at a party. This case became a legal battle between the right of Quinlan's mother (who, as her guardian, wished to withdraw life-sustaining treatment from her daughter and allow her daughter to die with dignity) and the state's interest in preserving life. In the end, the Supreme Court of New Jersey decided that, if it was believed, to a reasonable degree, that the coma was irreversible, life-sustaining treatment (e.g., with a respirator) could be removed.[115] Now, more than 30 years later, the standard medical recommendation in the case of irreversible coma is to stop all treatment (including nutrition and hydration). This judgment is made on the principle of the inevitability of death and the futility of any treatments to prevent it.

For patients in a persistent vegetative state (a state in which patients have a functioning brainstem but total loss of cortical function), a complicated scenario emerges.[116,117] The many clinical dilemmas in this condition are perhaps best exemplified by the Nancy Cruzan case in 1990. Seven years after the automobile accident that left her in a persistent vegetative state, Nancy Cruzan's feeding tube was removed. She died 12 days later. Her parents' request that the tube be removed initiated a journey that took them through the state and federal court system, up to the U.S. Supreme Court. The U.S. Supreme Court's decision[118,119] affirmed that competent patients have the right to refuse treatment, that foregoing nutrition and hydration is no different from foregoing other medical treatment (such as artificial ventilation or pressor agents), but that Missouri (and other states) could require "clear and convincing evidence" that the patient, while still competent, had rejected the idea of life-sustaining treatment under such circumstances. That is, the autonomy interest of the patient in a persistent vegetative state had to be weighed against the state's interest in protecting life. However, according to the U.S. Supreme Court, while Missouri could require clear and convincing evidence of a patient's wishes when that patient was previously competent, states could also adopt less rigorous standards.

The complicated scenario of the persistent vegetative state was more recently revisited in the Theresa Schiavo case of 2004.[120] In this case, Theresa Schiavo was determined to be in a persistent vegetative state, and her husband, who was her guardian, wished to withdraw life-sustaining nutrition and hydration from her, in accordance with what he believed her wishes would have been. However, her parents opposed removal of the life-sustaining measures. Although the Florida Supreme Court's decision upheld the decision to have her feeding tube removed, it did not revisit or alter the legal rights of patients, in that it rested on a narrow legal analysis of the proper powers of each branch of the state government. Nonetheless, the case revived public debate about withdrawal of care at the end of life. After the case, many states began debating the amount of proof required to establish that an incompetent patient, when competent, would have opted to have his or her life-sustaining care withdrawn, and clinicians have had to revisit the guidelines for the appropriate use of artificial nutrition and hydration.[121]

As a whole, the legal cases regarding end-of-life decision-making explicitly give patients the right to exercise their autonomy regarding what care they receive. For competent patients, these wishes may be expressed at the time that they are making decisions regarding end-of-life care through the use of advance directives that take effect in the event of future incapacity to make or express decisions about their care. These directives may be instructional, may appoint a substitute decision-maker, or both. Instructional directives placing limits on life-sustaining treatment, however, may be difficult to interpret on clinical grounds. For example, requests (such as the desire that "no extraordinary means" be taken to preserve life) may be difficult to interpret in actual clinical settings. Advance directives that appoint a substitute decision-maker with whom the patient has discussed his or her wishes may be a more flexible way to enact a patient's wishes. Specifically, a substitute decision-maker can use his or her knowledge of the patient's prior expressed wishes in combination with the actual clinical scenario in order to more reliably lead to the outcome that the patient would have wanted, if competent.

Physician-Assisted Suicide

Although patients have broad rights of autonomy in expressing their wishes for end-of-life care, there are limits on a patient's ability to control his or her death. A patient may express the wish to have a physician end his or her life (euthanasia). One study of terminally ill cancer patients

found that attitudes toward euthanasia and assisted suicide were determined by psychosocial traits and beliefs, including religious beliefs and perceptions of the amount of burden on families, rather than symptom intensity or disease severity.[122] Euthanasia, even when requested by the patient, is illegal in all 50 states and all U.S. districts and territories. Physicians are prohibited from administering life-ending medication or directly causing death through affirmative actions throughout the United States.

Unlike euthanasia, the practice of physician-assisted suicide, which allows physicians to help patients acquire the means to end their lives but does not permit the physician to actually administer those means, has begun to gain acceptance in the United States. Specifically, physician-assisted suicide is legal in the state of Oregon and has survived numerous legal challenges in the U.S. Supreme Court. Most recently, in 2006, the Supreme Court in *Gonzales v Oregon* held that the U.S. Attorney General did not have the authority under federal law to prohibit doctors from prescribing regulated drugs for use in physician-assisted suicide in the setting of state law authorizing the practice.[123]

Under the Oregon Death with Dignity Act (DWDA),[124] physicians in Oregon are permitted to write prescriptions for lethal doses of medications to patients who request to die and meet the other requirements of the state law. Overall, the practice has contributed to a small proportion of deaths in Oregon (0.01%): from 1998 to 2008, there were 401 deaths by ingestion in Oregon.[125] The specific prevalence of psychiatric symptoms in individuals requesting physician-assisted suicide has not been extensively characterized. One study of 58 Oregon residents who had requested aid in dying from a physician or had contacted an aid-in-dying advocacy organization found that 15 participants met criteria for depression and 13 for anxiety.[126] Three of the 18 participants in the study who received a prescription for a lethal drug under the DWDA met criteria for depression.

Although Oregon has legalized the practice, organized medicine (and psychiatry) oppose the practice. Nonetheless, a second state, Washington, in 2008 passed an initiative for the Washington Death with Dignity Act[127] modeled on the Oregon DWDA. The debate[128–130] over physician-assisted suicide will no doubt continue as other states consider passing laws that authorize it.

CONCLUSION

The aim of end-of-life care is to maximize the quality of life and to minimize the suffering of patients who are terminally ill. For many patients, the end of life marks an important opportunity to reflect, reconcile, and pursue remaining hopes. The psychiatrist can play an important role in the diagnosis and treatment of psychiatric illness in this setting, as well as in facilitating treatment, enhancing communication, and modeling caregiver qualities for families. From a psychiatric perspective, major depression and anxiety are commonly seen; suicidality should not be considered "understandable" or "normal" in this setting. Delirium, pain, and difficulties with coping are also common reasons for consultation requests. As in all other forms of psychiatric evaluation and treatment, it is crucial to consider any medical contribution to psychiatric symptoms. Aggressive treatment of depression, anxiety, and other psychiatric symptoms is a crucial part of holistic management. Additionally, psychosocial factors may play an important (and, at times, complicating) role in the care of these patients. Psychiatrists also should be aware of, and prepared to manage, many of the complex ethical and legal issues that arise in the care of these patients. Physicians have clear obligations in caring for their patients, and patients have rights to autonomy in their decision-making.

Sound clinical and ethical practice requires that the physician assist the terminally ill patient in the complex and often simultaneous processes of grieving and celebrating, reconciling conflicts and completing unfinished business, achieving last hopes and accepting that some goals are unrealized, while alleviating suffering and maximizing autonomy and personhood until death.

Pediatric Consultation

Brian P. Kurtz, M.D.
Anna C. Muriel, M.D., M.P.H.
Annah N. Abrams, M.D.

Psychiatric consultants are called on to respond to a diverse set of needs originating with the child, the family, and the hospital staff. The child psychiatrist consults directly with the pediatric patients and their families, acts in a liaison capacity with medical and nursing staff, manages the needs and demands of difficult parents, and helps a divided treatment team understand divisive dynamics and unite around common goals of quality care.

Stocking and associates[1] found that 64% of children on their pediatric wards had emotional problems that warranted psychiatric consultation, even though only 11% were referred for such consultation. In a more recent study of pediatricians, Burket and Hodgin[2] found that more than half of the pediatric staff stated that they rarely or never referred to child psychiatry, yet these same pediatricians estimated that more than 30% of their patients had emotional problems.

Fritz and Bergman[3] surveyed more than 1000 members of the American Academy of Pediatrics; they questioned pediatricians about their experiences with psychiatric consultation during residency training. They found that 68% of those who had had an interaction with a psychiatrist remembered the consultation as helpful. However, although the experiences were positive and the need identified was substantial, half of the pediatricians rarely consulted psychiatrists. As identified in the survey, there were several obstacles to referral (the corresponding percentage of pediatricians agreeing with the statements is shown in parentheses): "Patients are reluctant to see psychiatrists" (51%), "No one will pay for it" (46%), "There are too few interested, competent psychiatrists" (44%), and "Other mental health professionals are more readily available" (39%).[4] Burket and Hodgin also found that the pediatric house staff reported referring to child psychiatry somewhat more often than did their attending physicians. This pattern suggests that less-experienced staffers are more comfortable requesting psychiatric consultations.

Potential barriers to psychiatric consultation are abundant. One factor is that child psychiatrists are unavailable in many pediatric hospitals. However, early identification of children in need of consultation remains crucial. To overcome resistance to consultation requests, routine psychiatric consultations for specific diagnoses (such as cancer, diabetes, cystic fibrosis, and failure to thrive), as well as for protracted or frequent hospital stays, nonadherence, and psychosocial dysfunction, may be initiated. A psychosocial screening tool, such as the Pediatric Symptom Checklist (PSC)[5] or the Psychosocial Assessment Tool (PAT2.0),[6] can also help identify high-risk patients. Once consultation has been initiated, pediatricians highly value accessibility and timeliness of child psychiatry consultants. Close follow-up, liaison work, and provision of specific recommendations are also valued.[2]

The consultant needs to be attuned not only to the needs of the child and the family but also to the dynamics of the pediatric unit.[7] Assessment of how the child's situation is experienced by the pediatric team requires an awareness of the patient mix on the unit, recent deaths or other traumas, and attitudes toward certain diseases and presentations that can evoke strong emotions among staff (e.g., irritation when caring for a patient whose problems are perceived as "self-induced," such as with an eating disorder or intentional overdose). At times, the consultant might identify a psychologically vulnerable team member who needs referral for additional support.

The consultant needs to make assessments and treatment plans quickly, to facilitate rapid high-quality communication between members of the health care delivery team, and to create seamless transitions from inpatient to outpatient care (involving follow-up and specific recommendations). These goals are facilitated by creating relationships between the consultant and the pediatricians, interacting with community resources, and appreciating the medical challenges from within the child's developmental frame of reference.[8,9]

DEVELOPMENTAL AND FAMILY-CENTERED APPROACH TO CONSULTATION

In assessing a hospitalized child, the consultant must appreciate the child's phase of development and recognize that the child's presentation can be understood only in the context of his or her previous level of function and behavior. The task for the consultant is to place what is learned about an individual child and his or her family into a general context and to understand the challenges faced by all children at that particular developmental level.

The consultant uses a developmental perspective, informed by collateral data regarding temperament, premorbid personality, and the family's function, to evaluate the child's behavior, emotional state, and defensive style. Knowledge of defense mechanisms is often used to help children and their families cope with illness and hospitalization. In general, the maturity of a child's defensive style helps when coping with anxiety; however, defensive patterns are complex. Defenses (including denial, isolation of affect, and intellectualization) help with modulation of

anxiety.[10] For example, a teenager with cystic fibrosis might use isolation of affect and intellectualization when discussing what is needed for lung transplantation. An example of effective denial is the 10-year-old with metastatic cancer who is invested in completing his schoolwork and getting promoted to the fifth grade. Use of an array of defenses that permits adherence with the health care and facilitates investment in age-appropriate activities should be supported. Denial, when used by a withdrawn child, can mask psychopathology and prevent referral.[11]

Infancy

For the hospitalized infant, the key developmental challenge is to maintain the quality of the attachment between parent and child. The parental component of attachment begins while anticipating the infant's birth or adoption. An infant is a parent's most personal product, embodying the hopes that the child will ultimately possess the strengths and values the parent most values in himself or herself, and the wish that the child will have capacities that offset the parent's self-perceived deficiencies. No infant can meet all of the parents' conscious and unconscious expectations, yet most infants are accepted and loved when they enter the world. Parents adapt to the reality of the infant and embark on the lifelong process of attachment that enables child and parent to weather the stresses and strains of caretaking and growing up while remaining committed and connected.

Parents with affective illness (including postpartum depression), anxiety disorders, psychotic disorders, character pathology, or intense guilt can have difficulty achieving the attunement that is necessary for attachment. The psychiatric consultant may be called on to differentiate among depression, character pathology, or anxious adjustment in the setting of inadequate parental attachment. Infants with medical conditions that interfere with feeding, limit access to holding and soothing, affect appearance, or cause irritability present special challenges to the process of attachment. Ill infants require parents to be more mature because the unexpected circumstances can leave a parent feeling incompetent or unloved by the newborn. The medical staff can play a crucial role in successfully supporting new parents through this difficult early phase.

Infants and toddlers are largely nonverbal, and they rely on a small, consistent number of caretakers who know them well enough to be attuned to their nonverbal communications. Therefore, the infant's experience of the stress of hospitalization is exacerbated by separations from the mother or primary caretaker. Bowlby's classic work on attachment[12] described the three phases of separation anxiety seen in infants:

1. *Protest:* The infant acutely, vigorously, loudly, and thrashingly attempts to prevent departure of the mother or rapidly attempts to recapture her. In the older child, this phase can appear as clinging, nagging, or bargaining as a parent is about to leave.
2. *Despair:* The infant is less active, might cry in a monotone with less vigor, begins to withdraw, and appears hopeless. Sometimes the withdrawal phase is mistakenly seen as a good adjustment because the infant is quieter.
3. *Detachment:* The infant seems more alert and accepting of nursing care. These new attachments are superficial, however, and the infant concomitantly shows a loss of affect or positive feeling when the mother appears. With chronic disease that requires numerous prolonged hospitalizations, the infant or young child might make many brief, inconsistent attachments and suffer numerous losses if the primary caretaker is regularly absent and many different surrogate caretakers interact with the child. Spitz[13] referred to the overwhelmed infant's state as *hospitalism*.

Tronick and co-workers[14] found antecedents of Bowlby's more pronounced phases of separation occurring over minutes when a mother is unresponsive to her infant's attempts at relating. In response to these findings of short-term and long-term consequences of maternal separations, hospitals are increasingly encouraging mothers to stay overnight with children and to participate in their child's care.[10,14] In addition, nursing departments have instituted a primary nursing model to limit the number of nurses who care for each child.

Preschool Age

Medical conditions in the preschool phase (ages 2.5 years to 6 years) are affected by three important aspects of the child's emotional and cognitive development: egocentricity, magical thinking, and body image anxiety. Egocentricity is the child's perception that all life events revolve around him or her. The child cannot imagine that others see the world from a vantage point different from his or her own. Magical thinking is the creative weaving of reality and fantasy to explain how things occur in the world.

The combination of egocentricity and magical thinking can lead the preschool-age child to imagine that medical conditions are punishment for the child's own bad thoughts or deeds. For example, a 4-year-old with leukemia reported he got his "bad cells" from eating too many cookies. The young child needs ongoing support from family and medical staff to understand that the medical condition is not punishment or secondary to some unrelated experience. Without this support, the child's anxiety is likely to be much greater and be expressed as inhibition and withdrawal, or as behavioral outbursts.

One understanding of the cause of body image anxiety comes from the preschooler's cognitive development, which leads the child to envision the body as a shell (skin) filled with blood, food, and stool, which could ooze out of any hole in the skin. This concept of the body being like a tire or water balloon that can be punctured with dire results may explain the preoccupation with bandages at this age, as well as fear of needle sticks and surgical procedures that seem to exceed what can be explained by painful experiences alone.

Some regression is to be expected in the stressed preschooler.[11,15] This can take the form of enuresis in a previously toilet-trained child, increased dependence on parents for help with dressing or eating, and episodes of unwillingness to use words to express wishes or use of baby talk. Each of these regressed behaviors serves to engage parents and nursing staff in a style of caretaking that may be more commonly associated with a baby or toddler.

Treatment approaches can assist the preschooler with adjustment to medical illnesses and interventions and can

minimize regression. Pain should be controlled or eliminated whenever possible, even when it is not the fastest way to proceed. Procedures should be explained in simple terms to the child. The child needs to hear in the most basic terms what will be done, why it is needed, and what parts will be uncomfortable or painful. Children will want to know where their parents will be before, during, and after the procedure. Interventions should be performed in designated locations, such as treatment rooms, and there should be safety zones, usually the child's hospital room and the playroom, in which no procedures are done. It is crucial for children of all ages to have safe places within the hospital setting, so that they are not on high alert at all times. Similarly, warning children about impending procedures can lead to protest acutely but over time allows children to relax and not be constantly anticipating an unpleasant surprise attack.

School Age

School age (6 to 12 years), also referred to as latency, is characterized by a host of new and developing skills in many arenas: academic, athletic, and artistic. The world outside the family becomes more important with the advent of best friends and status in friendship or interest groups. In the context of medical illness, the age-appropriate investment in mastery of skills can lead to improved coping, with a better understanding of medical illnesses (although still rudimentary), pride in learning to anticipate regular treatments, medications, and procedures, better capacity to verbalize needs, and establishment of relationships with nursing staff and physicians. Children with premorbid competencies might weather the stress of illness somewhat better than their less-capable peers.

The stress of medical conditions, however, routinely leads to regression in all age groups, so the improved coping skills of latency might not be observed in the hospital setting. Regression is common early in a chronic illness, with the potential for developing better coping after there has been time for adjustment. The level of function fluctuates according to the individual stressors (e.g., mood, malaise, pain, procedures, and prognostic changes) and family function. Offering age-appropriate activities (such as board games, video games, computers, puzzles, arts and crafts) and school tutors helps children to function closer to their premorbid level and serves as a counterweight to the regressive pull of dependency, helplessness, and loss of control that often accompanies hospitalization.

Later in a chronic illness, flexible denial can be a healthy component of coping. Flexible denial denotes the child's ability to suppress thoughts about the illness and invest in an array of activities without abandoning the appropriate measures necessary for treatment of the illness.

It is common for school-age and older children to have distorted or magical notions of the cause of the illness, which are typical of the thinking of younger children. It is helpful to invite all questions—by saying things like "I like to hear what children wonder about" or "There is no such thing as a silly question" and invite fantasies about the medical condition by direct questions such as "What do you think might have caused your cancer?" Some children may be uncomfortable expressing themselves in a direct dialogue but may be willing to draw a picture of their cancer or to write a story about a child with an illness. Any outlet for expression can be helpful to elucidate the fears that underlie the child's anxiety.

In chronic illness, the school-age years offer a less conflicted opportunity to foster positive health-related behaviors. The child should be able to give a simple, accurate explanation of the illness. The child should be learning the names of medications, their purpose, and when they are to be taken. At this age, a partially independent relationship between the child and the treating physician can be developed. Psychiatric intervention is warranted if the child is resistant to learning about the illness, if the child is regressed, if parents are noted to be intrusive or overinvolved in the health care regimen, or if nonadherence to the medical treatment plan has become a means of fighting between child and parent. Allowing these patterns to proceed into adolescence will likely increase risk of dysfunction and make intervention more difficult.

Adolescence

The adolescent, similar to an adult, enters the medical setting with the capacity to understand the meaning of an illness, including its possible ramifications. Developmentally, adolescents venture out with a more independent posture and leave behind the intense dependency on parents that is seen in younger children. This brings with it a particular sensitivity and vulnerability. The multiple demands of hospitalization, including deciphering the meaning of diagnoses and treatments and bearing the physical discomfort, limitations, pain, impact on appearance, and fears about the present and future, can overwhelm the adolescent's ability to exercise newly acquired independence in a developmentally appropriate way. The physical limitations imposed by illness can put adolescents at risk for major depression, especially when the illness interferes with activities that are key to the adolescent's emerging self-image.[16]

The assault on the teenager's autonomy may be particularly difficult to bear because it coincides with the strong developmental pull to individuate from parents and to establish an independent identity. Often the illness occurs at a time when other tensions between the adolescent and parent make relying on the parents uncomfortable or unacceptable. Faced with this emotionally complex dilemma, some teens become sullen, aggressive, nonadherent, or withdrawn, whereas others are able to negotiate the discomfort of returning to a more dependent, supportive relationship with parents.

Interview styles should respect the adolescent's wish for autonomy. One should engage the adolescent first before looking to the parents for their input. Adolescents should also be offered private time to share information that might not be easily shared in the company of parents. Sexual experiences or concerns and worries about parental coping or even death may not be voiced without privacy. The risks and benefits of treatments need to be presented to the adolescent with the recognition that his or her adherence is central to the success or failure of any treatment plan.

Family-Centered Care

The concept of family-centered care has emerged as a care philosophy that highly values effective collaboration

among patients, families, and health care providers and promotes principles and practices that improve this collaboration.[17] It can be helpful to use this term when communicating with pediatric health care providers, who may be less accustomed than child psychiatrists to thinking about the family in a systemic manner, in order to share a common language about the need to include families in psychiatric assessments and treatment planning.

The child cannot be understood separately from the family. Serious or chronic illness in a child is a family crisis. The parents must cope with the uncertainty and the highs and lows associated with hospitalization. Abnormal laboratory results, adverse reactions, life-threatening crises, limitations on the child's future, and the specter of death suddenly become their reality. They observe their child in distress and they often feel fundamentally unable to protect the child.

The hospital environment brings with it a host of medical professionals with as many personalities as there are consultants and caretakers; often, each seems to hold a crucial piece of the puzzle. Small nuances in the presentation of data or differing styles of optimism or pessimism among staff can radically shift the family's mood. There is rarely much privacy and sometimes none at all, whether in a shared room or an intensive care unit. Parents' anxiety negatively affects the child's capacity to cope; to expect a parent to be other than anxious is unthinkable.[18,19]

Parents are the child's most trusted and valuable resource; therefore, strategies to support the parents are crucial. Most parents evoke staff empathy and appreciate the skill and compassion of the treatment team. Certain parents are particularly challenging to support because of a combination of personality difficulties and coping style. Their distress, often fueled by a sense of helplessness, is typically expressed either as devaluing staff or as apparent insensitivity to the sick child's needs. The consultant helps the team of caregivers understand the psychological meaning of the parents' troubling behavior so they can continue to provide optimal care.[20,21]

Siblings are often the forgotten sufferers in the context of chronic or life-threatening illness.[22] They not only have worries about the sick sibling, but often they also lose the support of their parents. The parents may be physically absent, spending time at the hospital with the ill child and attempting to meet at least minimal work demands to support the family financially. They are often emotionally absent, depressed, or drained by the emotional demands of the sick child. Many parents feel angry at the well siblings for making any demands and for not selflessly understanding the seriousness of the ill child's predicament. This compounds the well siblings' guilt at the expectable feelings of resentment and jealousy toward the ill child who is receiving so much attention and so many gifts. If the illness results in death, the feelings of guilt and responsibility may become overwhelming.

Family interviews can aid in the assessment of the physically ill child and help the consultant target areas in the family system that might benefit from support. Families of ill children need to express their feelings about hospitalization and to obtain emotional support. Siblings often have distorted concepts of the child's illness that need to be corrected. A carefully planned family meeting can begin to clarify distortions, reduce family turmoil, improve coping skills, and dispel conflict between family and staff. During the meeting, the ward staff or the psychiatrist should evaluate the family's psychological state, including an assessment of coping mechanisms, anxiety level, available support, and ability to comprehend information.

INITIAL STEPS IN THE CONSULTATION PROCESS

The first step in any consultation is to fully understand the consultation questions (e.g., "Who initiated the consultation?," "What concerns underlie the question?," "What feedback does the consulting person need to be satisfied, and within what time frame?"). Once the questions are clarified, the consultant must gather the necessary history including data provided by members of the medical team, the hospital record, and clinical interviews with the child and parents, as well as social agencies or nonparental caretakers, when appropriate.

Some pediatricians are especially sensitive to psychological concerns and have known the patient and family for several years. In university-affiliated hospitals, the consultant often deals with less-experienced house staff on monthly rotating schedules, and discussion with the referring physician is shifted toward teaching. A crucial function of ongoing consultation is the trusting relationship that should develop among the pediatrician, unit personnel, and the consultant. This trust creates an atmosphere in which the psychological needs of children are recognized and the consultant's recommendations are carried out even when these take additional time and effort.

In the review of the medical record, it is especially important to note the observations of the nurses and child-life specialists, who often have a wealth of information from sustained contact with the child and the family. They often have had considerable experience with other children of similar age and with the same diagnosis; thus, they have a sense of how this child is coping as compared with a relevant peer group. The nurse usually takes a self-care and daily habit history on admission that emphasizes the child's premorbid level of function. The nurse may also record the most careful observations of the child's level of anxiety, state of aggression, and temperamental characteristics.[23,24] The role of the child-life specialist, trained in development, is to help children cope with the stress of hospitalization by organizing individual and group play activities in the recreation room. The child-life specialist often has the opportunity to observe children interact with peers and to use special hospital play materials.[25] The staff's input is a critical adjunct to the consultant's impression, which is based on one or two interviews. Many pediatric inpatient services have a social worker who reviews all or some of the admissions; this expanded social history may be helpful before the consultant meets the family and child.

Techniques of Child Psychiatric Consultation

The child and family should be prepared for the consultation. The referring physician should discuss the reasons for the referral with both the child and the parents so that

the child feels more included and does not feel that information is being withheld. Parents of a preschool-age and young school-age child (younger than 8 years) should be interviewed by the psychiatric consultant before the child is interviewed. The interview of the young child requires largely indirect means of expression of feelings and concerns via play rather than by direct questioning.

In the initial interview, the psychiatrist needs to create an environment as normal as possible as he or she gets to know the child. The consultant's interactive style should be active, interested, and playful. The assessment room should contain some toys and not be the site of painful procedures. First, one should carry out an unstructured observation, after which a gross developmental assessment is conducted.

In the child younger than 3 years, observations of the parent–child dyad are crucial. One should note: "What is the eye contact like between parent and child?," "Does the parent respond to cues in the child and vice versa?," "Are the parent and child in sync?," "Does the child look to the parent for reassurance and comfort?," "What is the child's temperament like, and how does the parent handle frustration?," "How do the child and parent handle separation?," "How does the child respond to strangers?" Stranger anxiety in the very young is expected, and the lack of any stranger anxiety may be a sign of attachment difficulties.

The 3- to 6-year-old child might still require that a parent be present throughout the interview. That request should be respected, although at some point in the interview an attempt should be made to have the parent leave the room. Developmental assessment, including language, social interaction, and gross and fine motor coordination, is a mandatory part of the interview. Drawings become a more important tool for some children to express troublesome thoughts and feelings. The psychiatrist should not expect to complete the evaluation in one visit. It can take several sessions, and the sessions may be short because of the child's fatigue or because other tests have been scheduled. The consultant might need to arrange visits to coincide with appropriate times for observing key behaviors, such as around meal times or dressing changes.

The school-age child can be a more verbal participant in the interview. The child should be questioned about current and previous school attendance, school behavior, school performance, after-school activities, friends, health (including mental health) of family members, family problems, and interaction of family members in response to traumatic events. The mental status examination should initially focus on the manner of relating. The child may be active and verbal or shy and inhibited. The consultant's approach should be flexible depending on the child's way of relating. The active verbal child can be approached in the more traditional interview. The shy child may be engaged through drawings or games, such as checkers or video games. These activities can prove helpful in facilitating an alliance and in demonstrating organic deficits. The first several sessions may be necessary for the child to trust that the consultant will not be performing invasive or painful procedures. Many helpful observations of the child can occur in this initial phase, including assessment of pain, anorexia, and insomnia, assessment of coping strategies, and supportive comments about ways to deal with symptoms and difficult feelings.

Interviewing an adolescent can be most challenging with regard to building an alliance. Some adolescents flatly refuse to talk, and others substantially distort their psychosocial histories. Adolescents are often labile and experience emotions intensely. The consultant should not become discouraged by an adolescent's initial silence. This response might represent anxiety and vulnerability. The adolescent should be given a thorough explanation and reason for referral. The consultant should clarify the limits and expectations of the interview as well as his or her knowledge of the adolescent's medical condition. The consultant can present himself or herself as a member of the medical treatment team with expertise in trying to understand what is most taxing about an illness or situation and working with the patient and the team to find the best approach for helping the patient.

Confidentiality should be addressed, and the interview should be conducted in a private setting. In general, the consultant should be patient and easygoing. It may be helpful to initiate the conversation with some safe topics, such as a sporting event, television show, or question about a photo or other belonging in the hospital room. The consultant should let the adolescent know the intended length of the visits, initially giving the adolescent some control over length and timing when possible. Over time, questions about body image, school, family relationships, friendship patterns, goals, and sexuality need to be addressed.

The role of the family interview as the initial interview for the assessment of a child is somewhat controversial. Many clinicians believe that a family evaluation is mandatory to understand the child,[26] but that the timing of the family assessment may vary. A family evaluation is necessary in certain disorders, specifically somatoform disorders, anorexia nervosa, school phobia, or recurrent abdominal pain, in which family interaction can precipitate or maintain the symptoms. In the pediatric intensive care unit, we routinely prescribe family evaluation sessions for families with the following characteristics: when the response to the child's hospitalization is inappropriate (either excessive or severely constricted), when there is a history of psychiatric illness in family members, when there is a question of maltreatment, or when there is a question of whether the family is able to comprehend the clinical information adequately.[27] For other families, the assessments are less urgent.

REASONS FOR CONSULTATION REQUESTS

Consultation may be requested for assessment and treatment planning of primary psychiatric disorders, somatoform illness, psychiatric factors affecting a medical illness, behavioral difficulties contributing to hospitalization, behavioral difficulties during hospitalization that compromise optimal medical care, child maltreatment in the form of physical or sexual abuse or factitious disorder by proxy, and supportive interactions in children and families who must cope with life-threatening or chronic illness.[8,9]

Primary Psychiatric Illnesses

Depression

Depression is a prevalent disorder in hospitalized children. It may be a secondary response to acute or chronic

illness, or it may be the primary diagnosis and manifest with somatic symptoms or behavior problems. One of the obstacles to making the diagnosis of depression in the hospitalized child is the misconception that the child's dysphoric mood is appropriate to the stress of the situation and therefore does not deserve to be called depression. On the contrary, stress increases the likelihood that depression will occur; it does not invalidate the diagnosis.

Depression may be used to refer to a mood, a symptom, or a syndrome. As a syndrome, depression in childhood is characterized by a persistent mood disorder or dysfunctional behavior, or both, and in older children it is characterized by self-deprecatory ideation. These symptoms or behaviors should represent a significant change in the child's premorbid function and not be a long-standing temperamental trait. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*[28] (DSM-IV-TR), characterizes a depressive episode as prolonged depressed or irritable mood, with the loss of interest in all or almost all activities and other associated symptoms. Although the criteria are the same for children and adults, there are some differences. Associated symptoms that are particularly common in prepubertal children with an episode of major depression are separation anxiety, somatic complaints, irritability, or behavior problems.[29]

Making the diagnosis of depression is difficult in children who are sick because many of the symptoms they exhibit (e.g., decreased energy or loss of appetite) may be attributed to their illness.[30] Also, children who are sick often use denial as a coping mechanism and underreport their symptoms of depression.[31] Prepubertal children cannot give an accurate self-assessment of sustained mood, so dysphoria must be observed by caretakers over a prolonged period. For children younger than 6 years, the hallmarks of depression include poor appetite or failure to grow and gain weight appropriately, disturbance of sleep, hypoactivity, and indifference to the surroundings and to primary caretakers.[32]

Treatment involves use of antidepressants in conjunction with psychotherapy to support the child and family, as well as child-life and recreational therapy. There has been significant attention to the question of whether antidepressant treatment increases the likelihood of suicidal ideation, and in October 2004 the U.S. Food and Drug Administration (FDA) issued a black-box warning related to this concern. Patients, families, and medical providers often benefit from education about the impact of this warning on decisions about the risks and benefits of pharmacotherapy. (See Chapter 35 for further discussion of the use of psychopharmacologic agents in children.)

Suicide Gestures and Attempts

Suicide is one of the leading causes of death among adolescents.[33,34] In 2005, suicide accounted for 11.6% of all deaths in the United States in persons between the ages of 15 and 19 years.[35] Although the incidence of completed suicide among children aged 6 to 12 years may be relatively low, suicidal threats and attempts by children in this age group are not uncommon.[33] In most cases, children who have made a suicide gesture must remain in the hospital or another secure facility until a thorough evaluation and disposition are completed. This can occur via admission to the pediatric ward, in conjunction with crisis intervention services in the emergency department, or in some cases by transfer directly to a psychiatric facility.

During the assessment of a potentially suicidal child, one should:

- Gather details of the suicide attempt.
- Assess the risk of an attempt: What did the child imagine would happen? What was the likelihood of rescue?
- Determine the child's mindset at the time of the attempt: Was there a clear precipitant? Was it an impulsive or a planned act?
- Determine whether there is a history of suicide attempts in the child, family members, or peers.
- Pursue the child's understanding of death and fantasy of what his or her death would elicit in the family or other significant person (such as a boyfriend or girlfriend).
- Ask about the child's feelings of remorse about the attempt or regrets about having survived.
- Assess whether the child expresses feelings of hopelessness, helplessness, or despair.
- Determine whether the child used drugs or alcohol at the time of the attempt.
- Determine whether the child is depressed, manic, or psychotic.
- Determine whether the child identifies with someone who has committed suicide.
- Assess the probability of physical or sexual maltreatment.
- Conduct a family interview. Determine whether the parents are sad and frightened by the attempt or angry at the child for being manipulative.
- Learn about therapeutic interventions that have been tried in the past. What is in place currently, and how good has adherence been with outpatient treatment?

Family issues should be assessed, including a family history of depression or suicide, tension in the family, and real or imagined rejection of the suicidal child by the parents. If maltreatment is suspected, the appropriate child protective services agency must be contacted.

The consultant is initially asked to decide on the appropriate safety management for the suicidal child. This can include one or more of the following: one-to-one supervision, use of physical restraints, sedation, and the presence of or separation from the parents. Ultimately the consultant needs to determine whether the child or adolescent should be psychiatrically hospitalized or managed as an outpatient (while either living at home or in another setting). Criteria for psychiatric hospitalization include serious risk of death through suicide, little wish to be rescued, psychosis, identification with someone who has committed suicide, co-morbid drug or alcohol abuse, intense feelings of hopelessness and helplessness, intense anger or severe depression, lack of support systems, history of inability to use help, and vulnerability to further losses. Appropriate outpatient or day treatment will be required if the patient is not transferred to a psychiatric facility. In this case it is important to educate and engage the patient and his or her family in safety planning. This includes developing a plan for dealing with a crisis (e.g., having contact information for treaters and access to hotlines), directing attention to limiting availability of lethal means of suicide (e.g., guns

and medications, including over-the-counter medications such as acetaminophen) and emphasizing the need for vigilance about likely environmental contributors to suicidal behavior (e.g., substances and psychosocial stress).

Anorexia Nervosa

Anorexia nervosa (AN) is an illness characterized by significant weight loss or absence of appropriate weight gain for age and height in the context of a fear of gaining weight and a distorted perception of the thin body as fat. Amenorrhea is also a symptom of AN in postmenarcheal girls. Onset of AN is typically in mid to late adolescence (14 to 18 years), and it is predominantly seen in girls; it may be associated with a stressful life event.[28]

Hospitalization of afflicted children is usually associated with severe weight loss, cardiovascular abnormalities (usually bradycardia), hypothermia, or electrolyte imbalance. Electrolyte imbalance can reflect binging or purging, which can include vomiting or abuse of laxatives or diuretics. The goal of pediatric hospitalization is medical stabilization; additional interventions in the hospital are nutritional assessment and treatment, psychological assessment of the child and family, and recommendations for appropriate levels of psychiatric intervention after medical stabilization.[36] The assessment as to whether or not medical stabilization must be followed by intensive day or inpatient psychiatric treatment includes determination of the adolescent's recognition that he or she has a problem with eating behavior and self-image, the adolescent's motivation to participate in psychotherapy (e.g., is he or she in denial about the eating disorder and resistant to eating the adequate nutrition presented in the hospital diet), and the parents' ability to support the adolescent and the need for psychotherapy (e.g., are they angry, intrusive, or controlling of the teen, or do they want to deny that the eating disorder is a problem?).

The consultant will be called on to make a recommendation about disposition once the patient is medically stable. Placement is based on whether the adolescent can live at home safely while consuming adequate calories and attending outpatient treatment appointments (e.g., psychotherapy, nutrition, and pediatric) versus the need for a more intensive and structured program such as a day treatment or residential eating disorder unit. Often, the consultant, in conjunction with the social worker, spends a significant amount of time helping the parents accept the plan for psychotherapeutic treatment, especially if the team recommends that the adolescent not return home.

Somatoform Disorders

Some patients present to the pediatrician with intense somatic complaints (such as headaches, abdominal pain, constipation, dysmenorrhea, or fatigue). In general, when cases are referred for psychiatry consultation, the pediatrician suspects that the intensity or the nature of the complaints is more likely to be an expression of emotional factors than medical conditions. Somatoform disorders, as described in DSM-IV-TR, refer to a clustering of physical symptoms suggestive of a medical condition, but the severity of the symptoms or the level of functional impairment is not fully explained by the medical condition.[28] Although the DSM-IV-TR lists specific disorders, including somatization disorder, conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder, the criteria for these conditions were established for adults; children rarely meet full criteria for these specific diagnoses. Recurrent somatic complaints are common in the pediatric population and are a common reason for psychiatric consultation. There may also be developmental considerations, with prepubertal children most often presenting with recurrent abdominal pain or headache and older children presenting with other pain and neurologic symptoms.[37]

The pediatrician's assessment that symptoms are emotional in origin is often at odds with the patient's and the parents' assessment. In psychosomatic illness, the child and family are highly invested in a medical cause to explain the somatic complaints. They are not reassured by routine medical work-ups and they pressure the physician to continue to search for a medical cause. Although the families of somatizing children have been found to have higher rates of anxiety and depression and to be more dysfunctional than other families,[37] they are typically resistant to psychiatric assessment.

Parents might view any suggestion of the important role of psychological factors as an insult and an indication that the clinician does not believe that the symptoms are real. These families prefer to have the child radiographed and endoscoped for abdominal pain, rather than to discuss stressors, such as the child's increasing difficulty at school, the death of a grandparent, or parental discord. Often the child and parents focus on borderline test findings and they pressure the physician to pursue these findings. They might connect a series of irrelevant bits of data to create a medical causal theory that is not supported by the pediatrician. Commonly, families consult multiple specialists in an attempt to find one who will support their medical theory. Unfortunately, if the parents search long enough, they will find either a specialist who will ignore the psychological factors and validate the parents' perspective or a more junior clinician who lacks the clinical experience to stop the rule-out approach. If the psychological issues are not attended to, the condition is likely to become chronic and result in significant morbidity.

The presenting somatic symptoms serve as a solution, albeit a maladaptive one, to an emotional dilemma. For example, it may be easier for a child to get his recently divorced mother to focus on his needs by vomiting and by complaining of relentless abdominal pain than by articulating his deep sadness at his father's absence. Moreover, it may be easier for the mother to champion the cause of discovering a medical cause for her child's vomiting than to support and acknowledge the child's level of distress about the divorce.

The psychiatric consultant is well poised to advocate for a balance of attention to medical and psychiatric factors in the consideration of somatization. This includes keeping in mind that it is not necessary to make the whole diagnosis the first day, week, or month, despite the wishes of the family. Restraint is called for in the pursuit of equivocal organic findings, without sacrificing a complete and appropriate medical work-up. It is often helpful to minimize the importance of a final diagnosis and instead to focus on reducing dysfunction.

Campo and Fritz[38] have proposed a method for assessing and managing pediatric somatization that includes the following key elements in the assessment: acknowledge the patient's suffering and the family's concerns, explore prior assessment and treatment experiences, investigate the patient's and family's fears provoked by the symptoms, remain alert to the possibility of unrecognized physical disease and communicate an unwillingness to prejudge the etiology of the symptom, avoid unnecessary tests and procedures, avoid diagnosis by exclusion, and explore the timing, context, and characteristics of the symptoms. Mainstays of management include honesty, reassurance, emphasis on the rehabilitative approach (as opposed to the curative approach) to symptoms, consideration of family and group interventions in addition to individual management, and consolidation of care.

Therapeutic interventions for the somatizing patient include a medical–psychiatric team approach that emphasizes a consistent relationship among the clinicians, the child, and the family. It is important to foster the continued presence of the pediatrician, because there may be a tendency for the pediatrician to withdraw after psychiatric referral has been made. If the family believes the presence of the psychiatrist leads to diminished access to the pediatrician, there may be escalating anxiety about physical symptoms, and it becomes difficult for the psychiatrist to maintain the critical alliance with the family. Pediatric re-examination without retesting helps calm the family's medical anxiety and reduces the likelihood of continued doctor-shopping. Ongoing psychoeducation from team members can help the family reframe the medical symptoms and enhance communication with caregivers. Inpatient pediatric rehabilitation is sometimes necessary to address the physical components of the presentation and allow the child to regain strength and function in a supportive environment.

Often the child and family need different forms of psychotherapy to allow the child to let go of somatic symptoms and to move on to a healthy role. The child's medical symptoms often serve to stabilize the family system; therefore, family therapy may be required to change patterns of interactions. Couples therapy may also be used to help parents strengthen their adult relationship so the child's illness is not needed to hold the couple together or to distract from their discord. A child's individual therapy helps to build self-esteem and allows the child to engage in developmentally appropriate activities that can increase his or her sense of agency or mastery, which leads to greater confidence and less need to rely on the sick role. Co-morbid psychiatric disorders in the child or family members must also be identified and treated appropriately, with the use of pharmacologic agents as needed.

Psychiatric Factors that Affect a Medical Illness

Medical illness and psychiatric illness are often co-morbid. Studies have shown higher rates of mental health problems in youth with a variety of chronic medical illness,[39] such as asthma,[40,41] diabetes,[42,43] epilepsy,[44-46] and inflammatory bowel disease.[47] In addition to the impact of illness-related symptoms and impairments on psychological function, complex interactions can arise between psychiatric factors and the symptoms, severity, complications, and even treatment of a medical illness. For instance, in youth with type 1 diabetes, depression is associated with poorer glycemic control,[48,49] need for hospitalization,[50,51] and retinopathy.[52] In adolescents with asthma, there is an association between severity of anxiety and depressive disorders and asthma symptom burden.[53] The co-occurrence of mental retardation in children with epilepsy predicts increased behavioral problems.[45,54] In children and adolescents with inflammatory bowel disease, both disease-related inflammation and steroid treatment have been hypothesized to affect the presence and expression of psychiatric symptoms, posing additional challenges in detection and treatment of psychiatric illness.[55,56] And in patients and families who have experienced fear and helplessness in the course of life-threatening medical illness and treatment, pediatric medical traumatic stress can result in posttraumatic symptoms of intrusive thoughts, hyperarousal, and avoidance.[57] Future medical care can then be complicated by posttraumatic symptoms that have been triggered by the medical setting.

Pediatricians rely on parents' reports in young children and self-reports in older children to assess the need for intervention in many chronic conditions. When anxiety, dysphoria, emotional lability, or apathy is present, this increased distress often leads to more medical interventions. In a study of asthmatic patients, it was found that steroid prescription was correlated with the patient's expressed anxiety about an exacerbation and not with the degree of change on pulmonary function tests.[58] Apathy or dysphoria in a patient with severe lung disease, as may be seen in a child with cystic fibrosis, can lead to less therapeutic coughing and to significant pulmonary compromise. Apathy as a result of frustration or helplessness in a child undergoing rehabilitation after a cerebrovascular accident (CVA) or car accident can prevent physical therapy from being optimal. Motivation is often a function of mood, and it is an essential feature of the sense of mastery and agency that we associate with striving toward maximal health. To help children be invested in their own best level of function, it is necessary to understand the emotional issues that impede the health-seeking process.

To understand the psychiatric factors involved in coping one should:

- Ask the child what aspects of the illness and treatments are most difficult or scary for him or her.
- Invite the child to describe his or her own treatment goals and any disappointments in reaching those goals.
- Pursue the child's experience of how the illness and treatment affect his or her life outside the hospital.
- Learn whether the child feels someone understands what it is like to be him or her.
- Find out whether there is someone the child is particularly disappointed in for not understanding. Has the child felt deceived by anyone?
- Determine whether the child knows someone with this condition, and how that person's condition has evolved and why.
- Know the condition and its evolution.
- Learn about the worst thing that could happen.

The goals of the physicians are sometimes at odds with the goals of the child. For example, a teenage girl who suffered

a stroke but did not want to walk "like an old lady" with a cane was sullen in rehabilitation because she did not want to give up her crutches. The many disappointments during hospitalization and unexpected rehospitalizations are compounded when a patient feels his opinion was not sought or her best efforts still resulted in setbacks, leading to anger, frustration, mistrust, anxiety, or apathy.[59] Engaging the child in voicing his or her experience may be therapeutic in itself. There may be ways of altering the hospital protocols to suit the child or adapting the child's treatment program to accommodate home-life priorities. The consultant is asked to assist the child during the hospital stay and to determine whether outpatient psychotherapy is warranted. Knowing how time is spent outside of the hospital and what the content of the frustrations covers informs this decision. Psychopharmacologic interventions can also be helpful, depending on the symptoms and the psychiatric diagnoses.

Behavioral Difficulties that Contribute to Hospitalization

Accidents and nonadherence are the two major categories of behavioral difficulties that lead to the hospitalization of children. Accidents are a leading cause of pediatric emergency department visits and childhood deaths. It is not uncommon to find multiple accident-related emergency department visits for the same child; therefore, identifying the accident-prone child and gaining a better understanding of the causes of accidents can serve to prevent future and possibly more disabling injuries. Medical nonadherence is pervasive, but it runs along a spectrum from benign to potentially life-threatening. As a result, many cases of nonadherence (such as an incomplete course of antibiotics for an ear infection) go undetected; some cases of nonadherence can lead to death, such as a diabetic teen who skips his or her insulin and embarks on a drinking binge.

Accidents

All children experience accidents, but they are more likely to occur in children who are reckless, active, impulsive, or inadequately supervised. Predisposing conditions include attention-deficit/hyperactivity disorder (ADHD), fetal alcohol syndrome, and lead exposure. Adolescents tend to view themselves as invulnerable and therefore may be prone to greater risk-taking and to accidents. It is necessary to gather the following information about the child's behavior before the accident:

- Has the child had behavioral difficulty in school, at home, or with peers?
- Has there been a change in the child's mood?
- Is there evidence of a thought disorder?
- Have there been problems leading to legal interventions?
- Are these worrisome behaviors new or are they longstanding?

Supervision, particularly in younger children, plays a significant role in maintaining child safety. When a child presents with an accidental injury, an assessment must be made as to whether the supervision has been adequate for the child's age; this usually involves an assessment of the parents or other caretakers. It is necessary to entertain the possibility that an accidental injury could be the result of maltreatment (see the section on child maltreatment), a suicide gesture, or an act of self-destructiveness (see the section on suicide). These causes should be part of the clinician's routine consideration for an injured child.

Nonadherence

Nonadherence may be secondary to an inadequate understanding of, or capacity to implement, the intended medical regimen. Often nonadherence is not an active decision to defy treatment recommendations. Rather, it can result from the patient's being overwhelmed by a medical regimen or being tired of the chronicity of one. Some children leave the hospital on numerous medications that are to be administered several times each day. It is crucial for the pediatrician to review the medications with the family before planned discharge. Simplifying medication regimens as much as possible and having honest dialogues with parents and children about what is realistic at home is recommended. Highlighting critical medications and the consequences of not taking them engages the child and family as educated collaborators in the child's health care.[60,61] Patients and families who are refractory to simple educational interventions to improve adherence might benefit from a more-intensive intervention to address the issue, and the medical team can seek the consultant's input. A meta-analysis of psychological interventions to promote adherence in pediatric chronic illness concluded that adherence was most likely to be improved by interventions that emphasized applied behavioral methods, such as problem-solving or parent training, or multicomponent interventions, usually incorporating combined behavioral and educational treatments.[62]

In contrast to the passive nonadherence just described, some children or parents actively disregard medical recommendations. There are many emotional issues that underlie such a course of action. Denial on the part of either the child or the parent can result in nonadherence. In this scenario, the child or caretaker has the conscious or unconscious notion that if the prescribed medication or prescribed restrictions are ignored, it is as if the illness does not exist. The clinician might hear from the child, "Taking my pills makes me feel like I am sick," or from the parent, "I cannot make myself bring him in for his doctor's appointments because sitting in the clinic reminds me he has a bad liver." Suppression of thoughts about illness can be a healthy defense, allowing medically ill children and their families to cope with the stress of the illness, but denial when it leads to nonadherence is maladaptive and warrants psychotherapeutic intervention to minimize serious medical consequences.

Sometimes, nonadherence is an expression of anger, be it the child's anger at the parent or the child's or family's anger at the physician or at the illness itself. When the child is angry at the parents, nonadherence becomes a foolproof weapon guaranteed to elicit the parent's distress, which is then emotionally satisfying for the child. Psychologically absent in this schema is the child's awareness that he or she is actually harming himself or herself. The consultant can assist in altering the medical relationship from a physician-to-parent-to-child relationship toward a more direct relationship between physician and child. By diminishing

the parent's role in the communication of the health care regimen and of policing adherence, to the extent possible depending on the child's age, the pediatrician has the opportunity to build an alliance with the child that fosters a wish to please and thus to enhance adherence.

Psychotherapy serves the function of allying with the healthy part of the child and helping the child or adolescent appreciate that this style of acting-out anger and frustration with parents is self-injurious. Similarly, when the anger being acted out is against the illness or the physician, the psychotherapeutic goal is to ally with the healthy part of the child, helping the child articulate the frustration with words rather than by acting them out in a self-destructive way. The consultant is called on to assess what aspect of this goal can be achieved during the hospital stay and when outpatient psychotherapy is warranted. The nonadherent child may be resistant to the idea of outpatient psychotherapy. Hospitalization offers the consultant a valuable opportunity for alliance-building by letting the child experience how talking (therapy) can be helpful.

Behavioral Difficulties During Hospitalization

Some children are referred for consultation for the management of specific behavioral symptoms that interfere with medical care or with their own safety and the safety and comfort of other patients and medical staff. Their symptoms can include excessive activity, agitation, verbal or physical threats to staff and other children, seizure-like episodes, and temper tantrums. Assessment should include medical, developmental, and social history from the child and family, a neurologic examination, nursing and child-life observations, and school reports, as needed.

Psychopharmacologic interventions might also be appropriate. The child with generalized anxiety or separation anxiety might benefit from a trial of a long-acting benzodiazepine[63] (e.g., clonazepam). Children with anxiety in association with particular procedures might benefit from premedication with shorter-acting benzodiazepines (e.g., lorazepam). Anticipatory anxiety can be managed with behavioral interventions (e.g., relaxation and visualization techniques) as well as pharmacologic therapy.[64,65] When ADHD is diagnosed, the child might respond quite dramatically to the addition of stimulant medication. Occasionally an underlying psychosis may be discerned, and the appropriate antipsychotic agent should be instituted. (See Chapter 35 for in-depth discussion of pediatric psychopharmacology.) Agitation associated with delirium might require the use of antipsychotics to maintain a child's safety and to help clear the delirium.

Behavioral plans, especially for younger children, may be instrumental in establishing good behavior. The guiding principle underlying behavioral plans is to identify the key behaviors that are most problematic and provide incentives for the child to behave in positive ways. In younger children, sticker charts for swallowing pills and allowing blood drawing without a temper tantrum are examples of common behavioral interventions. Younger children may receive stickers as the full reward, or after receiving a predetermined number of stickers, a child may earn a toy. Older children may work toward special privileges (such as a trip to the gift shop, time outside with the child-life specialist, or a favorite meal brought in from outside the hospital). Other incentives (such as tickets to a hockey game), may be provided by the family. In addition to behavioral plans, children benefit from having a schedule for the day. An unstructured day increases uncertainty, boredom, and anxiety. Scheduling activity times, meal times, rest times, and procedure times can be helpful in providing the child with an increased sense of control over the hospital milieu.

Parents' interactions often play a major role in the child's behavior. Some behavioral outbursts might reflect the child's anxious response to a parent's escalating anxiety and inability to help the child feel safer in the hospital setting. Some parents might find it difficult to set limits on the child in light of the sadness the parent feels at the child's medical condition. The child's behavior might represent an unconscious need to re-engage the parent in what had been the usual style of parenting. A parent's lack of limit-setting often feels to the child like emotional abandonment. In conjunction with the social worker doing family work or parent guidance, the consultant needs to help the parent feel competent to be an active parent again.

Children with behavioral difficulties invariably arouse negative feelings in the staff. There may be disagreements between staff members about how best to respond to particular behaviors, and the inconsistencies can foster further behavioral disturbances. Team meetings to develop a consistent plan and to facilitate good communication are essential. These team meetings are a good opportunity for the consultant to share his or her understanding of the psychological meaning of the behavior in a way that helps the staff feel more empathic with the child and the family.

CHILD MALTREATMENT

Child maltreatment is defined as any act or series of acts of commission or omission by a parent or other caregiver that results in harm, potential for harm, or threat of harm to a child.[66] Acts of commission constitute child abuse, in the form of physical abuse, sexual abuse, or psychological abuse. Acts of omission constitute child neglect, including a failure to provide (physical neglect, emotional neglect, medical neglect, or educational neglect) or a failure to supervise (inadequate supervision or exposure to violent environments).[66] In general, data collected from child protective service agencies by the National Child Abuse and Neglect Data System (NCANDS), overseen by the U.S. Department of Health and Human Services, have shown a significant decline in the rate of physical and sexual abuse, but not neglect, since data collection was initiated in 1990.[67-69]

Because the etiologic contributions to child maltreatment are diverse, a developmental–ecological perspective has been advocated in understanding the determinants of maltreatment, in which parenting behaviors are understood to be influenced by factors across multiple levels, including characteristics of the parent, the characteristics of the child, and the broader context.[70,71] Maltreatment can occur in the setting of multigenerational inadequate parenting, substance abuse, and multiple family stressors including domestic violence, a disrupted family unit, and cognitively limited or psychiatrically ill parents.[72] Low family income[73]

is a risk factor, particularly among single-parent families.[74] Risk factors notwithstanding, maltreatment occurs in all socioeconomic and demographic environments, demanding constant vigilance in those who work with children.

The consequences of child maltreatment, including mental health problems, can be far-reaching.[75] Psychiatry may be consulted in cases where maltreatment is suspected. In some health care settings, a specialized child protection team is also available to provide consultation and coordinate care. All physicians are mandated reporters of maltreatment, but only a suspicion is required; it is not necessary to prove maltreatment to file with the appropriate state child welfare agency.

Physical Abuse and Neglect

Physical abuse is defined as the intentional use of physical force against a child that results in, or has the potential to result in, physical injury.[66] Acts constituting physical abuse can include hitting, kicking, punching, beating, stabbing, biting, pushing, shoving, throwing, pulling, dragging, dropping, shaking, strangling or choking, smothering, burning, scalding, and poisoning.[66] The incidence of child physical abuse, based on data gathered by NCANDS, has decreased from 3.6 per 1000 in 1990 to 1.1 in 2007.[67,76] It occurs most commonly in the 4- to 15-year-old range, with a peak incidence in the 4- to 7-year-old range.[76] Specific determinants of risk for recurrent abuse include age of the child, the number of previous child protection services referrals, and certain caretaker characteristics such as emotional impairment, substance abuse, lack of social support, domestic violence, and a history of childhood abuse.[77] Children with disabilities have been thought to be at higher risk for maltreatment, but whereas there may be an association with emotional and learning problems, it is not clear that studies support an association between physical disabilities and maltreatment.[78,79]

Neglect, by comparison, is the failure by a caregiver to meet a child's basic physical, emotional, medical, or educational needs.[65] These children might present with failure to thrive or other consequences of inadequate nutrition, the occurrence of preventable accidents, dermatologic conditions related to poor hygiene, lack of routine and specialized medical appointments, and school absences.

Abuse and neglect must be suspected before they can be diagnosed. Certain types and locations of injuries are suspicious. Bruises that resemble finger or hand prints, and those that appear on body surfaces that normally do not bear the brunt of an accidental fall (such as welts on the back as opposed to anterior shin bruises), should raise suspicion. Multiple bruises in various stages of healing are suggestive of abuse that has been ongoing. Clinicians should be suspicious when bruises, broken bones, and accidents have occurred that are inconsistent with the caretaker's explanation, when the caretaker admits and then recants culpability, or admits having observed the abuse being perpetrated and then recants the story. The caretaker might blame the injury on the child, suggesting it was self-inflicted, or blame a sibling for an injury that appears beyond the developmental capability of the child. There may have been an inexplicable delay in seeking medical attention, or the person bringing the child for medical assistance may be vague or report having not been with the child during the injury and not knowing how it happened.

When physical maltreatment is suspected, the child at risk should be kept in a safe facility until the child welfare agency has determined the safety of the child's disposition. A full physical examination should be performed and well documented, checking the whole child for evidence of bruising or injury in various stages of healing. This is important both to ensure the child's safety and because there may be subsequent legal proceedings. A radiologic bone series should be performed to look for evidence of old and new fractures. A funduscopic examination should be performed for evidence of traumatic shaking of a young child. Siblings of a child suspected of having been abused must be assessed immediately because they are also considered to be at high risk for abuse.

Sexual Abuse

Sexual abuse is defined as any completed or attempted sexual act with, sexual contact with, or exploitation of (i.e., noncontact sexual interaction) a child by a caregiver.[66] This involves the exposure of a child to a sexual experience that is inappropriate for his or her emotional and developmental level and that is coercive in nature.[80] Like physical abuse, reported rates of sexual abuse have declined since the 1990s.[68,69] However, the incidence of sexual abuse is significantly underreported and there are many methodologic difficulties with estimating the prevalence of sexual abuse. The most common form of sexual abuse is father–daughter incest.[81] Incest is present when sexual contact occurs between a child and a family member, including stepfamily members or members of a surrogate (foster) family. The highest reported rates of sexual abuse (35.2% of sexual abuse reports) occur in the 12- to 15-year-old age range.[76] Sexual abuse tends to be so disturbing and so emotionally intense a topic that there is risk of medical professionals abandoning a logical approach to assessment.

There are three common presentations of sexual abuse in children: presentation with an unmistakable traumatic injury or a sexually transmitted infection, testimony that sexual abuse has occurred in the context of no physical evidence, and presentation of a patient who has physical or behavioral symptoms suggestive of sexual abuse but who has neither disclosed abuse nor implicated a perpetrator.[82]

In the first two presentations described, assessment and documentation of the sexual abuse and disclosure must be approached with the assumption that legal proceedings are likely to follow. In these cases, there is ample information to make mandated reporting of the suspicion of abuse a requirement. The fewest people should question the child to minimize further trauma to the child and to decrease distortions. Ideally a single interview of the child should be conducted by a mental health professional with expertise in child sexual abuse and the appropriate police agency representative. The child psychiatry consultant's role may be as the interviewer or as the supporter of the child on the pediatric unit, without being involved in the sexual abuse examination

In the third scenario, the child might present with medical symptoms, such as a urinary tract infection or vaginitis, or behavioral changes, such as sleep problems

or depression.[80] These findings can arouse suspicion and should be followed up with a psychological assessment. A play therapy assessment of a preschooler may be helpful, looking for themes of abuse in the fantasy play. During the play, the young child might reveal new information about sexual experiences. In the school-age child, additional information may be gleaned from the child's drawings, especially self-portraits or pictures of the family. Children and teenagers should be invited to disclose sexual abuse to the consultant with questions such as, "Has anyone touched you in ways that made you feel uncomfortable or scared?" A follow-up question might be, "Would you tell me if they had?" and "Who could you tell, if someone was touching you or making you uncomfortable?" It is helpful to learn who a child feels he or she can talk to and to add new choices to the list, such as the pediatrician or schoolteacher as well as the consultant or another counselor. Even if a child is not yet ready to disclose, one hopes that it is therapeutic to assist a child in conceptualizing a plan for disclosing when he or she does feel ready.

In any case in which abuse is entertained, a family assessment is essential. There is no single personality profile of a perpetrator of sexual abuse. Perpetrators can come from within the family or the community. The task of the psychiatric consultant is to explore sensitively the meaning of general symptoms that can indicate sexual abuse without suggesting that nonspecific symptoms are pathognomonic of sexual abuse.

Factitious Disorder by Proxy

Factitious disorder by proxy, previously known as Münchausen syndrome by proxy, was first described as a pair of case reports in 1977.[83] It is a form of child maltreatment in which a parent, usually a mother,[84] consciously distorts her description of her child's symptoms or does things to the child to fabricate a picture of medical illness and then seeks hospitalizations and medical interventions for the child. The parent might report periods of apnea or seizures at home that have not occurred or might cause life-threatening illness by injecting the child with medication, blood, or feces to ensure that a medical work-up continues.

Some of the persons with this syndrome have had medical training in a health-related profession, such as nursing,[84,85] and they use their medical knowledge to create "illness" in their child. The mother is usually at the infant's or young child's bedside. She tries to establish friendships with the nursing staff and is content as long as continued hospitalization and medical procedures are being scheduled and performed. She may become angry and agitated if she receives a report that her child is well and should be discharged home. Often she appears earnest and less anxious when serious diagnoses of the child are being entertained. If discharged, she may return within hours or days to the emergency department with an escalation of symptoms. The psychological understanding of this syndrome is that the mother needs the child to be sick to maintain her role as a "nurturant" mother in the protected, supported environment of the pediatric ward. She may gain a "curious sense of purpose and safety in the midst of the disasters which [she herself has] created."[84] She perceives the nurses to be her friends and the male physicians as caretaking men in her life. She lacks the empathy to be troubled by the pain and suffering she is inflicting on her child.

Factitious disorder by proxy is a difficult diagnosis to make without observing the mother doing something to the child. It may be suspected when a child's medical condition does not follow the expected course and the symptoms are persistently inconsistent. The symptoms may be observed only by the mother or might occur in conjunction with the mother's presence and may be consistent with an intentional action. Undertaking the investigation of this diagnosis, and seeking concrete evidence of risk to the child at the hands of a parent might require input from hospital legal counsel and administration.

It is crucial to protect the child's safety if this diagnosis is suspected. The reporters of this syndrome have described mortality rates and significant morbidity.[86,87] The hospital legal department and child protective services should be notified of this diagnosis to protect the best interest of the child. If the parent thinks that she is being suspected of having hurt her child she might become angry and leave against medical advice (sometimes going straight to another hospital under the same or an assumed name). Perpetrators of factitious disorder by proxy are difficult to treat due to their psychological difficulties, persistent denial, and capacity for deception; recidivism is common.[88]

LIVING WITH CHRONIC ILLNESS

The vast majority of children with chronic illnesses cope well. They are not defined by their illnesses but rather by their individual strengths, weaknesses, personalities, and age-appropriate developmental issues. However, children with chronic illnesses are more likely than their peers to have a psychiatric disorder.[8,39,89] There is no one personality that coincides with a particular illness, but each chronic illness, such as asthma, diabetes, rheumatoid arthritis, cystic fibrosis, and sickle cell anemia, presents particular challenges. These challenges include coping with the symptoms, such as pain or shortness of breath; the timing of diagnosis at birth, childhood, or adolescence; and the requisite health care regimen, such as inhalers, IV antibiotics, or dietary restrictions. The meaning of the illness evolves according to relevant developmental issues throughout the child's life. The consultant's task is to understand the meaning of the illness to the individual child and family at this moment in development. The earlier section on development provides some general principles for understanding the effect of chronic illness throughout childhood, but the consultant must assess the unique experience of a particular child and family.[90-92]

The consultant needs to ask many questions to elucidate the child's subjective experience of living with the chronic illness. Diagnostic instruments used in physically healthy children might not be useful in children with chronic illnesses.[8] Some useful questions include what the worst or hardest thing is about the illness and if there is anything good about the illness. Similarly, what is the child's personal experience of the health care regimen? How has the child's experience of the disease changed as the child has grown older, or what events in the future are of concern? What are the child's peer relationships like, and how, if at all, does the illness affect these relationships? Whom does the child tell about his or her illness, and when does the

child do so in the course of the relationship? How does the child explain the illness to others, and how can he or she explain it to the consultant? What is the child's perception of the parents' concerns about the illness? What are the areas of conflict between parent and child and between child and pediatrician or subspecialist?

Chronic illness requires adjustment on the part of the child, the family, and sometimes the school. The child's personal strengths, such as music, sports, or academics, are assets in maintaining self-esteem and building important peer supports. Some children enjoy peer group opportunities, such as specialized camps for children who share a particular illness. Temperament and interpersonal capacities are also factors in the ease of a child's adjustment. The parents' attitude toward the illness is crucial in setting the stage for the child's attitude. This can raise difficulties, because feeling worried, burdened, and isolated is a common experience among parents of children with chronic illness.[93] Excessive parental anxiety, anger, sadness, and guilt, however, are likely to impede the child's adjustment.[92]

The extent to which an illness interferes with age-appropriate activities, especially school, is an important factor in adjustment. Multiple hospitalizations are associated with greater emotional morbidity than is seen in an individual hospital stay.[94] Structuring the admissions to provide the child with protected times and protected places for play and dialogue, appropriate to the child's age, decreases the stress of the hospital environment. In-hospital tutoring for prolonged hospital stays and continued contact with friends in person, by phone, or online can assist the child's comfort in returning to school.

CARE AT THE END OF LIFE

The emerging subspecialty of pediatric palliative care has helped focus the attention of clinicians who participate in end-of-life care on the complex challenges to providing the best possible care to these children and their families.[95-97] Some treatment settings have specialized clinical services dedicated to pediatric palliative care, and the psychiatric consultant can work closely with these services to address psychosocial needs.[98] In circumstances where these services are not available, the psychiatric consultant may be called upon to aid the patient, family, and medical team in a variety of ways.

A request for consultation might stem from issues related to problem-solving and decision-making in the context of life-limiting illness.[99] This can include initiating a dialogue between the medical team and the patient and family of the patient with life-threatening illness, clarifying the goals and hopes of treatment, and assisting in the evaluation of pros and cons related to specific treatments or treatment settings, including end-of-life care outside of the hospital[100] and planning for location of death.[101] Because these issues are often accompanied by emotional distress on the part of patients, families, and caregivers, psychiatric expertise may be sought. The psychiatric consultant may help to facilitate affectively intense discussions and to help anticipate and interpret the reactions of children to issues around death and dying in the relevant developmental context.

In children, a mature conception of death can be viewed in components that might not be acquired simultaneously.[102] Key components include, in approximate order of typical acquisition,[103] concepts of universality, irreversibility, nonfunctionality (i.e., that the functions of life cease with death),[104] and causality. It should not be assumed that children either do not understand the concept of death or are too fragile to talk about it. The child's parents and the medical team might need education about whether and how to talk with the child about death and to involve the child in the plan of care.[105-107] In addition, helping the seriously ill child to communicate his or her many small preferences, from being called by a nickname rather than a formal name to whether or not to wake him or her for optional events or social activities, can create a greater sense of agency and help stave off the destructive force of helplessness.

Facilitating peer interactions in the hospital playroom for the child and encouraging both formal and informal support groups for children and their parents can be invaluable. Many parents and children feel that the immensity of the child's illness has so changed their lives that old friends feel inadequate. The worries of the well world can feel alienating and out of touch with the child and the family's new reality. This experience can be isolating. Sharing pleasures and frustrations with other families facing cancer, a terminal neurologic syndrome, or a metabolic disease can be an antidote to the isolation. Many family friendships that begin on the ward survive long after a child dies.

The consultant might also have a role in helping with the treatment of symptoms at the end of life, which may be underrecognized or undertreated. Studies of children who died of cancer have found that symptoms of pain, fatigue, and dyspnea occur in large numbers of patients, result in significant suffering, and persist despite attempts to treat.[108-111] In children with life-limiting illness of all kinds, the consultant may have a role in assisting with treatment of pain,[112-114] fatigue, dsypnea,[115] agitation,[116] anxiety, and depression.[117] Although the psychopharmacologic treatment of seriously ill or dying children is complicated, compassion dictates considering the use of psychiatric medications in this population if they may help relieve suffering.[118]

Families also need varying amounts of assistance to cope with the impending loss of a child, ranging from sympathy for their grief to guidance with how to make end-of-life decisions that reflect their values, preserve dignity, and minimize suffering. In a retrospective study of parents who lost children to cancer, the presence of unrelieved pain and a difficult moment of death were the most significant factors still affecting parents 4 to 9 years after the loss.[119] The same study also demonstrated that most parents had worked through their grief "a lot," and that factors that were associated with working through grief were sharing their problems with others during the child's illness, having access to psychological support during the last month of the child's life, and counseling being offered by health care staff within the last month of life.[120] Parents who reported that they had not worked through their grief reported more physical and psychological health problems, increased sick leave, and increased utilization of health care services.[121] Parents who felt that health care given to their children was inadequate, that anxiety or pain had gone unrelieved, or that the parents' own needs (such as support and communication) were not met reported more feelings of guilt in the year following the death of the child.[122] Although support

for grieving families at their time of loss can be beneficial, it is important to remember that grieving for the death of a child is a lifelong process and community resources for bereaved families can help to work through grief and find meaning in a tremendous loss.

The child's care team might also struggle with the loss of a patient. Commonly, feelings of sadness and helplessness can surface, and it can feel difficult to maintain empathy for patients and families whose circumstances appear trivial by comparison or whose disorders seem "less real" or self-inflicted. Even when these factors are not present, continuous compassion directed at those in crisis can create emotional exhaustion that is termed *compassion fatigue*.[123] The intensity of relationships formed in the course of providing care to children at the end of life can contribute to this phenomenon. The consultant may assist by educating members of the team about this phenomenon and dispelling stigma and by helping develop personal, professional, and organizational strategies to prevent and manage compassion fatigue.[124,125]

WORKING WITH STAFF

Child psychiatric consultation almost always involves more than the patient and the referring physician. Parents are inherently a part of treatment because they give critical information and need to be actively involved in implementation of recommendations. During hospitalization, nurses can assume some parental roles while the ward is the child's temporary home. Child and family behaviors have an impact on other patients and staff and are likely to evoke intense feelings. Because many pediatric units encourage parents to visit and room-in, the potential impact of a distraught or disturbed parent on the entire ward is substantial. Lastly, patients with chronic illness can return repeatedly to the same floor over a 5- to 10-year period. Thus, many children become well known, and the depth of the staff's involvement grows over the years. Child psychiatric consultation includes an essential liaison role that is relevant to patient and family care, to interstaff tensions, and individual staff stress.

Primary nursing encourages continuity of care as one or two nurses are assigned to the child during the hospitalization, often for repeated admissions. This practice is beneficial for the child's sense of trust, makes the nurse's role more personally satisfying, and can add a needed perspective if too many subspecialists forget the whole child's needs. Unavoidably, primary nurses become intensely involved in the child's personal and family life; thus they have critical information and share the stress of the child's illness. The child psychiatrist can provide suggestions and supervision for dealing with difficult families or crisis, review when psychiatric referral is indicated, and help in understanding the painful issues of chronic disease, suicide, and terminal illness.

For house staff, a basic stressor is being relatively inexperienced and yet forced to deal with complex medical and psychological circumstances. The source of stress is clearest in the intensive care unit, where frustration mounts rapidly as children do not respond to treatment or suffer life-long physical and neurologic damage. The consequences of multiple stresses (frustration with the patient's course, lack of sleep, and feeling incompetent) can lead to depression, substance abuse, or bitter tensions among house staff or nurses.

Part of the child psychiatrist's liaison function is to attend rounds, be aware of difficult clinical and family situations, get to know nurses and house staff through teaching and informal discussion concerning patients, and be aware of the early signs of behavior destructive to patient care and fellow staff. With sufficient credibility, the child psychiatric consultant can organize family or interstaff meetings that have a beneficial impact on the unit's functioning and can relieve family or staff suffering.

ETHICAL ISSUES

The psychiatric consultant faces many challenging ethical issues in the hospital. The consultant may be involved in helping children and families come to terms with psychologically complex decisions, such as pursuing continued aggressive treatments or assenting to do-not-resuscitate orders. Staff and families need help assessing the extent to which a child at a particular developmental level can understand and be included in such decision-making.

Confidentiality is complex in the hospital setting. The consultant must be clear about with whom information gathered in the consultation will be shared and what the limits of confidentiality are. What cannot be kept confidential may be clear, such as suicidal ideation, but what can be confidential, such as a child's worry about a parent's sadness or a parent's trauma history, may be less apparent. The medical record is open to the full medical and support staff, and some personal information may be disclosed that is not relevant to the child's medical care.

FUTURE CONSIDERATIONS

The long-term benefits of psychiatric intervention must be assessed through outcome studies examining the impact on quality of life and on further use of health care dollars. Professionals who work with children are called on to advocate for the special needs of the young because they are not yet able to do so for themselves. Interventions that improve the psychological well-being of children maximize their productivity long into the future, and interventions that support families strengthen the community. As managed care, critical pathways, and advances in care decrease lengths of stay, increasingly consultation work will bridge to or be centered in outpatient settings and schools.[126] Being accessible, responsive, and communicative with primary care pediatricians will continue to be essential in the future.

Efforts have resulted in closing some of the distance between pediatrics and child psychiatry. Some subspecialty clinics, including those treating cystic fibrosis, cancer, diabetes, and endocrine disorders, are more open to consultation at the time of diagnosis, at key points in the illness, and for nonadherence. For primary care settings, the Bureau of Child and Maternal Health of the Public Health Service and the American Academy of Pediatrics have collaborated on projects that emphasize the psychosocial needs of children. Bright Futures[127] integrates psychosocial issues into every recommended primary care visit. The *Diagnostic and Statistical Manual of Mental Disorders*—

Primary Care[128] bridges variations and problems common to pediatric practice with the DSM-IV-TR. Symptom checklists, such as the Pediatric Symptom Checklist,[129] are being used to screen for psychosocial dysfunction as part of ensuring comprehensive care and assessing mental health services. Sustained improvement in pediatric mental health services will require continuing and expanding collaboration between medical and child and adolescent psychiatric providers.

Consultation to Parents with Serious Medical Illness: Parenting at a Challenging Time

Kristin S. Russell, M.D.
Paula K. Rauch, M.D.

Millions of children in the United States grow up in families in which a parent is medically ill. The National Cancer Institute estimates that 25% of cancer patients have at least one child 18 years of age or younger[1] and that one third of patients with breast cancer have dependent children.[2] Psychiatric consultants are often asked to consult with parents who have questions about how their medical illness will affect their children. The psychiatric consultant can assist medical and surgical teams by facilitating communication about these topics among the treating clinicians and the patient, providing specific guidance about parenting to the patient, and assisting with connections to community resources.[3–23]

FACILITATING COMMUNICATION WITH MEDICAL TEAM

In general, medical teams often err on the side of not talking to patients about parenting concerns (because they believe they lack the expertise, it isn't their place, and they do not have enough time). Consultants can help parents get the medical information they need to help with planning (e.g., what to expect regarding symptoms secondary to the illness and side effects of treatment). They can also guide patients to get information that will help answer a child's specific questions or concerns (e.g., how long they will have to be in the hospital, whether they will lose their hair as a result of chemotherapy, whether medications may interfere with driving, and how much energy they might expect after they return home).

PARENT GUIDANCE

The most common question that parents who face serious medical illness ask is, "How can I make all this easier for my child?" Given the limits of the current research in the field, the content discussed in this chapter is derived from the accumulated clinical experience of the team of clinicians who staff the Parenting at a Challenging Time (PACT) program at the Massachusetts General Hospital (MGH).[3–25] This chapter will address important ways to support childhood coping, including the following: using a developmental perspective to understand the child's current cognitive, emotional, and social abilities and needs; facilitating communication with the child about the illness and the treatment; and applying practical approaches to routines and family life.

RESOURCES

A list of community and online resources for patients can be found in Table 43–1. In addition to connecting parents with resources, clinicians can help parents assess when further intervention is needed; parameters to assist clinicians with this are discussed in the chapter and outlined in Table 43–6. Clinicians may be interested to read about a parenting-focused consultation-liaison (C-L) model, which has been used at the MGH for a number of years to serve the needs of parents with severe medical illness.

Although it is difficult when a parent develops a serious medical illness and perhaps dies, children and families are resilient, particularly when supported. For clinicians who have only recently begun to work with families facing medical challenges, the sadness and anxiety can feel overwhelming. However, our clinical experience compels us to underscore the strength, grace, and resilience that parents and children so often exhibit during and after exposure to illness. Indeed, many families return to us, sometimes years later, with memories and thoughts about this time in their lives. For many this experience has been not only one of pain but also one of enormous growth for themselves and their children. Through the process of pulling together, finding support in the community, prioritizing values, and appreciating each day and each other, they feel their children have learned to actively cope with challenges and appreciate their strength.

PARENTAL ILLNESS: A REVIEW OF THE LITERATURE

The body of research in the field of parental illness is relatively young; most studies have involved small numbers of parents and children, and some suggest conflicting results about the impact on the children. Much of the literature concerning parental illness has involved patients with cancer; several reviews provide recent summaries of this work.[15,21,26] We will highlight several areas of ongoing research.

TABLE 43–1 Resources for Patients

Resources for Cancer Patients

People Living with Cancer, from the American Society for Clinical Oncology (ASCO)
Offers educational information for patients and families (www.plwc.org)

American Psychosocial Oncology Society (APOS)
Provides a free help line to connect patients and families with local counseling services, as well as webcasts for professionals on topics such as "Cancer 101 for Mental Health Professionals" and "Psychosocial Aspects of Cancer Survivorship" (co-sponsored by the Lance Armstrong Foundation) (www.apos-society.org)

American Cancer Society (ACS)
Provides information on talking to children about cancer, as well as numerous other cancer-related topics (www.cancer.org)

The Wellness Community
A national, nonprofit organization that provides free online and in-person support and information to people living with cancer and their families (www.thewellnesscommunity.org)

Living Beyond Breast Cancer
A national education and support organization with the goal of improving quality of life and helping patients take an active role in ongoing recovery or management of the disease (www.lbbc.org)

Young Survival Coalition
Through action, advocacy, and awareness, this nonprofit seeks to educate the medical, research, breast cancer, and legislative communities and to persuade them to address breast cancer in women 40 and younger—and serves as a point of contact for young women living with breast cancer. (www.youngsurvival.org)

Breast Cancer.org
Offers medical information about current treatments and research in breast cancer care and survivorship (www.breastcancer.org)

Hurricane Voices Breast Cancer Foundation
Among other breast cancer–related resources, this organization offers a family reading list of books and stories for children of all ages dealing with cancer, in particular with breast cancer. (www.hurricanevoices.org)

CancerCare
The mission of this national nonprofit is to provide free professional help to people with all cancers through counseling, education, information, and referral and direct financial assistance. They offer online, telephone, and face-to-face support groups to those affected by cancer. (www.cancercare.org)

Lance Armstrong Foundation (LAF)
LAF offers information and services to cancer survivors and the professionals who care for them. (www.livestrong.org)

The Life Institute
This organization's online publication "Conversations from the Heart" provides an annotated list of resources for parents and professionals who want to learn more about how to have developmentally appropriate conversations with children about serious illness and death. (www.thelifeinstitute.org)

Resources for Other Illnesses

American Heart Association (www.americanheart.org)
American Diabetes Association (www.diabetes.org)
ALS Association (www.alsa.org)
Brain Injury Association of America (www.biausa.org)
Colitis Foundation (www.colitisfoundation.org)
Cystic Fibrosis Foundation (www.cff.org/home)
Epilepsy Foundation (www.epilepsyfoundation.org)
National Multiple Sclerosis Society (www.nmss.org)
National Neurofibromatosis Foundation (www.nf.org)
Pulmonary Fibrosis Foundation (www.pulmonaryfibrosis.org)

Stress and Family Function

Parental cancer is a significant stressor for children.[27–31] Parents often underestimate their children's level of psychological distress.[31,32] Re-establishing normal routines is key to successful family coping.[33] Interestingly, families with parental cancer perceive themselves as functioning in a positive fashion compared with the norm (believing that they are more expressive and social, better organized, less controlling, and with less conflict).[34] Maternal depression negatively affects marital relationships, a child's coping, and family function.[35,36] Moreover, patients with dependent children were more likely to meet criteria for panic disorder; their spouses were more likely to meet criteria for major depressive disorder and generalized anxiety disorder.[37]

Childhood Coping

Children move in and out of their worries about a parent's cancer.[38] Their developmental stage affects their style of coping and their response to a parent's illness.[39] Children employ a range of coping strategies when facing parental illness (e.g., relying on normal activities, the support of friends, and family cohesion; understanding the medical situation).[40] Among children, distraction and maintenance of normality were common strategies for coping. Noticeable changes in children's lives included increased responsibilities and decreased social activity; positive aspects of the experience were stronger relationships and learning to value important people and things.[41] Some children used coping strategies that included helping others, parentification (i.e.,

acting like a parent) distraction, internalization, and wishful thinking; in these children communication patterns and parental coping were highly correlated with a child's coping repertoire.[42]

In a number of studies, approximately one fourth of children who faced parental cancer experienced clinically significant depression, anxiety, or somatic symptoms compared with approximately 10% to 15% in normative samples; of note, some studies demonstrated no difference between groups.[21] Adolescent girls of an ill parent may be at greater risk for distress than other demographic groups.[43] In particular, it may be adolescent daughters with ill mothers who are at the highest risk.[44]

Communication

Parents desire developmentally sophisticated assistance to facilitate communication about their illness with their children.[45,46] Moreover, better communication helps children cope.[47–50] Children want honest communication about their parent's illness and its treatment, as well as any genetic implications of the disease for them; communication stalls because they worry about upsetting parents by asking them directly.[51]

SUPPORTING CHILDHOOD COPING

The following discussion pertains to three key ways to support a child's coping. The first is to use a developmental perspective to understand the child's current cognitive, emotional, and social abilities and needs. The second is to facilitate communication with the child about the illness and treatment. The third is to apply specific practical approaches to routines and family life.

Developmental Considerations

A developmental perspective helps inform parents and clinicians. Although there are many factors that contribute to variations among children (e.g., temperament and environment), the vast majority of children pass through common developmental stages at fairly predictable ages. Familiarity with these stages and the cognitive, emotional, and social implications of each can lead to a more nuanced understanding of the impact of the illness on the child, facilitate communication, and guide decision-making to best support the child (Table 43–2).

Infants and Toddlers (0–2)

Attachment and self-regulation are the primary tasks of infants and toddlers. Accordingly, it is likely that infants will be distressed by separation from familiar caregivers and changes in routines. They also tend to be affected to some degree by the emotional tone in the home, and they may be more irritable during times when the family is most distressed. Parents can help infants and toddlers feel more secure and comfortable by maintaining regular routines, using familiar blankets and animals, and providing detailed instructions to caregivers to keep care as consistent as possible. In this vein, minimizing the number of caregivers is optimal. Helping the parent who is ill feel engaged (to the extent that this is feasible) in the care of the child is beneficial, and sharing videotapes or hearing voicemail messages with caregiver updates can be ways to help maintain a connection. Children of this age cannot understand explanations about illness, and the narrative of the experience will occur later. To help prepare for this, parents can create photo albums, videos, or letters for the child to read.

Preschoolers (3–6)

It is likely that preschoolers will be affected more profoundly by the changes in daily routine than by the idea of the illness. Alterations in the family rhythms (e.g., the parent being unavailable to tuck them in at night, changes in the dinnertime routine, new caregivers in the home) are likely to be distressing. Cognitively, preschoolers use magical thinking to intermingle fantasy and reality, and they lack a clear understanding of cause and effect. They remain largely egocentric at this age, and the combination of these factors can lead them to conclude that something they did, said, or thought caused the illness. For instance, a 5-year-old girl, after learning her father "has cancer in his stomach," might conclude that the rough hug she gave him before he went to work caused his illness. Children may feel powerful and dangerous, which may lead to anxiety; alternatively, they may react to the overwhelming feelings by becoming aggressive and ignoring limits. It is useful to check in with children this age to discuss what they think caused the illness and correct misconceptions; preschoolers need to be reminded repeatedly that nothing they did caused the illness. In any discussions about death and dying, it is important to recognize that children this age see death as reversible and temporary.

It is not uncommon for preschoolers to regress (e.g., beginning to wet themselves again) or to complain of stomachaches or headaches from time to time. Usually these changes do not persist. As with infants and toddlers, maintaining daily routines and familiar surroundings for preschoolers is crucial. Caregivers may be tempted to relax discipline because the child is already going through so much; however, consistent limits are in fact essential to remind the child that the world is a predictable and safe place.

Latency/School-Age Children (7–12)

School-age children are focused on the mastery of skills. They feel strongly that everything, including illness, should be fair and follow rules; they can get very angry with unexpected changes. Although they are cognitively able to connect cause and effect, they may regress under stress and feel responsible for a parent's illness. Also, their cause-and-effect logic is fairly simplistic and inflexible, and they may insist, for instance, that illnesses must be contagious or that cancer is always caused by cigarettes. It is common for latency-age children to care deeply about appearances as they strive to figure out where they fit into their social world; as a consequence, they may be particularly embarrassed about the ill parent's appearance (e.g., if the parent has lost his or her hair as a result of chemotherapy, they may insist that the parent wear a wig). In conversations about death, school-age children are able to understand that death is both permanent and universal. They may be surprisingly matter-of-fact about death, intellectualizing about the topic rather than being immersed in the feelings. They may also be particularly curious about the details of death and dying; preparing parents for these questions may help them feel more comfortable engaging with their child.

TABLE 43–2 Key Points and Parenting Tips by Developmental Stage

DEVELOPMENTAL STAGE	KEY POINTS	PARENTING TIPS
Infancy (birth to 2.5 years)	Concern with attachment and self-regulation	Maintain familiar routines. Keep number of caretakers to a minimum
Preschool years (ages 3 to 6 years)	Egocentricity + magical thinking = "I am to blame" Death is temporary and reversible	Maintain routines and loving limit-setting Repeatedly remind the child that the illness is not his or her fault
Latency (ages 7 to 12 years)	Mastery of skills Rules and fairness; simple cause-and-effect logic Peer-focused and image-conscious Intellectualization of death	Protect family time by limiting visitors and turning off the phone at meal times Set regular times for the child to show the ill parent the accomplishments of the week; attend to the details
Adolescence (ages 13 to 18 years)	Abstract thinking and behavior are not on the same plane Separation is developmental task but complicated by vulnerability of parent	Be cautious about assigning teens a parenting role with younger siblings Support relationships with trustworthy nonparental adults Foster safe independent behavior
Young adults (19 to 23 years)	Living away from home Serious relationship formation Longer time frame with regard to decision-making	Provide enough information to allow for decision-making Encourage balance between pursuing new life experiences and putting these on hold to spend precious time with the ill parent

Adolescents

Adolescents have the capacity to think in a more mature way and use abstract thought. For instance, they are cognitively able to understand more of the nuances of the illness and the potential consequences of death (e.g., less money for college or the sorrow of the other parent). However, there is often a lack of connection between their cognitive ability and its translation into behavior. Adolescents may respond to their emotional distress by spending more time away from home, with peers, or in non–family-related activities. This may leave parents feeling that the teen is self-absorbed or uncaring, when in reality he or she is trying to cope with the painful awareness of the parent's vulnerability.

This is a particularly poignant time in the child's life for illness to strike a parent. One of the primary developmental tasks of adolescents is to negotiate comfortable separation from their parents; their feelings about separation and family may become intolerably complex at times, with the developmental pull to separate mixed up with the intense fear of losing the parent. The adolescent will likely need an adult's help (and limit-setting) to find an appropriate balance between engaging in (safe) independent behavior and spending time with the ill parent and the family. Although teens should be expected to help with chores at home, caution should be exercised when shifting a parenting role with younger siblings to teens. This is particularly common with adolescent girls. Adolescents often seek nonparental adults to confide in, and it is important for parents to foster these relationships when they are with adults whom they trust. Intense feelings about death are often the rule; many adolescents make use of existential conversations or readings, journaling, and peers to absorb some of these feelings.

Young Adults

Given their stage of life, young adults may be away at college or living on their own. They may feel unsure about whether, and when, to come home. They may feel conflicted about having a separate life outside the family (on the one hand relieved, and on the other somewhat isolated from the family). There may be particular strain among siblings, some of whom may still be at home and facing struggles that the older sibling is not. Young adults who are themselves parents may have complicated feelings such as anger, fear, and loss because they do not have access to the help and guidance with their own parenting that they had expected to receive from the ill parent or family members who are now absorbed by the illness.

Communicating About Parental Illness

It is important to begin a dialogue. Children cope better when parents initiate communication about the illness (e.g., asking what questions they have, finding out what they understand and what kind of information they do and do not want). The worst way for children to find out about bad news is to overhear discussions between others. There are multiple reasons for this. Children may think that they are not being told because the information is too awful to discuss with them. Alternatively, they may believe that they are not sufficiently valued to be involved in the discussion. Finally, if they overhear it, they often will be confused by the information and reluctant to tell the parent that they were listening, so the opportunity to clarify the situation may not come until a long period of anxiety has elapsed for the child.

It may be best to wait a short time to communicate so that the parent is calm enough to help the child process his or her emotions. It helps to make it clear from the beginning that the parent trusts the child by sharing honest information. Parents should start by calling the illness by its real name (e.g., "breast cancer" as opposed to "a lump"). Children will not trust future information if they think their parents are not being straightforward, and they

will tend to search for clues that their parents are lying to them. It is also important not to make promises that cannot be kept. Instead, parents should say that they are just not sure of something; comfort with uncertainty is a helpful trait to model. It is also all right to take time to think through responses to questions (e.g., a parent could say, "That's a good question. I need to think about that, and I'll get back to you."). One of the most dreaded questions is, "Are you going to die?" Children can be reassured by hearing that their parent plans to get the best treatment possible, take good care of himself or herself, and live as full a life as possible in the meantime. As with other questions, it can be helpful to find out what the child really wants to know (e.g., what will happen to the child, who will care for the child).

Although parents should give children ample opportunities to talk about the illness, children should not be pushed if they resist. Some children tend to be talkers, whereas others are not, and the illness is unlikely to change these qualities. At the same time, for children who are less inclined to share their thoughts, parents can help by wondering aloud about some of the questions that the child might have and noticing whether the child becomes engaged and interested. If so, parents can continue talking, while taking particular notice of the child's nonverbal signals. Children are generally able to indicate whether they want the conversation to stop, and if they do, this desire should be respected. Parents may want to consider the time at which they bring up the topic, because children often are most communicative when the intensity is lessened in some way (e.g., when cooking or doing a craft project together, driving in the car, or getting ready for bed with the lights out).

Children often do better with more specific questions (e.g., "Did it annoy you to miss your play rehearsal last week because dad was driving me to the hospital?") rather than open-ended "feeling" questions (e.g., "How are you feeling about my illness?"). When children do ask questions, helping them refine the question so that the appropriate amount of information is given in response is important. For instance, a child who asks, "When is Mom getting out of the hospital?" may be thinking about whether she ever will (or whether she is going to die), or the child may be thinking about whether she will be home in time to attend the child's upcoming play performance. Very different responses would be appropriate in these two situations, and understanding what the child is really asking will help keep the child from feeling overwhelmed with more information than he or she can handle as well as convey the parent's concern and sensitivity.

Parents should encourage children to share what they hear from others about the illness and not to worry alone. Sometimes people with good intentions share their (unhelpful) observations about the parent's illness or their own (frightening) experiences with illness, and it is easy for the child to become overwhelmed or scared. Parents should tell children how much the illness varies among different people and how much misinformation exists. Anticipating these moments together and planning to talk about them if they happen can make a big difference. Table 43–3 summarizes some of these communication tips for parents.

TABLE 43–3 Tips for Communicating with Children About Parental Illness

Be honest.
Remember that the worst way to hear difficult news is to overhear it.
It is not necessary to answer questions immediately.
Welcome all questions warmly.
Encourage elaboration of the question.
Notice the child's best times for reflection and discussion.
Encourage children to share everything they hear from others about the parent's cancer.
Remind children not to worry alone.

Routines and Family Life

The following sections outline practical suggestions for parents regarding daily routines and family life. General principles include keeping routines as consistent as possible, preserving family time, and using support wisely.

Routines

Following regular daily routines (as much as possible) helps let children know that despite the illness, there is stability and thus security. Particularly for young children, parents should keep the schedule the same from day to day (e.g., mealtimes and bedtime) with just a few familiar caretakers. It is best if older children continue their activities to the extent possible (e.g., school, soccer practice). It helps to post schedules, make lists, and use calendars to help children and caregivers know what each day holds. For childcare or driving help, parents of the child's friends are often available and accepted by the child.

As much as is feasible, parents should keep family routines as consistent as possible. Children are highly attuned to any shifts at home (e.g., new people answering the phone or cooking, new smells, and dinnertime patterns done in a different way). Many children identify these types of changes as the most upsetting part about the illness. Remembering how important this consistency is to children can help parents set priorities that may initially seem inconsequential; for instance, even though doing so might be difficult, it may really matter that dinner begin at 6:30 and continue without interruptions, with dinner clean-up chores maintained the way they were before the illness.

In addition to trying to maintain routines, parents should look for ways to create new, predictable family time, such as having a certain meal each day of the week (e.g., Monday is pasta; Tuesday is tacos). It helps to elicit input from children about fun activities (e.g., watching cartoons in bed on Saturdays). It can lift everyone's spirits to find opportunities to celebrate. Taking videos and photos may become an important part of the family record for the future.

Keeping family time off-limits from visits, phone calls, and technology (e.g., e-mailing and texting) is crucial. This keeps the focus on togetherness and prevents children from overhearing conversations about the illness that are not intended for their ears. It is important to have ample time when the illness is not the focus of conversation. Staying as up-to-date as possible about the child's

friendships, schoolwork, and daily activities helps the child feel that his or her world remains right-side-up and gives the child permission to pursue these things even though the parent is ill.

Captain of Kindness

Appointing a "captain of kindness" to organize support so that volunteers are not directly contacting the family can be beneficial. There can be an overwhelming swell of support in communities when a beloved member has a life-threatening illness, and it quickly becomes a time-consuming task to coordinate the kind offers to help. Having a designated person to organize these efforts allows the family to conserve their resources and focus on the children. An additional benefit is that the captain of kindness can ensure that the support is concentrated on tasks that would be most helpful for the family (e.g., making lunches for the kids, providing a vegetarian dinner on Wednesdays).

Minister of Information

Designating a "minister of information" to organize the flow of communication, providing updates to concerned family and friends so that the immediate family is able to save precious time and energy for family time, can be valuable. It is also helpful to have volunteers in each of the family's communities (e.g., school, church, neighborhood, and work friends); these volunteers can help keep well-wishers informed and spare the family the trouble of providing individual updates. They can also help by organizing or diverting visits (so the family is not in the position of having to explain that they need quiet time).

School

Parents should tell the child's teachers about the illness and outline the approach they would like the teacher to take. Typically, school should be a protected place in which the child can have life go on as usual. Although teachers sometimes think that they are helping by trying to engage the child about the topic, it is best for the child to lead the way. The parents should let the teacher know that they would like to be informed if the child volunteers his or her worries about the illness (most children do not). Likewise, the teacher should keep the parents apprised of any other struggles, including academic ones, that the child is having so that these can be addressed promptly. Teachers sometimes consider it a kindness to withhold upsetting information, but it is in fact a disservice to the child and the family who need—more than ever—to stay on top of any developing problems.

Self-Care

Parents with medical illness and their co-parents need to take sufficient care of their own physical and emotional needs. For instance, it is critical to take time to get necessary medical care and to follow treatment recommendations to minimize physical and emotional stressors and setbacks. If the ill parent or spouse is feeling overwhelmed, panicked, or hopeless, seeking additional support in a timely way is important. Children look to their parents as models; demonstrating care during times of physical and emotional challenge provides an important lesson. Children feel more secure when they see that their parents are taking care of themselves.

Hospital Visits

With a few exceptions, children who want to visit a parent in the hospital should be allowed to do so. Parents often worry about their child seeing them looking ill and wonder if it is better for them to stay home. In reality, children seem to do much better with the actual—rather than the imagined—images. Preparation for the visit is important and should include a description of how the parent looks (e.g., what he or she is wearing, what tubes he or she might have) and how the hospital room looks (e.g., presence of a roommate) (Table 43–4). If there will be multiple agendas for the visit (e.g., if there are several children wanting to visit, or if the other parent wants to visit with the ill parent as well), an additional, familiar adult should come along and be available to take the child for a break when he or she is ready. For younger children, or when longer visits are anticipated, quiet activities (e.g., drawing pictures, coloring) can be planned and snacks can be packed. The child may want to bring something to do with the parent or show the parent during the visit (e.g., a new toy, a grade on a test). After the visit the child should be given the opportunity to discuss his or her impressions of the visit and ask questions.

There are a few exceptions to consider. For instance, when parents are delirious, children may be frightened or confused by the parent's agitation or disorientation. Or, if a parent is recovering from an intervention and is expected to be feeling or looking much better in a short time (e.g., 24 hours), it may be sensible to defer the visit. If an in-person visit is not possible, phone calls or even videophone calls can be very helpful.

Preparing for Death

End-of-Life Care

When a parent's care shifts from life-extending treatment to end-of-life care, the parent may be able to choose where to receive this care. Common options include institutional care (at a hospital or a hospice) or home care. There are pros and cons to each; some of these are detailed in Table 43–5.

Home-based hospice care is one way that families who want the parent at home but need help with the medical and nursing care can sometimes find a balance.

These choices are complicated and fraught with emotion. Although having this conversation is incredibly difficult, it is important for children to be able to participate in the process so they can express their feelings and concerns.

Saying Goodbye

It is helpful to have a conversation in advance of death about how the child wants to be told about a parent's death. For instance, if it happens in the night, does the child want

TABLE 43–4 Tips for Hospital Visits

Describe what the child will see before entering the room.
Let the child determine the length of the visit.
Bring a familiar adult who is available when the child is ready to go.
Bring play materials.
Discuss the visit after leaving.

TABLE 43–5 Pros and Cons of Institutional and Home Care

TYPE OF CARE	PROS	CONS
Institutional (Hospital/Hospice)	Less burden of caretaking on family	More difficult to visit May be less comfortable for patient
Home	Easier to visit More comfortable in own home	Concern about nursing needs, pain control, and medical equipment Best to have room with a door to allow privacy; ideal to not disrupt children's space Concern about death happening in home (e.g., what children will be doing, what happens when the coroner comes, possibility of discomfort in the room after the patient dies there)

to be awakened? If it happens during a school day, does the child want to be told at the end of the day?

When possible, children should have the opportunity to visit with a parent at the end of life. If children are reluctant to see a parent at this time, they can be encouraged to be nearby, such as in the waiting room. If a parent is unresponsive by this time, it is often helpful to let children know that we do not know what someone can hear when in this state, but we believe that the person may sense that loved ones are nearby. Children may want to say something to the parent, hold the parent's hand, or think something they want the parent to know. It is important for others to articulate that the parent was loved by the child and that the child was loved by the parent. If the relationship was strained or conflicted in some way, it is helpful to acknowledge this and then to say that despite these arguments, the parent loved the child and knew that he or she was loved by the child. It is this expression of love, rather than the word "goodbye," that is important to share in these final hours or days.

Leaving a Legacy

Many parents feel moved to leave behind something for their child. Parents have different ideas about what to leave and what leaving something represents. Much of the impetus is for the parent to communicate to the child that the child was loved. There may be moments for this in the final days, but the parent may also want to write a letter to the child describing his or her feelings. A letter affords the opportunity to provide details that may be cherished by the child, such as a description of the way the parent felt when the child was born, took his or her first steps, or went to kindergarten for the first time. A letter may also provide an opportunity for the parent to let the child know that he or she can form attachments to, and love, other adults without feeling disloyal.

Parents may find other means to convey these feelings. Some leave belongings, such as a favorite piece of clothing or jewelry. Others leave funds dedicated to something particular for the child to experience (e.g., a trip after graduation). Still others leave scrapbooks, CDs, recipe boxes, or lists of friends to contact to learn more about the parent at different phases of his or her life.

Financial and Legal Planning

For families facing serious medical illness, taking time out to attend to financial and legal issues is an important part of creating security for their children. This may be a task they can take on themselves, or they may need to employ the help of a friend, relative, or professional. These are weighty issues and thus ones that are often avoided by healthy families. In cases of illness, however, it is even more critical to confront these issues directly to minimize the likelihood of negative, and even catastrophic, consequences. Even when difficult circumstances prevail, it is crucial for children to be able to feel that their parents worked hard to create as much safety and security as they could.

Medical illness can have many financial implications (e.g., shortening the time a parent is able to generate income, depleting savings because of the cost of medical care or additional help). It can be helpful to start the process by getting a handle on current income and expenses and then working through several scenarios (e.g., parent becoming disabled or dying), including modifying the family budget. Looking carefully at benefits and insurance policies (e.g., medical, disability, and life insurance) is a critical part of this process.

Legal issues to consider include preparation of documents such as a will, health care proxy, power of attorney, and living will. Consultation with an attorney may be necessary, particularly if issues of custody are at play. Although custody is a complex topic and varies from state to state, there are several rules of thumb that are commonly followed. First, if the parents of a child are married and one dies, the child will remain in the custody of the surviving parent. If the parents are not married, custody typically will go to the surviving parent unless there is a very clear reason for the judge to decide against this. In situations in which the custodial parent is approaching death and feels strongly that the noncustodial parent is an inappropriate primary caregiver, one option is to contact that parent and ask him or her to voluntarily relinquish parental rights (i.e., giving up right to custody and responsibility for financial support). Another option is to seek help from the court in requesting a guardian *ad litem* to evaluate the best interests of the child.

Funerals and Memorial Services

Ideally, planning for a service should begin before the parent's death. This allows the parent to share his or her wishes about the service and helps minimize family conflict that might arise after the fact. It can be helpful for children to have a familiar person preside over the service and to have the service in a familiar location (where their friends can attend).

Many of the suggestions (e.g., having an adult prepare the child with as many specifics as possible about the event and answering any questions the child may have) that apply to hospital visits are appropriate for funerals and services as well. An adult should be available to talk with the child after the event to discuss his or her feelings and questions. Younger children should have a familiar adult who is specifically designated to support them and take them outside, if needed. The usual recommendation is for children age 4 and older to attend the ceremony. Preschool children often are not taken to the cemetery (after the ceremony) because they may have trouble understanding the fact that death is irreversible and therefore may become especially distraught at the image of the parent being buried.

Memorial services provide an opportunity for children to see that the community valued their parent. Children should be allowed to participate in whatever ways they are comfortable. Some may want to speak, play an instrument, or choose a song; others may just want to listen. If a child does not want to participate actively, this should be accepted and the child should not be made to feel that he or she is failing to meet an expectation.

WHEN TO RECOMMEND FURTHER INTERVENTION

One of the most rewarding aspects of working with children is their resilience; most children are able to adjust to a parent's illness or death relatively well with supportive caregivers. However, in some situations children struggle, and further evaluation and perhaps support by pediatric mental health providers may be helpful. An important role of the psychiatric consultant is to help parents determine when this is necessary; the following discussion and the guidelines in Table 43–6 may help guide the consultant.

When a child specifically requests to speak to someone, this should be facilitated. Because children with previous psychiatric challenges are at higher risk for difficulty when a parent is ill, it is often prudent to reconnect these children with their previous providers when possible. Children with symptoms of depression or anxiety that interfere with their daily activities (e.g., school, friendships, family life) for more than a few weeks should be referred for consultation. These symptoms may include depressed, anxious, or irritable mood for more than a few weeks; a change in sleep, appetite, energy, and concentration; or feelings of guilt or anhedonia. Suicidal ideation should be evaluated on an urgent basis. Finally, children who are engaging in risky behaviors (e.g., substance abuse, promiscuity, fighting, reckless driving) should be referred for consultation. There are many types of mental health supports for children, and access to services varies by location. A reasonable place to start is to ask the child's pediatrician or school guidance counselor.

TABLE 43–6 When to Recommend Further Intervention

When the child requests to speak to a counselor
When the child has previous psychiatric issues
When the child has symptoms of depression or anxiety that interfere with daily activities (e.g., school, friendships, family life) for more than a few weeks (Suicidal ideation should be evaluated on an urgent basis.)
When the child is engaging in risky behaviors (e.g., substance abuse, promiscuity, fighting, reckless driving).

PACT TEAM: A PARENTING-FOCUSED CONSULTATION–LIASION MODEL

The Parenting at a Challenging Time (PACT) program at the MGH Cancer Center was started in 1997 to provide expert consultation to parents with cancer. Referrals are made through any member of the medical team or by patients themselves. Typically, consultations consist of 2 to 10 visits; patients or families may choose to pursue further consultation if the cancer recurs, if a new parenting concern emerges, or after the patient dies. Indeed, the most common times for consultation include after the initial diagnosis, at the recurrence of illness, and at the end of life. The content of the meetings is generally focused on three general areas: communication with the child or children, behavior issues of the child or children, and general family coping. Clinicians (child psychiatrists and psychologists) meet with the patient and, if the situation warrants, with children, spouses, and other family members. Consultations occur on inpatient units, in outpatient offices, during chemotherapy infusion or dialysis, or by telephone. Patients and families who need more extensive intervention or psychiatric treatment are referred for treatment.

The PACT team (Table 43–7) meets during weekly rounds to coordinate care and discuss challenging cases. Oncology team members attend these rounds to collaborate in the care of complicated patients and families. When appropriate, PACT clinicians work more extensively with the oncology, medical, or surgical teams. Liaison work also includes education, outreach, and advocacy. Consultations are provided free of charge, and funding is secured through the MGH Cancer Center and through philanthropic donations (see www.mgh.pact.org).

CONCLUSION

Clinicians who care for patients with a serious medical illness must recognize that many of them are parents with pressing concerns about how the illness and treatment may affect their children. The psychiatric consultant can assist the team by facilitating communication about these topics among the treating clinicians and the patient and providing specific guidance to the patient and family about support-

TABLE 43–7 Parenting at a Challenging Time

Free to patients
Staffed by child psychiatrists and psychologists
Patient or any member of team can request a consult
Usually consist of 2 to 10 visits
Meet at patient's convenience (e.g., on inpatient floor, outpatient office, infusion unit or by phone)
Sometimes include the child or children

ing childhood coping. Use of a developmental perspective to understand a particular child's cognitive, emotional, and social capacities will inform both the approach to communication about the parental illness and the specific parenting interventions that may be helpful. General principles include keeping daily routines as consistent as possible, preserving family time, and using support wisely.

44 Care of the Geriatric Patient

M. Cornelia Cremens, M.D., M.P.H.
Ilse R. Wiechers, M.D., M.P.P.

The U.S. population over the age of 65 years has been increasing dramatically, reflecting improvements in health, nutrition, and medical care for the elderly. Illness (both medical and psychiatric) increases with advancing age in part due to stressful life events, the burden of co-morbid conditions, and combinations of medications used.[1] Roughly 40% to 60% of those hospitalized with medical and surgical illnesses are over the age of 65 years; such problems place them at greater risk for functional decline.[2] In addition, a reduction in hepatic, renal, and gastric function further impairs the elderly's ability to metabolize drugs.[3] By the year 2030, one in five Americans will be older than 65 years. Thus, psychiatric consultation to this group of patients is becoming ever more necessary while providing both complicated challenges and rewards.

CONSULTATION WITH GERIATRIC PATIENTS

Depression

Mood disorders associated with later life are a major public health problem. Depression is prevalent, unrelenting, immobilizing, and frequently fatal, especially in those with co-morbid medical illness.[4,5] In the United States, depression in the elderly accounts for higher rates of suicide than any other condition. Moreover, rates of suicide are higher in later life than they are in any other age-group.[6] More than 90% of older individuals who commit suicide have a risk factor for suicide (e.g., depression or other mental disorders, a personal or family history of substance abuse disorder, stressful life events, a prior suicide attempt or a family history of an attempt, family violence [including physical or sexual abuse], firearms in the home [the method used in more than half of suicides], incarceration, or exposure to the suicidal behavior of others [e.g., family members, peers, or media figures]).[7] In addition to having a higher prevalence of depression, older persons are more socially isolated and they use highly lethal methods more frequently. Suicide occurs early (often during the first 6 months) in the illness, but it can occur at any time, often in combination with other mental disorders.

Approximately 50% of those with neurologic diseases, cardiac diseases, or cancer have depressive symptoms. The risk for depression in the poststroke period is also high, with 25% to 50% developing depression within 2 years after a stroke.[8] Alzheimer's disease (AD) carries an increased risk of depression (found in 20% to 30% either before or at the time of diagnosis), and delusions are also prominent in depression associated with dementia.[9] Recent research confirms the association of depression with the increased risk of developing late-onset AD.[10] Fifty percent of patients with Parkinson's disease develop depression or have a history of depression with anxiety, dysthymia, or frontal lobe dysfunction.[11] Use of medications for medical problems often generates adverse effects and complicates the diagnosis of depression; moreover, medical illness may mimic depression and depression may mimic medical illness. In short, the elderly are at greater risk for depression due to the prevalence of these illnesses and their downstream sequelae.

Despite the fact that depression is a mood disorder comprising far-ranging symptoms (involving disordered sleep, diminished interests, guilt and ruminations, decreased energy or fatigue, impaired concentration, disturbed appetite, and suicidal thoughts or attempts), clinicians find that somatic complaints, rather than depressed mood, are often the reason for referral of the elderly and the medically ill.[12] These physical complaints lie on a continuum and can mimic medical problems (e.g., chest pain, headache, joint pain, nausea, dizziness, and weakness). Teasing out the symptoms of medical or surgical problems from the symptoms of depression can be a daunting task in the hospitalized patient. Physicians often misdiagnose or undertreat depression in the medically ill due to an overlap of these symptoms. The Geriatric Depression Scale (Table 44–1)[13] is a helpful tool in this regard; often the information provided by caregivers is crucial because elders may not be forthcoming with their symptoms.[14] The criteria for diagnosing depression at this time are the same as they are in the general population.

Substantial progress has been made in the treatment of elderly individuals with mood disorders, especially major depression.[15] Once the diagnosis has been established, prescription of an appropriate medication is part of the art of geriatric psychiatry. Since most of the antidepressants are equally effective for depression (Table 44–2), knowledge of how an antidepressant may alter the metabolism and therapeutic drug levels of other medications is crucial. For example, one may wish to start with an antidepressant agent with less cytochrome P450 drug interactions (e.g., citalopram). One needs to review the side effects of the antidepressant and then tailor its use to the patient's symptoms. For example, if a depressed patient is sleeping poorly and losing weight, one should select a sedating agent that is associated with weight gain. Drugs with anticholinergic effects and undue sedation should be avoided to reduce complications (e.g., falls, confusion,

TABLE 44–1 Geriatric Depression Scale

Choose the best answer for how you felt this past week:

1. Are you basically satisfied with your life?
2. Have you dropped many of your activities and interests?
3. Do you feel that your life is empty?
4. Do you often get bored?
5. Are you hopeful about the future?
6. Are you bothered by thoughts you can't get out of your head?
7. Are you in good spirits most of the time?
8. Are you afraid that something bad is going to happen to you?
9. Do you feel happy most of the time?
10. Do you often feel helpless?
11. Do you often get restless and fidgety?
12. Do you prefer to stay at home, rather than going out and doing new things?
13. Do you frequently worry about the future?
14. Do you feel you have more problems with memory than most?
15. Do you think it is wonderful to be alive now?
16. Do you often feel downhearted and blue?
17. Do you feel pretty worthless the way you are now?
18. Do you worry a lot about the past?
19. Do you find life very exciting?
20. Is it hard for you to get started on new projects?
21. Do you feel full of energy?
22. Do you feel that your situation is hopeless?
23. Do you think that most people are better off than you are?
24. Do you frequently get upset over little things?
25. Do you frequently feel like crying?
26. Do you have trouble concentrating?
27. Do you enjoy getting up in the morning?
28. Do you prefer to avoid social gatherings?
29. Is it easy for you to make decisions?
30. Is your mind as clear as it used to be?

Scoring

1. no	6. yes	11. yes	16. yes	21. no	26. yes
2. yes	7. no	12. yes	17. yes	22. yes	27. no
3. yes	8. yes	13. yes	18. yes	23. yes	28. yes

5. no	10. yes	15. no	20. yes	25. yes	30. no

This is the original scoring for the scale: One point for each of the correct answers.

Normal—0-9; mild depressives—10-19; severe depressives—20-30.

Adapted from Yesavage JA, Brink TL, Rose TL, et al: Development and validation of a geriatric depression rating scale: a preliminary report, *J Psychiatr Res* 17:37-49, 1983.

poor compliance). Moreover, since depression can complicate one's recovery from the medical or surgical problems, treatment should be swift and aggressive. Often, stimulants are used alone or in conjunction with a traditional antidepressant, such as a selective serotonin reuptake inhibitor (SSRI).[16] Electroconvulsive therapy (ECT) should be considered (and discussed with the patient and his or her family members) if a patient is not responsive to medications.[17]

Bipolar Disorder

Patients over the age of 65 years with bipolar disorder (BPD) may not have developed their affective illness early in life[18]; for many the illness began in middle age or later life, often in association with co-morbid neurologic insults.[19] Those patients with co-morbid neurologic diseases have a significantly later age-of-onset of their affective illness and are less likely to have a family history of a mood disorder. Snowdon[20] reported that 25% of patients whose mania arose after the age of 50 had a history of a neurologic disease and had significantly fewer genetic (familial) risk factors. A number of biological risk factors (including genetic factors and medical illnesses, particularly vascular conditions) have been identified for BPD in the elderly.[21]

Symptoms of mania or hypomania are manifested differently in the elderly, with more anger, irritability, aggressivity, delusions, and paranoia. In addition, less grandiosity and euphoria appear, episodes of mania are longer, and cycling may be more rapid. Treatment response is inconsistent, although lithium, anticonvulsants (e.g., divalproex sodium, carbamazepine, and lamotrigine), atypical antipsychotics (e.g., olanzapine, quetiapine, and risperidone), and antidepressants have all been beneficial in the treatment of elderly patients with BPD. Moreover, the differential diagnosis of secondary mania warrants special consideration.[22] Many of those with dementia or delirium present with mania secondary to their underlying illness. Although the treatment of secondary affective symptoms is similar to those of primary affective illness, an accurate diagnosis is important.

Delirium and Dementia

The discussions of consultation involving individuals with delirium or dementia are handled separately in chapters elsewhere in this book (see Chapters 10 and 11 respectively, for detailed discussions of diagnosis and management). However, they also warrant discussion in this chapter, given that the prevalence of dementia increases as age advances (3% to 12% of patients over the age of 65 years, and 25% to 46% of those over the age of 85 years have dementia)[23] and patients with mild dementia are at greater risk for developing delirium (leading to serious behavioral problems) during a hospitalization.[24] Dementia and delirium are often confused in the geriatric population; when consultants are asked to assess a patient for one condition, they often find the other.

The elderly are more vulnerable to delirium because of the numbers of medical problems encountered, changes in brain function, brain disorders (such as dementia), reduced hepatic metabolism of medications, and multisensory dysfunction. The elderly are at the highest risk for delirium, as are those with brain damage (including dementia and strokes), cardiac surgery, burns, substance withdrawal, and autoimmune diseases.[25–28] The morbidity and mortality of elderly patients with delirium is high; 15% to 26% die, often as a result of the problem responsible for the delirium.[28]

Performing a comprehensive medical evaluation (e.g., with assessment of oxygenation and infections [such as urinary tract infections]) with an examination of the patient

TABLE 44–2 Treatments Recommended for Depression in the Elderly

DRUGS	DOSE RANGE (mg/d)	COMMENTS
Tricyclic Antidepressants		
Nortriptyline	10–150	Reliable blood levels, minimal orthostasis
Desipramine	10–250	Mildly anticholinergic
Monoamine Oxidase Inhibitors		
Tranylcypromine	10–30	Orthostasis (may be delayed), pedal edema, weakly anticholinergic, dietary restrictions
Stimulants		
Dextroamphetamine	2.5–40	Agitation, mild tachycardia
Methylphenidate	2.5–60	
Modafanil	50–200	
Selective Serotonin Reuptake Inhibitors		
Fluoxetine	5–60	Akathisia, headache, agitation, GI complaints, diarrhea/constipation
Sertraline	25–200	
Paroxetine	5–40	
Fluvoxamine	25–300	
Citalopram	10–40	
Escitalopram	2.5–20	
Serotonin–Norepinephrine Reuptake Inhibitors (SNRI)		
Venlafaxine	25–300	Increased systolic blood pressure (SBP), confusion, lightheadedness
Duloxetine	20–60	Diarrhea
Alpha-2 Antagonist/Selective Serotonin		
Mirtazapine	15–45	Sedation, weight gain
Atypical Antidepressants		
Trazodone	25–250	Sedation, orthostasis, incontinence, hallucinations, priapism
Bupropion	75–450	Seizures, less mania/cycling headache, nausea

(including a careful neurologic assessment, even if it has been done by another physician), review of medications, and review of medication compliance, are keys to uncovering the etiology of the delirium and directing appropriate management. Medications with anticholinergic effects are often responsible for cognitive dysfunction and should be avoided. Diphenhydramine, a medication commonly given to elderly patients for sleep, can be problematic because of its strong anticholinergic properties.

Agitation and behavioral symptoms occur frequently in geriatric patients with dementia and delirium. First-line treatment for behavioral and psychological symptoms of dementia involves use of nonpharmacologic strategies that manipulate environmental and behavioral features (such as regularly scheduled routines for meals, sleep, and bathing). For geriatric patients with delirium, whenever possible, a family member or a familiar person should stay with the patient to re-orient them; this may minimize the need for medications or restraints. However, in those with delirium, both restraint and medication may be necessary. Restraints may also be required as a reminder not to get out of bed without supervision, because falls and subsequent hip fractures are common in confused elderly. Hip fractures are associated with delirium and a poor prognosis for the elderly; they may never return to independent function following a hip fracture.[29] On the other hand, the risks associated with use of restraints are also greater among the elderly. Whenever possible, other ways to prevent falls should be entertained. Memory impairment in those with delirium persists in half of afflicted patients and becomes permanent.[30] Nursing home patients and patients with dementia are also at greater risk of delirium due to their impaired status.

Low doses of antipsychotics, either typical or atypical agents, are generally adequate to treat delirium in the elderly. One should increase the dose slowly, so as not to give more than is needed. Table 44–3 lists the types and doses of antipsychotics frequently used in the elderly. When patients are agitated and fail to cooperate with care or are unable to take oral medications, then IV haloperidol is often used to sedate and to reduce psychotic symptoms of delirium.[31,32] Elderly patients are initially started on lower doses (e.g., 0.5 to 2.0 mg of IV haloperidol). To adequately treat the delirium, the dose will need to be titrated.[30] While IV haloperidol can cause cardiac problems (with QTc widening and torsades de pointes), the etiology of polymorphic ventricular tachycardia is often difficult to determine.[33]

Atypical antipsychotics have been successfully used for treatment of delirium and agitation in elderly and in those who are critically ill.[34,35] Again, doses must be titrated slowly to minimize adverse effects. Patients are maintained on the optimal dose until their symptoms resolve. Symptoms of delirium in the elderly can last up to 6 to 12 months, and it may be necessary to discharge a patient home on an antipsychotic medication. Patients with underlying dementia are at greater risk for developing delirium; the impact of cholinesterase inhibitors have been studied in this population.[36,37]

TABLE 44–3 Antipsychotics Commonly Used in the Elderly

AGENT/DOSE (mg)	SEDATION	ANTICHOLINERGIC	EXTRAPYRAMIDAL	COMMENTS
Low Potency				
Thioridazine (Mellaril) 10–50	High	High	Low	Significant hypotension
Intermediate Potency				
Perphenazine (Trilafon) 0.5–5	Medium	Medium	Medium	
High Potency				
Haloperidol (Haldol) 0.25–2	Low	Low	High	
Thiothixene (Navane) 0.5–4	Low	Low	High	
Fluphenazine (Prolixin) 0.5–2	Low	Low	High	
Atypical Antipsychotics				
Clozapine (Clozaril) 12.5–100	High	High	Very low	White blood cell (WBC) count each week Excessive drooling Hypotension
Risperidone (Risperdal) 0.25–3	Low	Low	Low	More EPS than initially reported
Olanzapine (Zyprexa) 2.5–10.0	Moderate	Medium	Low	
Quetiapine (Seroquel) 12.5–200	High	Low	Low	
Ziprasidone (Geodon) 20–120	Moderate	Low	Low	
Aripiprazole (Abilify) 5–20	Low	Low	Moderate	

FDA ALERT (6/16/2008): FDA is notifying health care professionals that both conventional and atypical antipsychotics are associated with an increased risk of mortality in elderly patients treated for dementia-related psychosis.

In April 2005, FDA notified health care professionals that patients with dementia-related psychosis treated with atypical antipsychotic drugs are at an increased risk of death. Since issuing that notification, FDA has reviewed additional information that indicates the risk is also associated with conventional antipsychotics.

Antipsychotics are not indicated for the treatment of dementia-related psychosis.

Psychosis

Psychosis (manifested by hallucinations, delusions, disorganized speech, or disorganized or catatonic behavior) in the elderly has multiple etiologies. New-onset psychosis in the elderly should be rigorously worked up for possible organic causes, such as trauma (e.g., concussion, subdural hematoma, intraparenchymal hemorrhage), organ failure (e.g., hepatic encephalopathy, hypertensive encephalopathy, electrolyte abnormalities, stroke, and seizures), drugs and toxins, infections (e.g., pneumonia, urinary tract infections), and substrate deficiencies (e.g. hypoxia, hypoglycemia, vitamin B_{12} or folate deficiencies). Once organic causes have been ruled out, the remaining differential diagnosis of psychosis in the elderly includes: various types of dementias (e.g., AD, Lewy body dementia, vascular dementia, frontal lobe dementia [Pick's disease], Parkinson's disease), all of which can manifest with symptoms of psychosis at any point during the illness; delirium; delusional disorders; BPD; schizoaffective disorder; schizophrenia (either early-onset or late-onset); and major depression with psychotic features.

Psychosis is most commonly associated with schizophrenia and delusional disorders, but in the elderly, delirium and psychosis are more commonly associated with dementia and have behavioral complications that accompany these diagnoses. Psychosis in dementia is often manifested by one of three general categories (i.e., delusions, hallucinations, and misconceptions). Delusions often include the themes of stolen items, infidelity, imposters, disorientation, a lack of familiarity with ordinary items, and fear of being alone or abandoned. Hallucinations may relate to sensory losses and to the usual sensory domains (e.g., visual, auditory, tactile). Frequent misconceptions include the misperceptions of objects, not recognizing oneself, and believing that television scenes are real here-and-now events. Symptoms of psychosis are distressing to family members and to caregivers. They can become dangerous if the individual is frightened or energized by them.

Although schizophrenia usually begins before the age of 30 years, late-onset schizophrenia is not rare. More than 20% of cases are diagnosed after the age of 40 years, and at least 0.1% of the population over age 65 years has a diagnosis of schizophrenia that started late in life, with a prognosis that may be made worse by delay and avoidance of treatment.[38] Aggressive treatment of symptoms and supportive care for patients with this diagnosis is imperative. Schizophrenia remains plastic into later life, with more prominent negative symptoms than positive

symptoms. Numerous confounding factors (including cognitive decline, dementia, depression, medical co-morbidity, and use of medications for medical conditions) occur with aging. Further complications from treatment of psychosis include drug-induced side effects. In the elderly these side effects are often dramatic. Drugs with anticholinergic, orthostatic, sedative, and extrapyramidal symptoms (EPS) are relatively commonplace.[39] The elderly are more susceptible to tardive dyskinesia than are other age groups. The conventional antipsychotics have more adverse side effects than atypical agents, and higher potency agents may be more useful than lower potency ones. Atypical antipsychotics are often used in the elderly because of their sedative properties and their lack of EPS (when used at lower doses).[32,33] Atypical agents also reduce aggression associated with dementia.[40,41] However, they should be used with care, because there is a risk of adverse cerebrovascular events in patients with dementia.[42] The risk of death in patients taking typical antipsychotics is comparable to, or higher than, the rates in patients taking atypical antipsychotics.[43–45]

Dose equivalents of the atypical antipsychotics have been problematic, but a recent report by Woods[41] (using 100 mg/day of chlorpromazine as the standard), compared 2 mg/day for risperidone, 5 mg/day for olanzapine, 75 mg/day for quetiapine, 60 mg/day for ziprasidone, and 7.5 mg/day for aripiprazole, and outlined a more useful schedule. The caveat "start low and titrate up slowly" remains the gold standard; adding more medication is less harmful than is giving a large bolus of a drug with a long half-life. In certain instances, when agitation without psychosis is the primary problem, other medications to reduce anger (e.g., SSRIs, or other antidepressants that may cause sedation) are more apt to induce calm.[40,46]

Substance Abuse and Withdrawal

Patients of all ages should be asked about their use of alcohol and illicit substances. Alcoholism in the elderly is common; however, it often goes unreported by patients and overlooked by physicians.[47,48] Alcohol-related problems in the elderly are a growing public health concern. A life-long pattern of daily drinking, even in small amounts, is problematic. The National Institute on Alcohol Abuse deems one drink (12 oz beer, 1.5 oz spirits, or 5 oz wine) per day to be the maximum intake considered to be moderate alcohol use for men and women 65 years of age or older.[49,50] The prevalence of alcoholism in the elderly is about 10% to 18% and is the second most frequent reason for admission to an inpatient psychiatric facility.[50] As with those in the general population, the risk of suicide in the elderly who abuse alcohol is staggering; it is second only to major depression.[51]

Older alcoholics often refuse treatment due to perceived negative stigma and significant denial of the problem.[49] Screening tools have not been of significant benefit, but as in all aspects of geriatric care, use of the team approach to diagnosis and treatment is essential.[52] Symptoms of problem drinking include insomnia, memory loss, confusion, anxiety, and depression, as well as somatic complaints that may mimic medical illness, further delaying accurate diagnosis. Alcohol withdrawal is characterized by two or more of the following signs and symptoms: autonomic hyperactivity; tremor; insomnia; nausea or vomiting; transient visual, tactile, or auditory hallucinations or illusions; psychomotor agitation; anxiety; or tonic–clonic seizures.[47] With the loss of lean body mass associated with aging, the volume of distribution for alcohol is reduced; this results in an increased peak ethanol concentration after any amount of alcohol is consumed.[3]

Co-morbid illnesses, both psychiatric and medical, confound accurate diagnosis of both alcoholism and medical presentations.[48] Patients seen in consultation often are admitted for infection, trauma, cardiac disease, gastrointestinal disorders, renal diseases, and pulmonary conditions. Treatment of withdrawal in the elderly is more complex and requires close monitoring. Shorter-acting benzodiazepines (e.g., lorazepam) are the medications of choice, and one should begin with low doses and increase them slowly, so as to avoid oversedation. In some older patients, larger doses and longer-acting benzodiazepines (e.g., diazepam or chlordiazepoxide) are indicated, especially with those who have a history of seizures or *delirium tremens* (DTs). Often in chronic alcoholics with a history of DTs or seizures, the gold standard remains chlordiazepoxide because its long-acting metabolites provide a slow taper and reduce the risk of seizures. Most important, aggressive treatment of symptoms limits the possibility of complications due to withdrawal or the development of DTs.

Anxiety

Recently, anxiety in the elderly (generally associated with normal aging and with medical, financial, and health-related hardships) has been recognized more often than it had been in the past. However, anxiety is not a direct consequence of normal aging, and the symptoms of anxiety should not be ignored. Beekman and associates[53] noted that loss of control and vulnerability to stress were the strongest risk factors for anxiety in later life. Both of these risk factors were common among elderly hospitalized patients. Anxiety co-exists with many other psychiatric diagnoses (such as depression, BPD, alcoholism, and dementia). Diagnostic challenges often arise when anxiety (e.g., worry, fear, apprehension, concern, foreboding) as well as somatic complaints (such as tachycardia, sweating, abdominal distress, dizziness, vertigo) develop in the context of a medical illness (e.g., diabetes with hypoglycemia, hyperthyroidism, or cardiac disease with hypoxia), because it can be manifested by similar symptoms.[54] Worries, fears, and concerns are often related to finances, dependency issues, loneliness, and memory loss. Manifestations of medical illness can mimic psychiatric symptoms; certain substances or medications (e.g., caffeine, stimulants, ephedrine, bronchodilators) produce anxiety-like symptoms. Withdrawal from a prescribed or an illicit drug can precipitate severe anxiety and panic; life-threatening withdrawal can result from sudden abstinence from alcohol, benzodiazepines, or barbiturates.

Fortunately, anxiety can be effectively managed in the elderly by use of medications, therapy, or a combination of the two.[54] In the general hospital, the treatment for anxiety involves use of benzodiazepines. However, because some older patients develop significant side effects (such as confusion, falls, oversedation, and paradoxical agitation) from benzodiazepines[55] they should be

used cautiously (while observing for exacerbation of other problems, such as sleep apnea). Other agents (including selected antidepressants, such as trazodone and mirtazapine) can be used as well.

SPECIAL CONSIDERATIONS IN THE GERIATRIC POPULATION

Pharmacotherapy

Polypharmacy, the treatment with many medicines for the same condition, is extremely common in the elderly.[56] Older patients are at higher risk for polypharmacy because of the increased rates of chronic and co-morbid medical illness in this age group. Thus concurrent use of multiple drugs does not necessarily connote inappropriate prescribing; it may in fact be sensible. Regardless, polypharmacy puts the elderly at increased risk for multiple adverse outcomes, including adverse drug reactions, falls, hospitalizations, nursing home placement, malnutrition, pneumonia, and death.[57–59]

The four key concepts relevant to polypharmacy in the elderly are the "prescribing cascade," the effects of aging, altered pharmacokinetics and pharmacodynamcis, and multiple co-morbidities.[3] The "prescribing cascade" begins when an adverse drug reaction is misinterpreted as a new medical condition, for which another drug is then prescribed, placing the patient at risk of developing additional adverse effects relating to this potentially unnecessary treatment.[60] Age-related changes may exacerbate medication side effects in the elderly. Of particular concern are side effects like orthostatic hypotension, anticholinergic reactions, parkinsonism, sedation, and cardiac conduction disturbances. Changes in metabolism, distribution, and excretion that occur with aging result in longer half-lives, increased or decreased drug effects, and increased occurrence of drug toxicity. All of these issues need to be taken into consideration with the increased medical co-morbidities in the older population, which at times necessitates the use of multiple medications.

One of the primary goals of the consultant is to prevent polypharmacy and its associated negative outcomes. One of the first and most critical steps of any geriatric psychiatry consultation should be a careful and detailed review of current medications and all recent medication changes, including both psychotropic and nonpsychotropic agents as well as over-the-counter medications. A new medication should be added only when there is a clear indication for its use; one should consider nonpharmacologic treatments when appropriate. When starting new medications, one should start with low doses and slowly titrate them to achieve a therapeutic response. Many clinicians will stop titration too soon, thus giving the patient an inadequate trial of a medication; this is also a negative outcome. Hence, remember the adage "start low, go slow, but go all the way."

Health Care Decision-Making

Consultants are often called to make determinations about the ability of elderly patients to make decisions regarding their health care. It is sometimes assumed that the elderly, regardless of the level of the cognitive impairment, cannot make such decisions. Although the details regarding capacity evaluations are dealt with elsewhere (see Chapter 48), it is worth noting the unique issues that surround surrogate decision-makers and the geriatric population.

As a rule, one should not assume that patients with cognitive impairment are unable to make their own health care decisions. Each case should be considered individually, taking into consideration the level of impairment, the medical decision being considered, and the risks of treatment versus nontreatment. As a result of the Patient Self-Determination Act of 1990, Medicare and Medicaid providers are required to educate all adult patients upon hospital admission about their right to participate in and to direct their own health care decisions, the right to accept or refuse treatment, and the right to prepare an advance directive. Geriatric patients should be encouraged to have conversations with family, friends, and caregivers about their wishes related to these issues, and should have surrogate health care decision-makers in place even if they are in the best of health.

Emergency Department Care

Emergency department (ED) visits are especially problematic for the elderly (who often manifest atypical presentations of illness); when elderly are evaluated by someone with geriatric expertise, outcomes are improved. EDs are chaotic, even more so for elderly patients with cognitive or functional impairment. In such settings the elderly often have extended waits, as those with more dramatic presentations are tended to; when this occurs, their symptoms may progress to a point where the physiologic reserves become exhausted. Although timely and accurate diagnosis is crucial, the diagnoses of delirium, depression, and dementia are frequently missed. One should remember that two thirds of all cases of delirium in this age group occur in those with dementia.

Physicians in the ED may not have access to the patient's history; as a result they often attribute the presenting complaints to chronic problems or to symptoms of aging. Acute symptoms that bring an elderly patient to the ED are not a direct result of normal aging, even though physiologic functions and reserves diminish with aging; a rapid decline is not typical of the aging process and it requires immediate attention. Communication with third parties (e.g., caregivers, family members, primary care physicians or nurses) is essential, because the elderly often deny or minimize their symptoms or situation. The elderly can be at risk for abuse or neglect, and be embarrassed or ashamed about their situation. The hurried, chaotic, and noisy ED environment exacerbates impairments in communication (that arise secondary to hearing loss, poor vision, and cognitive impairment).[61] Implementation of simple and compassionate interventions (such as providing warm blankets, keeping patients informed, re-orienting them, hydrating and feeding them, as well as attending to the needs of caregivers) improves care. Caregivers of elderly ED patients should also be mindful of the propensity for skin breakdown (when lying for protracted periods on hard surfaces). Psychiatric consultants with expertise in geriatrics can facilitate shorter stays and prevent iatrogenic complications. Education of ED staff with regard to the care of older patients in the acute setting (including management of end-of-life issues[62]) is still sorely needed.

It is also worth mentioning a fairly new initiative, medication reconciliation, outlined in the July 2006 Institute of Medicine (IoM) Report on Preventing Medication Errors.[63] This effort encourages development of a partnership between patients and their health care providers. It involves creation of a medication list (including new ones and those to be discontinued) that is provided to and discussed with older outpatients and their family members or caregiver. The IoM report found that a simple review of a patient's medications can eliminate numerous errors that increase the cost of care and improve communication with other healthcare providers. Use of electronic prescriptions (a recommendation of the IoM) is aimed at eliminating prescription errors and enhancing communication among providers about medications. According to a study cited in the IoM report, the annual cost of avoidable medication errors in Medicare enrollees (65 years and older) was over $887 million. Over and above the monetary issue is the impact on pain and suffering, the need for family or caregiver assistance, and the loss of earnings. Ensuring medication reconciliation (with clear and concise instructions about the medications, their indications and side effects, and their various names and acronyms), at the time of hospital (or ED) discharge can lead to improved adherence and to fewer adverse drug reactions.

ELDER ABUSE

Each year thousands of elderly are abused, neglected, and exploited by family members, caregivers, and others. Many of the victims are frail and vulnerable; they are unable to help themselves and they depend on those who abuse them to assist them with their basic needs. The psychiatric consultant often identifies these issues that may result in noncompliance with medications or with medical care. These issues may have contributed to the hospital admission and to ongoing medical or psychiatric problems.[53] All 50 states have reporting systems and toll-free hotlines to report concerns anonymously. Adult protective services (APS) agencies investigate the reports of suspected elder abuse and determine if abuse or neglect exists. Types of abuse are physical, sexual, psychological, financial, exploitative, and negligent. More than a half million cases were reported to the APS in 1996 during a national incidence study done through the Administration on Aging. The cohort at greatest risk were those 80 years of age and older. In 90% of the cases the perpetrator was a family member; in two thirds they were either adult children or spouses.[64]

The warning signs of abuse may be subtle, and the patient may not be willing to cooperate or to agree to go forward with an investigation. Family or caregivers may be overwhelmed, depressed, or physically unable to continue to care for the elderly patient; the APS can guide them to appropriate services.

Families and Caregivers

Families and caregivers are often an integral part of the evaluation of the elderly. The consultant should begin by gathering information directly from the patient. However, when the patient is unable to provide information (e.g., because of altered mental status or cognitive impairment), gathering further collateral information is essential. Caregivers often serve as a crucial source of information regarding medication regimens and the patient's baseline in terms of both cognitive and functional status.

Dementia often causes tremendous suffering for patients, their families, and society. Patients are forced to become more dependent and to lose their independence in basic caring for themselves, which complicates other comorbid conditions. An important part of any evaluation is the assessment of the health and well-being of the caregivers, family members, or employees of the patient, because they are at risk for developing anxiety and depression.[65,66] Caring for the caregiver is as important as is caring for the patient. The inordinate stress and burden can place the caregiver at risk for both medical and psychiatric crisis.

Aggressive and Impulsive Patients

45

Guy Maytal, M.D.
Kathy M. Sanders, M.D.

Patients who display aggressive and impulsive behavior frequently come to the attention of the consultation psychiatrist.[1] Because aggression and violence are complex behaviors that occur both inside and outside of the medical setting, they require a systematic approach to evaluation and management. In the medical setting, aggressive behavior is associated with delirium, dementia, and other organic medical conditions; these conditions must be assessed before ascribing the behavior to a psychiatric condition, to a life circumstance, or to character pathology.[2]

Although an exhaustive review of aggression and violence in our society (as well as workplace violence and its economic and sociocultural impact) is beyond the scope of this chapter,[3–6] we will focus on the differential diagnosis of aggressive acts as it pertains to the medical setting and discuss the causes of impulsivity. However, in an era of growing sensitivity to the effects of terrorism and the residual psychological and behavioral effects on tortured patients, psychiatrists must recognize the complex biopsychosocial context of each patient who displays aggression or impulsive behavior.[7] Psychiatrists must accurately assess for the risk of violence and develop the skills to manage it.[8]

DEFINITIONS, EPIDEMIOLOGY, AND GENETICS

Aggression, defined as a "hostile, injurious, or destructive behavior or outlook especially when caused by frustration,"[9] can be classified in a number of ways: by the target of aggression (i.e., self-directed versus other-directed), by the mode of aggression (i.e., physical or verbal), or by the cause of the aggression (e.g., medical). However, the most widely used and clinically useful classification of aggressive behavior is that of premeditated versus impulsive aggression. Premeditated aggression (usually goal-directed) is not usually associated with frustration or an immediate threat. On the other hand, impulsive aggression is a response to a perceived stress or threat. It is labeled as pathologic when the aggression is out of proportion to the actual stressor. (When there is an imminent and dangerous threat, unplanned aggression can be defensive.) Because the lines between pathologic and more acceptable forms of aggression are unclear, some individuals with pathologic aggression can justify their violence as being within the bounds of normal behavior. It is the consulting psychiatrist's task to tease out motivation and response, and to manage the impulsivity of patients in the general hospital.[10,11]

Violence and aggression (particularly impulsive and irritable aggression) is extremely common. The World Health Organization estimates that each year, 1.43 million people die from violent acts (excluding war); many more individuals suffer after nonfatal acts of violence. Most of this violence is an outgrowth of impulsive aggression. After the age of 18, one fourth of all men and half of all women are the target of an act of impulsive aggression.[12,13]

Controversy exists regarding whether individuals with mental illness are at greater risk for violence than those in the general population.[14,15] Several large studies have shown that the majority of individuals seen in the mental health arena are not more violent than those in the general population. Rarely does violence in this population result in serious injury or death, and these individuals are less likely to use weapons.[16] In fact, a recent analysis from the National Epidemiologic Survey on Alcohol and Related Conditions found that severe mental illness did not independently predict future violent behavior. Rather, those factors associated with future violence are more likely to be reported by those with mental illness[17,18] (Table 45–1).

A growing body of literature reveals that individuals with chronic mental illness are far more likely to be victims of violence (25%) than the general population (3%).[17–19] Nonetheless, there is a small minority of mentally ill individuals who engage in regular violent behavior. The rates of violence differ across diagnostic categories, with untreated schizophrenia-spectrum illnesses, substance use disorders, and personality disorders being most closely associated with violent behavior; however, violence may occur more commonly in those with mental illness (e.g., 8% of patients with schizophrenia commit violent acts as compared with 2% of individuals without mental illness). Among violent offenders, 47% of men and 21% of women have been diagnosed with an antisocial personality disorder. When substance abuse is a co-morbid condition, the risk of violent behavior rises by 70% in those with schizophrenia, and by 240% in individuals with a personality disorder.[16,17] A recent review analyzed the risk of violence in mental illness along four dimensions: Low impulse control and affective dysregulation increased the risk of violence (particularly in substance use disorders), whereas having a paranoid cognitive personality style or a narcissistic injury was likely to increase the risk of violence in those with schizophrenia-spectrum disorders and personality disorders.[20]

Data from twin and family studies suggest that aggression (particularly irritable and impulsive aggression) has significant heritability (44% to 72%).[21] Violent

TABLE 45–1 Risk Factors Associated with Violent Behavior

Past history: Past violent behavior, substance abuse, early victimization (e.g., physical abuse), juvenile detention, parental arrest record
Demographic: Male, young (age 15 to 24), poor, uneducated, unemployed, limited social supports, recently divorced
Diagnostic: Organic brain syndrome (e.g., delirium), personality disorder, psychosis, co-morbid substance abuse
Clinical features: Command auditory hallucinations, current substance abuse, paranoid delusions, poor impulse control, poor insight, low IQ score
Psychological: Low tolerance for frustration and interpersonal closeness, low self-esteem, tendency toward projection and externalization, anger

Adapted from Rocca P, Villari V, Bogetto F: Managing the aggressive and violent patient in the psychiatric emergency, *Prog Neuropsychopharmacol Biol Psychiatry* 30(4):586-598, 2006.

and aggressive behavior is greatly influenced by gene–environment interactions (including familial relationships and experiences, and the witnessing or experiencing of violence during childhood), as well as cultural and socioeconomic factors that encourage aggression. People who have a biological risk for aggression may be more vulnerable to environmental adversity and more likely to engage in violence later in life.[22]

NEUROBIOLOGY

Phenomenology

Violence and aggression have complex biological, environmental, and psychological determinants.[4,11] Furthermore, the susceptibility to aggression depends on the overall psychopathologic context. For example, emotional dysregulation in the context of a susceptibility to aggression may lead to aggressive acts only within interpersonal relationships—as with borderline personality disorder. For individuals with a posttraumatic stress disorder and a susceptibility to aggression, aggressive behavior may be triggered only by cues reminiscent of the original trauma. Alternatively, the cognitive distortions and disinhibition associated with substance abuse lead to unpredictable or purposeful aggressive behaviors.[11]

Brain Circuitry

In any of the examples just mentioned, impulsive aggression can be thought of as having a lower threshold for aggressive (motor) responses to stimuli without reflection on the consequences of their actions. In other words, there is too little input from the orbital frontal cortex and anterior cingulate cortex (which provide top-down control, interpretation of social cues, and prediction of reward and punishment) and too much input from the limbic regions (the repositories of aggressive drives).[11,23,24]

The limbic system (which includes the amygdala, hippocampus, septum, cingulate cortex, and fornix) has regulatory control of aggressive behaviors in humans and animals. The hypothalamus regulates neuroendocrine responses through output to the pituitary gland and the autonomic nervous system. In the hypothalamus, the anterior, lateral, ventromedial, and dorsomedial nuclei are often described as areas crucial to animal aggression; they are considered to be involved in the control of aggression in humans. In individuals with borderline personality disorder and in perpetrators of domestic violence, functional neuroimaging studies have demonstrated increased activity of the amygdala and the hypothalamus.[25,26]

The prefrontal cortex modulates input from both the limbic system and the hypothalamus. In particular, the orbital frontal cortex and anterior cingulate cortex have been strongly implicated in calibrating behavior to social cues, and modulating behavior based on expectations of negative consequences.[11,27,28] Functional neuroimaging has also demonstrated decreased glucose metabolism in the frontal cortices of individuals with a history of physical aggression (i.e., violent criminals and patients with borderline personality disorder). This suggests inefficient processing by the frontal regions in these individuals, which leads to ineffective suppression of limbic signals that occur in response to provocative stimuli. Furthermore, damage to the frontal lobe from a variety of causes (including anoxic injury, violent trauma, and closed head injury) results in increased impulsivity and reduced executive control of emotional reactivity.[11,29–31]

Neuromodulators and Other Neuroactive Substances

Low central serotonin (5-HT) function has been correlated with impulsive aggression. More specifically, serotonin facilitates prefrontal cortical lesions. Therefore, 5-HT innervation decreases in these regions can lead to increased aggression.[32,33] This is supported by studies showing that selective serotonin reuptake inhibitors reduce impulsive aggression.[34] Violent patients have also been found to have a low turnover of 5-HT, as measured by its major metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid (CSF). Furthermore, antagonists of the 5-HT_{2A} receptor reduce impulsivity in animal models, and atypical neuroleptics with 5-HT_{2A} antagonism reduce aggressive behavior in clinical populations.[11,35] More recent neuroimaging studies have demonstrated reduced serotonergic stimulation in the orbital and ventromedial prefrontal activation in patients with intermittent explosive disorder, in those with borderline personality disorder, and in depressed patients with a history of suicide attempts.[11,36–38]

Catecholamines (e.g., dopamine and norepinephrine) may facilitate aggression directed toward others. They are believed to be involved in the initiation of aggressive behavior by affecting frontal lobe circuits.[11,39] Acetylcholine in the limbic system stimulates aggression in animals; cholinergic pesticides have been cited as provoking violence in humans. Furthermore, imbalance in glutaminergic–gamma-aminobutyric acid (GABA) activity in the limbic regions may induce hyperactivity in these areas and lead to aggressive behavior. Reduced activity at GABA receptors may contribute to aggression, whereas increased activity at glutamate receptors is believed to inhibit aggression.[11,39]

Other proteins that act on the central nervous system (CNS) influence the likelihood of aggressive behavior. Above-normal concentrations of vasopressin in CSF

TABLE 45–2 Neurobiological Implications for Pharmacotherapy of Aggression

	ANATOMIC SUBSTRATES FOR AGGRESSIVE BEHAVIOR	
PHARMACOLOGIC CLASS	**SUBCORTICAL AREAS**	**FRONTAL AREAS**
Anticonvulsants	↓ Limbic irritability	—
Atypical neuroleptics	↓ Subcortical dopamine stimulation	↑ Frontal inhibition
Opiate antagonists	↓ Endogenous opiates	—
Serotonergic agents	—	↑ Frontal inhibition
Stimulants	—	↑ Frontal inhibition

Adapted from Siever LJ: Neurobiology of aggression and violence, *Am J Psychiatry* 165(4):429-442, 2008.

have been correlated with a life history of aggression in personality-disordered patients. Oxytocin has been shown to influence trust and affiliative behaviors; a deficit of oxytocin may contribute to hostility and mistrust, setting the stage for aggressive behavior.[40,41] Endogenous opioids have also been associated with aggressive behavior. Reduced CSF endogenous opioid concentrations have been associated with self-injurious behavior in those with a borderline personality disorder. Increased levels of testosterone and steroids induce aggression and enhance the brain circuitry related to social aggression[11,42] (Table 45–2).

Systemic hormones also influence the propensity for aggression. Cortisol concentrations are lower in individuals with high aggression (e.g., in antisocial criminals and perpetrators of domestic violence).[11,42] More recently, lower cholesterol levels in patients with personality disorder have been associated with aggressive and impulsive behavior.[43–45]

DIFFERENTIAL DIAGNOSIS

The multiaxial *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)[46] diagnostic system has five domains to categorize aggressive or violent behaviors. Because management of aggressive behaviors is predicated on an accurate diagnosis, the diagnosis of the underlying cause is crucial; it hinges on initial consideration of organic causes (including intoxication or drug withdrawal) and psychiatric etiologies. A wide range of psychopathology (from major mental illness to personality disorders to life circumstances, such as job stress or loss—situations that alter coping mechanisms) should be considered.

Medical Causes

When considering the differential diagnosis of violent and impulsive behavior, the psychiatrist should assume that a medical condition or substance abuse problem is at the root of the behavior before considering psychiatric illnesses.

A variety of primary CNS disorders can generate aggressive and violent behavior. These include traumatic brain injury, intracranial hypoxia or bleeding, an intracranial mass, and dementia of any type. Because of the protean nature of aggression, particular attention should also be paid to that caused by seizure disorders. Seizure-related aggression involves ictal aggression (typically nonpurposeful, stereotypical behavior during the seizure), postictal aggression (secondary to confusion or agitation), and interictal aggression (which may result from subthreshold electrical brain activity) that elicits violence.

Other medical causes of aggression include delirium (from a host of underlying medical conditions and hormonal and metabolic abnormalities). For a more exhaustive differential diagnosis of the underlying medical causes of delirium and dementias (Table 45–3), see Chapter 10.

Violence is more prevalent in patients with substance abuse and dependence than in those without.[18] In the acutely intoxicated state, behavior is often characterized by disinhibition, which places individuals at greater risk for violence. During withdrawal from alcohol and other sedative–hypnotics, delirium or agitation may also precipitate aggression. Chronic alcohol abuse with secondary brain damage or dementia may lead to aggressive behavior that persists beyond the state of acute intoxication or withdrawal. Acute intoxication or withdrawal from psychostimulants (e.g., cocaine, amphetamine) can lead to agitation, paranoia, psychosis, and violence. Hallucinogens (e.g., phencyclidine, lysergic acid diethylamide) may also precipitate psychosis and violence. Opiate intoxication and withdrawal, as well as behaviors required to obtain these drugs, may also increase the risk for violence.

Other prescription medications (e.g., anticholinergics, steroids) and over-the-counter preparations may induce aggression. In the fitness subculture, the use of various herbal and nutritional supplements and the abuse of hormone therapies may result in an altered mental status that could manifest as violence, aggression, and impulsivity.

When determining the likelihood of medical factors that play a role in an aggressive or impulsive episode, one should take a history, obtain corroborating information from family or friends, perform pertinent laboratory studies, and conduct a physical examination that will hone the differential diagnosis. The following three clinical examples illustrate how agitated behavior with a medical cause can be mistaken for a psychiatric diagnosis.

CASE 1

Mr. A, a 37-year-old man with chronic alcohol abuse, was brought by police to the emergency department (ED) after getting into an argument with staff at a local shelter. The argument escalated in an uncharacteristic manner for Mr. A: he pulled a knife on a staff member. Fortunately, Mr. A was subdued before being able to use it. He was uncooperative during the examination in the ED, and he shouted expletives at nursing and security staff. He was thought to be acutely intoxicated until his vital signs were checked: his temperature, pulse, and blood pressure were all elevated. Furthermore, Mr. A's doctors were surprised that laboratory studies revealed a negligible blood alcohol level and no other substances of abuse in his system. He was diagnosed with alcohol withdrawal and treated with benzodiazepines, which led to a resolution of his agitation and aggression.

CASE 2

Ms. B, a 45-year-old woman with chronic schizoaffective disorder, returned to the ED because of a decompensation of her illness. Her case manager found her roaming the streets of her neighborhood and picking fights with neighbors and strangers. Although she readily backed down before becoming violent, her persistent and impulsive temper continued to flare, and she required containment and further evaluation. In the ED, laboratory studies showed a sodium blood level of 115 mEq/L. She was admitted to the medical service for management of her hyponatremia caused by inappropriate antidiuretic hormone secretion.

CASE 3

Ms. C, a 26-year-old woman, was brought to the ED by her family after aggressively and uncharacteristically shoving her mother without provocation. Ms. C had been invited to a family dinner in honor of her recent job change. She was extremely irritable and accused her family of being part of a plot to prevent her from being successful in her new job. When they tried to dissuade her from thinking that, she became belligerent, aggressive, and threatening. The family brought her to the ED, worried that she was emotionally unstable. At triage, she was alert but shaking and irritated by any questions. She admitted to intentionally taking extra (i.e., an overdose of) isoniazid tablets (which had been prescribed for a positive purified protein derivative skin test during a preemployment medical screening) while overwhelmed by concerns about her new job. Within minutes of her arrival in the ED, she had a grand mal seizure and was admitted for further tests and treatment.

Psychiatric Causes

Violent and impulsive behaviors are nonspecific; they may be part of most major mental illnesses at some time during the course of the illness. When assessing whether a psychiatric illness contributed to violence, it is important to consider Axis I conditions, Axis II disorders, and organic causes on Axis III.

Diagnoses on Axis I

Schizophrenia or Psychosis, Not Otherwise Specified

The prevalence of violent behavior in individuals with schizophrenia is similar to that for those with major depression or bipolar disorder. Individuals who are paranoid (e.g., with delusions of persecution) may act violently toward a perceived threat. Command hallucinations associated with violent content (toward oneself or others) dramatically increase the potential for violence in individuals with schizophrenia. Disorganized thought and behavior may also lead to violence.

Affective Illness

Unipolar depression may be accompanied by an increase in hostility and by anger attacks (in nearly half of cases) that can lead to violent behavior.[47] Depression that is co-morbid with psychotic features may further increase the risk of violence. Patients with bipolar disorder (with a manic, hypomanic, or mixed presentation) often display irritability, anger outbursts, omnipotence, and paranoia, which may lead to impulsive aggression.

TABLE 45–3 Differential Diagnosis of Psychosis and Agitation

GENERAL CATEGORY	CAUSE/DIAGNOSIS
Organic mental disorders	Aphasia
	Catatonia
	Delirium
	Dementia
	Frontal lobe syndrome
	Organic hallucinosis
	Organic delusional disorder
	Organic mood disorder (secondary mania)
	Seizure disorders
Drugs	Substance abuse (e.g., cocaine and opiates)
	Steroids
	Procarbazine HCl
	Antibiotics
	Anticholinergics
Drug withdrawal	Alcohol and sedative–hypnotics (barbiturates and benzodiazepines)
	Clonidine
	Opiates
Psychotic disorders	Schizophrenia
	Delusional disorder
	Psychotic disorders not otherwise specified (NOS)
	Brief reactive psychosis
	Schizoaffective disorder
	Shared paranoid disorder *(folie à deux)*
Mood disorders	Bipolar disorder
	Major depression with psychotic/agitated features
	Catatonia
Anxiety/fear	Anxiety disorders
	Acute reaction to stress
Discomfort	Pain
	Hypoxia
	Akathisia
Personality disorder	Antisocial
	Borderline
	Paranoid
	Schizotypal
Disorders of infancy, childhood, and adolescence	Autism
	Mental retardation
	Attention deficit hyperactivity disorder
	Conduct disorder

Impulse-Control Disorders

Impulsive disorders, as classified by the DSM-IV, are a "residual" diagnostic category.[48] Diagnoses in this category include kleptomania, pyromania, pathologic gambling, trichotillomania, intermittent explosive disorder, and impulse-control disorder not otherwise specified (NOS).[49,50] Each of these conditions involves a drive or a temptation to perform an act that is harmful to the person or to others, or the failure to resist an impulse. Other associated features are the experience of increasing tension (e.g., dysphoria or arousal, often sexual) before committing the act that is followed by a release of tension, a sense of gratification,

or a sense of pleasure and relief during and after the act. There also may be a sense of guilt, regret, or self-reproach after the behavior.

Patients diagnosed with an impulse-control disorder have an increased risk of being diagnosed with a substance abuse disorder, with obsessive–compulsive disorder (OCD) or another anxiety disorder, with an eating disorder, or with a mood disorder. Moreover, there is an increased incidence of substance abuse disorders and mood disorders in family members of those with impulse-control disorders. Theories place impulse-control disorders on a spectrum of affective disorders, as a variant of OCD, or as a blend of mood, impulse, and compulsive disorders. Historically, these disorders were thought to result from psychodynamic conflicts; however, more biological hypotheses have been explored since improvement of impulsive symptoms has been accompanied by use of the serotonergic antidepressants.[50–52]

Intermittent explosive disorder is a diagnosis that characterizes individuals who have episodes of dyscontrol, assaultive acts, and extreme aggression that is out of proportion to the precipitating event and is not explained by another Axis I or an Axis II disorder. It is considered rare and a diagnosis of exclusion.[53,54] Intermittent explosive disorder and personality change that results from a general medical condition, aggressive type, are the current diagnoses available to patients with episodic violent behavior. Most violent behavior can be accounted for by a variety of psychiatric and medical conditions. The most common diagnosis associated with violence is personality change resulting from a general medical condition (e.g., seizures, head trauma, neurologic abnormality, dementia, or delirium), aggressive or disinhibited type. Personality disorders of the borderline or antisocial type must also be ruled out. Psychosis from schizophrenia or a manic episode may also cause episodic violence. Aggressive outbursts while intoxicated or while withdrawing from a substance of abuse would rule out the diagnosis of intermittent explosive disorder. Psychopharmacology is commonly used in the management of this chronic disorder. Anticonvulsants, lithium, β-blockers, anxiolytics, neuroleptics, antidepressants (both serotonergic and polycyclic agents), and psychostimulants have all been used with varying degrees of success. The acute management of aggressive and violent behavior may involve the use of physical restraints, parenteral neuroleptics, and benzodiazepines. Long-term outpatient management of intermittent explosive disorder requires attention to the therapeutic alliance between the clinician and the patient.

Impulse control disorder NOS is a category of disorders that do not meet diagnostic criteria for any of the previously discussed impulse-control disorders or for another mental disorder involving impulse control. Included in this category are diagnoses such as pathologic spending, pathologic shopping, repetitive self-mutilation, compulsive sexual behavior, and compulsive face picking. Most of the literature on this diagnostic category focuses on repetitive self-mutilation. It is more common in women than in men; however, it is considered endemic in male prisons. Two thirds of self-mutilators have a history of sexual and physical abuse during childhood. The disorder starts in adolescence and is characterized by severe psychosocial morbidity.[48]

Attention Deficit Disorders

Attention deficit disorder (ADD) and attention deficit hyperactivity disorder (ADHD) begin in childhood and can persist into adulthood. The impulsivity, inattentiveness, and behavioral problems that accompany these conditions may lead to aggressive acts. Other childhood developmental disorders and learning disorders are also associated with aggressive and impulsive behaviors, including self-mutilation.[55]

Diagnoses on Axis II

Antisocial personality disorder is frequently associated with violent and impulsive behavior and criminality. Further complicating this is that sociopaths frequently have co-morbid substance abuse. Patients with borderline personality disorder may display aggression toward themselves or others as part of their impulsive behaviors. Those with a paranoid personality disorder often react to perceived threats with violent reactions toward that perceived threat. Those with mental retardation and other developmental disorders tend to have poor impulse control; depending on the underlying cause (e.g., head trauma), these states may lead to violence.[56–58]

Diagnoses on Axes IV and V

Environmental precipitants are as important as underlying psychiatric or medical diagnoses when determining how dangerous a patient might be. Axis IV parameters (e.g., occupational, social relationship, educational, housing, economic, and legal problems) can lead to aggression and to violence. A patient's current level of function (as measured on Axis V) can also aid the clinician in predicting the threat of violence. The more stressors one has (on Axis IV) and the lower the level of function (on Axis V), the higher is the possibility for violence in those prone to violence.

ASSESSMENT OF THE VIOLENT PATIENT

General Considerations

To ensure the safety of a patient and those around him or her, the evaluator must provide a timely diagnosis and an appropriate acute management plan.[59,60] In crisis situations, the ABCs of emergency evaluation of aggressive and impulsive behavior include safety, diagnosis, and management.[8] Safety is the first priority when confronted by a potentially violent patient. Control of the patient and of the environment must be obtained to prevent harm to the staff and to the individual being assessed. Without proper safety mechanisms, adequate evaluation is impossible. Diagnosis of underlying psychopathology, substance abuse, or medical conditions then guides specific treatment. If there is no medical or psychiatric diagnosis, then perhaps the legal authorities are more suitable for the management of the patient's behavior. Management, in the form of chemical sedation (with neuroleptics or benzodiazepines, or both), along with seclusion or restraint (or both) may be necessary to ensure the safety of patient and staff, as well as to allow the evaluator to perform an accurate assessment.[59,60]

Interview of the Potentially Violent Patient

Before the examiner can interview the potentially violent patient, a safe environment must be secured. All potentially dangerous materials should be removed from the patient

and from the interview room. The room should be scrutinized, before and during the interview, for objects that can be used as weapons (e.g., pens, needles, phones). Escape from the room should be possible, and all activity in the room should be highly visible (i.e., through a window or via a security camera). The ideal interview room would contain an emergency call button, and it should not be possible to lock the room from within. The consultant should pay careful attention to the patient's behavior for signs of imminent danger. Escalating behaviors include verbal threats or threatening gestures, physical agitation (e.g., rapid movements, pacing, knocking over furniture, slamming doors), muscle tension (e.g., clenching of the jaw or fists), and invasion of personal space. If an escalating behavior is seen, the examiner's interventions should direct the patient to regain the locus of control. If the examiner's attempts to redirect the behavior fail to calm the patient and merely increase his or her level of self-control, then tranquilization and application of restraints may be necessary to regain control and to ensure safety.

Once a safe environment is established, the assessment of a violent patient includes two distinct but interconnected steps: the diagnostic assessment and the violence risk assessment. Both require a thorough history, a directed physical examination, and (often) obtaining corroborating sources of information and laboratory data.[17]

History

The diagnostic history must be obtained in the initial phases of the interview process to ascertain and to treat any potentially life-threatening medical causes for the patient's agitation or aggressive behavior. The mnemonic WWHHHHIMPS can be used to quickly rule out life-threatening causes (see Table 10–3).

Once life-threatening medical causes of aggressive behavior have been ruled out, the clinician should evaluate the patient for other medical causes (e.g., previous head trauma, neurologic difficulties such as seizure disorders), for substance-related causes (e.g., intoxication or withdrawal), and for primary psychiatric diagnoses (e.g., mania or acute psychosis) that may increase the patient's risk for aggression and may guide treatment.

Given the assortment of patients who engage in violent behavior, a violence risk assessment is one of the most difficult tasks for the medical and psychiatric professional. The best indicator of future violence remains a history of violence.[17,18] Therefore, seeking a history of previous violence in a patient is an integral part of the interview. Unfortunately, it is often difficult to elicit an accurate account. The best approach involves direct questioning of violent behaviors (Table 45–4). Other factors associated with an increased risk of violent behavior are listed in Table 45–1.

TABLE 45–4 Assessment of Violence

1. Ask screening questions.
   a. Do you ever think of harming anyone else?
   b. Have you ever seriously injured another human being? (Tell me about the most violent thing that you have ever done.)
2. Determine the specifics of past violence.
   a. At what age did violent acts begin?
   b. How frequently did those acts occur?
   c. What was the most recent act?
   d. How severe were the actions?
   e. Has there been a recurring pattern of escalation preceding violence?
   f. Have there been common precipitants surrounding the acts?
   g. Have any violent actions resulted in legal recourse or incarceration?
   h. Has there been a history of recklessness, suicidal ideations, arrests, or impulsivity?
   i. Does the patient have a family history of violence, abuse, or gang involvement?
3. Ask about prior evaluations and treatments related to violent behavior, including medical work-ups, diagnostic tests, and old records.
4. Collect information from as many ancillary sources as possible, including family members, victims, court records, medical records, and previous professional caregivers.

Examination of the Violent Patient

The mental status examination of the potentially violent patient begins like a standard examination. However, careful consideration must be given to safety. If at any time during the examination, the examiner feels unsafe, he or she should stop the interview and resume it only after safety has been ensured. The initial assessment should focus on elements of the mental status (e.g., the sensorium, disordered thought, mood and affect, cognition, agitation, hallucinations, evidence of intoxication by drugs or alcohol). Mental status abnormalities or symptoms (as listed earlier) can increase the likelihood of aggressive action and alert the physician to medical conditions that require further work-up or immediate treatment. For example, affective disorders, either mania or depression, may impair a patient's judgment and lead to violence. The impulsivity accompanied by mania can lead to irrational thoughts and aggression. The hopelessness of a depressed individual, combined with psychotic thoughts, may lead a person to attempt suicide or murder. Thought disorders, psychosis with paranoid features, and command hallucinations create a situation that can produce dangerous and difficult-to-predict behavior. Just as in the evaluation of the suicidal patient, patients with violent thoughts toward others must be assessed in terms of their specific plan, the lethality of their plan, and the possibility that the plan can actually be carried out. Determination of the relative risk of violence in this manner helps in the development of a disposition plan (e.g., inpatient versus outpatient management). Documentation of agitation through standardized rating scales, such as the Overt Agitation Severity Scale (OASS), is useful in anticipating escalating behaviors and determining when to intervene.[1]

Physical examination, guided by findings from the history, should target medical causes of violence. Because violence is more likely in a patient with an organic brain

syndrome or acute intoxication/withdrawal, the clinician should tailor the examination toward identifying or ruling out these diagnoses. Based on physical findings and the patient's medical history, appropriate diagnostic tests should be performed. These can include laboratory tests (e.g., routine chemistry tests, blood counts, tests of serum and urine toxicology; and a pregnancy test should be considered for all women of childbearing age); an organic work-up for dementia; an electroencephalogram; neuroimaging and other radiologic tests as indicated; and neuropsychological and cognitive testing.

TREATMENT OF THE VIOLENT PATIENT

Management of the aggressive patient can be divided into acute management and chronic management. There are no medications that specifically target aggressive behavior; the psychiatrist must apply general principles to guide treatment. Treatment of the underlying psychiatric illness, if present, should be optimized; if that fails, it is best to use the most benign treatments in an empirical and systematic way. Target symptoms should be well defined and monitored in response to specific interventions. Efficacy should be defined by parameters that can be observed and measured. The symptom checklist in the OASS is useful for documenting progress in the management of agitation and aggressive behaviors.

Acute Management

In the acute setting, the goal in treatment of the violent patient is to reduce the risk of harm to both the staff and the patient and to facilitate the diagnostic process. Clinical intervention should strive for the least coercive and aggressive interventions available.[61] Noncoercive interventions (including verbal and behavioral techniques, such as talking in a soft, nonconfrontational tone, providing a quiet room with an easily accessible exit, and offering the patient a meal) aim to de-escalate the situation. All of these interventions seek to separate the emotional and behavioral aspects of the patient's condition. By using an approach that is as empathic as possible, the clinician attempts to ally with the patient so that the patient feels understood and has an opportunity to alter the aggressive behavior. However, if the patient is unable to de-escalate with noncoercive interventions, then coercive interventions (including a show of force, forced seclusion, physical restraint, and the involuntary use of sedating medications) should be used as appropriate to ensure patient and staff safety.[17,62]

These interventions should be used solely to limit patient dangerousness, and never as punishment or for staff convenience. A show of force is not actually a coercive intervention; it implies that force will be used as a last effort to stop violent behavior. It also gathers the necessary personnel in the event that physical restraint or the administration of involuntary medication is needed. Furthermore, it is important for the patient to understand that through the show of force, the staff is still there to help him or her, even if it is only to help contain dangerous behavior.[17,61]

Often, when noncoercive means are insufficient to help a patient calm down, combining a show of force with an offer of voluntary acceptance of a sedating medication (e.g., an antipsychotic or a benzodiazepine) can help achieve safety (see later).

Physical restraint (the direct application of physical force to a patient without the patient's permission, to restrict freedom of movement) and seclusion (the involuntary confinement of a person alone in a locked room) are often a necessity; although controversial, they ensure safety of patients and staff. Once the decision is made to apply physical restraints, it is important to gather the appropriate number of staff members (a minimum of five) so that the intervention can be done quickly and safely. The patient should be informed of what is going to happen and should be invited to cooperate with staff. Once the physical intervention is complete, documentation (including the ineffectiveness of less coercive means) should be completed. Finally, to preserve the patient's rights, dignity, and privacy, there should be specific institutional guidelines for how often the patient should be monitored while restrained, how long a patient can be in restraints, and what conditions need to be met before releasing the patient.[17,61]

Acute Medical Management

Use of sedating medications (e.g., neuroleptics and benzodiazepines) is a humane and effective means for managing agitated and impulsive patient behavior. Because they are less coercive, oral formulations should be the first-line means of medicating patients. However, in the setting of acute aggression and agitation, drugs that can be delivered intramuscularly and that have a rapid onset and a favorable side-effect profile should be used. Once the patient is calm, the psychiatrist can perform a more thorough assessment to determine the diagnosis, treatment, and disposition.

Benzodiazepines are rapid, safe, and easily administered agents for moderate to severe agitation and when the potential for escalating behavioral dyscontrol exists. However, benzodiazepines may cause a paradoxical reaction in certain character-disordered individuals and in elderly persons. In general, when given in the intramuscular or oral form, these medications are effective sedatives in the acute care setting[17,61–63] (Table 45–5).

Alprazolam acts rapidly, but it can only be administered orally. The initial dose is usually 0.5 mg, and the initial dosage should not exceed 4 mg/day. Diazepam (with an initial dose of 5 mg) has a rapid onset of action and can be administered intramuscularly, orally, or intravenously. It has a long half-life (30 to 100 hours), and therefore it should be used cautiously in elderly patients, who will metabolize it slowly. Lorazepam may be given sublingually, orally, intramuscularly, or intravenously. The usual starting dose is 1 mg; its intermediate half-life (10 to 20 hours) makes it an ideal medication for initial treatment. Because it has no active metabolites, there is little risk of drug accumulation if the patient requires more than one dose to manage agitation and to maintain behavioral calm. In addition, lorazepam is metabolized by glucuronidation in the liver and excreted by the kidneys, which makes it easier to use in those with organ system failure.[64] The following case is an example.

TABLE 45–5 Selected Medications for Use in the Setting of Acute Agitation

MEDICATION	STARTING DOSE	MODE OF ADMINISTRATION	COMMENTS
Benzodiazepines			
Alprazolam	0.5 mg	Oral only	Short half-life requires frequent dosing.
Lorazepam	0.5-1 mg	Sublingual, oral, IM, IV	No active metabolites Preferred in patients with liver disease
Diazepam	5-10 mg	Oral, IM, IV, rectal	Use with caution with elderly patients because of long half-life.
Typical Antipsychotics			
Haloperidol	2-10 mg	Oral, IM, IV	Monitor QTc interval. Monitor for extrapyramidal symptoms (EPS).
Chlorpromazine	25-50 mg	Oral, IM	Highly sedating Monitor for anticholinergic effects and orthostatic hypotension.
Atypical Antipsychotics			
Olanzapine	2.5-10 mg	Oral, sublingual, IM	Sublingual dose does not have faster onset of action than oral. Sedating Much lower incidence of EPS
Ziprasidone	10-20 mg	Oral, IM	Monitor QTc interval
Aripiprazole	5-10 mg (oral) 9.75 mg (IM)	Oral, IM	Monitor for extrapyramidal symptoms.

CASE 4

Mr. D, a 54-year-old married executive, was seen in the cardiac care unit (CCU) because he was unable to remain in bed or to cooperate with the nursing staff. He had been admitted earlier that day from the ED, where he was diagnosed with an acute myocardial infarction and was given IV tissue plasminogen activator. On arrival in the CCU, he was distractible: he made frequent attempts to get out of bed and to pace. He could be redirected only briefly before resuming his efforts to get out of bed. Before the consultant arrived in the CCU, Mr. D was given diazepam and morphine for sedation to allow a computed topography scan of the head to be completed. The neuroimaging study revealed a midline intraventricular bleed presumably associated with the anticoagulant treatment initiated in the ED. Although staff initially characterized him as a type A personality with restlessness in a structured and controlled environment, his agitated and impulsive behavior actually stemmed from CNS irritability due to the presence of blood in his ventricles. Because further use of benzodiazepines and opiates would very likely only worsen his mental status, his behavior was managed with a high-potency neuroleptic.

Antipsychotics, particularly high-potency agents, are often highly effective in reducing agitation and violence in both psychotic and nonpsychotic patients (see Table 45–5). Haloperidol is a high-potency neuroleptic that is frequently used in this setting because of its favorable side-effect profile and overall cardiopulmonary safety. It may be given orally, IM, or IV, and it is usually effective when one or two 5-mg doses are administered IM or IV. It is often administered along with an anticholinergic agent (e.g., diphenhydramine or benztropine mesylate) to minimize the risk of extrapyramidal symptoms. Given IV, it is less likely to precipitate extrapyramidal symptoms; however, regardless of route, one must attend to the risk for torsades de pointes.[17,61,65] Virtually any antipsychotic may diminish aggression, but careful consideration should be given to the potency of, history of response to, and side-effect profile of the particular medication, and to the psychiatric and medical history of the patient. Atypical antipsychotics (e.g., clozapine, olanzapine, aripiprazole, quetiapine, ziprasidone, risperidone) have been used more in recent years.[17,61,65,66] In general, atypical neuroleptics are better tolerated than conventional agents; they have fewer extrapyramidal side effects and are associated with better long-term compliance.[17,65,66] As with other agents, oral doses should be considered first to encourage patient cooperation; however, if they are refused or the aggressive behavior escalates, intramuscular (IM) use should be considered. Currently, olanzapine, aripiprazole, and ziprasidone are available for IM use in the acute care setting.[67–69]

CASE 5

Mr. E, a 32-year-old single Russian immigrant, was forcibly brought to the ED after calling 911 and seeking "help" by provocatively expressing passive suicidal ideation. He was agitated and angry and intoxicated with alcohol, so staff were unable to reason with him. He was placed in four-point restraints, and a psychiatry consult was called to assess his mental status and his risk for suicide. He would not engage in a meaningful exchange. Therefore, haloperidol 5 mg IM and diphenhydramine 50 mg IM were administered. He became more cooperative and was examined. It became apparent that his right arm hurt. He described how he was forcibly removed from his apartment and taken down four flights of stairs. Once he was controlled, his restraints were removed for a radiographic examination, which revealed a fractured elbow that was then placed into a cast.

Long-term Management

The long-term management of the violent patient poses a complex challenge for the treating psychiatrist. First, appropriate treatment of any underlying psychiatric disorder should be maximized, using both psychotherapy and pharmacotherapy (see Table 45–2). Selective serotonin reuptake inhibitors have been used with some efficacy in patients with personality disorders, dementia, and mental retardation. One should be cautious when using any antidepressant in patients with bipolar disorder, because this may exacerbate, rather than lessen, certain symptoms.[70] Lithium has been used to reduce aggression in patients with mental retardation, conduct disorder, and antisocial personality disorder and in prison inmates; the target lithium level should be between 0.6 and 0.9 mEq/L. Anticonvulsants (e.g., carbamazepine, valproic acid, phenytoin) have been used with some success in reducing impulsive aggression. Gabapentin also has significant mood-stabilizing benefits that may be used in the management of aggression in a wide range of patients. It has also been used for patients with substantial anxiety and character pathology.[71] Benzodiazepines may be used in chronic, as well as acute, settings. Buspirone, a 5-HT_{1A} partial agonist, is a nonbenzodiazepine anxiolytic that has been used as an adjunct treatment for agitation and aggression.[72] β-adrenergic blockers have been used in high dosages to treat aggression; their effects may not be seen for several months. All patients should be started at a low dosage and then titrated to effect and tolerance. Propranolol may be gradually increased up to 1 g/day; it has been used successfully in patients with dementia and organic brain disorders.[73] Nadolol 40 to 120 mg/day and metoprolol 200 to 300 mg/day may also be used in patients who are chronically aggressive. Psychostimulants may be effective in reducing impulsive aggression in children with ADD/ADHD and in adults with residual ADHD. Bupropion and desipramine have been efficacious in adults with residual ADHD.

The long-term use of atypical neuroleptics in the management of aggression may provide behavioral control while addressing the underlying psychotic and affective components of aggression. Clozapine, risperidone, quetiapine, olanzapine, ziprasidone, and aripiprazole broaden the options for the treatment of psychosis.[74] Their relatively benign side-effect profile improves compliance, and their ability to enhance mood increases the options for the types of patients that can be treated for aggressive and impulsive behaviors.

Psychotherapeutic approaches (e.g., behavioral techniques, cognitive-behavioral therapy, and group and family therapy) have also been used to treat aggression and violence.[75] Such techniques (e.g., limit-setting, contingent reinforcement, distraction and redirection, relaxation, biofeedback) have been used in the ongoing inpatient and outpatient management of aggressive and impulsive patients with mixed success. The combination of medication and psychotherapy is still the best approach to the chronic management of aggression and violence.

Psychiatric Illness during Pregnancy and the Postpartum Period

Betty Wang, M.D.

Ruta Nonacs, M.D., Ph.D.
Adele C. Viguera, M.D., M.P.H.
Lee S. Cohen, M.D.

Psychiatric consultation to obstetric patients typically involves evaluating and treating an array of psychopathology. Once thought to be a time of emotional well-being for women,[1] studies now suggest that pregnancy does not protect women from the emergence or persistence of psychiatric disorders.[2–7] Because many psychiatric conditions are chronic or recurrent and have high prevalence rates in women during the reproductive years, many women will become pregnant while receiving psychiatric treatment. Because many pregnancies in the United States are unplanned, women of reproductive age should know the risks and benefits of their medications even if they are not planning to become pregnant. Optimally, a woman and her psychiatrist should plan ahead for a pregnancy and assess the risks and benefits of treatment before conception. Given the prevalence of mood and anxiety disorders in women during the childbearing years[8,9] and the number of women who receive treatment for these disorders, it is apparent that many women become pregnant either shortly after discontinuing psychotropic medications or following a decision to maintain treatment during efforts to conceive.

Because rapid discontinuation of medication appears to increase the risk of relapse of mood episodes,[10,11] women should be educated about the risks and benefits of medications during pregnancy so that medications are not abruptly stopped (out of fear of exposing the fetus to medication). Furthermore, medications with relatively benign reproductive safety profiles should be used as first-line agents in women of reproductive potential. With increasing evidence of high rates of relapse following discontinuation of psychotropic medications (e.g., antidepressants,[12] mood stabilizers,[13] antipsychotics,[14] benzodiazepines[15]) and other data that describe new-onset psychiatric illness during pregnancy,[2,6,16] the value of psychiatric consultation during pregnancy and after delivery is evident. The risks of untreated psychiatric disorders to the mother and the baby include preterm delivery, poor nutrition, inadequate weight gain, poor prenatal care, inability to care for oneself, substance use (such as cigarettes or alcohol), termination of the pregnancy, and postpartum depression,[17,18] and these also deserve attention. Depression during pregnancy is a strong predictor of postpartum depression, a condition that can have dire consequences for the mother, the baby, and the entire family. Therefore, it is critical to sustain maternal emotional well-being during pregnancy.

Psychiatric evaluation of pregnant women requires careful assessment of symptoms (such as anxiety or depression) and decisions about the nature of those symptoms, including normative or pathologic, manifestation of a new-onset psychiatric disorder, and exacerbation of a previously diagnosed or undiagnosed psychiatric disorder. Unfortunately, screening for psychiatric disorders during pregnancy or the puerperium is uncommon. Even when depressed pregnant women are identified, definitive treatment is often lacking[19] and patients are often untreated or incompletely treated.[20] Screening for depression during pregnancy followed by thoughtful treatment can minimize maternal morbidity as well as the potential impact of an untreated psychiatric disorder on infant development and family functioning. Pregnancy is an emotionally laden experience that evokes a spectrum of normal reactions, including heightened anxiety and increased mood reactivity.

Normative experience needs to be distinguished from the manifestations of psychiatric disorders. Treatment of psychiatric disorders during pregnancy involves a thoughtful weighing of the risks and benefits of proposed interventions (e.g., pharmacologic treatment) and the documented[21,22] and theoretical risks associated with untreated psychiatric disorders. In contrast to many other clinical conditions, treatment of psychiatric disorders during pregnancy is typically reserved for situations in which the disorder interferes in a significant fashion with maternal and fetal well-being; the threshold for treating psychiatric disorders during pregnancy tends to be higher than with other conditions. Moreover, women with similar illness histories often make very different decisions about their care in collaboration with their physicians during pregnancy.

DIAGNOSIS AND TREATMENT OF MOOD DISORDERS DURING PREGNANCY

Although some reports describe pregnancy as a time of emotional well-being[1,23–25] that confers "protection" against psychiatric disorders, at least one prospective study describes

equal rates of major and minor depression (approximating 10%) in gravid and nongravid women. Several other studies also note clinically significant depressive symptoms during pregnancy (prenatal depression).[2,6,26,27] Women with a history of major depression appear to be at high risk for recurrence of depression during pregnancy, particularly when antidepressants have been discontinued.[5,28]

Making the diagnosis of depression during pregnancy can be difficult because disturbances in sleep and appetite, symptoms of fatigue, and changes in libido do not always indicate an evolving affective disorder. Clinical features that can support the diagnosis of major depressive disorder (MDD) include anhedonia, feelings of guilt and hopelessness, poor self-esteem, and thoughts of suicide. In addition, symptoms that interfere with function signal a psychiatric condition that warrants treatment. Suicidal ideation is not uncommon[29–31]; however, risk of clear-cut, self-injurious or suicidal behavior appears to be relatively low in women who develop depression during pregnancy.[30,31]

Treatment for depression during pregnancy is determined by the severity of the underlying disorder, by a history of treatment responses, and by individual patient preferences. Nonetheless, neurovegetative symptoms that interfere with maternal well-being require treatment. Women with mild to moderate depressive symptoms might benefit from nonpharmacologic treatments that include supportive psychotherapy,[32] cognitive therapy,[33] or interpersonal therapy (IPT),[34] all of which can ameliorate depressive symptoms. Given the importance of interpersonal relationships in couples who are expecting a child and the significant role transitions that take place during pregnancy and after delivery, IPT is ideally suited for treating depressed pregnant women; preliminary but encouraging data support the efficacy of this intervention. [35]

Using Antidepressants During Pregnancy

Several reviews have been published [28,36–40] regarding the risks associated with fetal exposure to antidepressants. Although data accumulated over the last 30 years have suggested that some antidepressants have favorable risk-to-benefit profiles during pregnancy,[41–43] information regarding the full spectrum and relative severity of risks of prenatal exposure to psychotropic medications is still incomplete. Moreover, the risks of medication use must be balanced against the risks associated with untreated psychiatric disorders that might adversely affect the mother and the fetus.

As is the case with other medications, four types of risk are typically cited with respect to potential use of antidepressants during pregnancy: risk of pregnancy loss or miscarriage, risk of organ malformation or teratogenesis, risk of neonatal toxicity or withdrawal syndromes during the acute neonatal period, and risk of long-term neurobehavioral sequelae.[42] To inform physicians about the reproductive safety of various prescription medications, the U.S. Food and Drug Administration (FDA) has established a system that classifies medications into five risk categories—A, B, C, D, and X—based on data derived from human and animal studies. Medications in category A are designated safe for use during pregnancy, whereas category X drugs are contraindicated, because they are known to have risks to the fetus that outweigh any benefit to the patient. Most psychotropic medications are classified as category C agents, for which human studies are lacking and for which risk cannot be ruled out. No psychotropic drugs are classified as safe for use during pregnancy (category A).

Unfortunately, this system of classification has noteworthy limitations. First, categorization is often ambiguous and can lead to unwarranted conclusions. For example, certain tricyclic antidepressants (TCAs) have been labeled as category D agents, indicating "positive evidence of risk," although the pooled available data do not support this assertion and, in fact, suggest that these drugs are safe for use during pregnancy.[44,45] Second, the categorization is often assigned on the basis of only a small amount of animal data and when human data are sparse or absent. Third, when larger and more rigorous studies become available on the reproductive safety profile of a medication, the category is rarely altered. Fourth, the categorization system fails to take into account the risks of the untreated maternal psychiatric disorder for the woman and her fetus. Therefore, the physician must also rely on other sources of information when counseling patients about the potential use of psychotropic medications during pregnancy.

Randomized, placebo-controlled studies that examine the effects of medication use on pregnant populations are lacking and are considered unethical. Therefore, much of the data related to the profile of reproductive safety for a medication is derived from retrospective studies and case reports. Studies that have evaluated the reproductive safety of antidepressants have used a more-rigorous prospective design,[44–49] or they have relied on large administrative databases or multicenter birth-defect surveillance programs.[50,51] Given the lack of clarity of the FDA risk categories, there will likely be a modification with the classification system that incorporates a more individualized and sophisticated approach to the use of medications in pregnancy.[52] Studies have not yet demonstrated a statistically increased risk of spontaneous miscarriage following prenatal exposure to antidepressants.[53]

Cumulative reports that describe the reproductive safety of selective serotonin reuptake inhibitors (SSRIs) have been reviewed.[39,40] These reports provide some reassurance that as a group of medicines, SSRIs are not major teratogens. Initially, some[54–57] reports suggested that first-trimester exposure to paroxetine was associated with an increased risk of cardiac defects (including atrial and ventricular septal defects). These findings prompted the FDA to change the labeling of paroxetine from category C to D, but two independent, peer-reviewed, comprehensive meta-analyses of studies assessing paroxetine exposure during the first trimester[50,51,53,58] failed to demonstrate the increased teratogenicity of paroxetine. Therefore, although it is widely believed that paroxetine might increase the risk of congenital malformations with first-trimester exposure, the most comprehensive studies to date have not supported this; paroxetine should still be considered a first-line agent for women who have responded well to it before pregnancy.

At present the data about the risk of major malformations after first-trimester use of SSRIs remain inconsistent. A large body of literature has failed to demonstrate a risk of major malformations with first-trimester exposure, but one study suggested that first-trimester use of SSRIs was

associated with increased risk of omphalocele, craniosynostosis, and anencephaly[50] and another suggested that first-trimester SSRI use was not associated with significantly increased rates of craniosynostosis, omphalocele, or cardiac defects, but it did note an increase in malformations with particular SSRIs. Sertraline was associated with omphalocele and septal defects, and paroxetine exposure was associated with right ventricular outflow tract construction defects.[51]

Bupropion may be an attractive option for women who have not responded well to fluoxetine or TCAs. Data thus far have not indicated an increased risk of malformations associated with bupropion use during pregnancy.[59–61] Bupropion deserves special consideration if a woman is attempting to abstain from smoking during pregnancy, as it helps with smoking cessation, and cigarettes are teratogenic. Bupropion may be an attractive option for women with attention deficit disorder who are receiving stimulants, because the reproductive safety profile of stimulants is more concerning than that of bupropion, an antidepressant that has been used with benefit in some patients with attention-deficit/hyperactivity disorder (ADHD).[62,63]

Limited data are available on the use of the serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine[49] during pregnancy. Nonetheless, given the frequency of use of these medicines and the frequency of unplanned pregnancy[64] the data supporting the safety of venlafaxine is increasingly reassuring. Unfortunately there is little information available on the use of duloxetine in pregnancy.

Mirtazapine is a novel piperazinoazepine antidepressant; the data regarding the use of this medication during pregnancy is sparse, but in one small study it did not appear to increase the rate of major malformations.[65] Small studies of medication exposures can provide reassuring preliminary information, but large definitive trials are necessary to assess risks that might be rare and thus only observable with adequate sample sizes. Despite the growing literature that supports the relative safety of fetal exposure to SSRIs, multiple reports[46,66,67] have described adverse perinatal outcomes including decreased gestational age, low birth weight, and poor neonatal adaptation. However, others [44,68,69] have failed to note these associations. Particular concern has been raised regarding the potential effects of late-pregnancy exposure to SSRIs; one report[70] noted jitteriness, tachypnea, and tremulousness. Importantly, these effects have been described as transient (limited to several days following delivery). In general, most reports characterize as mild a neonatal syndrome following maternal use of antidepressants.

Conflicting reports have also raised a question about whether SSRI use in later pregnancy is associated with a serious but rare developmental lung condition, persistent pulmonary hypertension of the newborn (PPHN). Chambers and co-workers sounded the alarm when they found an increased risk of PPHN with SSRI use in a nested case-controlled study. They reported the risk of PPHN with exposure to SSRIs after 20 weeks at about 1%.[71] However, more-recent research has been more reassuring. Kallen and colleagues[55] also found an association between late SSRI use in pregnancy and PPHN, albeit a substantially smaller risk than that found by Chambers and co-workers.[71] The most recent study, however, failed to demonstrate any association between SSRI use during pregnancy and PPHN.[72] Readers must be mindful that PPHN is correlated with multiple risk factors including cesarean section, race, body mass index, and other factors not associated with SSRI use.[73]

Further investigation is warranted to clarify the association between SSRI use and neonatal risks, because previous studies that investigated neonatal outcomes in infants exposed to antidepressants *in utero* have not described serious complications with significant morbidity; instead neonatal adaptation syndromes have generally been considered mild, transient, and not requiring specific medical interventions. Unfortunately, the vast majority of reports that have attempted to delineate the potential effects of peripartum exposure to SSRIs have been limited by small sample size, by nonsystematic assessment of infant outcome, and by frequent use of nonblinded raters. Moreover, these studies have typically failed to assess the impact of maternal depression, which has also been associated with compromised perinatal outcome and neonatal behavioral differences.[17,22]

A limited amount of data is available on the long-term implications of *in utero* antidepressant exposure, and fluoxetine and TCAs are the best-characterized agents. In children exposed to fluoxetine, TCAs, or no medication, no differences have been detected in behavioral or cognitive development (in terms of intelligence quotient [IQ], language, temperament, behavior, reactivity, mood, distractibility, and activity level[47,68] among groups when followed through early childhood. Although the emphasis of research regarding use of antidepressants in pregnancy has addressed the effect of antidepressant drugs on risk for congenital malformation, more research is needed to assess the long-term effects of prenatal antidepressant exposure. In addition, there does not appear to be any difference in the level of internalizing behavior in children exposed to SSRIs during pregnancy compared to children of nondepressed mothers not on medication during pregnancy.[74] Therefore, while the data available are reassuring, further investigation into the long-term neurobehavioral effects of prenatal exposure to antidepressants is warranted.

Pharmacologic Treatment of Depression during Pregnancy: Clinical Guidelines

Since the turn of the century, increased attention has been directed to the question of how to best manage women who suffer from depression throughout reproductive events. Clinical lore has suggested that women enjoyed positive mood during pregnancy, but more-recent data demonstrate that many women face substantial risk for recurrence or the new onset of depression during pregnancy. There is also a greater appreciation that depression poses risks for fetal and neonatal well-being that need to be taken into account during the risk-to-benefit decision-making process.[28,37,41,43,75,76]

The majority of women who suffer from depression during pregnancy do not receive adequate treatment, despite the prevalence and consequences of untreated illness.[19] Despite the growing number of reviews on the subject, management of prenatal depression is still largely guided by experience, with few definitive data and no

controlled treatment studies to inform treatment. The best treatment algorithms depend on the severity of the disorder, the patient's psychiatric history, her current symptoms, her attitude toward the use of psychiatric medications during pregnancy, and, ultimately, the patient's wishes. Clinicians must work collaboratively with the patient to arrive at the safest treatment plan based on currently available information.

In patients with less-severe depression, discontinuation of pharmacologic therapy during pregnancy should be considered. Though data on the use of IPT or cognitive-behavioral therapy (CBT) to facilitate antidepressant discontinuation before conception are not available, it makes sense to pursue such treatment for women on maintenance antidepressant therapy who are planning to become pregnant. These treatment modalities can reduce the risk of recurrent depressive symptoms during pregnancy; however, this has not been studied systematically. Close monitoring of affective status during pregnancy is essential throughout pregnancy for women with a history of a mood disorder, regardless of whether medication is continued or discontinued. Psychiatrically ill women are at high risk for relapse during pregnancy, and early detection and treatment of recurrent illness can significantly reduce the morbidity associated with having prenatal affective illness.

Many women who discontinue antidepressants during pregnancy experience recurrent depressive symptoms.[77,78] In one study, women who discontinued their medications were five times more likely to relapse (with a rate of relapse of 68%)[5] as compared to women who maintained their antidepressants across pregnancy. Thus, women with recurrent or refractory depressive illness may decide (in collaboration with their clinician) that the safest option is to continue pharmacologic treatment during pregnancy to minimize the risk of recurrent illness. In this setting, the clinician should attempt to select medications during pregnancy that have a well-characterized reproductive safety profile that might obviate switching to one with a better reproductive safety profile.

In an ideal world, switching would occur before pregnancy and allow time for stabilization on a new medication. For example, one might switch from duloxetine, a medication for which there are sparse data on reproductive safety, to an agent such as fluoxetine or citalopram. In other situations, one may decide to use a medication for which information regarding reproductive safety is sparse, for example, a woman with refractory depression who has responded only to one particular antidepressant for which specific data on reproductive safety are limited (e.g., venlafaxine). She may choose to continue this medication during pregnancy rather than risk potential relapse associated with discontinuing the antidepressant or switching to another antidepressant for which the patient has no history of response.

Even if a woman continues taking an antidepressant during pregnancy, relapse can occur. Cohen and colleagues[5] reported that 26% of women who continue antidepressants had a relapse of MDD during pregnancy. Therefore, careful monitoring is required even if maintenance medications are continued. Only a small amount of information is available on the pharmacokinetic profile of SSRIs and newer antidepressants across pregnancy,[79–82] and some women experience lower serum medication levels in late pregnancy. Therefore, some women can require higher doses of medication as pregnancy progresses to maintain therapeutic benefits; this supports a need for frequent assessment. Older reports demonstrated that women might also have lower serum levels of TCAs in the third trimester.[45,79,80,83]

Women might also experience the new onset of depressive symptoms during pregnancy. For women who present with minor depressive symptoms, nonpharmacologic treatment strategies should be explored first. IPT or CBT may be beneficial for reducing the severity of depressive symptoms and can limit or obviate the need for medications.[33–35] In general, pharmacologic treatment is pursued when nonpharmacologic strategies have failed or when it is felt that the risks associated with psychiatric illness during pregnancy outweigh the risks of fetal exposure to a particular medication.

In situations in which pharmacologic treatment is more clearly indicated, the clinician should select medications with the safest reproductive profile. Fluoxetine and citalopram, with extensive data that support their reproductive safety, can be considered as first-line choices. Among the SSRIs, paroxetine is the most controversial (given reports regarding cardiovascular malformations with first-trimester exposure). However, more-comprehensive studies did not support this risk. Nevertheless, many women and their obstetric health care providers might remain apprehensive about use of paroxetine in pregnancy. The TCAs and bupropion have also been relatively well characterized and can be considered reasonable treatment options during pregnancy. Among the TCAs, desipramine and nortriptyline are preferred because they are less anticholinergic and less likely to exacerbate orthostatic hypotension during pregnancy. The amount of literature on the reproductive safety of the newer SSRIs is growing, and these agents may be useful in certain settings, particularly if a woman has had a good response to one of them in conjunction with poorer responses with better-characterized antidepressants.[9,48,84]

When prescribing medications during pregnancy, an attempt should be made to simplify the medication regimen. For instance, one may select a more sedating antidepressant for a woman who presents with depression and a sleep disturbance instead of using a more activating antidepressant in combination with trazodone or a benzodiazepine.

In addition, the clinician must use an adequate dosage of medication. Often the dosage of a medication is reduced during pregnancy in an attempt to limit risk to the fetus. However, this type of modification in treatment might instead place the woman at greater risk for recurrent illness. During pregnancy, changes in plasma volume and increases in hepatic metabolism and renal clearance can significantly affect drug levels.[85,86] Several investigators have described a reduction (up to 65%) in serum levels of TCAs during pregnancy.[45,83] Subtherapeutic levels may be associated with depressive relapse[45]; therefore, an increase in daily TCA or SSRI dosage may be required to obtain remission.[80]

With multiple studies supporting the finding of transient jitteriness, tremulousness, and tachypnea associated with peripartum use of SSRIs[70,87] some physicians (as well as FDA-mandated labeling across the SSRIs) have suggested

discontinuing antidepressants just before delivery to minimize the risk of neonatal toxicity. Another potential rationale for discontinuing antidepressants before delivery is derived from the assumption this would attenuate the risk of PPHN that has been associated with third-trimester exposure to SSRIs.[71] However, the recommendation is not data-driven and such a practice can actually carry significant risk because it withdraws treatment from a patient precisely as she is about to enter the postpartum period, a time of heightened risk for affective illness. In consideration of the well-characterized risks to the baby and to siblings in the family of a woman with maternal depression, treatment goals should include having a woman approach the postpartum period in remission from depression. The strategy of discontinuing medication before delivery, however, can increase the risk of a woman's entering the postpartum period with depression, and recovery could require substantial time.

Severely depressed patients who are acutely suicidal or psychotic require hospitalization and treatment; electroconvulsive therapy (ECT) is often selected as the treatment of choice. Reviews of ECT during pregnancy note the efficacy and safety of this procedure.[88–90] In a review of the 339 cases of ECT during pregnancy published since 1941, only 11 of the 25 fetal or neonatal complications, including two deaths, were likely the result of ECT. Given its relative safety, ECT may also be considered an alternative to conventional pharmacotherapy for women who wish to avoid extended exposure to psychotropics during pregnancy or for women who fail to respond to standard antidepressants.

BIPOLAR DISORDER DURING PREGNANCY

Historically, women with bipolar disorder (BPD) have been counseled to defer pregnancy (given an apparent need for pharmacologic therapy with mood stabilizers) or to terminate pregnancies following prenatal exposure to drugs such as lithium or valproic acid. However, more-recent and comprehensive data suggest that women can select treatment strategies that allow pregnancy with both the mother's and baby's safety in mind.

The risk of lithium exposure during pregnancy has been reassessed and is considered far safer than it was decades ago. Concerns regarding fetal exposure to lithium, for example, have typically been based on early reports of higher rates of cardiovascular malformations (e.g., Ebstein's anomaly) following prenatal exposure to this drug.[91,92] More recent data suggest the risk of cardiovascular malformations following prenatal exposure to lithium is smaller than previous estimates (1/2000 versus 1/1000).[93] Prenatal screening with a high-resolution ultrasound and fetal echocardiography is recommended at about 16 to 18 weeks of gestation to screen for cardiac anomalies. Nonetheless, the woman with BPD is faced with a decision regarding use of lithium during pregnancy; it is appropriate to counsel such a patient about the very small risk of organ dysgenesis associated with prenatal exposure to this medicine.

Lamotrigine is another mood stabilizer that is an option for pregnant women who have BPD and who demonstrate a clear need for prophylaxis with mood stabilizer. Although previous reports failed to show an elevated risk of malformations associated with lamotrigine exposure,[94–97] data from the North American Antiepileptic Drug Pregnancy Registry indicates an increased risk of oral cleft in infants exposed to lamotrigine during the first trimester; the prevalence was approximately 9 per 1000 births.[98]

Compared with lithium and lamotrigine, prenatal exposure to some anticonvulsants is associated with a far greater risk of organ malformation. An association between prenatal exposure to mood stabilizers, including valproic acid and carbamazepine, and neural tube defects (3% to 8%) and spina bifida (1%) also has been observed.[99–102] Fetal exposure to anticonvulsants has been associated not only with relatively high rates of neural tube defects, such as spina bifida, but also with multiple other anomalies including mid-face hypoplasia (also known as the "anticonvulsant face"), congenital heart disease, cleft lip or palate (or both), growth retardation, and microcephaly. Factors that can increase the risk for teratogenesis include high maternal serum anticonvulsant levels and exposure to more than one anticonvulsant. This finding of dose-dependent risk for teratogenesis is at variance with that for some other psychotropics (e.g., antidepressants). Thus, when using anticonvulsants during pregnancy, the lowest effective dose should be used, anticonvulsant levels should be monitored closely, and the dosage should be adjusted appropriately. Ideally, women of reproductive age should avoid treatment with valproate, and it should not be considered a first-line therapy in women with reproductive potential.

Information about the reproductive safety of newer anticonvulsants sometimes used to treat BPD, including gabapentin, oxcarbazepine, and topiramate, remains sparse.[103] Other efforts are under way to accumulate data from prospective registries regarding teratogenic risks across a broad range of anticonvulsants. The North American Antiepileptic Drug Pregnancy Registry was established as a way of collecting such information rapidly and efficiently (http://www.aedpregnancyregistry.org).

Prenatal screening for congenital malformations following anticonvulsant exposure (including cardiac anomalies) with fetal ultrasound at 18 to 22 weeks of gestation is recommended. The possibility of fetal neural tube defects should be evaluated with maternal serum alpha-fetoprotein (MSAFP) and ultrasonography. In addition, 4 mg a day of folic acid before conception and in the first trimester for women receiving anticonvulsants is often recommended. However, the supplemental use of folic acid to attenuate the risk of neural tube defects in the setting of anticonvulsant exposure has not been systematically evaluated.

Whereas use of mood stabilizers (including lithium and some anticonvulsants) has become the mainstay of treatment for managing both acute mania and the maintenance phase of BPD, the majority of patients with BPD are not treated with monotherapy. Rather, use of adjunctive conventional and newer antipsychotics has become common clinical practice for many patients with BPD. With growing data supporting the use of atypical antipsychotics as monotherapy in the treatment of BPD, patients and clinicians will seek information regarding the reproductive safety of these newer agents.

To date, abundant data exist that support the reproductive safety of typical antipsychotics; these data have been reviewed extensively elsewhere.[41] However, despite

their growing use in psychiatry, available reproductive safety data regarding the atypical antipsychotics are limited but increasing. Some patients who benefit from treatment with antipsychotics may decide with their clinician to discontinue the atypical antipsychotic or to switch to a typical antipsychotic with a better-characterized safety profile. Atypical antipsychotics are best avoided if possible, although they are not absolutely contraindicated during pregnancy. Atypical antipsychotics should be reserved for use in more-challenging clinical situations where treatment with more-conventional agents has not been helpful. Given the limited data supporting the use of typical antipsychotics as monotherapy for BPD, that course of therapy should not be pursued.

Patients with a history of a single episode of mania and prompt full recovery, followed by sustained well-being, may tolerate discontinuation of a mood stabilizer before an attempt to conceive.[93,104] Unfortunately, even among women with a history of prolonged well-being and sustained euthymia, discontinuation of prophylaxis for mania may be associated with subsequent relapse. In one study, the risk of recurrence of a mood episode during pregnancy in women who discontinued their mood stabilizer during pregnancy was 71%.[11]

For women with BPD and a history of multiple and frequent recurrences of mania or bipolar depression, several options can be considered. Some patients may choose to discontinue a mood stabilizer before conception as outlined earlier. An alternative strategy for this high-risk group is to continue treatment until pregnancy is verified and then taper off the mood stabilizer. Because the uteroplacental circulation is not established until approximately 2 weeks following conception, the risk of fetal exposure is minimal. Home pregnancy tests are reliable and can document pregnancy as early as 10 days following conception, and with a home ovulation predictor kit, a patient may be able to time her treatment discontinuation accurately. This strategy minimizes fetal exposure to drugs and extends the protective treatment up to the time of conception, which may be particularly prudent for older patients because the time required for them to conceive may be longer than for younger patients. However, a potential problem with this strategy is that it can lead to relatively abrupt discontinuation of treatment, thereby potentially placing the patient at increased risk for relapse. With close clinical follow-up, however, patients can be monitored for early signs of relapse, and medications may be reintroduced as needed.

Another problem with the strategy of discontinuing mood stabilizers when the patient is being treated with valproic acid is that the teratogenic effect of valproic acid occurs early in gestation (between weeks 4 and 5), often before the patient even knows she is pregnant. In such a scenario, any potential teratogenic insult from valproic acid may have already occurred by the time the patient actually documents the pregnancy.

For women who tolerate discontinuation of maintenance treatment, the decision of when to resume treatment is a matter for clinical judgment. Some patients and clinicians prefer to await the initial appearance of symptoms before restarting medication; others prefer to limit their risk of a major recurrence by restarting treatment after the first trimester of pregnancy. Preliminary data suggest that pregnant women with BPD who remain well throughout pregnancy might have a lower risk for postpartum relapse than those who become ill during pregnancy.[104]

For women with particularly severe forms of BPD, such as with multiple severe episodes, and especially with psychosis and prominent thoughts of suicide, maintenance treatment with a mood stabilizer before and during pregnancy may be the safest option. If the patient decides to attempt conception, accepting the relatively small absolute increase in teratogenic risk with first-trimester exposure to lithium or lamotrigine with or without an antipsychotic, for example, may be justified because such patients are at highest risk for clinical deterioration if pharmacologic treatment is withdrawn. Many patients who are treated with sodium valproate or other newer anticonvulsants, such as gabapentin, for which there are particularly sparse reproductive safety data, never received a lithium trial before pregnancy. For such patients, a lithium trial before pregnancy may be a reasonable option.

Even if all psychotropics have been safely discontinued, pregnancy in a woman with BPD should be considered a high-risk pregnancy, because the risk of major psychiatric illness during pregnancy is increased in the absence of treatment with a mood-stabilizing medication, and it is even higher in the postpartum period. Extreme vigilance is required for early detection of an impending relapse of illness, and rapid intervention can significantly reduce morbidity and improve overall prognosis. Therefore, close monitoring with assessment of mood, sleep, and other symptoms is urged throughout pregnancy and the immediate postpartum period.

Although the impact of pregnancy on the natural course of BPD is not well described, studies suggest that any "protective" effects of pregnancy on risk for recurrence of mania or depression in women with BPD are limited,[104] and the risk for relapse and chronicity following discontinuation of mood stabilizers is high.[10,105–108] Given these data, clinicians and bipolar women who are either pregnant or who wish to conceive find themselves between a teratologic rock and a clinical hard place.[109]

PSYCHOTIC DISORDERS DURING PREGNANCY

Although anecdotal reports describe improvement of symptoms in some chronically mentally ill women during pregnancy, as a group these patients are at increased risk for having poor fetal outcome.[110,111] Acute psychosis during pregnancy is an obstetric and psychiatric emergency. Similar to other psychiatric symptoms of new onset, first onset of psychosis during pregnancy requires a systematic evaluation. Psychosis during pregnancy can inhibit a woman's ability to obtain appropriate and necessary prenatal care or to cooperate with caregivers during delivery. [110–112]

Treatment of psychosis during pregnancy may include use of high-potency neuroleptics, such as haloperidol or thiothixene, which have not been associated with an increased risk of congenital malformations when used in the first trimester of pregnancy.[113,114] Historically, lower-potency antipsychotics have been avoided because of data that support an increased risk of congenital malformations associated with prenatal exposure to these compounds.[115,116] However, their use is not absolutely contraindicated.

Psychiatric consultation may be requested to consider treatment options for mild or intermittent symptoms of psychosis or for pregnant women with chronic mental illness, such as schizophrenia, who have discontinued therapy with neuroleptics. Although as-needed high-potency neuroleptics are appropriate for treating milder symptoms of psychosis, introduction or reintroduction of maintenance high-potency antipsychotics should be considered in schizophrenic women who have new-onset illness or a recurrent disorder. This approach can potentially limit overall exposure to these drugs by reducing the need for treatment with higher doses of drug during relapse. Patients with florid psychosis during labor and delivery might benefit from intravenous haloperidol, which can facilitate the patient's cooperation with the obstetrician, thereby enhancing the overall safety of the delivery.[117,118]

Less reproductive safety information on the newer atypical antipsychotic medications is available as compared to data on the conventional antipsychotics. Thus far, most of the reproductive safety data on atypical agents have often been limited to manufacturers' accumulated case series, and some terato-vigilance data that reflect a small number of total drug exposures and spontaneous reports. Data on olanzapine, clozapine, quetiapine, and risperidone are increasing but remain sparse.[119,120] The largest prospective study to date included relatively small numbers of women using olanzapine, risperidone, ziprasidone, and clozapine, but it did not demonstrate a greater risk of malformations in comparison to women who were not using medications (although users of atypical agents were more likely to smoke and to use other medications and were less likely to take prenatal vitamins). Aripiprazole was not included in this study, and at this time there are no data to inform its use in pregnancy. Although these results are somewhat reassuring, significantly larger studies are necessary to inform the reproductive safety profiles of atypical antipsychotics. To increase safety data regarding the use of atypical antipsychotic medications and pregnancy, the National Pregnancy Registry for Atypical Antipsychotics[121] and the National Register of Antipsychotic Medication in Pregnancy[122] were established.

Decisions regarding the use of these agents and other psychotropics must be made on a case-by-case basis. Given the limited data regarding the reproductive safety of atypical agents, patients taking an antipsychotic drug may choose to discontinue their medication or switch to a better-characterized conventional antipsychotic, such as perphenazine or haloperidol. However, many women do not respond as well to the typical agents or have such severe illness that making any change in their regimen can place them at significant risk. Thus, women and their clinicians may choose to use an atypical agent during pregnancy to sustain function, while acknowledging that information regarding their reproductive safety remains incomplete.

ANXIETY DISORDERS DURING PREGNANCY

Although modest to moderate levels of anxiety during pregnancy are common, pathologic anxiety (including panic attacks) has been associated with a variety of poor obstetric outcomes, including increased rates of premature labor, low Apgar scores, and placental abruption.[123–126] The course of panic disorder (PD) in pregnancy is variable. Pregnancy can ameliorate symptoms of panic in some patients and can provide an opportunity to discontinue medication.[127–130] Other studies have noted the persistence or worsening of panic-related symptoms during pregnancy.[3–5,131]

Consultation requests regarding appropriate management of anxiety symptoms during pregnancy are common. The use of nonpharmacologic treatment, such as cognitive behavior and other types of psychotherapy, may be of great value in attenuating symptoms of anxiety, and for most patients it should be part of the treatment plan.[132,133] For some patients, psychotherapy may be sufficient to manage anxiety disorders during pregnancy.

For other patients, especially those who experience panic attacks associated with new-onset or recurrent PD or those with severe generalized anxiety, pharmacologic intervention may be necessary. Many patients respond well to antidepressants, whose risks and safety profiles are discussed earlier. Concerns regarding the potential association between first-trimester exposure to benzodiazepines, such as diazepam, and increased risk for oral clefts have been noted in some older studies,[134–136] although other studies do not support this association.[137,138] One meta-analysis that pooled data from multiple samples of patients exposed to different types and doses of benzodiazepines for variable durations supported an increased risk of oral clefts following first-trimester exposure to these drugs[41]; this risk for oral clefts was approximately 0.6% following first-trimester exposure. However, a more recent meta-analysis that evaluated this potential association did not support the increased risk.[139]

For patients with PD who wish to conceive, a slow taper of their anxiolytic medications is recommended. Adjunctive CBT can help patients discontinue anti-panic agents and can increase the time to a relapse.[133] Some patients conceive inadvertently on anxiolytics and present for emergent consultation. Abrupt discontinuation of anxiolytic maintenance medication is not recommended given the risk for rebound panic symptoms or a potentially serious withdrawal syndrome. However, a gradual taper of a benzodiazepine (over more than 2 weeks) with adjunctive CBT may be pursued in an effort to minimize fetal exposure to medication.

If the taper of a medication is unsuccessful or if symptoms recur during pregnancy, reinstitution of pharmacotherapy may be considered. For patients with severe PD, maintenance medication may be a clinical necessity. TCAs or SSRIs are reasonable options for managing PD during pregnancy.[41] If patients do not respond to these antidepressants, benzodiazepines may be considered.[140] Although some patients choose to avoid first-trimester exposure to benzodiazepines (given the data on the risk for cleft lip and palate), benzodiazepines may be used without significant risk during the second and third trimesters and can offer some advantage over antidepressant treatment because they may be used on an as-needed basis.

Pharmacotherapy of severe anxiety during pregnancy includes treatment with benzodiazepines, TCAs, SSRIs, or SNRIs. These classes of drugs have demonstrated efficacy in the management of either generalized anxiety disorder (GAD)[141,142] or PD.[143–145] Pharmacologic treatment

of severe anxiety during pregnancy includes the use of TCAs or SSRIs as a nonbenzodiazepine alternative for panic attacks. Nonetheless, patients treated with an antidepressant alone for anxiety symptoms might not respond optimally. For these patients, benzodiazepines represent a reasonable alternative.

With respect to the peripartum use of benzodiazepines, reports of hypotonia, neonatal apnea, neonatal withdrawal syndromes, and temperature dysregulation[146–152] have prompted recommendations to taper and discontinue benzodiazepines at the time of parturition. The rationale for this course is suspect for several reasons. First, given data that suggest a risk of puerperal worsening of anxiety disorders in women with a history of PD and obsessive–compulsive disorder (OCD),[153–155] discontinuation of a drug at, or about the time of, delivery places a woman at risk for postpartum worsening of these disorders. Second, data describe the use of clonazepam during labor and delivery at doses of 0.5 to 3.5 mg/day in a group of women with panic disorder without evidence of perinatal sequelae.[140]

ELECTROCONVULSIVE THERAPY DURING PREGNANCY

Consideration of the use of ECT during pregnancy typically generates anxiety among clinicians and patients. However, its safety record has been well documented since the 1940s,[156–158] particularly when instituted in collaboration with a multidisciplinary treatment team, including an anesthesiologist, a psychiatrist, and an obstetrician.[90,158–160] Requests for psychiatric consultation on pregnant patients who require ECT tend to be emergent and dramatic. For example, expeditious treatment is imperative in instances of mania during pregnancy or psychotic depression with suicidal thoughts and disorganized thinking. Such clinical situations are associated with a danger from impulsivity or self-harm. A limited course of treatment may be sufficient followed by institution of treatment with one or a combination of agents (such as antidepressants, neuroleptics, benzodiazepines, or mood stabilizers).

ECT during pregnancy tends to be underused because of concerns the treatment will harm the fetus. Despite one report of placental abruption associated with the use of ECT during pregnancy,[161] considerable experience supports its safe use in severely ill gravid women. Thus, it becomes the task of the psychiatric consultant to facilitate the most clinically appropriate intervention in the face of partially informed concerns or objections.

BREAST-FEEDING AND PSYCHOTROPIC DRUG USE

The emotional and medical benefits of breast-feeding to mother and infant are clear. However, for some women, establishing breast-feeding can be difficult and can contribute to extreme sleep deprivation that can worsen the postpartum course of illness. It is important to consider the benefits and risks of breast-feeding given each woman's situation.

Given the prevalence of psychiatric illness during the postpartum period, a significant number of women might require pharmacologic treatment while nursing. Appropriate concern is raised, however, regarding the safety of psychotropic drug use in women who choose to breast-feed while using these medications. Efforts to quantify psychotropic drugs and their metabolites in the breast milk of mothers have been reported. The serum of infants can also be assayed to assess more accurately actual neonatal exposure to medications. The data indicate that all psychotropic drugs, including antidepressants, antipsychotic agents, lithium carbonate, and benzodiazepines, are secreted into breast milk. However, concentrations of these agents in breast milk vary considerably.

The amount of medication to which an infant is exposed depends on several factors[162]: the maternal dosage of medication, the frequency of dosing, and the rate of maternal drug metabolism. Typically, peak concentrations in the breast milk are attained approximately 6 to 8 hours after the medication is ingested. Thus, the frequency of feedings and the timing of the feedings can influence the amount of drug to which the nursing infant is exposed. By restricting breast-feeding to times during which breast milk drug concentrations would be at their lowest (either shortly before or immediately after dosing medication) exposure may be reduced; however, this approach might not be practical for newborns, who typically feed every 2 to 3 hours.

The nursing infant's chances of experiencing toxicity depend not only on the amount of medication ingested but also on how well the ingested medication is metabolized. Most psychotropics are metabolized by the liver. During the first few weeks of a full-term infant's life, there is a lower capacity for hepatic drug metabolism, which is about one third to one fifth of the adult's capacity. Over the next few months, the capacity for hepatic metabolism increases significantly and by about 2 to 3 months of age, it surpasses that of adults. In premature infants or in infants with signs of compromised hepatic metabolism (e.g., hyperbilirubinemia), breast-feeding typically is deferred because these infants are less able to metabolize drugs and are thus more likely to experience toxicity.

Since 1998, data have accumulated regarding the use of various psychotropics during breast-feeding.[162–165] The available data, particularly on the TCAs, fluoxetine, paroxetine, and sertraline during breast-feeding, have been encouraging and suggest that the amounts of drug to which the nursing infant is exposed are low and that significant complications related to neonatal exposure to psychotropic drugs in breast milk appear to be rare.[166–173] Typically very low or nearly undetectable levels of drug have been detected in the infant's serum; one report indicated that exposure during nursing does not result in clinically significant blockade of serotonin (5-HT) reuptake in infants.[173] Although less information is available on other antidepressants, serious adverse events related to exposure to these medications have not been reported.[163,164]

Anxiety is prevalent during the postpartum period, and anxiolytics often are used in this setting. Data regarding the use of benzodiazepines have been limited; however, the amounts of medication to which the nursing infant is exposed are low.[166] Case reports of sedation, poor feeding, and respiratory distress in nursing infants exist[148,174]; however, the data, when pooled, suggest a relatively low incidence of adverse events. [163,166]

For women with BPD, breast-feeding can pose more significant challenges. First, on-demand breast-feeding can significantly disrupt the mother's sleep and thus can increase her vulnerability to relapse during the acute postpartum period. Second, there have been reports of toxicity in nursing infants related to exposure to various mood stabilizers, including lithium and carbamazepine, in breast milk. Lithium is excreted at high levels in the mother's milk, and infants' serum levels are relatively high, about one third to one half of the mother's serum levels,[175–177] thereby increasing the risk of neonatal toxicity (which includes cyanosis, hypotonia, and hypothermia).[178] Although breast-feeding typically is avoided in women taking lithium, the lowest possible effective dosage should be used and both maternal and infant serum lithium levels should be followed in mothers who breast-feed. In collaboration with the pediatrician, the child should be monitored closely for signs of lithium toxicity, and levels of lithium, thyroid-stimulating hormone (TSH), blood urea nitrogen (BUN), and creatinine should be monitored every 6 to 8 weeks while the child is nursing.

Several studies have suggested that lamotrigine reaches infants through breast milk in relatively high doses, ranging from 20% to 50% of the mother's serum concentrations[179,180]; this may be explained by poor neonatal metabolism of lamotrigine. In addition, maternal serum levels of lamotrigine increased significantly after delivery, contributing to the high levels found in nursing infants. However, none of these studies has reported any adverse events in breast-feeding newborns. One worry shared by clinicians and new mothers is the risk for Stevens–Johnson syndrome, a severe, potentially life-threatening rash, most commonly resulting from a hypersensitivity reaction to a medication, that occurs in about 0.1% of patients who have BPD and are treated with lamotrigine.[181] Thus far, there have been no reports of Stevens–Johnson syndrome in infants exposed to lamotrigine. In fact, it appears that cases of drug-induced Stevens–Johnson syndrome are extremely rare in newborns. A single case report described a neonate who developed the syndrome after exposure to phenobarbital.[182]

Similarly, concerns have arisen regarding the use of carbamazepine and valproic acid. Both of these mood stabilizers have been associated in adults with abnormalities in liver function and with fatal hepatotoxicity. Hepatic dysfunction associated with carbamazepine exposure in breast milk has been reported several times.[183,184] Most concerning is that the risk for hepatotoxicity appears to be greatest in children younger than 2 years; thus, nursing infants exposed to these agents may be particularly vulnerable to serious adverse events. Although the American Academy of Pediatrics has deemed carbamazepine and valproic acid to be appropriate for use in breast-feeding mothers, few studies have assessed the impact of these agents on fetal well-being, particularly in mothers who are not epileptic. In women who choose to use valproic acid or carbamazepine while nursing, monitoring of drug levels and liver function testing is recommended. In this setting, ongoing collaboration with the child's pediatrician is crucial.

Consultation about the safety of breast-feeding among women treated with psychotropics should include a discussion of the known benefits of breast-feeding to mother and infant and the possibility that exposure to medications in the breast milk can occur. Although routine assay of infants' serum drug levels was recommended in earlier treatment guidelines, this procedure is probably not warranted; in most instances, infants have low or nondetectable serum drug levels and, uncommonly, serious adverse side effects have been reported. This testing is indicated, however, if neonatal toxicity related to drug exposure is suspected. Infant serum monitoring is also indicated when the mother is nursing while taking lithium, valproic acid, or carbamazepine.

PSYCHIATRIC CONSULTATION AND POSTPARTUM PSYCHIATRIC ILLNESS

The postpartum period has typically been considered a time of risk for the development of affective illness.[24] Although several studies have suggested that rates of depression during the postpartum period are equal to those in nonpuerperal controls, other research has identified subgroups of women at particular risk for postpartum worsening of mood.[26,185–187] At highest risk are women with a history of postpartum psychosis; up to 70% of women who have had one episode of puerperal psychosis experience another episode following a subsequent pregnancy.[24,187] Similarly, women with a history of postpartum depression are at significant risk, with rates of postpartum recurrence as high as 50%.[188] Women with BPD also appear to be particularly vulnerable during the postpartum period, with rates of postpartum relapse ranging from 30% to 50%.[10,186,189] The extent to which a history of MDD influences the risk for postpartum illness is less clear. However, in all women (with or without a history of MDD) the emergence of depressive symptoms during pregnancy significantly increases the likelihood of postpartum depression.[26]

Postpartum Depression

Diagnosis

During the postpartum period, about 85% of women experience some mood disturbance. For most women the symptoms are mild; however, 10% to 15% of women experience clinically significant symptoms. Postpartum depressive disorders typically are divided into three categories: postpartum blues, nonpsychotic major depression, and puerperal psychosis. Because these three diagnostic subtypes overlap significantly, it is not clear if they actually represent three distinct disorders. It may be more useful to conceptualize these subtypes as existing along a continuum, where postpartum blues is the mildest and postpartum psychosis the most severe form of puerperal psychiatric illness.

Postpartum blues does not indicate psychopathology; it is common and occurs in approximately 50% to 85% of women following delivery.[190,191] Symptoms of reactivity of mood, tearfulness, and irritability are, by definition, time-limited and typically remit by the 10th postpartum day. Because postpartum blues is associated with no significant impairment of function and is time-limited, no specific treatment is indicated. Symptoms that persist beyond 2 weeks require further evaluation and suggest an evolving depressive disorder. In women with a history of recurrent mood disorder, the blues may herald the onset of postpartum MDD.[26,192]

Several studies describe a prevalence of postpartum MDD of between 10% and 15%.[27,190] The signs and symptoms of postpartum depression usually appear over the first 2 to 3 months following delivery and are indistinguishable from the characteristics of MDD that occur at other times in a woman's life. The presenting symptoms of postpartum depression include depressed mood, irritability, and loss of interest in usual activities. Insomnia, fatigue, and loss of appetite are often described. Postpartum depressive symptoms also co-mingle with anxiety and obsessional symptoms, and women might present with generalized anxiety, PD, or hypochondriasis.[193,194]

Although it is sometimes difficult to diagnose depression in the acute puerperium given the normal occurrence of symptoms suggestive of depression (e.g., sleep and appetite disturbance, low libido), it is an error to dismiss neurovegetative symptoms (such as severe decreased energy, profound anhedonia, and guilty ruminations) as normal features of the puerperium. In its most severe form, postpartum depression can result in profound dysfunction. Risk factors for postpartum depression include prenatal depression, prenatal anxiety, and a history of depression.

Treatment

A wealth of literature on this topic indicates that postpartum depression, especially when left untreated, may have a significant impact on the child's well-being and development.[195,196] In addition, the syndrome demands aggressive treatment to avoid the sequelae of an untreated mood disorder, such as chronic depression and recurrent disease. Treatment should be guided by the type and severity of the symptoms and by the degree of functional impairment. However, before initiating psychiatric treatment, medical causes for mood disturbances (e.g., thyroid dysfunction and anemia) must be excluded. Initial evaluation should include a thorough history, physical examination, and routine laboratory tests.

Although postpartum depression is relatively common, few studies have systematically assessed the efficacy of nonpharmacologic and pharmacologic therapies in the treatment of this disorder. Nonpharmacologic therapies are useful in the treatment of postpartum depression, and several preliminary studies have yielded encouraging results. Appleby and associates[197] have demonstrated in a randomized study that short-term CBT was as effective as treatment with fluoxetine in women with postpartum depression. IPT has also been shown to be effective for treating women with mild to moderate postpartum depression.[198]

These nonpharmacologic interventions may be particularly attractive to patients who are reluctant to use psychotropic medications (e.g., women who are breast-feeding) or for patients with milder forms of depressive illness. Further investigation is required to determine the efficacy of these treatments in women who suffer from more-severe forms of postpartum mood disturbances. Women with more-severe postpartum depression may choose to receive pharmacologic treatment, either in addition to or instead of nonpharmacologic therapies.

To date, only a few studies have systematically assessed the pharmacologic treatment of postpartum depression. Conventional antidepressants (e.g., fluoxetine, sertraline, and venlafaxine) have shown efficacy in the treatment of postpartum depression.[69,197,199–201] In all of these studies, standard antidepressant doses were effective and well tolerated. The choice of an antidepressant should be guided by the patient's prior response to antidepressants and a given medication's side-effect profile. SSRIs are ideal first-line agents because they are anxiolytic, nonsedating, and well tolerated; bupropion is also another good option. TCAs are often used, and because they tend to be more sedating, they may be more appropriate for women who have prominent sleep disturbances. Given the prevalence of anxiety in women with postpartum depression, adjunctive use of a benzodiazepine (e.g., clonazepam or lorazepam) may be very helpful.

Some investigators have also explored the role of hormone manipulation in women who suffer from postpartum depression. The postpartum period is associated with rapid shifts in the reproductive hormonal environment, most notably a dramatic fall in estrogen and progesterone levels, and postpartum mood disturbance has been attributed to a deficiency (or change in the levels) in these gonadal steroids. Although early reports suggested that progesterone may be helpful,[202] no systematically derived data exist to support its use in this setting. Two studies have described the benefit of exogenous estrogen therapy, either alone or in conjunction with an antidepressant in women with postpartum depression.[203–205] Although these studies suggest a role for estrogen in the treatment of women with postpartum depression, these treatments remain experimental. Estrogen delivered during the acute postpartum period is not without risk and has been associated with changes in breast-milk production and more significant thromboembolic events. Antidepressants are safe, well tolerated, and highly effective; they remain the first choice for women with postpartum depression.

In cases of severe postpartum depression, inpatient hospitalization may be required, particularly for patients who are at risk for suicide. In Great Britain, innovative treatment programs involving joint hospitalization of the mother and the baby have been successful; however, mother-and-infant units are much less common in the United States. Women with severe postpartum illness should be considered candidates for ECT. The option should be considered early in treatment because it is safe and highly effective. In choosing any treatment strategy, it is important to consider the impact of prolonged hospitalization or treatment of the mother on the infant's development and attachment.

Postpartum Panic Attacks and Obsessive–Compulsive Disorder

Symptoms of postpartum panic attacks and OCD symptoms are often included in the description of postpartum mood disturbance, but a growing literature supports the likelihood that postpartum anxiety disorders are discrete diagnostic entities.[153,194] Several investigators have described postpartum worsening of PD in women with pregravid histories of this anxiety disorder but with an absence of co-morbid depressive illness.[4] Postpartum OCD has also been described in the absence of co-morbid postpartum MDD. Symptoms often include intrusive obsessional thoughts to harm the newborn in the absence of psychosis. Treatment with anti-obsessional agents, such as fluoxetine or clomipramine, has been effective.[155]

Postpartum Psychosis

Postpartum psychosis is a psychiatric emergency. The clinical picture is most often consistent with mania or a mixed state consistent with an episode of BPD[24] and can include symptoms of restlessness, agitation, sleep disturbance, paranoia, delusions, disorganized thinking, impulsivity, and behaviors that place mother and infant at risk. The typical onset is within the first 2 weeks after delivery, and symptoms can appear as early as the first 72 hours after delivery.

Although investigators have debated whether postpartum psychosis is a discrete diagnostic entity or a manifestation of BPD, treatment should follow the same algorithm to treat acute manic psychosis, including hospitalization and potential use of mood stabilizers, antipsychotics, benzodiazepines, and ECT.

Prevention

It is difficult to reliably predict which women will experience a postpartum mood disturbance, but it is possible to identify certain subgroups of women (e.g., women with a history of mood disorder) who are more vulnerable to postpartum affective illness. Several investigators have explored the potential efficacy of prophylactic interventions in these women at risk.[206–209]

Several studies demonstrate that women with a history of BPD or puerperal psychosis benefit from prophylactic treatment with lithium, instituted either before delivery (at 36 weeks of gestation) or no later than the first 48 hours following delivery.[206–209] Prophylactic lithium appears to significantly reduce relapse rates and diminish the severity and duration of puerperal illness.

For women with a history of postpartum depression, Wisner and colleagues[210] have described a beneficial effect of a prophylactic antidepressant (either TCA or SSRI) administered after delivery. However, a subsequent randomized, placebo-controlled study from the same group did not demonstrate a positive effect in women treated prophylactically with nortriptyline.[211] The authors have suggested that nortriptyline may be less effective than SSRIs for the treatment of postpartum depression. The efficacy of prophylactic treatment with SSRIs in this population is under investigation.

In summary, postpartum depressive illness may be conceptualized along a continuum, where some women are at lower risk for puerperal illness and others are at higher risk. Although a less-aggressive, wait-and-see approach is appropriate for women with no history of postpartum psychiatric illness, women with BPD or a history of postpartum psychiatric illness deserve not only close monitoring but also specific prophylactic measures.

PERINATAL PSYCHIATRY: FROM SCREENING TO TREATMENT

Clinicians who manage the care of female psychiatric patients before, during, and after pregnancy may be called on to evaluate women who experience a broad spectrum of difficulties. Symptoms may be mild, although the consultant is typically requested when symptoms become severe. It is not uncommon for women to present weeks or even months after the onset of psychiatric symptoms. Many women and their health care providers mistakenly believe that even serious mood symptoms are normal postpartum reactions, and many women may be afraid or embarrassed to disclose that they are suffering from depression. Psychiatric disorders may emerge anew during pregnancy, although more often clinical presentations represent persistence or exacerbation of an existing illness. Physicians therefore should screen more aggressively for psychiatric disorders either before conception or during pregnancy, integrating questions about psychiatric symptoms and treatment into the obstetric history. Identification of at-risk women allows the most thoughtful, acute treatment before, during, and after pregnancy and signals the opportunity to institute prophylactic strategies that prevent psychiatric disturbances in women during the childbearing years.

One report has described the finding that even among women with identified psychiatric illness during pregnancy, definitive treatment is often lacking or incomplete.[19] The extent to which women suffering from postpartum psychiatric illness are undertreated as a group is also very well described. Perhaps one of the reasons for failure to treat women who have psychiatric disorders during pregnancy is the concern regarding fetal exposure to psychotropics. Many clinicians can conceptualize the need to weigh relative risks of fetal exposure on the one hand versus the risk of withholding treatment on the other. However, given the inability to absolutely quantify these risks, clinicians often defer treatment entirely and consequently put patients at risk for the sequelae of untreated maternal psychiatric illness. Clinicians should realize that the process of managing psychiatric illness during pregnancy and the puerperium is not a process like threading a needle; it is not clear-cut, and much treatment described in the literature is not evidence-based. However, thoughtful decisions can still be made with these patients as clinicians review available information with them and as clinician and patient realize that no decision is risk-free and no decision is perfect. Thoughtful treatment decisions can be made nonetheless, taking into account available information regarding relative risks of treatment and the patient's wishes.

Culture and Psychiatry

David C. Henderson, M.D.
Dana Diem Nguyen, M.D.
Marketa M. Wills, M.D.
Gregory L. Fricchione, M.D.

Gender, race, ethnicity, and culture may all have a tremendous impact on the diagnosis, treatment, and outcome for many individuals with psychiatric and medical problems. Although understanding every culture is impossible, use of some basic principles will help minimize clashes of cultures and lessen the risk of providing compromised medical care. When evaluating and treating a patient from a different culture, the clinician must be careful when making observations or applying stereotypes. The clinician must be aware at all times of his or her own feelings, biases, and stereotypes. In addition, the consulting psychiatrist must assess the impact of the hospital environment, the attitudes of the medical and ancillary care team, and the patient's experience within the health care system. Mistrust of the health care system is common and may influence a patient's behavior, level of cooperation, and adherence with recommendations. On the other hand, disparities in health care delivery exist and are influenced by factors such as gender, race, ethnicity, and culture.[1] Understanding a patient's culture will aid in the delivery of high-quality medical and psychiatric care. However, a little knowledge may be a dangerous thing. Variability among individuals is common; a patient may not fit into preconceived notions of his or her culture. The clinician must probe for cultural clues while remaining flexible enough to recognize that a patient's patterns and behaviors do not necessarily match the clinician's expectations.

CULTURE

Culture comprises a pattern of beliefs, customs, and behaviors, which a group (or people) acquire socially and transmit from one generation to another through symbols, shared meanings, teachings, and life experiences. It provides the tools by which people of a given society adapt to their physical environment, their social environment, and one another. It organizes groups with ready-made solutions to the problems and challenges that a people often face. Culture (as exemplified by art, literature, architecture, tools, machines, food, clothing, and means of transportation) can be observed directly through the five senses and through items collected in a museum or recorded on film. Other aspects of culture must be observed indirectly, usually through the behavior of people. These include the beliefs and values of the people, the reasons for considering some things sacred and other things ordinary, the things and events of which they are proud or ashamed, and the sentiments that underlie patriotism or chauvinism.

Each society establishes its own criteria regarding which forms of behavior are acceptable or abnormal and which represent a medical problem. Understanding an individual's culture or working with bicultural and bilingual interpreters may help clarify normal and abnormal behaviors. It is also important to recognize that an individual may have multiple cultures or subcultures that influence his or her behaviors. The consulting psychiatrist must often employ the skills of a detective to verify whether a patient's statements or beliefs are appropriate to his or her environment, heritage, and culture.

Cultural Assessment

A cultural assessment related to diagnosis and treatment should be included in the clinician's formulation of patients and their problems. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[2] Appendix I, provides an outline for cultural formulations. The DSM-IV emphasizes that a clinician must take into account an individual's ethnic and cultural context in the evaluation of each of the DSM-IV axes. This process, called *cultural formulation*, contains the following components:

Determination of Cultural Identity

Ethnic or cultural references and the degree to which individuals are involved with their culture of origin and their host culture are important. It is crucial to listen for clues about culture and ask specific questions concerning a patient's cultural identity. For instance, an Asian-American man who grew up in the southern United States may exhibit patterns, behaviors, and views of the world that are more consistent with those of a Caucasian southerner. Attention to language abilities and preferences must also be addressed.

Determination of Cultural Explanations

How an individual understands distress or the need for support is often communicated through symptoms (e.g., nerves, possession by spirits, somatic complaints, misfortune); therefore, the meaning and severity of an illness in relation to one's culture, family, and community should be determined. This explanatory model may be helpful when developing an interpretation, a diagnosis, and a treatment plan.

Determination of Psychosocial Function

Cultural factors can have a significant impact on the psychosocial environment and on function. Cultural interpretations of social stress, support, and one's level of disability and function must also be addressed. It is the physician's responsibility to determine the level of disability and help the patient and his or her family adjust to role changes caused by illness.

Determination of the Relationship Between the Clinician and the Patient

Cultural aspects of the relationship between the individual and the clinician should be considered. Moreover, cultural differences and their impact on the treatment must not be ignored. Language difficulties, difficulties eliciting symptoms or understanding their cultural significance, difficulties negotiating the appropriate relationship, and difficulties determining whether a behavior is normal or pathologic are common barriers to care. In the hospital the consulting psychiatrist must also attend to the environment in which the patient is receiving treatment. An intervention of this nature may improve the comfort of patients and their health care providers and the quality of the care provided.

Impact of Ethnicity on Psychiatric Diagnosis

In the United States, race and ethnicity have a significant impact on psychiatric diagnosis and treatment.[3–5] The need to reduce disparities in the mental health care of racial and ethnic minorities was recently underscored by the United States Surgeon General.[6] African Americans are frequently misdiagnosed as having schizophrenia when instead they have bipolar disorder or a psychotic depression. Moreover, treatment approaches and responses often differ depending on the diagnosis. The reasons for misdiagnosis are complicated. They include the fact that individuals from some ethnic or cultural backgrounds may present to the medical system later in the course of their illness than do Caucasian individuals; this results in the perception of a more severe illness.[5] The late presentation may be related in part to mistrust of the health care system. Physician biases also play a major role in misdiagnosis. Psychiatric diagnoses are often established by eliciting symptoms from patients that are then interpreted by the psychiatric expert. Many disorders have overlapping symptoms and can be used to support one diagnosis or disregard another. In the case of African Americans, affective symptoms are frequently ignored and psychotic symptoms are emphasized. This pattern has also been seen in other ethnic populations, including Hispanics, some Asian populations, and the Amish in the United States. African American patients are also more likely to receive higher doses of antipsychotics and depot preparations and to have higher rates of involuntary psychiatric hospitalizations and significantly higher rates of seclusion and restraints while in psychiatric hospitals.[3,5,7] The tendency is to oversedate such patients to reduce their so-called risk of violence despite, in some cases, little evidence that the patient was ever violent. These biases in psychiatric treatment continue and must be addressed.

Differences in Presentation of Illness

Cultural differences in the presentation of psychiatric illnesses abound. For instance, a Cambodian woman may present with complaints of dizziness, fatigue, and back pain, while she ignores other neurovegetative symptoms and is unable to describe feelings of dysphoria. American mental health care providers are generally unfamiliar with various Indo-Chinese culture-bound syndromes and with the meaning attributed to those symptoms by various cultures.[8,9] For example, common American expressions such as "feeling blue" cannot be readily translated into Indo-Chinese languages. A Cambodian clinician will ask Cambodian patients if they "feel blue" by using Cambodian terms which literally translate as "'heavy, overcast, gloomy." The Laotian way of describing feeling "tense" is feeling "like a balloon blown up until it is about to burst." Westermeyer,[10] in a case-controlled study in Laos, documented the general inability of Western psychiatrists to recognize the Laotian symptoms of depression.

Psychiatrists and primary care physicians who search for biological and structural reasons for complaints (e.g., back pain, headaches, and dizziness) may miss depression. Afflicted patients are often treated with meclizine for dizziness and analgesics for pain when an antidepressant would have been most appropriate.

From a cross-cultural perspective, evaluating the meanings of bizarre delusions, hallucinations, and psychotic-like symptoms remains a clinical challenge. A nonpsychotic patient may admit to hearing the voices of her ancestors (a feature that is culturally appropriate in certain cultural groups). In many traditional, non-Western societies, spirits of the deceased are regarded as capable of interacting with and possessing those still alive. It is difficult to determine whether symptoms are bizarre enough to yield a diagnosis of schizophrenia without an adequate understanding of a patient's sociocultural and religious background. On the other hand, caution must be taken not to assume that bizarre symptoms are culturally appropriate when in fact they are a manifestation of psychosis. The use of bicultural and bilingual interpreters, along with the search for information from other sources (e.g., family, community leaders, religious officials), may help determine whether an individual's experience is culturally appropriate or acceptable.

Additionally, while a great deal of attention has been paid to the study of panic disorder in Caucasians, little empirical research within the United States has looked at the phenomenology of panic disorder among minority groups. Compared with their Caucasian peers, African Americans with panic disorder report more intense fears of dying or going crazy, higher levels of numbing and tingling in their extremities, and higher rates of co-morbid posttraumatic stress disorder (PTSD) and depression. African Americans also use somewhat different coping strategies (e.g., religious practice and counting one's blessings) and endorse less self-blame. The incidence of isolated sleep paralysis is also higher in African Americans.[11]

Acculturation and Immigration

Recent immigrants or refugees arrive in the United States with a host of difficulties and psychosocial problems. A physician must ask about, and make an effort to

understand, the circumstances surrounding immigration. An individual may have been a political prisoner or a victim of trauma and torture, or he or she may have been lost or separated from family members. Under these circumstances the level of depression and PTSD experienced may be high. Literature on the contribution of acculturative stresses to the emergence of mental disorder is abundant.[12] The impact of acculturation may also lead to symptoms of depression, anxiety, "culture shock," and even PTSD-like symptoms.

The trauma and torture experienced by many refugees are also unfamiliar to the majority of American practitioners.[8] In spite of the numerous reports of the concentration camp experiences in Cambodia; the sexual abuse of Vietnamese boat women; and the serious emotional distress associated with escape, refugee camps, and resettlement experiences, limited research exists on refugee trauma and trauma-related psychiatric disorders and social handicaps.

Culture-Bound Syndromes

A culture-bound syndrome is a collection of signs and symptoms that is restricted to a limited number of cultures by reason of certain psychosocial features. Culture-bound syndromes are usually restricted to a specific setting, and they have a special relationship to that setting. Because culture-bound syndromes are classified on the basis of common etiology (e.g., magic, evil spells, angry ancestors), clinical pictures may vary.

Projection is a common ego defense mechanism in many non-Western cultures. Guilt and shame are often projected into cultural beliefs and ceremonies. Guilt and shame are attributed to other individuals, groups, or objects and may involve acting out, blaming others, and needing to punish others. Projection is also seen in magic and supernatural perspectives of existence. This leads to projective ceremonies and may lead to illness when the ceremonies are not performed.

Cultural psychoses are difficult to define. In cultural syndromes hallucinations may be viewed as normal variants. Delusions and thought disorder must be re-evaluated within a particular cultural setting. A culture may interpret abnormal behavior as relating to some kind of voodoo or anger and may regard the symptoms as normal even though symptoms are consistent with schizophrenia. Table 47–1 lists a number of culture-bound syndromes and the countries or regions where they have been described.

In the past it was believed that culture-bound syndromes occurred only in the country or region of origin. However, with significant population movements and the tendency for immigrants to remain within their culture (despite having moved to a new country), culture-bound syndromes have been observed in other parts of the world. One common culture-bound syndrome is *ataque de nervios*, which is commonly known and observed in Hispanic populations. As with many culture-bound syndromes, there may be significant overlap with DSM-IV psychiatric diagnoses. In one study 36% of Dominican and Puerto Rican subjects[13] diagnosed with *ataque de nervios* also met the criteria for panic attacks, although the features did not necessarily present together during the *ataque* episode.[13]

TABLE 47–1 Culture-Bound Syndromes

SYNDROME	CULTURE
Sleep paralysis *(amafufanyane)*	Zulu population of southern Africa
Sudden mass assault *(amok/benz)*	Malaysia, Indonesia, Laos, Philippines, Polynesia (called *cafard* or *cathard*), Papua New Guinea, Puerto Rico (called *mal de pelea*), and the Navajo (*itch'aa*)
Ataque de nervios	Latin American and Latin Mediterranean groups
Boufée delirante	West Africa and Haiti
Genital retraction *(koro)*	China and Malaysia
Startle-matching *(Latah)*	Malaysia and Indonesia
Running *(piblokto)*	Eskimos
Falling-out or blacking-out	Southern United States and Caribbean groups
Fright illness (hexing, voodoo, ghost illness)	Africa, Brazil, and native West Indians in Haiti
Ghost sickness	Kiowa Apache Indians
Mal de ojo "evil eye"	Mediterranean cultures and elsewhere
Qi-gong psychotic reaction	China
Taijin kyofusho	Japan
Shenjing shuairo or neurasthenia	China

Working with Interpreters

Communication problems are common even between English-speaking doctors and patients from similar socioeconomic backgrounds. Therefore it is not difficult to imagine the challenges and obstacles that a physician faces when working with limited-English–speaking patients whose culture may be unfamiliar to the doctor. Misunderstandings or a lack of comprehension about a patient's physical or psychiatric complaints may lead to misdiagnosis and result in unnecessary or inappropriate treatment. Patients, in turn, may feel frustrated, discouraged, or dissatisfied with their health care; this may lead them to refuse treatment or terminate their visits altogether.[14] Fortunately, interpreters can help bridge the communication gap between doctors and non–English-speaking patients.

Many states now have laws that require federally funded medical facilities to provide interpreters for their non–English-speaking patients. Whereas many interpreters are trained and certified to work with medical providers, translating for a mental health professional is very different and potentially challenging. Both interpreters and clinicians need to be aware of issues that may arise when using

interpreters in psychiatric settings. Some of the issues that clinicians face when working with interpreters may include the following[15]:

- Clinicians may feel they have less control in their work because their direct contact with the patient is decreased by the presence of the interpreter.
- Clinicians may feel uncertain about their role when working with interpreters who are more active and involved in the treatment process.
- Clinicians may have transference issues toward the interpreter.
- Conflicts may arise when clinicians and interpreters hold opposing views on a patient's diagnosis and treatment plans.
- Interpreters may find it difficult to work with clinicians of a different gender than their own.
- Clinicians may feel frustrated when they cannot verify what is being said to the patient.
- Clinicians may feel left out if the patient appears to have more of a connection with the interpreter.
- Interpreters may feel uncomfortable when asked to translate certain issues (e.g., sexual history or childhood abuse).

Recommendations When Working with Interpreters

Clinicians need to know the qualifications of interpreters. Do the interpreters have experience working with psychiatrists and psychologists? How much do they know about mental illness and mental health services? What are their personal views about mental illness? Interpreters who come from cultures wherein mental illness is highly stigmatized may bring biases or beliefs into the therapeutic process. It is well known that patients from certain cultures have been advised by their interpreters not to seek mental health services because only "crazy" people see psychiatrists and psychologists.

Clinicians should avoid using family members, friends, or clerical staff as interpreters.[16] Patients may not be able to disclose certain information in front of spouses or children. At the same time, it may be too difficult or distressing for a young child to have to hear certain details about his or her parent. In addition, family members have been known to omit or alter information they feel is too embarrassing or inappropriate to reveal to the clinician. In the past janitors and clerical staff were used as interpreters. This, of course, is strongly discouraged because cleaning and clerical staff may not have adequate medical or mental health language skills to provide accurate translations for clinicians. Unless there are no other alternatives, clinicians should avoid using family members and clerical employees as interpreters.

Trained interpreters should be treated as professional colleagues by clinicians.[16,17] Most interpreters are now well trained and can offer important cultural knowledge that can help promote the doctor–patient relationship. Clinicians should use the interpreters' language skills as well as their cultural expertise to help increase the clinician's understanding of the patient's culture, religion, and worldview. For some clinicians, interpreters are used only as voices to communicate with patients. These clinicians prefer word-for-word translations and do not want the interpreter to filter or alter what the patients say. Although this allows the clinician to maintain his or her role as the primary caregiver and to a certain extent control for what is being said to the patient, using direct translations can often lead to misunderstandings and confusion for both the patient and the clinician.

Literal translations from one language to another can be inaccurate and inappropriate. For example, "feeling blue," when translated word-for-word into Vietnamese, does not make any sense to the patients because it literally translates to "*cam giac xanh*," which means "feeling color blue." Certain words or concepts, such as depression and mental health, may not exist in the patient's country of origin. Interpreters may have to explain or describe the concept of depression to the patient, which requires much more time than what the clinician might expect. Clinicians must be patient, keeping in mind that it may take 10 minutes to translate one word. In addition, certain issues may be culturally inappropriate to discuss with a patient. Most women from Asian and Hispanic backgrounds feel uncomfortable if asked directly about sensitive topics (e.g., sexual abuse, family discord). Interpreters can be used as cultural consultants to assist clinicians with these more complex cases. Allowing interpreters the freedom and flexibility to re-phrase or summarize what is being said can help prevent misunderstandings and improve the exchange between the clinician and the patient.

Clinicians should meet with the interpreter briefly before each session to discuss expectations and clarify any issues or points that the clinician would like to address during the session.[15,16] Patients do not get as much time with the clinicians when they have to go through interpreters. Because everything must be translated back and forth, clinicians may find that they do not get as much accomplished in their session as they do with English-speaking patients. Time is a crucial factor when interpreters are involved. Thus clinicians should protect the patient's time by deferring any discussions with the interpreters that can wait until after the session.

Clinicians should always remember to introduce the interpreter to the patient at the start of the session if they have not met. This is also a good time to reaffirm issues of confidentiality.[15,16] Many patients feel uneasy about revealing personal issues or conflicts to members of their own community. Because most ethnic communities are small and close-knit, patients may fear that the interpreter will divulge their private information to others in the community. Patients are more likely to open up if they feel reassured that what they share with the clinician and interpreter will be kept in strict confidence. If possible, clinicians should try to use the same interpreter to help build trust and ensure continuity of care for the patient.[18]

During sessions clinicians should face and speak directly to the patients rather than the interpreters.[15–17] Although the patient and clinician may not be able to communicate through language, they can communicate and connect through eye contact, gestures of acknowledgment, and other nonverbal behaviors. It is helpful for the interpreter if the clinician can speak slowly and avoid using long and complicated sentences. The clinician should eschew technical or psychological terminology that does not translate easily and pause often to allow the interpreter time to translate. It is important to ask for clarification if there is

any confusion.[17] Two-way conversations should be avoided. Just as clinicians and interpreters should not engage in lengthy discussions in front of the patient, clinicians should interrupt when the patient and interpreter are talking for too long a time. Tension may arise when someone in the group feels left out.

After each session the clinician should encourage the interpreter to give his or her impression of the session; the interpreter often can provide important observations and feedback.[15] The clinician should ask the interpreter to clarify any issues or points that were not clear during the session. Clinicians can use this time to learn more from the interpreter about the patient's culture. The clinician and interpreter can also provide feedback about each other's performances. Good communication and trust between the clinician and interpreter are essential to care for patients with little or limited English.

ETHNICITY AND PSYCHOPHARMACOLOGY

There is emerging research on transcultural psychopharmacology (i.e., ethnopsychopharmacology)[19,20] that may aid the clinician's effective treatment of diverse populations. An understanding of ethnicity and its psychopharmacology and psychobiology is necessary to ensure high-quality care for ethnic minorities. Biological and nonbiological issues have a significant impact on the use of psychotropic medications.

Culturally shaped beliefs play a major role in determining whether an explanation about an illness and a treatment plan will make sense to a patient (explanatory models); for example, Hispanics or Asians often expect rapid relief with treatment and are cautious about potential side effects associated with Western medicine. Concerns about addictive and toxic effects of medications also arise. Some populations continue to use a mixture of herbal medicines and typically believe that polypharmacy is more effective. The use of herbal medicines is of great concern because of the risk of drug interactions and medical or psychiatric side effects or toxicity. The Food and Drug Administration (FDA) has issued a number of warnings on herbal medicine products, including the most popular weight loss products containing *Ephedra sinica (ma huang)*, which is the main plant source of ephedrine and which has been reported to cause mania, psychosis, and sudden death.

Patient compliance may be affected by incorrect dosing, medication side effects, and polypharmacy. Other factors include a poor therapeutic alliance and a lack of community support, money, or transportation; in addition, substance abuse or concerns about the addictiveness of a medication may be crucial. Communication difficulties and divergence between a patient's and a clinician's explanatory model play important roles in why a patient from an ethnic minority is significantly more likely to drop out of treatment. Exploring these beliefs will improve communication, adherence, and outcome.

Examining each patient's social support systems is vital. The ways in which a family interacts and functions have a significant impact on psychiatric treatment. For example, some Hispanics have more interactions with relatives and may become increasingly demoralized when their relatives are not involved in their treatment. Hispanics and Asians typically have a "closed network," which consists of family members, kin, and intimate friends.

Biological Aspects of Psychopharmacology

Pharmacokinetics deal with metabolism, blood levels, absorption, distribution, and excretion of medications. However, other pharmacokinetic variables (e.g., conjugation, plasma protein–binding, and oxidation by the cytochrome [CYP] isoenzymes) also play a role. Pharmacokinetics may be influenced by genetics, age, gender, total body weight, environment, diet, toxins, drugs, and use of alcohol, as well as disease states. Environmental factors include medications, drugs, herbal medicines, steroids, dietary factors, sex hormones, and use of caffeine or tobacco.

The activity of CYP liver enzymes is controlled genetically, although environmental factors can alter their activity. Understanding how pharmacokinetics and environmental factors relate to different populations will help the clinician predict side effects, blood levels, and potential drug–drug interactions. For example, CYP 2D6 is the isoenzyme that metabolizes many antidepressants (including the tricyclic and heterocyclic antidepressants and the selective serotonin reuptake inhibitors [SSRIs]); SSRIs can inhibit this enzyme, leading to accumulations of other substrates. CYP 2D6 also plays a role in metabolizing antipsychotics such as clozapine, haloperidol, perphenazine, risperidone, thioridazine, and sertindole. Although much emphasis has been placed on the CYP 2D6 metabolism of psychotropics, it is a major enzyme for the metabolism of numerous nonpsychotropic medications as well. This fact, which is often ignored clinically, can have a significant effect on the tolerability or toxicity of medications.

The incidence of "poor metabolizers" (i.e., individuals with little enzyme activity) at the CYP 2D6 is roughly 0.5% to 2.4% in Asian populations, 3% to 7.3% in Caucasians, 3.1% in Mexican Americans, 3.6% in Nicaraguans, and 1.9% in Tanzanians. African Americans and blacks have now been found to have 2% to 8% poor metabolism.[21–25] CYP 2D6*4 (CYP 2D6B) appears to be responsible for poor metabolizers in Caucasians. CYP 2D6*17 and CYP 2D6*10 are found in individuals of African and Asian origin, respectively, and are responsible for lower enzyme (intermediate or slow metabolizers). Individuals from these backgrounds are at great risk for toxicity, even when medications are used at low doses. For instance, a woman who develops hypotension and a change in mental status several days after starting 20 mg of nortriptyline may be found to have toxic blood levels and require cardiac monitoring. Table 47–2 lists drugs that are metabolized through different CYP enzyme systems.

Recently, a genetic variation of the extensive metabolizer gene that decreases activity at the CYP 2D6 enzymes by approximately 50% ("slow metabolizer") was discovered. This group appears to have enzyme activity levels that are intermediate between poor and extensive metabolizers.[19,26–30] One study found CYP 2D6*17 in 33% of African Americans and a reduced capacity to metabolize dextromethorphan, a CYP 2D6 probe drug.[21–22] Additionally, approximately 33% to 37% of Asians are considered

TABLE 47–2 Cytochrome P450 Isoenzymes, Substrates, Inhibitors and, Inducers

CYP	CYP 1A2	CYP 2C9/10	CYP 2C19	CYP 2D6	CYP 2E1	CYP 3A3/4

"slow metabolizers," whereas 34% of Nicaraguans and 18% of Mexican Americans were found to be slow metabolizers. [29,31] This may explain ethnic differences in the pharmacokinetics of neuroleptics and antidepressants. Although these individuals are not as likely to experience toxicity at extremely low doses (e.g., poor metabolizers), they are likely to experience significant side effects at lower doses. These individuals may quickly be classified as "difficult patients" because they complain of side effects at unexpectedly low doses. The preceding information is striking considering that numerous studies have shown that African Americans, for instance, receive higher doses of antipsychotics, are more frequently treated with depot neuroleptics, and have higher rates of involuntary commitments and seclusion and restraints than do Caucasians. Whereas data on pharmacokinetics of neuroleptics have been mixed in African Americans, Asians have been shown to have a higher "area under the curve" for haloperidol.[20,32] Korean Americans have also been found to have higher blood levels of clozapine and to respond to lower doses of clozapine compared with Caucasians. In fact, although sertindole, metabolized by CYP 2D6, did not make it to the U.S. market, the phase II clinical trials included a sufficient number of African Americans to determine that their sertindole blood levels were 50% higher than Caucasian subjects who took the same dose.

The CYP 2C9 isoenzyme is involved in the metabolism of ibuprofen, naproxen, phenytoin, warfarin, and tolbutamide. Approximately 18% to 22% of Asians and African Americans are poor metabolizers of these drugs. CYP 2C19 is involved in the metabolism of diazepam, clomipramine, imipramine, and propranolol; it is inhibited by fluoxetine and sertraline. The rates of poor metabolizers of this enzyme are approximately 3% to 6% in Caucasians, 4% to 18% in African Americans, and 18% to 23% in Asians.[19,20]

Although ethnic or racial differences in metabolism at the 3A enzyme system have not been fully evaluated,[33–34] numerous substances have been found to either inhibit or induce this enzyme. Inhibitors include medications such as fluoxetine, fluvoxamine, nefazodone, norfluoxetine, clozapine, haloperidol, diltiazem, verapamil, gestodene, erythromycin, itraconazole, ketoconazole, and ritanovir. Grapefruit juice and corn have also been found to inhibit this enzyme system. This is clinically relevant because there are populations (including some Asian groups and Mexicans and Mexican Americans) that consume corn as a regular part of their diet. Many years ago, the "grapefruit juice diet" led to many patients having side effects with medications that were previously well tolerated.

Additionally, there is a CYP 3A4 "G" variant that is more common in African American men than Caucasian men. Within African American men, the "GG" (odds ratio 11.9) and "AG" (odds ratio 9.3) genotypes were associated with a risk of aggressive prostate cancer.[35]

Finally, lithium appears to be a drug with significant differences in dosing and tolerability across populations. African Americans are more likely to experience lithium toxicity and delirium compared with Caucasians (likely related to a slower lithium–sodium pathway and connected to higher rates of hypertension). Some Asian populations respond to lower doses and have lower serum levels of lithium (0.4 to 0.8 mEq/L).[19]

Also, the choice of medications, particularly atypical antipsychotics, should be tempered by an understanding of individual and population risk factors for medical morbidities (e.g., obesity, hypertension, diabetes mellitus, cardiovascular disease). For instance, many of the reports of diabetic ketoacidosis secondary to atypical agents have been in African Americans who are at higher risk for diabetes.[36,37]

THE "MEDICAL OMBUDSMAN" ROLE

In 1988 Pasnau[38] enumerated six fundamental functions of the consultation–liaison psychiatrist, including the role of "medical ombudsman" for the patient. Although the use of this term did not catch on, it signified the sometimes important need of medical and surgical teams to be reminded of the unique human nature of each patient in their care. Racial, ethnic, and cultural factors are obviously important characteristics of individuals. Psychiatrists in the general hospital can present these factors in their consultations and, as a result, enrich patient care.

TECHNIQUES TO MINIMIZE CULTURAL CLASHES AND MISDIAGNOSIS

Certain techniques may be employed to avoid misdiagnosis, mistreatment, and cultural clashes. The first moments of an encounter are often crucial. A clinician must be respectful to all patients and address them formally (e.g., Mr., Ms., or Mrs.). In some cultures an informal introduction is considered disrespectful and may have a lasting impact on the physician–patient relationship.

The relationship will be more complex and require more time to develop trust and an alliance. It will also take time to assure patients about confidentiality and educate them about mental illness to counteract stigmas that may be influenced by culture. Also, if the diagnosis is unclear or affected by ethnicity or culture, the clinician should consider a structured diagnostic interview (e.g., the structured clinical interview for DSM disorders [SCID]) to reduce the possibility of misdiagnosis. Finally, it is important to acknowledge the need to spend more time with patients from different cultures. A clinician must have patience and should expect longer sessions when using an interpreter.

Legal Aspects of Consultation

48

Ronald Schouten, M.D., J.D.
Rebecca W. Brendel, M.D., J.D.

Legal issues are common and acknowledged, although not willingly accepted, aspects of modern medicine. Physicians respond to these issues in various ways, ranging from denial of their existence, to resentment at the perceived intrusion into patient care they create, to obsessive concern that can ultimately interfere with good clinical care.

Although it is true that legal issues are ever-present, and at times are the dominant concerns of patients and providers, for the most part they exist in the background of care. When specific legal issues do arise, medical and surgical physicians often turn to the consultation psychiatrist for assistance (perhaps because the most common legal issues that arise [competency and treatment refusal], have to do with mental functions and abnormalities of behavior). Whatever the reason, the psychiatric consultant may be drawn into a turbulent atmosphere when medical and surgical staff are confronted with a legal issue. The well-prepared consultant can be invaluable in these matters.

The first and perhaps most important service provided by the consultant is to remind the consultee that the physician's safest havens within the law are the principles of good faith, common sense, and good clinical care. To be of maximum assistance, consultants should be familiar with relevant legal concepts, and use this knowledge to diminish consultees' anxiety and help them perform their jobs. The challenge for the psychiatric consultant is to ease the burden of the consultee by providing clinical insights and legal information and to know when and how to use the input of the hospital attorney.

Medicine has advanced rapidly in the twentieth century, giving rise to an evolving array of medicolegal issues. These issues are reflected in questions asked by residents and staff alike. How do I determine whether a patient is incompetent? If the patient is competent and making an irrational decision, does that decision have to be honored? What is my liability exposure as a consultant? If a managed care company refuses to pay for continued hospitalization or for a patient's admission to a psychiatric facility, can the physician be held liable if the patient commits suicide? If the patient has expressed a desire to hurt someone else, what are my obligations to that third party? What obligations do I have if my patient is human immunodeficiency virus (HIV)-positive and refuses to inform his or her sexual partner?

This chapter cannot provide definitive answers to these and all the other medicolegal questions faced by general hospital psychiatrists. Rather, this chapter outlines general principles that apply in almost all jurisdictions. Because state statutes and case law vary considerably on these medicolegal matters, hospital counsel and legal representatives of medical organizations and insurers should be consulted. They are excellent sources of information about legal aspects of general hospital psychiatry.

PHYSICIANS' RIGHTS AND OBLIGATIONS

Malpractice Liability

Malpractice, *negligence*, and *liability* are three terms that engender great concern and are often misunderstood. Malpractice law is a type of personal injury or tort law that concerns itself with injuries allegedly caused by the treatment activities of professionals. To establish a claim of malpractice, a plaintiff (the complaining party) must prove four things. First, it must be proved that the defendant physician owed a duty to the injured party. Where the injured party is the patient, the duty is to perform up to the standards of the average physician in the community practicing in that specialty. Failure to practice in accordance with that standard, unless there is some justification, constitutes the second element: negligence. The third and fourth elements are closely tied to the first two: The negligent behavior has to be shown to have been the direct cause of actual damages. In the event that all four elements are proved, the defendant may be held liable (responsible for the damage) and ordered to pay compensation to the plaintiff, either directly or through his or her insurer.[1–5] The four elements of malpractice are often summarized as the four Ds: duty, dereliction of duty, direct causation, and damages.

The liability exposure of consultants can be a concern for psychiatric consultants and others. Treating clinicians have the primary duty of care for the patient. Consultants, who by definition are brought in to provide advice to the treating clinicians, do not have the same duty to the patient. The consultant's duty of reasonable care is owed to the consultee, not the patient. This rule does not hold, however, where the consultant steps out of the purely consultative role and assumes direct responsibility for some aspect of the treatment relationship. For example, the consultant who evaluates a patient and then advises the treating physician that a course of antidepressant treatment is appropriate is not liable for an adverse outcome from the treatment. If, however, the consultant writes the prescription and monitors the treatment course, he or she has assumed the status of treating physician and may be held responsible for any adverse outcomes. [6,7]

Liability and Managed Care

Managed care and liability for injury when coverage is denied have been important issues ever since managed care arrived in force on the health care scene. The basic problem can be seen in this hypothetical example.

CASE 1

Mr. A was admitted to the trauma unit after leaping off a bridge into the river. After open reduction and internal fixation of his bilateral femoral fractures, the psychiatric consultant saw him. Mr. A was found to be suffering from major depression as well as alcohol abuse. He was believed to be at a moderate to high risk for suicide, and suicide precautions were instituted on the floor. Mr. A was begun on a course of antidepressants, but these had not yet begun to work when he was deemed surgically ready for discharge. The consultant recommended transfer to an inpatient psychiatry unit where Mr. A could undergo treatment for both his depression and substance abuse. Mr. A's mental health coverage had been carved out from his medical–surgical coverage. The utilization reviewer for his medical–surgical coverage insisted that he be discharged from the hospital and scheduled for outpatient physical therapy with visiting nurse coverage. The mental health management company sent its own psychologist reviewer to evaluate Mr. A. The reviewer agreed that Mr. A was depressed but denied authorization for psychiatric hospitalization. The reviewer opined that Mr. A was not acutely suicidal, did not need inpatient substance abuse treatment, and could be managed as an outpatient. He was given the names of the three psychiatrists in his town who were authorized under his plan and was able to get an appointment scheduled for 2 weeks after discharge. Mr. A was discharged from the hospital, over the objections of the consultant. The consultant had found that the patient was still significantly depressed and at risk of drinking again but not committable because he was not imminently suicidal. Ten days later, the visiting nurse found him hanged in his apartment. The death was ruled a suicide. Mr. A's family brought a malpractice action against the hospital, the treating physicians, the consultant, and the managed care company.

What liability does the managed care company have in a case like this, in which the denial of care results in harm to the patient? Would the managed care company's liability supersede that of the physicians? The answers to these questions are still unclear. There have been a series of legal cases addressing these issues, and the law is still evolving. At present, there is a possibility that managed care companies may be held liable in these situations if the company exerted such control over the decision-making process that the physician's judgment was overridden. In other words, for the physician to avoid liability, he or she must protest the denial of care, appeal it to the highest level that the insurer provides, and take other reasonable steps to ensure the patient's safety. Depending on the facts, the liability may be assigned entirely to the managed care company, to the physician, or be shared.[8–11] At present, treating physicians are regarded as independent contractors and therefore bear separate and often sole responsibility. There are policy arguments against that model, which may lead to future changes.[12]

Whatever the policy arguments, under federal law, there are specific limits on managed care companies' liability for denial of care. Most often, decisions made by managed care organizations to limit care are subject only to limited legal remedies under the Employee Retirement Income Security Act (ERISA) of 1974. ERISA limits most employees of private companies to suing their health plans for the cost of the care denied by the managed care organization only, and not for recovery of losses that result from the denial of care or for punitive damages.[13] ERISA's protection of managed care plans from liability for the consequences of their decisions is increasingly seen as unfair given the level of control over treatment decisions exercised by some plans. As a result, several federal court cases have eroded the prohibition on damages under the law, but these cases represent only small gains, the trend in cases has appeared to have come to a halt, and it remains to be seen whether lawmakers will amend ERISA.[14,15] In addition, state law efforts to hold managed care companies liable for damages have been largely unsuccessful.[16] For the time being, in the face of bad outcomes, patients may try to shift liability to physicians and hospitals to recover losses.[17]

Confidentiality and Privacy

Confidentiality is the clinician's obligation to keep matters revealed by a patient from the ears of third parties.[2,4] It is usually demanded and protected by statute and custom. A variety of exceptions to confidentiality exist, usually where the courts or the legislature determine that maintenance of confidentiality will result in more harm than good from a societal standpoint. This rationale provided the basis for the California court's decision in *Tarasoff v. Board of Regents*,[18] in which the court held that psychotherapists have a duty to act to protect third parties where the therapist knows or should know that the patient poses a threat of serious risk of harm to the third party.[19,20] In looking at the public policy issue, the court stated,

> The Court recognizes the public interest in supporting effective treatment of mental illness and in protecting the rights of patients to privacy. But this interest must be weighed against the public interest in safety from violent assault.[18]

Although not all states have adopted this view, the majority have. A number of states have enacted statutes dealing with this fertile area of malpractice liability.[21] The consultant should be familiar with the relevant statutory and case law concerning this issue in his or her jurisdiction. The consultant should also be aware that liability can arise when medical or surgical colleagues fail to breach confidentiality and do not warn family members or other contacts about the potential for contagion from an infectious disease.[22] In fact, liability for such failure set the stage for the court's decision in *Tarasoff*.[18] Additionally, a small number of states, including Massachusetts, have held that a physician may be held liable for injuries to a third person that result from the failure to warn a patient about the side effects of medications, such as where a patient falls asleep at the wheel of a car and was not warned of the sedating effects of a medication.[23]

Although infectious disease has been the subject of duty to protect cases in the past, infection with the HIV has been treated somewhat differently than other infectious diseases. Controversy persists about the obligation of a physician to warn the partner of an HIV-positive patient when the patient refuses to do so. Many states have statutes that address this issue, with varied approaches, adding to the confusion and highlighting the controversial nature of the issue. The psychiatric consultant should learn the

requirements of the jurisdiction in which he or she practices. Several articles and book chapters have addressed this controversial issue, some of which are cited in this chapter.[24–29]

In addition to situations in which disclosure is mandated to protect a third party, such as in *Tarasoff*[18] and infectious disease situations, other breaches of confidentiality may be mandated by statute or case law to protect vulnerable third parties. For example, all 50 states in the United States have statutes that require specific individuals, including physicians, to report suspected child abuse or neglect to state social service agencies.[30,31]

Many states also require that known or suspected abuse or neglect of the elderly or the disabled be reported.[31] Failure to comply with these requirements can result in substantial penalties. More recently, some states have begun requiring physicians and others to report known or suspected cases of domestic violence to law enforcement or to designated agencies. Mandatory reporting statutes serve an important societal purpose, but they are not without controversy. Every clinician should become aware of the specific requirements in his or her jurisdiction.[32]

Patient health information is also subject to regulation under a federal law known as the Health Insurance Portability and Accountability Act (HIPAA) of 1996. As of mid-2003, institutions and individual providers are required to comply with HIPAA rules. HIPAA has affected hospital practice by requiring distribution, in writing, of the institution's privacy policy to all patients and by mandating physicians to undergo training on privacy and disclosure provisions. The rules are too complex to review in full; however, several salient points stand out for psychiatrists.

Among the most relevant provisions of HIPAA is the treatment of medical records and the distinction between general psychiatric records and psychotherapy notes. Patients are entitled to a copy of their medical records; they also have the explicit right to request changes in the record. Whether or not the applicable staff person amends the contested information, the involved correspondence becomes part of the record. Although HIPAA affords special status to psychotherapy notes and allows psychiatrists not to disclose these notes to patients, this exception is narrow. To qualify for protection under the psychotherapy notes provision, the notes must be kept separate from the patient's medical record. However, even if kept in a separate psychotherapy record, specific types of information are not subject to the psychotherapy notes exclusion; these include medications prescribed, test results, treatment plans, diagnoses, prognosis, and progress to date.[33–35] It should be noted, however, that these notes are considered to be part of the medical record in the event that a subpoena is received for medical records in the course of litigation.

The practical implication of HIPAA regarding psychiatric record-keeping is that psychiatric records, whether in an outpatient clinic or contained in a medical chart from a nonpsychiatric hospitalization, are broadly accessible to patients or anyone they authorize to access their records. Therefore consulting psychiatrists should consider documentation of sensitive therapy material carefully because it will be treated like the rest of the medical record unless the psychotherapy notes are kept in a separate file.

Like patients, health insurance companies' access to psychotherapy records is restricted. Health insurance companies cannot demand access to information contained in psychotherapy notes as a requirement of payment for care. If, in a particular circumstance, psychotherapy notes are released to an insurance company, written consent from the patient is required under HIPAA. This consent requirement is in sharp contrast to the disclosure rules for the general medical and general psychiatric record for insurance purposes; HIPAA does not require consent for disclosure of this information to insurance companies for the purpose of obtaining payment for treatment—medical or psychiatric. HIPAA also does not require specific consent for the release of information for treatment or health care operations purposes. Operations purposes, for example, include quality assurance, licensing, and accreditation. There are 11 additional circumstances in which disclosure is permitted without patient consent, including emergencies and mandated reporting situations, such as child abuse—which are generally considered to be a part of current medical practice. But other situations, including exceptions for law enforcement and attorney requests, may be more concerning.[33,35]

Refusal to Treat Patients

Refusal to treat patients, in or out of the hospital, is a right that is rarely invoked by physicians. The physician–patient relationship is, at heart, contractual in nature. Both parties have the same right to enter, or to refuse to enter, the relationship as they do with other contracts. Once the physician offers to treat and the patient accepts, the contract is established and the physician's right to refuse or withdraw is limited in certain ways. For example, maintaining a walk-in clinic or emergency department (ED) can be construed as an implicit offer to treat on an emergent basis. The patient's presentation at the clinic or ED is an acceptance of the offer, creating a contract. It does not necessarily create an obligation to provide ongoing care, so long as the walk-in or emergency nature of the services is clear and appropriate information is provided regarding ongoing care. In a situation in which a prospective patient discusses his or her history with a physician, it may be difficult to assert that no relationship has been established, particularly if the patient is under the impression that a treatment relationship exists. Physicians should clarify at the outset of the treatment encounter that they may or may not accept a case. It is usually helpful to explain at the first visit that this is an initial evaluation to determine whether or not it is appropriate for the physician to take this particular individual as a patient. Clearly, this principle does not include the emergent, or even urgent, medical problem. In the event that no physician–patient relationship has been created in the initial contact, referral of such a patient to a health care facility, such as a walk-in clinic, demonstrates concern for the patient without necessarily creating an obligation to treat.[24–28,36–38]

When the physician elects not to treat an individual, the physician should make every effort to provide an alternative course to avoid claims of abandonment.[1,2] Abandonment is the unilateral severance of the relationship by the physician, leaving the patient without needed medical care.

The optimal care of the patient is the first consideration. Whenever a physician desires to transfer the patient to another physician, the transferring physician must take steps to ensure continuity of care by specific arrangement with the physician who is going to treat the patient. The physician may terminate the treatment relationship with a patient for a variety of reasons, including nonpayment, repeated failure to keep appointments, or threatening behavior. In such cases, the patient should be notified of the decision, the available treatment options (including a specific referral, if possible), and available sources of emergency care. The course pursued and the reasons and indications for the transfer or termination should be documented in the medical record.[2,3]

The physician's right to refuse to provide care for patients may be restricted where the refusal is based on the patient's specific illness or inherent characteristics. The refusal to care for patients of certain races, religions, ethnic origins, or disease type (e.g., acquired immunodeficiency syndrome) raises significant ethical concerns as well as potential liability under Title VII of the Civil Rights Act of 1964 and the Americans with Disabilities Act. These are beyond the scope of this chapter. The general rule, however, is that physicians and other clinicians may be charged with unethical conduct and in some situations with violation of patients' civil rights, when treatment is refused on a discriminatory basis.[39,40]

The issue of terminating the physician–patient relationship usually arises when some conflict has developed between physician and patient over the course of treatment or as a result of noncompliance.[41] Knowing about the physician's right not to treat is important for consultants. Often the knowledge that a physician can stop treating a particular patient allows enough "give" in a confrontation so that the consultee's anxiety diminishes and negotiation can begin.

End-of-Life Care and Advance Directives

Care of the dying and hopelessly ill patient continues to generate difficult questions, staff conflicts, and requests for help from physicians who find themselves faced with these clinical, ethical, and legal dilemmas.[42,43] Controversy and turmoil are generated when the patient loses the capacity to participate in the decision-making process. The decision of a competent patient to refuse life-sustaining treatment yields similar results. The general rule is that every competent adult has the right to make his or her own decisions about medical care, based on personal preference, even if that choice conflicts with what a majority of others would choose under similar circumstances. An important distinction must be drawn between the competent patient's request that treatment be withheld or withdrawn and requests that the physician take some active, independent step to terminate the patient's life. The former are generally regarded as being within the realm of the patient's right to make treatment decisions. The original illness, rather than the withholding or withdrawal of treatment, is regarded as the cause of death in such situations. Active steps taken to end a patient's life are considered euthanasia; in many states, the complying physician could be subjected to criminal prosecution.[43–45] In fact, in two 1997 cases, the Supreme Court of the United States upheld two state laws prohibiting physician-assisted suicide after physicians challenged the constitutionality of the laws.[45–47] However, the Supreme Court of the United States has also limited the ability of the federal government to prevent states from allowing physician-assisted suicide. Specifically, in 2006, the Court ruled against the federal government when it attempted to use federal law to block the ability of Oregon physicians to prescribe controlled substances for the purpose of physician-assisted suicide.[48] For more than a decade, Oregon was the only state that legalized physician-assisted suicide. Shortly before the submission of this chapter, Washington passed a physician-assisted suicide law based largely on the Oregon statute.

The treatment requests of the dying patient have not always been taken seriously, especially when the patient's choice is to terminate care. Physicians struggle when faced with a patient who refuses further treatment, especially when there is some hope of improvement. Physicians often find it difficult to give up the fight even at the request of the patient. Consulting psychiatrists in such circumstances should be concerned with determining whether the patient's request to forgo heroic efforts stems from depression or pain and whether or not the patient is capable of understanding the nature of the request. In other words, is the patient's refusal of further treatment informed? If so, the next challenge is working with the treatment team so that they can accept the patient's decision.

When minor children suffer terminal conditions, in the absence of any overriding legal requirements, parents are generally permitted to make decisions regarding continuation of extraordinary efforts.[32,49,50] The consulting psychiatrist is urged to seek the advice of the hospital's general counsel when confronted with these issues. The maze of governmental regulations, statutes, and case law in this area combined with the emotionally charged nature of the situation demand expert legal input. Nevertheless, the larger challenge for the consultant and the treatment team lies in helping the child's parents with the turmoil at hand and the grief ahead.

The psychiatrist should do what he or she can to ensure the comfort of the patient, such as seeing that treatment of clinical depression and alleviation of tractable pain are not overlooked in the anxiety that surrounds the dying patient (see Chapter 41). Development and documentation of written guidelines for the management of these difficult situations can be helpful in ensuring rational constancy in approach. Such attention to the relief of suffering decreases conflict between patient, family, and staff. In turn, this helps avoid legal involvement in the situation.

The status of the patient's right to refuse life-sustaining treatment varies among the states. In 1990 the Supreme Court of the United States handed down its opinion in *Cruzan v. Director, Missouri Department of Public Health*.[51] The Court held that all competent individuals have a constitutionally protected right to refuse life-sustaining treatment. When a patient is incompetent, however, the court held that the state can assert its interest in preserving life and require clear and convincing evidence of the now-incompetent patient's preferences in such matters before a surrogate decision-maker will be allowed to refuse the treatment on the patient's behalf. In most jurisdictions, surrogate decision-makers, whether family members or

guardians, are allowed greater freedom in drawing conclusions about the patient's preference.

Many states have statutes that allow competent individuals to issue advance directives concerning future medical care in these situations. All states have statutes providing for durable powers of attorney, an instrument that can be used to delegate decision-making authority to another person in the event of incapacity. All physicians should be aware of what prior directives are valid in their jurisdictions and encourage their patients to explore these issues with them and with their legal representatives. Under the Patient Self-Determination Act of 1990, all health care facilities, nursing homes, and health maintenance organizations must inquire on admission or enrollment whether a patient has an advance directive. If not, the patient must be offered information on the subject and an opportunity to create a directive.[52–54] Notwithstanding nearly two decades of this legal requirement, it is estimated that only a minority of Americans (30% to less than 50%) have executed an advance directive.[29]

RIGHTS OF PATIENTS

It is no news that the relationship between physician and patient has changed considerably over the years. The pendulum has swung between the extremes of paternalism and total patient autonomy. More recently, the impact of restrictions on patient choice imposed by managed care has been added to the equation. Most physicians and their patients operate on some middle ground between the extremes of complete patient autonomy and medical paternalism. The fundamental principle is that it is the patient, not the physician, who makes the ultimate choice regarding treatment. This ethical concept has been operationalized by legal decisions and by legislation. Although some physicians still view these changes as dangerous to patient care and as intrusions into their domain of clinical judgment, they represent much-needed measures for protection of the rights of mentally and medically ill patients. Nevertheless, food and drug laws, restrictions on new and experimental treatments and procedures, and commitment and restraint laws—all modified in recent years—trigger anxiety for physicians who previously concerned themselves with only consent, competency, and refusal of treatment against medical advice (AMA).

Informed Consent and Evaluation of Competency

Informed consent issues and the evaluation of competency are major components of the medicolegal workload. Informed consent has been an essential feature of medical practice since the 1960s. It is a process by which the patient agrees to treatment, in which the consent is based on adequate information, and it is voluntarily given by a patient who is competent to do so.[55] The term *informed consent* is somewhat misleading; we are as concerned with informed refusal as we are with informed consent. Bowing to convention, the term informed consent is used with the understanding that the same standards apply to informed refusal.

Informed consent is required before the initiation of any medical treatment, but exceptions do exist. Informed consent need not be obtained in an emergency in which delay would seriously threaten the well-being of the patient. In such cases, the physician is under an obligation to use his or her best judgment and to act in good faith. Such behavior is unlikely to result in litigation, especially if the physician documents (immediately after the emergency passes) the events and the reasons for the steps taken. Other exceptions to informed consent have been found where the patient waives the right to receive information, where the patient is incompetent, or where providing the information needed for informed consent would cause the patient's physical or mental health to deteriorate (known as *therapeutic privilege*). The therapeutic privilege is problematic; it is mentioned here because it has been invoked in the past and was for many years a mainstay of medical paternalism (e.g., patients who were treated for carcinoma without being told the diagnosis for fear it "would just upset them" and worsen their overall condition). Situations in which the therapeutic privilege can be justifiably invoked are rare. The fact that providing the information might lead the patient to refuse treatment or would cause the patient considerable anxiety does not justify invoking therapeutic privilege. The situation must be one in which the informed consent process itself would cause risk of grave harm. The physician who forgoes the informed consent process under the name of therapeutic privilege does so at his or her own risk.[55–57]

An essential feature of modern consent is that it be informed. Simple consent, in which the patient gives the physician blanket permission to take care of medical problems, is not deemed adequate, unless the patient has made a specific decision to waive informed consent. The amount and type of information to be provided to the patient or the surrogate decision-maker vary somewhat among jurisdictions.[2] The two basic standards are the professional standard and the patient-oriented standard. In the former, the physician is required to give that amount of information that the average physician in that specialty would provide under the circumstances. In other words, it looks to the standard of care. In other states, the amount of information to be provided is determined by what the patient would require to make an informed decision. This is also known as the materiality standard. In some states, the materiality standard is applied on the basis of what the average patient would require to make a decision, whereas in other states it is assessed in terms of what the specific patient would require. In either case, the physician who covers the following information, taken from a leading Massachusetts case,[58] with the patient will generally be held to have provided adequate information:

- The diagnosis and condition to be treated
- The nature of the proposed treatment
- The nature and probability of the material risks of the treatment
- The benefits that may be expected from the treatment
- The inability of the physician to predict results
- The irreversibility of the procedure, if that is the case
- The likely results of forgoing treatment
- The likely results, risks, and benefits of alternative treatments

The second requirement for informed consent is that the consent be given voluntarily. Coercion is often in the eye of the beholder; the fact that coercion ostensibly occurs in the service of the best interests of the patient does not justify it from the ethical standpoint or qualify it as an element of informed consent. The line between persuasion and coercion often appears both narrow and vague. Generally speaking, if some negative contingency (including an exaggerated prediction of a poor prognosis) is attached to the patient's refusal of treatment, there is coercion, and any subsequent consent is technically invalid.

Competency is the threshold issue in the informed consent process. The term is familiar to all physicians; typically, it is used imprecisely. Competency is defined as the legal capacity of an individual to perform either a specific function or a wide range of functions; before such a determination by a judge, all adults are presumed to be competent. Only a judge can declare a person incompetent for specific functions or for all activities (global incompetence). The psychiatric consultant can only make a clinical assessment of the patient's capacity to function in certain areas. That assessment is usually, but not always, accepted by the court in its determination of incompetence.[2,55] What then of the numerous requests received by the consultation psychiatrist to determine the competency of medical and surgical patients? The use of competency as a shorthand term is justifiable so long as the consultant and the consultee are clear that the most the consultant can do is to assess the patient's capacity to engage in the decision-making process in question. The change in the patient's legal status must be left to a judge.

Competency is usually task-specific and defined in relation to a specified act: to make a will (testamentary capacity), to testify in court (testimonial capacity), to consent to or to refuse treatment (decision-making capacity), and the like. Being competent to perform one act does not mean that one is necessarily competent to perform another. Hence, the consultant called to evaluate a patient's competency must first determine the specific type of competency in question and be aware of the applicable judgment criteria. Once the consultant has determined the type of competency in question, the judgment hinges on how well the patient meets the criteria. For example, with regard to capacity to make treatment choices, we look to the patient's understanding of three things: the illness (that some thing is wrong and to some degree how wrong), the treatment (what is proposed and why it is relevant to what is wrong), and the consequences of the decision. Although a variety of means of assessing decision-making capacity have been proposed, Appelbaum and Grisso[59] have suggested the following four criteria that are particularly useful and straightforward:

1. Does the patient manifest a preference? A patient who is unable or unwilling to express a preference presumably lacks the capacity to make a choice. It does not necessarily follow, however, that a patient who expresses a choice is competent.
2. Is the patient capable of attaining a factual understanding of the situation (nature of the illness, treatment options, prognosis with and without treatment, risks and benefits of treatment, and so on)? The patient need not possess this level of understanding at the time of admission; he or she need only be able to receive the factual information and retain it in some reasonable form during the decision-making process.
3. Does the patient have an appreciation of the significance of the facts presented? Appreciation, in contrast to factual understanding, indicates a broader level of understanding related to the significance of the facts presented and the implications these facts hold for the patient's future.
4. Is the patient able to use the information presented in a rational fashion to reach a decision, that is, to weigh the facts presented in a logical manner? The focus here is not on the rationality of the ultimate decision, but on the rationality of the thought processes leading to the decision.

When a substitute decision-maker is deciding on behalf of an incompetent patient, the same elements of capacity to make a decision apply. The patient's health care agent has the responsibility to express the patient's choice, with an awareness of the facts and appreciation for their significance, thinking through the material in a logical fashion before making a decision.

Competency is not an all-or-nothing proposition, and the same level of competence is not required for all medical decisions. Most experts agree that the strictness of the competency test should vary as the risk/benefit ratio changes. In essence, there is a sliding scale for the level of competence needed before a person can be deemed competent to make medical decisions.[60–62] The more favorable the risk/benefit ratio, the lower the standard for competence to consent and the higher the standard for competence to refuse. For example, the patient who agrees to accept incision and drainage of an obvious wound abscess would not have his or her competence subjected to rigorous assessment. Refusal could not be taken so lightly; the more serious the abscess, the more intense the examination of competency would have to be. If the risk/benefit ratio were unfavorable to the patient (e.g., extensive surgery to remove a slow-growing brain tumor in a 94-year-old), refusal would not have to be challenged as meticulously as would consent. Although some criticize this approach as being too open to manipulation by a paternalistic physician, it accurately reflects professional obligations to ensure that patients make a truly informed decision based on a rational weighing of the risks and benefits involved. A similar approach was endorsed by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research.[63,64]

Dementia, delirium, and psychosis are the conditions most often cited as causes of incompetence.[65–68] The consultant should always consider the possibility of a mood disorder as a basis for impaired competence to make medical decisions. The following example demonstrates some of the complexities of these evaluations.

CASE 2

A psychiatric consultant was asked to assess the competency of M. B., a 62-year-old man who presented to the ED with a massive subdural hematoma that he had suffered in repeated falls owing to bradycardia. He had a profound expressive aphasia; despite the size of the subdural hematoma, the patient was medically stable and intermittently lucid. Nevertheless,

neurosurgical staff were anxious to evacuate the subdural hematoma for fear of increased intracranial pressure. During his lucid intervals, the patient was verbally abusive to his physicians and to the consultant, stated clearly that he did not want surgery, and demanded to be discharged. The limited duration of his lucid intervals and his general irritability prevented the consultant from conducting a more complete mental status examination and determining the degree of his cognitive impairment, if any. An interview with his family members revealed that he had been drinking and becoming more depressed, with marked suicidal ideation, in the previous weeks. He had refused to see a physician about his bradycardia, stating that he would prefer to die. Based on this information, his mental status examination, and the risk/benefit ratio of the proposed treatment, the consultant determined that the patient lacked the capacity to give an informed refusal. An emergency court hearing was held with an "on-call" judge. The judge ruled that the patient was incompetent to refuse the planned procedure and appointed a family member to be his guardian. The guardian then consented to evacuation of the subdural. The patient tolerated the procedure well; on recovering from surgery and anesthesia, he informed the staff in a clear voice that he was going to sue all of them. The appointment of a guardian and receipt of informed consent by the guardian deprived the patient of any basis for a malpractice action.

Although depression must be considered as a possible cause of impaired judgment and incompetence, caution must be exercised. Just as a patient with schizophrenia is not automatically considered incompetent, a patient with major depression may also retain the ability to make rational decisions. Studies have found that medical decision-making capacity is altered by severe depression but not by depression of lesser severity.[69]

Patients may make decisions in one moment and change those decisions minutes or hours later. This can cause significant disruption of treatment for that patient and for others. Frequent shifts in patient choice can be the basis for questioning the patient's competence. Ideally the patient makes a competent choice before suffering a shift in mental status. Family members should be included in this process so they can assist the treatment team in the event of a subsequent change in the patient's decision.

The cause of incompetence may be treatable. Intense pain may lead a patient to refuse a needed procedure; treatment with adequate doses of analgesics may resolve the problem. Treatment of depression, when it is a factor, may be attempted with psychostimulants, which may act within 1 to 2 days. This can restore the patient's perspective so that the decision to refuse or accept is competently made. Delirium and agitation often interfere with treatment decisions and should be treated with a neuroleptic if no specific cause of the confusional state can be found. The consultant should not determine that the patient is permanently incompetent until these medications have been given an adequate trial, and other potential causes of the confusional state have been addressed. It must be remembered that even psychotic patients may have clear, rational reasons for refusing a treatment. Conversely, the refusal may be the result of voices telling the patient to leave the hospital, that they do not deserve treatment, or that the surgeon is a Federal Bureau of Investigation agent sent to spy on them.[70]

Occasionally, psychiatric consultants are asked to assess a patient's testamentary capacity, competency to execute a contract, financial competency, or the like. Such questions are unlikely to arise in the course of the usual medical consultation but instead are asked by an attorney or the courts, in anticipation, or as a result, of a challenge to the patient's competency to engage in these activities. In the case of testamentary capacity, for example, a psychiatrist may be asked to assess the mental status of a patient to determine whether he or she meets the legal standards for testamentary capacity and to provide documentation of this mental status in the event that the will is challenged after the patient's demise. To do so, the psychiatrist must possess both clinical skills and knowledge of the legal standards: The patient knows that he or she is executing a will, knows the extent of his or her estate, and knows the "natural objects of his or her bounty" (who would normally inherit). Because these assessments involve the application of specific legal requirements to clinical situations, the evaluation should be performed only after consultation with the referring attorney or court representative and with adequate knowledge of the legal standard. For this reason, many psychiatric consultants refer such consultations to colleagues who specialize in consultation to the legal system.[71]

To give consent, the patient must be able to make an informed judgment on the matter at hand. Patients with deficits in this area owing to communication difficulties (e.g., foreign language, deafness, or aphasia) or ignorance of important aspects of their care cannot technically give consent, whether or not they are competent. The physician who performs a procedure on a passive, confused, or fearfully mute patient who seems compliant or willing does so at his or her own peril; the physician risks a suit for battery. There is little protection in the ancient maxim *Qui tacet consentire videtur* ("silence gives assent").

The patient's capacity to give consent, understanding, and judgment should be documented in the chart or in office notes of the physician, along with the mental status examination and any specific questions asked about the proposed treatment. Impairment of intellect, memory, attention, or consciousness can limit the patient's understanding; impairment in reality testing, sense of reality, impulse control, and formal logic can influence judgment. The presence or absence of any or all of these should be documented clearly in the chart, along with their relationship to the illness and to the decision-making process.

The general rule in obtaining consent for treatment of minor children is that parents have both the obligation to provide care and the right to make treatment decisions. There are a number of complicating issues in this area, however. First, the age of majority varies by state. Second, minors' rights and the legal ability to consent vary according to the type of treatment being contemplated. Massachusetts, for example, permits minors to give consent for the treatment of drug addiction and sexually-transmitted diseases without seeking parental authorization. Virginia allows minors to consent to psychotherapy without parental consent. Third, the law is open to examination of the reason for the parents' denial of consent, rather than upholding it automatically. For example, denial of life-saving treatment because of the parents' religious beliefs will not be upheld.

Finally, the law recognizes the concept of the emancipated minor. This is a minor child who is free of parental control and dominance and is therefore deemed competent to consent in the eyes of the law, regardless of age. Informed consent by an emancipated minor, carefully documented in the record, usually protects the physician's action from criticism by the parent or guardian of that minor. Treating clinicians and consultants should learn the rules of their specific states concerning consent by minors.[49,50]

New drugs, treatments, and procedures should not be used without informed consent by patients (or the appropriate surrogate decision-maker) and proper authorization from hospital and government agencies. Although physicians have generally been given considerable freedom in prescribing medications and in doing procedures for off-label (not approved by Food and Drug Administration [FDA]) purposes, this freedom is constrained by federal and state regulations, the standard of care (enforced through malpractice actions), and the patient's right to be informed about the proposed treatment. Use of carbamazepine for treatment of bipolar disorder is a common example of this. As a matter of policy, patients should be informed that the medicine prescribed has not been given FDA-approval for that particular purpose and informed about the rationale for prescribing it.[36]

Civil Commitment and Restraint

Civil commitment and physical restraint are commonly encountered but poorly understood by patients and many nonpsychiatric physicians. Civil commitment is a process by which the power of the state is used to remove an individual from society and place him or her in an institutional setting. Originally the mentally ill were confined to institutions to protect the rest of society. As the approach toward the mentally ill became more enlightened, the goal of confinement was to provide treatment and protection. Under this approach, the state was fulfilling its role as protector of its citizens, much as a parent would act on behalf of a child. Hence, this is known as the state's *parens patriae* interest. With the blossoming of the civil liberties movement in the 1970s and the emphasis on individual autonomy, the individual's interest in personal freedom and privacy was given priority over the state's *parens patriae* interest. During the 1970s, the best interest or *parens patriae* approach to civil commitment was replaced by the dangerousness approach in most jurisdictions. This approach, based on the state's police powers, allows an individual to be involuntarily committed to a mental institution only if the individual poses a danger to himself or herself through direct injury, if there is a direct threat of physical harm to others, or if the individual is gravely disabled and unable to care for himself or herself in the community.[2,3,72]

In a general hospital, if a medical or surgical patient is psychiatrically committable but requires further medical or surgical treatment, the wisest course is to initiate commitment procedures and request that a local mental health facility accept the patient but allow the patient to remain in the general hospital for care. Budgetary concerns, insurance issues, and the general reluctance of both state and private psychiatric hospitals to take medically ill patients often make it difficult to place such patients. It behooves the consultation psychiatrist to learn how to anticipate the need for further psychiatric care and begin the search early. The need for commitment should be reassessed throughout this process and the process halted if appropriate.

This search for inpatient psychiatric placement increasingly requires negotiation with managed care companies to obtain permission for the hospitalization. Often, the interaction with health insurance companies occurs through the process of precertification, which requires the transferring hospital to gain approval for transfer and inpatient care from the insurer before the patient can be transferred and admitted to the receiving psychiatric facility. Because of frequent differences in general medical and psychiatric benefits within health plans, the same precertification process may be required even when a patient is transferred from a medical ward to a psychiatric unit in the same hospital. It is now commonplace for insurance plans to "carve out" or subcontract mental health benefits to a subsidiary or a different company with procedures and guidelines distinct from those of the parent company.

The psychiatric consultant often encounters questions regarding the restraint of patients on medical and surgical floors. Delirium, dementia, acute or chronic psychosis, or severe anxiety or panic can lead a patient to assault staff, to wander off the ward, or to fall. The suicidal patient being treated on an unlocked medical floor poses the risk of elopement and successful fulfillment of suicidal urges. Many hospitals have policies that allow the patient to be restrained before the psychiatric consultant is called. When this occurs, the role of the consultant is to provide management recommendations and approval for the restraint. Usually, the psychiatric consultant is asked to decide whether the restraints can be discontinued.

The legal aspects of restraint of patients on a medical or surgical ward vary among jurisdictions.[4,36] Generally speaking, a patient may be restrained for the purpose of protecting the patient or other patients and staff, for the purpose of allowing examination during an emergency, or for the purpose of treatment in situations in which the patient appears to lack the capacity to make treatment decisions and is refusing care. In this latter situation, no forced treatment should be initiated in the absence of an emergency unless surrogate consent has been obtained. In handling these situations, physician and staff are required to use the least restrictive alternative available. For example, where a sitter or observer is available for a potentially suicidal patient, that option is more appropriate than four-point restraints. Family members often ask whether they can substitute for a sitter. Although this may be possible in some situations, it requires careful clinical judgment that takes into account the type of pathology, the degree of impulsivity, the overall degree of risk, and the relative ability of the sitter to act objectively. Restraint is uncomfortable for the staff as well as for the patient and family, and there may be a tendency to avoid it whenever possible for some types of patients and a tendency to overuse it with others. Again, careful clinical assessment is essential so that protection is provided for those patients who need restraint without zealously overprotecting and restricting those who do not. The justification for restraint, including history and formal mental status examination, should be clearly documented in the

medical record, along with the psychiatric differential diagnosis, treatment, and management recommendations.

The restraint of patients gives rise to two potential sources of liability: battery and false imprisonment.[1] A battery is defined as the touching of another person without his or her consent (expressed or implied) or justification. False imprisonment may be charged where an individual is denied the right to move about freely by real or perceived methods of confinement. Failure to restrain a patient with a tendency to wander, who is subsequently injured, may result in a charge of professional negligence.

Malpractice claims based on battery or false imprisonment are rarely successful if the use of restraint is reasonable under the circumstances, the reasons for the measures are documented in the medical record, proper technique is used, and hospital policies are followed. Failure to restrain when indicated and improper restraining technique carry greater risks of harm to the patient and of malpractice claims.

Right to Refuse Treatment

The right to refuse a specific form of treatment or procedure has a long history and is firmly established in medicine. This right, based on the philosophical principle of autonomy, has been operationalized through the common law (case law), by legislation, and in state and the U.S. constitutions.[73–76] Although widely acknowledged, the right to refuse treatment is not absolute. It may be limited when it is in conflict with legitimate state interests of preserving life, preventing suicide, protecting the interests of third parties, or protecting the integrity of the medical profession.[77] Generally the decision of a competent patient to end treatment presents a difficult dilemma for the treatment team. If the issue ever reaches court, the competent patient's preference is rarely overridden. With the advent of advance directives (e.g., health care proxies and durable powers of attorney), the wishes of the patient, expressed when competent, can be honored after the onset of incompetence. The path to this conclusion is not as smooth as this might suggest. Consider the following example.

CASE 3

Ms. C, 22-year-old woman was admitted to the hospital after sustaining severe head injuries in a motor vehicle accident. After emergency evacuation of a subdural hematoma, her condition stabilized. She was unresponsive to verbal stimuli, did not track, but did withdraw to pain. She showed decorticate posturing. The treatment team urged aggressive measures, arguing that the injury was recent and the ability to predict ultimate outcome was limited. Tube feedings were begun and an early pneumonia treated with antibiotics. The patient's family told the treatment team that the patient would never want to be kept alive under such circumstances. The patient's mother explained that the patient's cousin had been in a motor vehicle accident 5 years earlier and had lingered in a persistent vegetative state for 3 years until her death. The family had to engage in a costly legal battle to get permission to terminate supportive care. When this occurred, the patient (who was a nursing student at the time) vowed that she would never allow this to happen to her or to her family. She told her family that she would want to be free of life-sustaining measures in the event of a serious injury if there were "no chance of recovery." In addition, she executed a health care proxy naming her mother as her agent for medical decision-making in the event of her incapacity. Her mother believed that the patient would have refused care if able to do so and insisted that the tube feedings be stopped. The treatment team resisted, arguing that there was hope for some recovery. After a series of meetings, the family acquiesced to the recommendations of the team and the patient was transferred to a rehabilitation facility, still posturing and not responding. Two weeks after transfer, she was returned to the hospital with septicemia. This time, the treatment team yielded to the family's preferences and the patient died peacefully.

As this example suggests, there are often no perfect answers to these problems. Both the treatment team and the family were well-meaning and tried to do what they believed was right for the patient. Meetings between the treatment team and the family, facilitated by the consultants to the unit, allowed a process to develop that gave the patient some chance at early recovery and for nature to take its course. Although difficult, the decision-making process was conducted with dignity, with the aim of maintaining the patient's autonomy and ensuring that the decision was informed and with concern for the ethical integrity of her caretakers. In a more contentious setting, the family could have charged the treatment team with battery. Under the law in that state, the agent appointed by the health care proxy (the mother in this case) had the same authority to make decisions as the patient would have if competent, including refusal of permission for further treatment. The treatment team could have raised legal challenges to the exercise of the proxy, arguing that it was not evident that there was "no chance of recovery." In some states, an argument would be made that shutting off the life support constituted murder or assisted suicide or that the state's interest in preserving life and preventing suicide outweighed the individual's expressed wish. The likelihood of such arguments being made or succeeding is much less in light of the Cruzan decision.[51] Finally, if the physicians or the institution had been ethically opposed to the termination of treatment, the request might have been denied and the patient transferred to the care of another physician or facility. The best solution to these challenging problems lies in the sharing of information and concerns between the family and the treaters. Immediate resort to legal posturing hardens positions and shuts off communications in most cases, to the detriment of all concerned.

The requirement of informed consent and the right to refuse treatment do not automatically apply in emergencies. In emergencies that appear to endanger the patient, or in acute situations that threaten the safety of the staff and other patients, the physician who acts in good faith while administering a treatment or procedure is generally not liable for failure to obtain informed consent. Good faith is in doubt, however, when the patient has made his or her preferences regarding treatment in the event of an emergency clearly known before the emergency and the physician chooses to disregard these preferences. For example, the physician who agrees to perform surgery on a Jehovah's Witness with the stipulation that there be no transfusions, even in an emergency, is hard pressed to plead good faith should he or

she violate that agreement in the event of a sudden hemorrhage. Some institutions have adopted policies specific to such situations. In the case of chronic medical conditions, ongoing situations, and prolonged heroic measures to sustain life, the emergency exception loses its applicability, and decisions regarding treatment must be returned to the competent patient or to an appropriate surrogate.

Leaving treatment AMA is the prerogative of any competent, nonconsenting patient.[78] The threat to leave AMA, similar to most other medicolegal conflicts, usually represents a clinical problem disguised as a legal dispute. The consultant called to evaluate the patient threatening to leave AMA must evaluate whether the patient is competent to make that decision. In the course of the evaluation, it is common to find that the patient is angry over a perceived lack of caring or dissatisfaction with the amount of information provided by the physician. The consultant who can restore communication between physician and patient may be successful in getting the patient to complete the course of treatment. If the patient does leave, the consultant may then have to calm the staff in preparation for the patient returning at a later date.

From a legal standpoint, if patients possess the capacity to make decisions and do not pose a risk of harm to themselves or others, they cannot be held against their will. A patient requesting to sign out AMA may be deemed to have the requisite capacity (competence) to do so if he or she understands the nature of the illness, the recommended treatment, the alternative treatments available, and the prognosis with or without treatment and is able to use this information in a rational manner to reach a decision. If the patient meets these criteria, he or she can leave against advice, whether or not the form is signed. In the event that the patient refuses to sign the form, the discussions before release and the fact that the patient refused to sign the form should be documented in the medical record.

CONCLUSION

This chapter began with a discussion of the role of the psychiatric consultant in helping consultees deal with medicolegal issues. It is appropriate to close it with a few cautionary words about the temptations present for those who undertake this task. Consultants are often tempted to meet the needs of their consultees by telling them what they want to hear. Nowhere is this more true than in the assessment of a patient's competency to consent to, or to refuse, treatment. This is compounded by the consultant's own inclinations, as a physician, to seek an outcome that is in the best clinical interests of the patient. In performing competency assessments and other consultations on medicolegal issues, such temptations must be strongly resisted. The assignment of the consultant is to be objective and focused on the issue at hand, rather than on what the consultant or consultee sees as the best overall clinical outcome. Such isolation of purpose is often difficult, but it is essential if the consultant is to serve the consultee and the patient. The consultant must also keep in mind that he or she is just that: a consultant whose job it is to advise, not to decide. The treating physician may choose to disregard the consultant's assessment that a patient is incompetent to make treatment decisions and proceed with treatment. The treating physician assumes both the legal and moral liability of his or her own actions. The consultant can serve only as a guidepost and only then by being both knowledgeable and objective. This task is made easier by taking the following approach to consultation on these highly charged medicolegal issues:

1. Know what you are being asked to do. That is, understand both the overt request and any covert agenda that may exist.
2. Know the clinical facts of the consultation.
3. Know, or find out, the salient legal requirements involved.
4. Determine the presence of any apparent conflict between good clinical care and the law.
5. Get to know the hospital attorney; share information and attempt to develop a multidisciplinary team approach to patient care.
6. Try to move all parties away from a crisis mentality to gain some time to resolve conflicts and to encourage compromise. Avoid ultimatums. Pushing back deadlines for procedures, treatment, leaving the hospital AMA, and the like decrease time pressures and allow people to think more clearly.
7. Understand the personalities of the physician and the patient.
8. Know the patient's next of kin, their understanding, fears, biases, personalities, and the probabilities of obtaining informed consent from them.
9. Act as a go-between so as to diminish anxiety and communication gaps among physician, patient, and family and try to find areas for compromise and agreement.
10. Search out covert disagreements and hidden fears in the physician and patient; try to find commonsense measures that would remedy these, and search for loopholes and areas in which conflicts can be mended or avoided.
11. Provide detailed documentation in the patient's medical record (or chart) of the patient's understanding, judgment, capacity to give consent, and clinical and psychiatric status as well as the course pursued.
12. Maintain an objective point of view while remaining mindful that the consultant's responsibility is to assess as accurately as possible the patient's capacity to give an informed consent and that truth is a higher goal than scheduling concerns of the consultee and ward staff.
13. Use such consultations to teach physicians that they have little to fear from the law and to teach patients that they have little to fear from their physicians.

Collaborative Care: Psychiatry and Primary Care

49

BJ Beck, M.S.N., M.D.

The convergence of several historic trends[1] in psychiatry, and more generally in the U.S. health care system,[2] has necessitated novel approaches to the psychiatric care of patients in the general medical setting. Such approaches, potentiated by advances in psychopharmacology, must contain cost, appropriately allocate limited health-care resources, and meet the mandates for safe, personalized, and high-quality care. Previously considered a hospital-based specialist, the psychiatric consultant must now be comfortable in the outpatient medical clinic, as shorter medical and surgical hospitalizations and more outpatient procedures, such as same-day surgery, have transitioned the locus of care for medically ill patients from inpatient to outpatient settings.[3] At the same time, primary care providers (PCPs) are seeing more seriously ill psychiatric patients in their outpatient practices, because shorter psychiatric hospitalizations have transitioned these patients back to their communities more quickly, without a concomitant increase in community mental health resources.[4] Consultation psychiatrists are well positioned to collaborate with their medical colleagues in the development and implementation of pragmatic and cost-effective outpatient models of care.

The burgeoning increase in medical expenses and the limited nature of our health care resources has moved the focus in the U.S. health care system from patient- to population-based care.[5] In a society that so highly values the individual, this painful transition has, nonetheless, exposed the tremendous fiscal burden of psychiatric morbidity. The psychiatrically disordered population experiences increased *physical* health care utilization, work absenteeism, unemployment, subjective disability,[6–8] and mortality. Although it is more difficult to demonstrate, there is also evidence of the cost-offset value of appropriate and timely psychiatric treatment.[9–11]

Changes in health care reimbursement have resulted in conflicted PCP incentives to recognize and treat psychiatric problems.[12] On the one hand, prepaid, provider-risk plans, such as health maintenance organizations (HMOs) and other capitated programs, have exposed the expensive use of general medical services by patients with untreated or poorly managed psychiatric illness. This statistic serves as an incentive for the PCP to initiate treatment for the more common psychiatric problems seen in primary care. On the other hand, the PCP gate-keeper system, which evolved to manage the expense of specialty care, can be a disincentive to the recognition of more serious mental illness or any mental condition the PCP is not comfortable treating. Managed care organizations (MCOs) often "carve out" behavioral health care and relegate it to managed behavioral health care organizations (MBHOs),[13] which may have limited referral networks that do not include the PCP's psychiatric colleagues. This situation makes the referral process a time-consuming disincentive and complicates future communication and collaboration between mental health and physical health providers.

Many of the MBHOs have spearheaded initiatives to promote treatment of common psychiatric problems in the primary care setting. However, because most do not have credentialed nonpsychiatric physicians, or have not contracted with them, this has essentially shifted the cost of the PCP's treatment of psychiatric problems to the (medical) MCOs. As managed care entities begin to see the value of promoting total health care, rather than focusing solely on cost containment, they also seek to "carve in" MBHO services (i.e., by co-locating behavioral health clinicians in their medical management units, for better collaboration and coordination of appropriate services). If another enlightened trend, the mixed services agreements (i.e., agreements between MCOs and MBHOs to reimburse providers for treating the patient in the most appropriate setting while negotiating their respective financial responsibilities based on the medical and psychiatric natures of the condition being treated) were to eventually migrate from the inpatient to the outpatient arena, negating the cost-shift issue, PCPs might have further incentive to treat their patients' common psychiatric problems in the primary care setting.

EPIDEMIOLOGY

In the early 1980s, the Epidemiologic Catchment Area (ECA) study attempted to quantify the prevalence of psychiatric problems in the general U.S. population. During a 6-month interval, the study found that roughly 7% of community residents sought help for a mental health problem. More than 60% of these individuals never saw a mental health professional but instead sought care in a medical setting (such as in the emergency department or from their PCP).[14] Even among those who met full criteria for a diagnosable psychiatric disorder, 75% were seen only in the general medical (rather than the mental health or psychiatric) setting.[15] Psychiatric distress, therefore, was exceedingly common among primary care populations. About half of general medical outpatients had some psychiatric symptoms. The use of structured diagnostic interviews detected a prevalence of 25% to 35% for diagnosable psychiatric conditions in this patient population. However, roughly 10% of primary care patients had significant psychiatric symptoms that did not meet criteria for a recognizable psychiatric disorder.[16] Of the full-criteria disorders, the vast majority were mood disorders (80%), with depression being the most

prevalent (60%) and anxiety a distant second (20%). The more severe disorders (e.g., psychotic disorders) were more likely to be treated by mental health professionals.[15]

The National Comorbidity Survey (NCS), conducted from 1990 to 1992, found a lifetime prevalence of one or more psychiatric disorders in U.S. adults of about 50%, with a 30% 1-year prevalence of at least one disorder.[17] Alcohol dependence and major depression were the most common disorders.

In 2001 to 2002, a rigorous replication of the NCS (NCS-R) was undertaken to incorporate measures of severity, clinical significance, overall disability, and role impairment.[18] The NCS-R revealed the risk of major depression to be relatively low until early adolescence, when it began to rise in a linear fashion. The slope of that line has become steeper for each successive birth cohort since World War II. The lifetime prevalence of significant depression is 16.2%; the 12-month prevalence is 6.6%.

Two findings, however, are of particular interest. One is that 55.1% of depressed community respondents seeking care now receive that care in the mental health sector. The other significant finding, attributable to advances in pharmacotherapy and educational efforts, is that 90% of respondents treated for depression in any medical setting now receive medication. Although this suggests improvement in the community treatment of depression, it is tempered by two further findings. One is that almost half (42.7%) of patients with depression still receive no treatment. The other significant finding is that only 21.6% of patients receive what recent, evidence-based guidelines (from the American Psychiatric Association and the Agency for Healthcare Research and Quality) would consider minimally adequate treatment (64.3% of those treated by mental health providers, and 41.3% of those treated by general medical providers).[18]

Much has been made of PCPs' failure to diagnose over half of the full-criteria mental disorders present in their patients,[19,20] but there is cause to reconsider the significance of the PCPs' failure to diagnose. Later studies have indicated that PCPs recognize disorders in their more seriously depressed[21] or anxious[22] patients, and that higher-functioning, less severely symptomatic primary care patients have relatively good outcomes, even with short courses of relatively low dosage medication. This spotlights the diagnostic ambiguity in primary care: these patients are different from those who seek specialty care (the population in whom most psychiatric research is done). Primary care patients tend to present earlier in the course of their illness, as they have an established relationship with their PCP that is not dependent on their having a psychiatric disorder. They frequently present with somatic complaints (the rightful domain of the PCP, after all), rather than psychiatric symptoms. Primary care patients also may have acute psychiatric symptoms that clear relatively quickly, even before medications have reached therapeutic levels (possibly because the condition being treated was an adjustment disorder). Such individuals might benefit as much from watchful waiting and from the empathic support of their PCP. There is a high noise-to-signal ratio in psychiatrically distressed primary care patients. That is, as many as one third of these significantly distressed patients have subsyndromal disorders that do not meet full *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) criteria for a diagnosable mental disorder. This diagnostic ambiguity in the general medical setting is paralleled by the relatively good outcomes that primary care patients experience on what most psychiatrists would consider subtherapeutic dosages of psychotropics for inadequate durations.[19,23] Much of the angst of primary care patients resolves spontaneously, either with resolution of an initiating event, with the expressed concern of caregivers, or with the placebo effect of a few days' medication.

BARRIERS TO TREATMENT

Although symptom recognition is necessary, it is not sufficient to ensure treatment of psychiatric problems in the primary care setting.[24] Even when PCPs are informed of the results of standardized screening tests, they may not initiate treatment. PCP, patient, and systems factors collude to inhibit the discussion necessary to promote treatment ("don't ask, don't tell").[25]

Physician factors, the "don't ask" part of the equation, include the failure to take a social history or to perform a mental status examination.[26] This behavior has been attributed to deficits in training of medical students and residents,[27] to time and productivity pressures, and to personal defenses (such as identification, denial,[28] or isolation of affect). PCPs are experienced and more comfortable addressing their patients' physical complaints. Some PCPs fear their patients will leave their practice if asked about mental health issues. The PCP, like many patients, may not believe treatment will help. Not having a ready response or approach to a problem is a major deterrent to identification of a new problem in the context of a 15-minute primary care visit. Denial or avoidance may prevail when the time-pressured PCP feels unsure of how, or whether, to treat or to refer.

Stigma, which is prevalent among patients and providers, is a major patient deterrent to initiating a discussion of psychiatric symptoms. Often, patients "don't tell" because of shame or embarrassment. They may believe psychiatric problems are a personal weakness, and they may perceive that their PCP shares this belief. Patients may not know they have a diagnosable or treatable mental disorder.[29] These are among the reasons that primary care patients more frequently have physical complaints. Somatic complaints also increase the diagnostic complexity,[30] because medical disorders may simulate psychiatric disorders, psychiatric disorders may lead to physical symptoms, and psychiatric and medical disorders may co-exist.

Systems factors include the ever-changing health care finance and reimbursement climate. This encompasses managed care, carve-outs, provider risk, capitation, fee-for-service, free care, coding nuances, differential formularies, and prior authorization, all of which promote financial imperatives to contain cost and to increase efficiency. The systemic instability, confusion, and administrative time-creep easily overshadow the impulse to pursue the treatment of a possibly self-limited condition. Mental health carve-outs have either eliminated or greatly complicated the possibility of reimbursing PCP treatment of mental disorders. Prepaid plans, such as HMOs, significantly decrease incentives to offer anything "extra."[31] The

necessity to increase productivity has excessively shortened the routine visit, now often lasting less than 15 minutes, and the excessive burden of required documentation further erodes clinically available time. (The implementation in some practices of the electronic medical record [EMR] has standardized and improved screening, documentation, and follow-up[32] but has introduced further time-consumption issues.) The care-promoting advent of new, safer, more tolerable psychotropic medications has been offset by soaring pharmacy costs and by restrictive (possibly short-sighted[33]) formularies. The practice of primary care has reached a crisis point where the pressures are so overwhelming that few PCPs can sustain full-time clinical practice.

THE GOALS OF COLLABORATION

The four major goals of collaboration are to improve access, treatment, outcomes, and communication.

Access

Collaborative care in the primary care setting addresses physician and patient factors that limit the patient's access to appropriate assessment and treatment. Most patients are not new to the general medical setting and, therefore, feel relatively comfortable and unstigmatized in that setting. On the other hand, they may believe that the mental health clinic is for crazy people, and that they do not identify with the (perceived) clientele (it's not that they *believe* they don't identify, it's that they *don't* identify). A specified mental health wing or floor in the primary care setting may hold that same stigma and act as a disincentive for patients to access treatment. Most patients do not know of a psychiatrist or how to access care from one and may not feel certain that they need one. The unaided decision to foray into the mental health arena may be fraught with shame and anxiety, powerful deterrents to making that first call. Calling the PCP's office and making an appointment for fatigue, sleep problems, weight loss, or palpitations is infinitely less threatening.

An established relationship between the PCP and a trusted, accessible psychiatric consultant removes the onus of recognizing, treating, or referring patients with mental disorders. With this availability of expert opinion and backup, PCPs more readily identify psychiatric distress in their patients and are more likely to initiate treatment.

Treatment

In the past, PCPs often prescribed insufficient dosages of medications (e.g., amitriptyline 25 mg) for major depression.[34] Since the advent of safer, better-tolerated medications, such as selective serotonin reuptake inhibitors, the selection of medications by PCPs has improved,[35,36] although the dosage chosen often remains suboptimal. Benzodiazepines have been prescribed by PCPs more frequently than any other class of psychotropic medication, even for major depression,[37] although they now are appropriately surpassed by antidepressant prescriptions.[36] Collaboration with the consultation psychiatrist can improve the choice, dosage, and management of psychotropic medications. Collaboration is also helpful when the medication with which the PCP might be most familiar is off-formulary on a given patient's pharmacy plan. Such a treatment deterrent may instead become an opportunity for brief and pragmatic education.

Outcomes

Several studies have demonstrated better outcomes for seriously depressed primary care patients treated collaboratively by their PCP and a psychiatrist.[38–40] Cost offset, however, is difficult to demonstrate because of the hidden costs of psychiatric disability.[7,41,42] Nonetheless, there is some evidence for a decrease in total health care spending when mental health problems are adequately addressed.[11] Even if this were not so, the case for cost-effectiveness could be made.[9,43–45] That is, care for the patient's psychiatric problem is more cost-effective than spending the same amount of money addressing the often nonresponsive, somatic complaints of high-maintenance, high-cost medical patients.

Communication

Collaboration ends the PCP's justifiable complaint of the "black box" of psychiatry, because communication is implicit in these models of care. The flow of information is useful for the psychiatrist and for the PCP and must be bidirectional. PCPs' referrals provide pertinent information and state the clinical question. In addition to the target psychiatric symptoms, the PCP has important information about the medical history, allergies, treatments, and medications. The collaborating psychiatrist shares findings, diagnostic impressions, and treatment recommendations. Information about referrals and consultations should be written and, whenever possible, provided verbally. This protocol improves documentation and ensures an understanding between collaborating care providers. Secure e-mail environments may also provide a venue for almost immediate feedback and a focus on the pertinent details for the busy PCP.

Patients, of course, must be aware of the collaborative relationship between the PCP and the psychiatrist, and of their shared communication.

ROLES, RELATIONSHIPS, AND EXPECTATIONS

Successful collaboration requires a clear understanding of roles and their definitions. All parties, including the patient, should recognize the PCP's responsibility for the patient's overall care. The PCP is the broker and overseer of all specialty services. The psychiatrist is a consultant to the PCP and sometimes a co-treater, depending on the model employed. Collaboration does not breach patient confidentiality because the PCP and the psychiatrist are now within the circle of care, and the patient is informed of this relationship.

However, this free flow of communication and documentation has reasonable limitations. If a patient asks that particular details not be placed in the general medical record and these details do not directly affect medical care (e.g., a history of childhood incest), it is reasonable to respect this wish. The pertinent information (e.g., the

experience of childhood trauma) can be expressed in more general terms. However, information that affects medical treatment (e.g., current or past drug addiction) or safety (e.g., suicidal or homicidal intent, or previous suicide attempt) cannot be withheld from the PCP, and the patient should be so informed.

When the PCP refers the patient to the psychiatrist, the patient should understand what to expect from the visit. At the start of the visit, the psychiatric consultant should clearly and consistently state the parameters of the contact (e.g., whether it will be a one-time consultation, with or without the possibility of medication follow-up, or a referral for therapy). If the psychiatrist sees the patient more than once, the relationship between the PCP and psychiatrist may need to be restated. The clarity of the providers' roles and relationship serves to spare the patient a sense of abandonment, either by the PCP when the patient is referred to the psychiatrist, or by the psychiatrist when the patient is returned to the PCP for ongoing psychiatric management.

In collaborative models of care, it is common for the psychiatric notes to be placed in the general medical record, which may raise issues of confidentiality and privacy. Most states require a specific release for mental health or substance abuse treatment records. Psychiatric or mental health notes in the general medical record should be color-coded or otherwise flagged so that they can be removed when records are copied for general medical release of information. In practices with an EMR, some coding system must also be in place to avoid the inadvertent release of this information. (As mental health issues are increasingly treated by PCPs, the question of how PCPs document and protect such information is a growing concern in the era of the Health Insurance Portability and Accountability Act [HIPAA] of 1996, and it is hoped that they will be addressed in a way that does not further complicate and deter such treatment.)

MODELS OF COLLABORATION

Collaborative models differ in a number of ways, such as where the patient is seen, whether there is a single medical record, how providers communicate, whether the consultant recommends or initiates treatment, and whether the psychiatrist sees the patient (at all, once, more than once) or is an ongoing treater. Other differences include whether both providers are part of the same medical staff and how (physically, by telephone, or electronically) available the psychiatrist is to the PCP.

Outpatient Consultation Models

Consultation implies collaboration: the PCP refers the patient to the psychiatrist, or the PCP presents the patient to the psychiatrist to obtain expert advice or recommendations. Depending on the setting or the system, one medical record may be shared, or providers may maintain separate records and share pertinent information. Patients may be seen in either the psychiatric or the primary care setting.

Outpatient consultation differs from the practice of private psychiatrists who may have established referral sources in the primary care sector. Such psychiatrists generally do not develop truly collaborative relationships, with ongoing communication or shared records. They treat in parallel, not in collaboration.

Specialty Psychiatric Clinics

Specialty psychiatric clinics (such as an eating disorders clinic) generally maintain separate records, require the patient to be seen in the psychiatric clinic, and develop some means of ongoing, clinically relevant communication with the PCP. Patients typically need to have well-defined and recognized problems to get referred, and such clinics are usually located in teaching hospitals or tertiary care centers, as opposed to the PCP's practice setting. Although stigma may interfere with patient adherence to such a referral, one major advantage of such clinics is the expert, multidisciplinary approach they provide for patients with complex psychiatric and medical problems.

Consultation Psychiatrists

Consultation psychiatrists[46,47] may render a one-visit opinion in the primary care clinic, or the patient may be seen in the consultant psychiatrist's office, just as with other specialty consultations. This model is similar to the consultation model used in the inpatient medical setting. The consultation should be written or transcribed into the primary care record. Immediate communication, in person, whenever possible, or by phone or secure e-mail or voice mail, greatly enhances the usefulness of such consultations. The consultant generally does not initiate treatment but makes practical recommendations. The role of the PCP (especially when the consultation occurs in the primary care setting) enhances patient participation and decreases stigma. This model also promotes opportunities for ongoing informal education between the PCP and the consultant.

Psychiatric Teleconsultation

Psychiatric teleconsultation[48] is a service with full-time, experienced consultation psychiatrists available for immediate telephone consultation to PCPs. This service, which is not accessible to patients, can provide general psychiatric information, consultation about pharmacologic or behavioral management, or triage and referral functions. Computer technology is used to maintain a database, to promote timely referrals, and to generate follow-up letters to PCPs. There is currently no direct third-party reimbursement for the full-time teleconsultant's services. At one time, increased capitation was expected to provide a funding source because of the cost-offset of this timely service. That expectation, however, was never realized, which effectively terminated some of these services. (Some rural states are funding this option for psychiatric consultation in remote areas.)

The Three-Component Model

Supported by the MacArthur Initiative on Depression and Primary Care, a three-component model[49] (TCM) is a formalized system of consultative care that promotes the

primary care treatment of depression as a chronic disease, with regular measures of adherence and outcome to guide the evidence-based protocol of medication and other treatment adjustments. Educational modules exist for PCPs, consultant psychiatrists, phone-based care managers, and patients. The Patient Health Questionnaire-9 (PHQ-9) (a 10-item, one-page, self-administered tool that quantifies the patient's neurovegetative symptoms of depression[50]) is repeatedly used to track the patient's progress. Multiple measures of symptoms and treatment adherence are recorded on a standard form that facilitates consultation, communication, organized treatment review, planning, and adjustment.

Dissemination of the TCM model, and of its standardized materials, manuals, and educational modules, addresses the need to improve care for this large population (i.e., patients receiving depression treatment in the primary care setting) while also providing data to inform policy (and payment) decisions. Similar evidence-based endeavors underway include the Health Disparities Collaboratives (the combined effort of the Department of Health and Human Services, Health Resources and Services Administration, and the Bureau of Primary Health Care) and the IMPACT model[51] (initially funded by the John A Hartford, California HealthCare, Hogg, and Robert Wood Johnson Foundations).

Psychiatrist on the Primary Care Clinic Medical Staff

When the psychiatrist is a medical staff colleague of the PCP, there are enhanced possibilities for collaboration and shared care. This PCP–consultant proximity facilitates communication, formal and informal education, immediate access via "curbside" consultation, and heightened PCP awareness of psychiatric problems in their patients. This arrangement can also provide an excellent opportunity for training of both psychiatric and primary care residents. Patients appreciate being seen in the more familiar primary care setting, and they feel less stigmatized.

Several models of care have evolved or been developed to use the services of an in-house psychiatrist. The psychiatrist may consult as a member of the medical team, evaluate and treat patients in parallel with the PCP, alternate visits with the PCP while treatment is initiated,[9,40,51] or evaluate, stabilize, and return the patient to the PCP with recommendations for continued care, or facilitate referrals to outside mental health providers.[52]

Staff Consultant

Consultations, as mentioned earlier, are written in the regular medical record. The permanency of the psychiatrist allows a more finely tuned consultant–PCP relationship. For instance, with a previously established agreement, the consultant may initiate the recommended treatment. The consultation psychiatrist may offer clinically relevant suggestions during case conferences or discussions of more complex patients. The psychiatrist may also see the patient with the PCP during the primary care visit, capitalizing on the PCP's extensive knowledge of, and long-term relationship with, the patient to provide more timely treatment recommendations. In one such consultation model, a consultant and several clinicians travel to several primary care clinics in the larger health care system, and provide a variety of consultative, educational, and treatment services.[47]

Parallel Care

Some clinics keep separate mental health charts when the psychiatrist assumes the ongoing psychiatric care of patients in parallel with the PCP. This option requires some overt means of communication to keep all providers informed. In clinics with EMR, a single up-to-date medication list at least keeps both providers aware of current medications and medication changes.

Some primary care clinics incorporate a mental health unit or clinic. If this is an identifiable, special area within the clinic, it has the same stigma that it has when the clinics are truly separate. The larger the clinic and the more separate the clinical services, even when they are in the same circle of care, the greater is the diligence required on the part of each provider to meet the challenge of continued communication.

The psychiatric capacity of primary care clinics that offer these services is often inadequate to meet the needs of the total patient population. This situation can be challenging and can delay access because most patients would like to be treated in this setting. Uniform criteria facilitate the triage of patients for in-house treatment or outside referral. These criteria include justifiable considerations such as diagnosis, available community resources, language requirements, or payment source. Certain unstable or less common psychiatric problems may be better served in the mental health sector, either in community clinics with wrap-around services or in specific subspecialty clinics. In most communities, English-speaking patients have more options for treatment. Depending on the location and availability of appropriate, non–English-speaking services, patients may be preferentially kept in house or referred out. When otherwise appropriate, capitation favors treating the patient in-house. Patients with insurance generally have more options outside the primary care setting, and some insurance plans with mental health carve-outs may not cover psychiatric care in the same setting in which they cover medical services.

Collaborative Management

In collaborative management,[40,53] the patient alternates visits between the psychiatrist and the PCP in the primary care setting during initiation of treatment (i.e., in the first 4 to 6 weeks). The PCP then assumes responsibility for the patient's continued psychopharmacologic treatment. This model was developed as a research protocol for the treatment of depressed primary care patients (and it has been extended to the treatment of panic disorder[9] and patients with persistent depressive symptoms[53]). Patients are referred by the PCP, usually after an initial ineffective trial of medication. This intensive program of care has been cost effective for more severely depressed primary care patients.

Implicit to this model are certain underlying assumptions. Collaborative management assumes that PCPs can initiate appropriate treatment for depression, manage the

care of patients stabilized on antidepressant medications, and better care for more seriously depressed patients with the collaboration of in-house psychiatric consultation.[54] This model also assumes that such collaboration begins with PCP education and training. In addition, PCPs participate in regular teaching conferences. A psychoeducational module for patients is also an integral part of the treatment.

Primary Care–Driven Model

The primary care–driven model[52] evolved from the practical need to assist PCPs in the provision of quality psychiatric care for their own primary care patients with limited psychiatric resources. This model incorporates elements of consultation, teleconsultation, and collaborative management, with the goal of maximizing the treatment of appropriate primary care patients in the primary care setting. Established criteria are used for triage, with the appropriateness of PCP management being the first consideration. Photocopies or electronic copies of all psychiatric notes and evaluations are sent to the PCP and placed in the regular medical record. The clinic provides psychiatric training for both psychiatric and primary care residents. The underlying assumptions of this model (Table 49–1) include those of the collaborative management model, but they are more extensive, reflective of the broader diagnostic scope.

In this model, the written (or electronic) request for consultation or referral comes from the PCP. The referral includes the clinical question or problem to be addressed and any PCP-initiated medication trials. PCPs are also encouraged to call or stop by the psychiatrist's office, located in the primary care clinical area, for more general information about diagnoses, medications, or psychiatric and behavioral management.

Psychiatric services include formal evaluation, stabilization over several visits, and return of the patient to the PCP's care (with recommendations on how to take and how long to continue medications and when to re-refer). The psychiatrist also provides informal (curbside) consultation, brief consultation with the patient and the PCP during the patient's primary care visit, and behavioral treatment planning for the difficult-to-manage patient. Re-evaluation of patients previously seen occurs when there is a change, such as roughening (i.e., the recurrence of symptoms during the course of treatment), the development of new psychiatric symptoms or medication side effects, or a change in the medical condition or medications that affect psychiatric symptoms or medications. When a patient does not meet criteria for in-house treatment, the psychiatrist facilitates the referral to an outside psychiatrist or therapist (or both). Other mental health services include focused, short-term, and goal-oriented therapy, either individual or group (with master's degree–level clinicians located in the primary care clinical areas they serve). Collaborative care management is another service that helps broker and coordinate the care of patients with complicated medical, mental health, and addiction problems who use services in multiple settings.

TABLE 49–1 Underlying Assumptions of the Primary Care–Driven Model

Collaboration begins with education of primary care physicians (PCPs) *and* psychiatrists.
Patients' psychiatric needs should be met in the primary care setting when consistent with good care.
PCPs can manage the care of patients stabilized on psychiatric medications.
PCPs can initiate appropriate treatment for some psychiatric disorders.
PCPs can better care for the psychiatric needs of more patients with the collaboration of in-house psychiatric consultation.
Some patients and some disorders are unlikely to be stable enough for PCP management.
Responsibility for total care requires communication between the PCP and any other involved care provider or consultant.

A premise of the primary care–driven model is that not all patients are appropriate for PCP management. The psychiatrist should help the PCP recognize which patients need ongoing specialty care, and then assist with appropriate referral. Patients not recommended for PCP management include those with inherently unstable conditions, or with complicated medication regimens, or those who require close monitoring. Examples include patients with bipolar disorder, psychotic disorders, suicidal ideation, severe personality disorders, or primary substance abuse or dependence problems.

Collaborative care management is a program that bridges the needs for communication and coordination when patients must access services outside the primary care setting. It improves the care of patients with complex medical, psychiatric, and addiction problems that often require treatment spanning several community agencies. After a comprehensive diagnostic and functional assessment, necessary releases are signed so that the care manager can serve as a liaison between the PCP and all other care providers. The care manager involves the patient and all treaters in the development of a comprehensive treatment plan within a network of services, and tracks the patient from site to site throughout this plan. As a member of the discharge planning team, the care manager ensures that the patient returns to the appropriate network of services after care in a hospital, a detoxification program, or another residential or institutional setting. Like teleconsultation, the existence of this useful program has been severely limited by the lack of sustainable reimbursement sources. Some insurance plans and MBHOs are now trying to fill this gap with their own intensive case (or care) management programs for members who are frequent users of multiple services.

CHOOSING THE RIGHT MODEL

The choice of model for a given clinical setting depends on a variety of factors—patient population, payer mix, range of available community resources, and the location, type and size of the practice. Patients with higher educational or socioeconomic status may feel less stigmatized and be more able and willing to seek and pay for outside psychiatric services.[55] Some patients feel more comfortable in private practice settings that allow the greatest possible privacy. Mental health problems are less acceptable or even shameful in some cultures. These patient populations will favor a

more integrated and less visible system of care in the primary care setting. Capitation would most clearly demonstrate the cost offset and cost effectiveness of in-house collaborative models (and teleconsultation, if the market penetration is ever high enough). The primary care–driven model requires adequate community resources to refer patients not considered appropriate for primary care management. Suburban or rural areas that lack these resources are better served by parallel, or shared, care models. Small groups or solo practitioners may favor consultation models, either with a part-time but regularly scheduled consultant or through access to an outside consultant or teleconsultant as needed. Large practices, and especially training facilities, benefit most from the full range of in-house consultative and collaborative services that include formal education, case conferences, curbside consultation, and collaborative care management.

SUMMARY

Though mandated by changes in the health care system, collaborative models increase access and improve treatment for patients who would be unable or unlikely to receive psychiatric care outside the primary care setting. As states move to promote the concept of the "medical home" (i.e., bringing all specialties into the primary care realm and under the coordinating auspices of the PCP, especially for patients with complex medical, mental, and developmental conditions),[56] psychiatric services in the primary care setting may become not only more acceptable but also expected or even mandated. A number of considerations determine the best model for a given practice setting. Such factors include size, patient population, available community resources, payer mix, and other reimbursement sources. To remain viable, high-quality and cost-effective models need to adapt and evolve with the changing health care system. Psychiatrists and PCPs need to be flexible and innovative in their approaches to patient care, and to be diligent in the documentation of cost-offset to encourage payers to reimburse their services.[57,58] Medical,[59] psychiatric, and patient education services need to reflect these changes in caregiver roles and expectations.

Coping with the Rigors of Psychiatric Practice

50

Abigail L. Donovan, M.D.
Edward Messner, M.D.
Theodore A. Stern, M.D.

The practice of medicine is focused on disease, not health, and on treatment, not primary prevention. Therefore, it should not be surprising that physicians have difficulty maintaining their own health, minimizing their stress, and preventing burnout in their own lives. Throughout medicine (and especially in psychiatry), clinicians confront suffering and despair more often than they see success and happiness. In addition, the very same character traits that make physicians successful (e.g., perfectionism, an exaggerated sense of responsibility, and selflessness) also make physicians vulnerable to stress.

Stress can be defined as the condition that occurs in response to adverse external influences; it is capable of affecting both physical and psychological health. The daily stress of practicing medicine, when left unaddressed or unmanaged, can progress over time to burnout. Burnout is a pathologic syndrome in which prolonged occupational stress leads to emotional and physical depletion and ultimately to the development of maladaptive behaviors (e.g., cynicism, depersonalization, hostility, detachment). Understanding the root causes of stress and burnout, exploring ways to reduce vulnerability to burnout, and learning skills to cope with the stresses inherent in psychiatric practice are important factors in building and maintaining a successful career and establishing a fulfilling life.

EPIDEMIOLOGY

Despite their academic, vocational, and societal success, physicians are immune to neither disease nor suffering. The practice of medicine is inherently stressful, and physicians are at high risk for burnout. Reported rates of burnout for practicing physicians range between 22%[1] and 60%[2]; these rates are even higher for residents (as high as 75% in one study[3]). In addition, physicians are also at risk for experiencing high levels of emotional distress, given the nature of their work; studies that have identified high rates of suicide among physicians support this idea. Whereas physicians, as a group, have lower mortality rates from several diseases (e.g., chronic obstructive pulmonary disease, liver disease), they have a higher rate of suicide than do other professionals and members of the general population[4] (Figure 50–1); for male physicians, the relative risk ranges from 1.1 to 3.4, and for female physicians, the relative risk ranges from 2.5 to 5.7.[5] In the general population, the suicide rate is four times higher for men than it is for women; in physicians, the rate of suicide for women is equal to that of men.[6] Up to 12% of physicians report an increased use of substances during residency[7]; psychiatrists have particularly high rates of substance abuse compared to those in other medical specialties.

ETIOLOGIES FOR STRESS AND BURNOUT

The practice of medicine in today's society is challenging and rewarding; however, it is also stressful and not without the potential for burnout. Several aspects of psychiatric practice leave the psychiatrist especially vulnerable to stress and, ultimately, to burnout (Figure 50–2).

Frequent Encounters with Distress

Psychiatrists encounter human suffering on a daily basis. The nature of psychiatric practice is that clinicians witness countless stories of sadness, anger, and betrayal. Although moments of joy and happiness can arise, they often seem few and far between. The chronic and devastating nature of many psychiatric diseases increases the emotional burden on the clinician. Because psychiatrists must remain emotionally available to their patients to experience and to express the empathy that is necessary for the formation of an alliance, this emotional availability makes psychiatrists particularly vulnerable to suffering alongside their patients (even though they must consistently maintain enough distance to remain objective). Therefore, a critical balance must be maintained and a precise emotional distance must be preserved.

Ethical Dilemmas

The patient's reliance on the psychiatrist for guidance can raise a host of ethical conflicts. Psychiatrists can find themselves in the position of watching their patients make unwise, and even dangerous, decisions and being unable to curtail this destructive behavior. Psychiatrists might have to enforce mandated treatment regimens, to hospitalize patients against their will, or even to physically or chemically restrain violent patients. There may even be times when a psychiatrist must intentionally break a patient's confidentiality for his or her safety or for the safety of another. None of these decisions is made lightly, and each requires a great deal of reflection and emotional energy.

Transference and Countertransference

The daily practice of psychiatry is filled by issues of transference and countertransference, which can lead to the development of intense emotions (e.g., hostility, aggression,

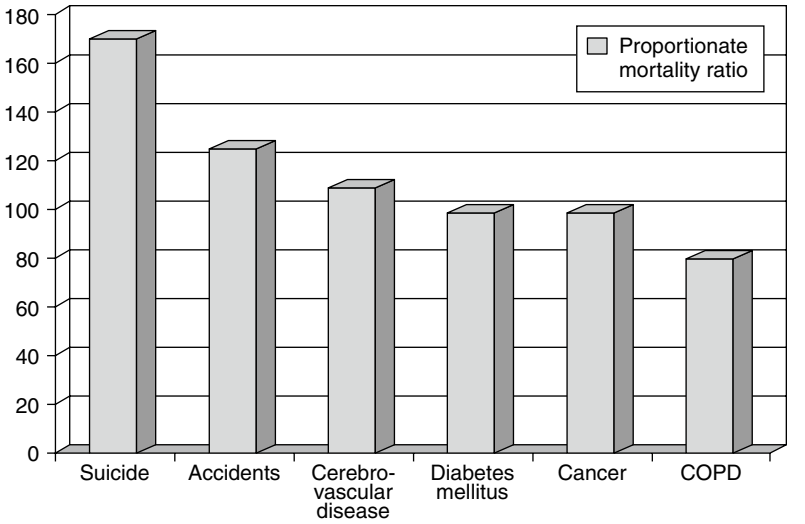

Figure 50–1. Proportionate Mortality Ratio for Causes of Death Among White Male Physicians. The Proportionate Mortality Ratio compares the proportion of deaths due to a specific cause in white male physicians with the proportion of that cause of death in all white male professionals. *(From Linzer M, Visser MR, Oort FJ et al: Predicting and preventing physician burnout: results from the United States and the Netherlands,* Am J Med *111(2):170–175, 2001.)*

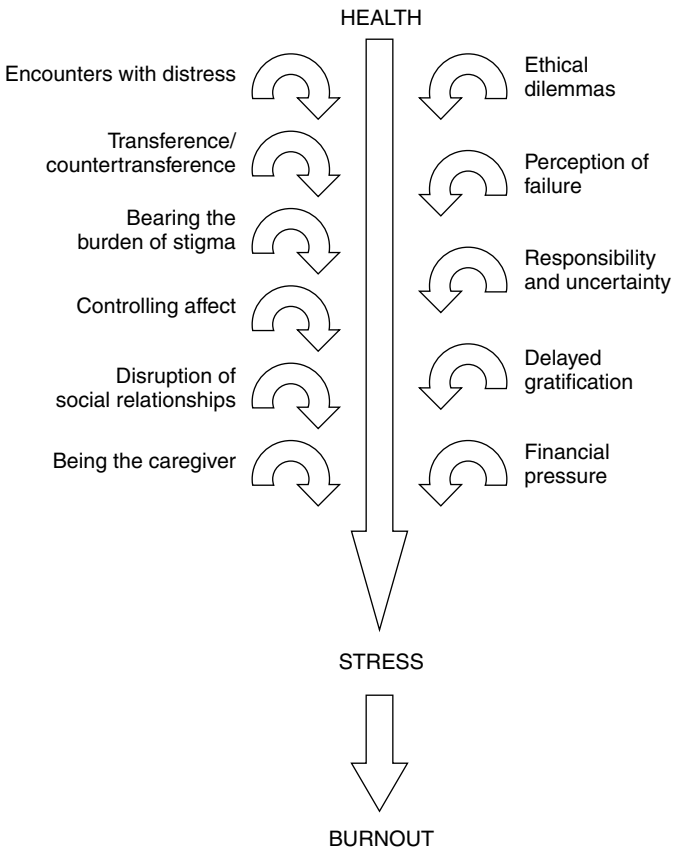

Figure 50–2. Etiologies of stress.

love) in the patient and in the clinician. Furthermore, several psychiatric illnesses have, as core symptoms, difficulty with interpersonal interactions. Afflicted patients, including those with borderline personality disorder and narcissistic personality disorder, can pose a special challenge to the psychiatrist. Coping with intense transference, while monitoring one's own countertransference, can be exhausting; it is a daily challenge for most psychiatrists.

The Perception of Failure

Psychiatrists treat chronic illnesses, which are subject to relapse and carry significant morbidity and mortality risks; thus, the very nature of psychiatric disease can lead the psychiatrist to experience feelings of failure as a doctor and as a healer. Despite knowledge of treatment-response rates, psychiatrists might ponder the notion that if they could

only find the right medication or say the right words, the patient would be healed. Failure to respond to treatment can be, and often is, viewed as a failure of both the medical intervention and the treater. The fact remains that due to the nature of psychiatric disease, not every patient will be healed; the psychiatrist then might experience feelings of failure.

BEARING THE BURDEN OF STIGMA

Psychiatry and its practitioners have come under intense public scrutiny. Psychiatric treatment, medications, and research have been called into question by the media, by the government, and by popular culture icons. Furthermore, whereas psychiatric successes take place behind closed doors, treatment failures have grown increasingly public and act as lightning rods for the stigma of mental illness. This public criticism can be disheartening and demoralizing; it can be difficult to maintain pride in one's work and accomplishments in the face of such challenges.

Controlling Affect

Despite the intensely emotional nature of psychiatric work, psychiatrists must consistently control their affect to do their jobs well. Although this control is necessary for the practice of psychiatry, it can ultimately lead to increased stress and vulnerability to burnout. Instead, informal debriefings with colleagues, or formal supervision, can encourage the necessary expression of what is controlled during patient encounters.

Responsibility and Uncertainty

The practice of psychiatry is multidimensional, and it incorporates interpersonal and individual dynamics, sociology, biology, and pharmacology. The complex nature of psychiatry also makes it an exhilarating, yet uncertain field. Although the breadth and depth of psychiatric research are growing exponentially, there is still a dearth of research to guide many clinical decisions; moreover, psychiatrists must often base clinical decisions on biased, incomplete, or ambiguous data. Challenges faced are further compounded by the added stress of answering to institutions, to insurers, to patients, and to their families. Health insurance organizations often establish standards of care without psychiatrist involvement; this can undermine the pride and self-determination of practitioners. Psychiatrists can find themselves in the difficult position of not being able to provide the treatment they believe is best; instead they may offer assistance based on the policies created by nonclinicians.

Disruption of Social Relationships

Psychiatrists often work in isolation; this leaves them alone to face the effect of psychopathology and disease. Furthermore, rules regarding confidentiality inhibit sharing the details of one's day with family and friends. Social engagements and family time can be interrupted (without warning) by emergencies. These factors can fracture social relationships, decrease social support, and increase the risk of burnout. Vocational burnout is, in turn, associated with low satisfaction in relationships (with patients and with clinical staff).

Delayed Gratification

The ability to delay gratification is an important developmental milestone. The practice of medicine raises it to an art form. But this skill, when taken to an extreme, can lead to burnout. Physicians may be tempted to put personal, non–work-related goals on hold, in the service of career success (e.g., "I can't get married, have children, or buy a house until I finish residency, have a stable practice, or have enough money in the bank."). Such rationalizations can be extended indefinitely and can lead to a life lacking balance and devoid of nonvocational success.

Being the Caregiver

Psychiatrists often have a strong need to be needed and to care for others. These traits are part of what initially draws individuals to the practice of psychiatry. At the same time, the dependence some patients develop on their psychiatrist can be overwhelming in its intensity. Focusing intently on the needs of others can lead to denial of one's own need to be cared for.

Financial Stress

Although the popular perception is that all doctors make copious amounts of money, the reality is quite different. The cost of medical education can be exorbitant, and it continues to rise each year; however, the salaries of many practitioners do not enjoy the same growth, and the increases in earnings over time might not match the rate of inflation. Many young doctors finish residency with enormous debt and with limited options for repayment and deferment of loans. Furthermore, the practical options for improving one's financial situation are limited to working longer hours or seeing more patients (for shorter periods of time). Either option is likely to increase, rather than to decrease, vocational stress; this pressure may be especially intense for physicians early in their careers.

SPECIAL SITUATIONS IN PSYCHIATRY

Coping with Patient Suicide

A Profound and Enduring Effect

Half of all psychiatrists have had one (or more) of their patients commit suicide[8,9]; approximately one third of those psychiatrists experienced such a loss while they were still in residency training.[8] One quarter of psychiatrists who had experienced patient suicide stated that it had "a profound and enduring effect" on them throughout their careers.[8] Although the practice of most medical specialties entails dealing with death, suicide in the practice of psychiatry takes on additional meaning. Because one of the primary tools in psychiatry is the individual, when the treatment fails, it can feel as if the treater has failed. Furthermore, whereas death from cancer can be seen as inevitable, death from suicide can be viewed as a choice.[10] When coping with a patient's suicide, it is important to remember that "a patient suicide is neither a unique event nor a personal failure."[11]

Reactions to Suicide

The reactions of a psychiatrist to a patient's suicide can be varied and intense. In addition, the psychiatrist must cope not only with his or her own reaction but also with the reactions of the patient's family and friends. The psychiatrist can experience grief, guilt, inadequacy, anxiety, depression, shock, shame, betrayal, and anger. The experience of anger and hostility toward the patient who committed suicide can further trigger guilt and self-blame. A sense of rejection can also be particularly poignant; although the psychiatrist was working to the best of his or her ability and trying all available therapies, the patient has said, through suicide, "You just weren't good enough." Younger clinicians may be especially vulnerable to this intense distress.

Coping

To cope effectively with a patient's suicide, the clinician must give himself or herself permission to experience a variety of emotions. While it may be extremely difficult, experiencing anger and hostility toward the patient is a necessary component of healing. Clinicians might also find themselves ruminating over treatment decisions, asking, "What if . . . ?" Although it is important to review the treatment course to learn from the unfortunate outcome, obsessive ruminations are likely to diminish one's confidence in decision-making and to impair coping with the tragedy. Shame and embarrassment, as well as a sense of personal failure, can prevent a psychiatrist from reaching out to colleagues. However, it is likely that several colleagues have had similar experiences and all may benefit from sharing their experiences.

Treating Dying Patients

In extreme situations, clinicians may find themselves refusing to care for suicidal (or for terminally ill) patients or wanting to leave the practice of psychiatry altogether. These wishes defend against the fear of future traumatic experiences with at-risk patients. Yet, as a seasoned therapist said about the treatment of suicidal patients, "If we do not treat dying patients, our patients will die alone."[12]

Coping with Boundary Crossings and Violations

Boundary Violations

The practice of psychiatry is filled with intense emotions (encouraged by regular, frequent, and lengthy patient contact). The intensity of these emotions, in combination with disruption in a clinician's personal and romantic relationships, can be a setup for boundary crossings and violations.[13] Boundary crossings are considered harmless deviations from clinical practice or from the therapeutic frame; however, boundary violations are deviations that are harmful and exploitive of the patient's emotional, financial, or sexual needs.

Decreasing Vulnerability

Of primary importance is the recognition by all clinicians that they are at risk for boundary violations; denial of this vulnerability prevents introspection and analysis of motives, as well as early consultation for difficult dilemmas. Other factors (including crises at work, at home, or in individual physical or psychological health) can make a psychiatrist particularly vulnerable to boundary violations. In such situations, the clinician may be tempted to confide his or her personal problems to the patient; such self-disclosure should serve as a warning that the clinician is on the precarious rim of the proverbial slippery slope. Other warning signs include idealizing the patient, and thus believing that he or she is deserving of special treatment; holding sessions at the end of the day or even "after hours"; allowing sessions to go on longer than the allotted time; allowing the patient to maintain a large, unpaid bill[14]; and, most important, a reluctance to discuss the case with colleagues or supervisors. Any of these signs should immediately prompt the clinician to seek objective consultation to examine these issues in depth.

Coping with Malpractice Litigation

Practicing medicine in today's society leads many doctors to fear litigation, regardless of actual negligence. This fear can be paralyzing and can lead to the desire to treat only "low-risk" patients. Unfortunately, there are no reliable methods to predict which patients are going to be litigious. Thus, it is the responsibility of the practitioner to cope effectively with the continuous risk of malpractice litigation.

Protecting Yourself

There are steps all practitioners can take to protect themselves against potential litigation. Appropriate documentation is critically important. The most common malpractice claim against psychiatrists occurs in cases where a patient has committed suicide; thus, documentation of both the risks and the protective factors, in addition to the rationalizations behind clinical decisions, is crucial.

Perhaps the most protective factor is a strong alliance with the patient. Maintaining and enhancing the therapeutic alliance can be accomplished in several ways. Clinicians might find it helpful to use language that speaks in terms of a joint effort with the patient, such as "Our problem is . . ." or "Our goal is . . . ." This language allows the clinician and the patient to speak of the therapy as a third entity in the room. It promotes a detachment from the illness and lets the patient know that he or she is not alone in the battle, but rather that he or she will fight right alongside the clinician.

Similarly, it may be beneficial for the clinician to maintain an alliance with the patient's family. This may be difficult to accomplish, because it is essential to maintain a patient's confidentiality. Even if the patient refuses contact, it may be helpful simply to convey one's desire to speak with the family, in the present or in the future. Building an allied and collaborative relationship with a patient is a key component of effective treatment and it might offer some protection against future litigation.

Coping with a Lawsuit

What if a clinician is actually faced with a lawsuit?[15] Unfortunately, the very same traits that constitute careful and competent doctors (e.g., responsibility, perfectionism, high standards) also subject them to self-doubt and to unearned guilt when confronted with a lawsuit. It may be of some solace to remember that only a small percentage of

malpractice lawsuits go to trial, and those that do usually find in favor of the physician. During the preparation, it may be helpful to work closely with your lawyer, restoring a sense of control and ownership over the future. It also is critically important to maintain personal interests and relationships outside of the workplace. Regardless of whether negligence actually occurred, it is normal to feel shame, guilt, and anger during (and even after) a lawsuit.

Coping with Residency Training

The rigors of a psychiatric practice can be demanding, and psychiatric residency training is often especially challenging (for example, a lack of control over daily schedules, sleep deprivation, a caseload filled with difficult-to-treat patients, responsibility without authority, and the need to balance autonomy and dependence). In training, there is also a desire to appear strong and competent to both colleagues and supervisors, leading some residents to view asking for help as a sign of weakness. These factors and multiple role conflicts conspire to make residents especially vulnerable to burnout.[16]

WHEN THE COBBLER'S CHILDREN HAVE NO SHOES

The cobbler was so busy making shoes for everyone else that he neglected to make them for his own children. Similarly, it is easy, in days filled with caring for the needs of others, to neglect one's own needs. Yet, to be good doctors, physicians must care for themselves. Several factors contribute to this type of self-neglect and burnout (Figure 50–3).

Denial of Vulnerability

Many doctors treat themselves as if they were superhuman. Although it is necessary for others to sleep, eat regular meals, and take vacations, physicians often deny their own basic needs. Moreover, psychiatrists wish to see themselves as consummate copers, immune to emotional impairment. When placed under stress, it is common for them to work harder and longer, which ends up compounding the initial problem.

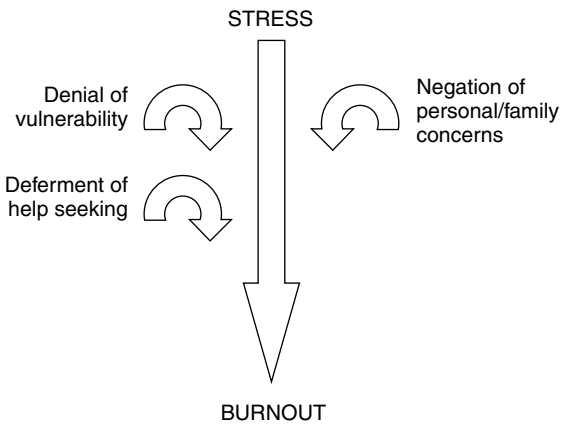

Figure 50–3. Factors contributing to self-neglect.

Negation of Personal and Familial Concerns

Personal and family concerns can be misjudged as being not as critical as is the relieving of pain and suffering. It can seem easy, if not important, to spend 1 more hour at work to see a patient in crisis; however, this can quickly become a practice that rapidly expands and soon becomes a pattern of working longer and sacrificing personal time. After long and stressful days, clinicians may be too emotionally exhausted for empathic listening, even-handed conversation, or recreation. As a result, clinicians can turn inward, internalizing their concerns and cutting themselves off from family and friends. This behavior compromises the strength of family relationships and decreases the support available for the clinician.

Deferment of Seeking Help

It is common to view seeking help for personal or family problems as a sign of frailty or personal failure. Some physicians are reluctant to seek help because of the stigma of mental illness. In general, although psychiatrists may be more open to psychotherapy for themselves, the possibility of a formal diagnosis and breaches of confidentiality, or having to report a problem to a licensing board, can make seeking help difficult. The intense pressure of a doctor's work can foster the creation of unachievable expectations. However, the physician's well-being is only undermined by this intolerance for human vulnerability.

How to Recognize Stress in Oneself

Psychiatrists are good at recognizing stress in others; however, recognizing stress in oneself requires a different skill set. Unrecognized and unmanaged stress can lead to anxiety or to depression, and it can have long-lasting effects for clinicians, patients, and families. Signs of stress include exhaustion, apathy, anhedonia, and despair, as well as somatic manifestations (including headaches and gastrointestinal disturbances). Further warning signs include disrupted sleep, conflict in family relationships, and changes in memory, concentration, and problem-solving ability. Perhaps the most important warning sign is the suggestion from friends, family, and colleagues that help is needed.

Stress can also affect attitudes toward patients. Clinicians may develop reactive misanthropy when they frequently encounter patients' pain and suffering, especially when expressed by the patient as hostility or devaluation. Clinicians might then find that warmth and concern are replaced with apathy, or even defensiveness and contempt. This emotional detachment can progress and carry over to all patients, so that the clinician is no longer able to appreciate fulfilling relationships with patients.

Stress, when prolonged or unmanaged, can progress to burnout. Signs of burnout include detachment from the meaning of one's work, open hostility, cynicism, and overwhelming occupational dissatisfaction. In addition, reactive misanthropy can progress to malignant misanthropy in the burned-out clinician. In this malignant form, the misanthropy one can develop toward a patient extends to other relationships, including those with staff, colleagues, other health professionals, and even friends or family. The unfortunate result is then a conflict with one's social values and intentions, leading to feelings of self-punishment and guilt.

HEALING THE WOUNDED HEALER

Be Your Own Most Important Patient

Maintaining a caring and empathic attitude toward one's patients requires treating oneself with kindness and concern. Whereas all doctors have strong coping skills (how else could physicians make it through training?), these skills can always be expanded and refined. Anticipating and preparing for difficulty, rather than relying on denial, can prevent emotional overload. Some useful coping strategies are outlined here and in Figure 50–4.

Process Experiences Regularly

One should talk with colleagues and supervisors regularly about difficult interactions, even when it means revealing personal vulnerability. Residents, in particular, may be tempted to use supervision as a time to discuss only therapeutic successes or positive interactions, in order to impress their supervisors or to project a sense of competence; however, supervision can be even more valuable when used to discuss difficult patient encounters or conflicted reactions to a patient. It is also possible to process experiences on one's own, perhaps reserving the commute home as a time for reviewing the day's events. Coping with stress on a daily basis, and processing emotions before one arrives home, can make it less likely for one to take the strain of the day out on family or friends. Furthermore, learning important lessons from difficult events can mitigate some of the distress that they cause.

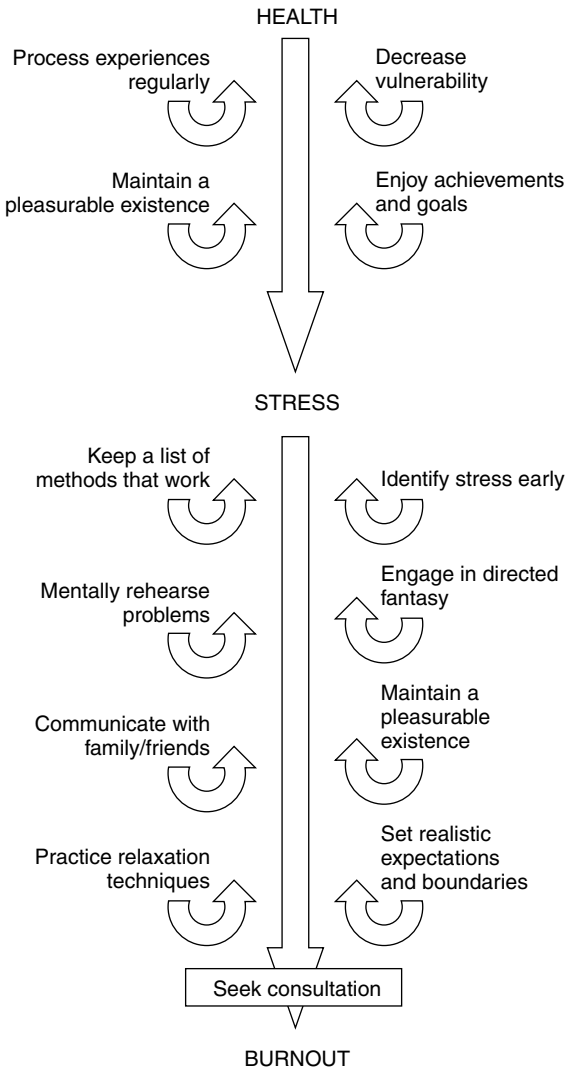

Figure 50–4. Coping with stress and preventing burnout.

Set Realistic Expectations and Boundaries

It can be gratifying and personally pleasing when a patient professes the need to communicate with their physician between sessions, or when a patient forgets an appointment but states he or she cannot possibly wait until the following week to see the treater. Being needed in this way can seem like an affirmation of why one became a doctor: to help those who cannot help themselves. However, speaking with patients frequently between encounters, or for extended periods, not only dilutes the therapeutic process but also adds a time-consuming burden for the physician. Rescheduling appointments again and again when a patient has forgotten the original appointment simply reinforces poor planning and adds additional stress to the physician's already crowded schedule. Although emergencies should be treated as such, physicians who maintain boundaries around phone calls and missed appointments for nonemergency issues protect the therapeutic frame and their own need for a manageable schedule, including time free from responsibilities of patient care.

Review Your Own History

Psychiatrists can identify useful coping strategies from the past and eliminate maladaptive ones. It can also be helpful to identify prior manifestations of stress, so that one can recognize them early and intervene before they reach a caustic level.

Keep a List of Methods That Work

One should make a list of coping strategies that have previously helped. During moments of extreme distress or crisis, it can be difficult to recall adaptive strategies. In addition, one can consider using constructive activities (such as athletics), as a means of discharging anger. Stretching or performing yoga can relieve muscle tension. Even an emotional release through tears can restore a psychic balance.

Decrease Vulnerability to Stress

There are many aspects of clinical practice (such as long hours and copious amounts of paperwork) over which clinicians have no control, but there are factors (e.g., treating physical illness, eating a balanced diet, exercising, getting enough sleep) that the individual can control that can reduce vulnerability to emotional stress.

Doctors are often poor patients. Despite access to health care, many physicians rarely visit their primary care physician, even when they are ill. Unfortunately, untreated illness only compounds stress.

Hectic schedules sometimes dictate meals on-the-go, or no meals at all, but proper nutrition is crucial for a healthy body and a healthy mind.

Exercise releases endorphins, and it can improve mood and energy. Enjoying exercise is an excellent way to relieve stress. Regular physical exercise contributes to physical health and to an overall sense of well-being.

Sleeping at least 8 hours every night has benefits; fatigue can leave one vulnerable to emotional stress and to dysregulation.

Mentally Rehearse Potential Problems

When a potentially difficult meeting or conversation is anticipated, it is helpful to rehearse statements and responses to questions. Having responses in mind before a crisis makes it more likely that one will stay calm in a tense situation. This technique also fosters a sense of control over the unexpected. One can also imagine expressing intense feelings (such as anger, sadness, or fear) as a means of decompression. Fantasizing in this way is most useful when one recognizes that the fantasy is distinct from real action; fantasies need not be enacted.

Engage in Directed Fantasy

One can imagine scenarios that are affectively intense (e.g., hitting a frustrating patient with a fire axe or duct-taping his mouth closed). The more outrageous the fantasies are, the more effective they will be at discharging emotion. The more unrealistic and outlandish, the easier it will be to distinguish between fantasy and a corresponding reality.

Communicate with Family and Friends about Anticipated Unavailability

Communication about one's unavailability will help others prepare and thereby lessen the likelihood that they will respond with anger and withdrawal. As one communicates about future work commitments, one can also make future social commitments. This action allows family and friends to know they are still held in high regard and it sets a framework for ongoing relationships. Above all else, open communication and a sense of togetherness should be maintained; hardship experienced as a team can deepen intimacy and mutual respect.

Enjoy Your Achievements and Your Goals

Previous triumphs should be pondered and joyful moments recalled. Original goals should be remembered, the progress made toward achieving them noted, and new goals for the future set. Being mindful of the progress toward life goals can instil a sense of pride and mastery. The strength gathered from memories of the high points of one's life can facilitate coping with everyday stresses.

Learn and Practice Relaxation Techniques

Tension and overstimulation can make sleep difficult, and the fear of returning to work without rejuvenation can only compound this difficulty. In the midst of this pressure, one may be tempted to resort to the use of alcohol or sedatives. However, one can learn deep-breathing techniques and progressive muscle relaxation to promote tranquillity and sleep. These exercises can also be used in the middle of a hectic day or during a stressful night on call to rejuvenate an exhausted mind and body. Clinicians can also learn self-hypnosis and use it to maximize relaxation during a busy day or to induce sleep reliably and quickly.

Maintain a Pleasurable Existence

It is often helpful to make a commitment to yourself to have one pleasurable experience each day. A pleasurable event can be something as simple as having a cup of tea, taking a short walk outside, reading a favorite poem, or speaking with a friend on the telephone. Even taking a few minutes between patients to stretch, to chat with a colleague, or to have a favorite snack can be rejuvenating. Keeping balance between stress and pleasure on a daily basis prevents burnout and promotes a positive mindset.

WHEN TO SEEK CONSULTATION

Consultation offers an objective point of view; it can be the first step in seeking help for the overwhelmed clinician. Consultation is not a sign of weakness; rather, it is the sign of a wise physician who recognizes that to help patients, one must first help oneself. Consultation should be considered for a variety of problems: symptoms of depression, disabling anxiety, self-prescription, escalating use or abuse of alcohol, inappropriate expressions of anger, impulsive behavior, or impaired clinical judgment. Other signals that should prompt consultation include working longer hours, having trouble in significant relationships, and becoming socially isolated.

TYPES OF PROFESSIONAL HELP

It might not be easy for a clinician to acknowledge that he or she needs professional help. It can be extremely difficult to surrender control when one is used to being in complete control. But it can also be a wise decision, especially to halt a downward spiral.

Psychotherapy

Psychotherapy provides the psychiatrist the valuable opportunity to experience the other side of the therapeutic relationship. Psychotherapy can be a rich, life-enhancing experience, it can improve coping skills, and it provides much-needed support for the overwhelmed clinician.

Psychopharmacology

Many physicians, and many psychiatrists, might see the need for medication as a sign of weakness or failure. However, doctors would rarely fail to use chemotherapy to treat a patient with cancer or insulin to treat a patient with diabetes. So too should medication be used to treat a biologically based psychiatric illness.

Couples Therapy

Strong family relationships are crucial for stress resilience. Unfortunately, family relationships are often among the first victims of vocational burnout. Couples therapy or family therapy can heal wounded relationships and restore lines of open communication, ultimately building protection against future stresses.

Group Therapy

Group therapy allows individuals to recognize that they are not alone in their suffering. Professional support groups can facilitate the sharing of common experiences and emotions and can promote connections between people who have similar strengths and difficulties. More general groups promote understanding of the difficulties inherent to all lifestyles.

Autognosis Rounds

Attendance at *autognosis* (literally "self-knowledge") rounds allow psychiatrists to share common experiences and to identify individual reactions to clinical situations. This knowledge can then be used to inform diagnoses and to minimize potentially harmful reactions to patients (e.g., managing hostility toward a patient so that it will not interfere with treatment). Autognosis rounds have proved valuable for psychiatric resident groups at the Massachusetts General Hospital for the past 4 decades.

CONCLUSION

The practice of psychiatry, with all its inherent stresses, is an honor and a fulfilling calling. "When we find ways to cope . . . ., we move toward the equanimity that can enable us to serve our patients with greater effectiveness and compassion. We also progress toward greater satisfaction in this noble profession of medicine and in our personal lives."[17]

Acknowledgment

This chapter is dedicated to [†]Dr. Messner, whose commitment to resident well-being was unparalleled. He taught us not only how to heal our patients but also how to heal ourselves.

51 Billing, Documentation, and Cost-Effectiveness of Consultation

Nicholas Kontos, M.D.
Robert M. Stern, M.D.
Theodore A. Stern, M.D.

The purpose of this chapter is to give psychiatric providers of consultation–liaison (C-L) services an understanding of the complex business aspects of their work. Understanding and appropriately adhering to the often-confusing guidelines for reimbursement can be stressful to clinicians and expose them to painful audits and substantial penalties, both personally and for their institutions. In this atmosphere providing ethical, legal, and appropriate services can be a daunting task. A fuller understanding of coding and billing will also help psychiatrists, C-L hospital-based programs, and hospital administrators to collect the appropriate reimbursement for services rendered. In this chapter we will address principles of coding, billing, and documentation that will improve medical documentation for C-L clinicians, as well as address improvements in clinical outcome and economic benefits accrued to the general hospital by operating a C-L service. Adherence to the following principles should facilitate capture of appropriate revenue for the services delivered while keeping the work of the C-L psychiatrist clinically focused. Pitfalls of "routine care" will also be explored.

DOCUMENTATION SHOULD REFLECT THE SERVICE ACTUALLY PERFORMED

Successful C-L services rely on the establishment of cooperative and collaborative relationships with medical colleagues. Hospital-based physicians are exposed to psychiatric co-morbidity on a daily basis. Their need for consultation may range from an opportunity to review their approach to a patient to a request for a comprehensive assessment. The needs of a physician do not always mirror the severity of the patient's medical condition. *Billing, however, is always geared to the patient's illness*. The insurance company or other third-party payer is paying for a service for an individual patient rather than purchasing the expertise of the clinician.

BILL ONLY FOR SERVICES DOCUMENTED IN THE MEDICAL RECORD

The overriding principle for third-party reimbursement is to bill for only those services documented in the medical record. The charge for service and the reimbursement available for the service are guided by definitions established by Current Procedure Terminology (CPT) codes. A brilliant, life-saving consultation that goes undocumented is not billable. The effectiveness and expertise of the consultant is not an issue for the collection of a reasonable fee. Moreover, significant pressure may be placed on clinicians to "maximize revenue" for the services they provide. This is especially true during difficult financial times. Efforts to "game" the system, by "up-coding" (i.e., charging for a more intensive service than delivered), are illegal and unethical. On the other hand, inadvertent "down-coding" on account of the sometimes-Kafkaesque documentation and billing rules is also unfair and ultimately damages the ability of hospitals and providers to care for patients. This chapter seeks to highlight the path that keeps consultations as clinically focused as possible while following the requisite rules for documentation.

FOLLOW THE MEDICARE GUIDELINES FOR ALL ENTRIES IN THE MEDICAL RECORD

Medicare is the predominant insurance coverage in the general hospital. This is especially true for a psychiatric consultation service for elderly or disabled patients. CPT codes were developed by the American Medical Association (AMA) and adopted by the Health Care Financing Administration (HCFA) in the early 1990s. The guidelines were established as mandatory for Medicare and Medicaid billing but are essentially universal in that they apply to most insurance plans. More important, Medicare guidelines for reimbursement are the strictest among insurance plans. *Adhering to the Medicare guidelines ensures that the provider will be in compliance with all insurance plans for appropriate coding for reimbursement purposes.*

For many psychiatrists, documentation requirements for inpatient psychiatric and consultation services are different in form and content from the documentation that might be employed in outpatient practices. Codes for billing inpatients reflect the need for the consultant to be aware of the physical status of the patient as well as the patient's psychiatric state. A premium is paid for thoroughness and attention to "process of care." Thus *documentation for inpatient consultative psychiatric services requires documentation of co-morbid medical problems*. An extensive psychiatric

examination, including recommendations for treatment and medication without the inclusion of elements of the review of systems, for example, can be billed only for the lowest consultation service code. Billing is otherwise considered "up-coding" and is prohibited by law. The critical ingredients of an appropriate note congruent with an appropriate billing code will be addressed in the section on documentation and coding.

OBTAIN PREAUTHORIZATION FOR SERVICES WHENEVER NECESSARY*

Health insurance companies vary in their requirements for precertification (i.e., permission for providing a consultation before the delivery of the service to enable payment for that service). Medicare, for example, does not require precertification, whereas most Behavioral Health Organizations (BHOs) require such precertification. Precertification is the rule for carve-out BHOs that are subcontracted to manage the mental health and substance abuse benefit for the larger medical insurance plan. A patient may be authorized by the primary insurance carrier for the medical admission, authorizing payment for all physicians performing medical consultations save the psychiatrist who requires specific and separate authorization from the carve-out company for payment for the psychiatric consultation.

Critical to the financial viability of C-L services is the management and monitoring of the billing and collection of third-party claims. Consultation services are often not billed for,[1] and the tracking of payments goes unmonitored. Each phase of the process between the provision of service and the receipt of payment for services presents its own dilemmas.

IDENTIFYING THE PAYER

During the admission process, most hospitals will have identified the primary, secondary, and supplementary insurance coverage.

It is critical for the managers of a C-L service to understand how each type of insurance adjudicates claims for professional services. Health insurance claims for hospital services are separated into two components: the technical or hospital charge and the professional or physician charges. For some insurers these charges are billed together, whereas for others they are billed separately.

Medicare, nonmanaged Medicaid, Blue Cross, and commercial indemnity plans will each pay both the technical (hospital) and professional (physician) components. Payments for each component are based on a previously negotiated fee schedule or percentage of charges submitted. Managed care plans will typically negotiate an all-inclusive fee for services rendered and will not pay for the professional (physician) charges separately unless they are specifically contracted for, apart from the day-rate for the hospital charge.

When a patient is insured by a managed care plan, C-L services must be contracted for separately to be reimbursed beyond the all-inclusive rate the hospital receives through the day-rate. If the insurer carves out the management of its mental health and substance abuse benefit to a behavioral health subcontractor, separate professional bills must be submitted to the carve-out behavioral health subcontractor. A common error for C-L services is the sending of the C-L consultation claim to the primary insurance carrier rather than the behavioral health subcontractor and receiving rejection for "service not covered" or "bill to carve-out." Too often these rejected claims are written off, which engenders increased irritation with the primary carrier or blaming of the C-L service for not obtaining prior authorization. The best method for ensuring that the correct payer is billed is to confirm with the medical insurer, usually by telephone, in advance of the treatment to determine whether the mental health benefit is carved out and, if so, to what organization. Then, one should contact the carve-out company to obtain prior authorization for the service. The critical request should be for both the initial consultation and follow-up visits, if necessary. Ideally, a systematic method for navigating this system should be built into the consultation process through departmental or hospital-level billing/reimbursement staff with at least initial guidance, and periodic review, by the C-L service administrator.

DEVELOP A STANDARD FORMAT FOR WRITING THE CONSULTATION NOTE

Several standards and guidelines collide when writing an efficient and effective consultation note. Standards established by the American Psychiatric Association (APA) Practice Guidelines for Psychiatric Evaluation of Adults[2] address the content of an appropriate psychiatric examination; these standards then must be adapted to the special conditions of the consultative examination. As noted by the Academy of Psychosomatic Medicine (APM) Practice Guidelines for Psychiatric Consultation in the General Medicine Setting,[3] the psychiatric consultation should also address the consultee-stated versus the consultant-assessed reason for referral, the extent to which the patient's psychiatric disturbance was caused by the medical or surgical illness, the adequacy of pain management, the extent of the psychiatric disturbance caused by medications or substance abuse, disturbances in cognition, the patient's character style, thoughts of dying, and psychiatric symptomatology. At the same time, those same APM Guidelines state that the "note is best if brief and focused on the referring physician's concerns."[3]

The consultation note should include the chief complaint, history of the present illness, medical and psychiatric history, social and family history, review of systems, mental status examination, and an impression and treatment plan (Table 51–1). It should also include data to support the billing code for reimbursement; documentation should reflect the appropriate level of care provided. Given this level of complexity, even the most competent and organized physicians may find it difficult to keep these guidelines in mind when they are writing a note.

*As this edition of the *Handbook* goes to press, mental health parity legislation has been passed (embedded in the President's economic stimulus package) in both congressional bodies. Consultation–liaison (C-L) service administrators and providers are strongly encouraged to monitor the effect that this and future legislation might have on such matters as carve-outs, prior authorization, and the like.

TABLE 51–1 Key Elements of the Initial Consultation Note

1. Document the date and time of the visit; write "psychiatry" at the top of the note.
2. Document the name of the doctor who requested the consultation and the reason for the consultation request.
3. Provide a chief complaint.
4. Provide a summary of the patient's medical history relevant to the current psychiatric situation; do not just duplicate information in the medical record and the problem list (provide at least four of seven categories of information [e.g., timing, severity, duration of symptoms, associated features]).
5. Provide a description of current psychiatric symptoms (or events leading up to the psychiatric consultation).
6. Document the psychiatric history; be specific about medication and other treatment effects and adverse reactions.
7. Document the family psychiatric history (include drug and alcohol use), including medication and other treatment responses.
8. Document the social history—work and school history, sexual history, drug and alcohol use history, legal history, social supports, and current living arrangements.
9. Provide the past medical history.
10. Document that a review of systems has been performed.
11. Provide a complete mental status examination, with at least nine fields of the following—appearance, behavior, speech, affect/mood, thought content (suicidal, homicidal, delusions, hallucinations), orientation, memory, attention, other cognitive tests, language, fund of knowledge, insight, and judgment.
12. List the current medications—review hospital medication records as well as doctor's orders.
13. Document recent and pertinent tests and procedures performed (e.g., laboratory studies, roentgenography [computed tomography, magnetic resonance imaging], electrocardiography, electroencephalography).
14. Document pertinent aspects of the physical examination (e.g., vital signs, neurologic examination findings, abnormal movements).
15. Provide your impression; use *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (DSM-IV) diagnoses and readily understandable terminology (avoiding psychiatric jargon) as well as a formulation.
16. Provide your recommendations; be clear and concise; list medications exactly how you wish them given (including suicide precautions, recommendations for restraints or other consultations, and so on). Please note that all notes from consultations and follow-up visits should be written with discretion; keep in mind that medical–surgical charts frequently are read by hospital staff and sometimes by patients and their families.
17. Document the date of next follow-up visit and the planned frequency of visits.
18. Sign and print your (i.e., the consultant's) name, along with a telephone and/or pager number.

One of the authors (T.A.S.) has developed a working template for documentation that facilitates compliance with HCFA and Medicare guidelines (Figure 51–1). Templates must be considered works in progress, given shifting standards with respect to required content; the format presented is intended as a guide to a flexible document that can be amended as needed (see Figure 51–1). Other consultation forms have been developed by Worley and co-workers.[4]

We believe that the use of such a template minimizes the intrusiveness of billing requirements that would otherwise not be clinically necessary or might alter the level of complexity of the consultation performed. In addition, a template can facilitate more complete consultations, serve as a teaching tool for trainees, and catalyze research or internal review projects. Templates also lend themselves to inclusion in computerized medical records, prevent loss of critical observations and recommendations resulting from illegible notes, and decrease medical errors. Furthermore, from a time-management perspective, such templates can make clinicians more efficient with regard to documentation of relevant information. With the developing capacity to import computerized (observational and laboratory) results, vital signs, recent laboratory values, medication orders, and drug administration, data can be more easily included in the consultation note. At the same time, care must be taken to keep computerized notes focused and helpful.[5] The ability, conferred by technology, to import information easily or cut and paste text can be more a hindrance than a help if not coupled with actual human attention to what is pertinent and accurate.

BILL THE APPROPRIATE CODE

As of 2010, and despite protests from the Academy of Psychosomatic Medicine and the American Psychiatric Association, CPT Evaluation and Management (E&M) codes for inpatient consultation (99251-99255) are no longer reimbursable by Medicare. Other insurers are expected to follow suit. Consultations remain reimbursable under other codes, but, at present, imperfect 1:1 translation of the old codes onto the available ones has impeded arrival at a consensus on which codes are optimal. Table 51–2 attempts loose connections based on the Inpatient Hospital Care (IHC) codes (99221-99223), which MGH and many other institutions are currently using. The Psychiatric Diagnostic Interview Examination code (90801) remains usable and, in some cases, the Psychotherapy Codes (90810-90847). Follow-up codes (99261-99263) are also unchanged. Clearly, this is a situation to be monitored closely.

To use consultation codes properly, it must be clear that the consultation is a service requested by another physician or another provider rather than by the patient or the patient's family. The requesting physician must enter a written or digital request for psychiatric consultation; a statement in a progress note indicating the desire for psychiatric input is insufficient for reimbursement purposes.

Problem-focused	1-3 items	None	None	1-5 elements
Expanded problem-focused	1-3 items	1 system	None	6-8 elements
Detailed	4 or more items	2-9 systems	1 field	9-13 elements
Comprehensive	4 or more items	10 + systems	3 fields	14-15 elements

*IHC codes are set in bold type.
HPI, History of Present Illness; *MSE,* Mental Status Examination; *Psych/FHx/SHx,* Psychiatric/Family History/Social History; *ROS,* Review of Systems.

The content of the history, comprehensiveness of the examination, complexity of medical decision-making, and average time required to complete the consultation determine the reimbursement that will be provided (Table 51–3). Engaging the assistance of a professional coder to perform periodic audits and training sessions for physicians is essential to remain abreast of changes in federal auditing guidelines. Additionally, providing psychiatrists with simplified pocket billing guidelines and definitions of terms for selecting the appropriate CPT code can be helpful.

EVALUATION OF THE COSTS AND BENEFITS OF A CONSULTATION SERVICE

C-L services are rarely lucrative cost centers.[6] Moreover, providing fee-for-service psychiatric consultation by independent practitioners rarely leads to a financially viable service or career. Meaningful consultation requires that clinicians expend significant time away from the bedside. Necessary tasks include the review of the medical record and case discussion before and after the consultation with the referring physician, nursing staff, and social service. Ancillary meetings with family members are often necessary to collect critical information unobtainable from a medically compromised patient. A cost–benefit analysis that sees cost as the psychiatrists' salary and the benefit as the lowest expenditure of finances to provide the service without severely compromising the service is far too common.

In contrast to the preceding scenario, we support a "value accounting" methodology that approaches the consultation service in a broader systemic manner.[7] This methodology looks at cost, clinical outcome, and consumer satisfaction as interrelated domains. With a broader view, we can examine the impact of a C-L service on the care of the patient, the educational or academic mission of the hospital, *and* the financial function of the hospital. From a fiscal perspective, the availability of C-L services results in decreased length of stays (LOSs)[8] and recidivism rates, outcomes especially critical in a capitated, managed care environment. Decreasing the LOS lowers overall hospital costs.[9] Moreover, a proactive C-L service identifies co-morbid medical, psychiatric, and substance abuse problems that result in increased payments to the hospital under the Diagnosis-Related Groups (DRG) payment system by including previously overlooked complications and co-morbid diagnoses.[8] For example, delirium is significantly underrecognized, with a prevalence of approximately 10% of hospitalized patients. Alcoholism in the general hospital has been reported in 20% to 40% of hospitalized patients.[9] Identifying and treating co-morbid

TABLE 51–3 Definitions of Medical Decision-Making

CODE	DECISION-MAKING	NUMBER OF DIAGNOSES/OPTIONS	COMPLEXITY OF DATA REVIEWED	RISK OF COMPLICATIONS
99221	Straightforward	Minimal	Minimal or none	Minimal
99221	Low complexity	Limited	Limited	Low
99222	Moderate complexity	Multiple	Moderate	Moderate
99223	High complexity	Extensive	Extensive	High

Straightforward: One or more self-limiting minor problems.
Low complexity: Two or more self-limiting or minor problems or one stable problem.
Moderate complexity: One or more chronic illnesses with mild exacerbations or progression of, or side effects, or two or more stable chronic diseases.
High complexity: One or more chronic illnesses with severe exacerbation or progression, side effects of treatment, or acute or chronic illness that poses a threat to life or bodily functions.

delirium, substance abuse, and psychiatric problems have a salutary impact on patient outcome as well as on the financial health of the general hospital. There is some evidence that effective consultation reduces the use of other medical services as well.[9] This additional revenue is quite separate from the financial savings in staff time expended while managing aggressive, confused, uncooperative, or "undesirable" patients; the costs of security; and the use of restraints and secondary problems of injuries or infections (e.g., from catheters placed in agitated elderly patients or pneumonias or aspirations secondary to patients being restrained in bed to control aggression and agitation).

From a public health perspective, the involvement of the C-L psychiatrist may lead to improved disease-management protocols and best practices, helping patients understand and cope with chronic illness states. Enrolling patients in smoking-cessation or weight-control programs may initiate or support their general health and wellness. Consider that 25% to 40% of patients in the general hospital are being treated for ailments secondary to alcoholism and that the societal losses secondary to alcoholism may exceed $115 billion per year.[9,10] With effective interventions as part of the medical team, future medical utilization and cost may be reduced.[11,12]

The impact on consumers of consultation services, with a focus on medical providers, results in many of the less tangible or nonspecific outcomes of that consultation. These outcomes include direct and indirect education of hospital staff about psychopathology. Such education, along with demonstration by a familiar consultant of an easily identified medical approach to psychiatric problems, serves the dual role of de-stigmatizing mental illness and psychiatry itself. Ideally, future patients then benefit from more effective psychiatric treatment, including better deployment of psychiatry C-L services. These activities occur within actual consultations as well as through the C-L psychiatrist's participation in in-services, clinically oriented committees, and collaborative care teams. All have the potential to improve patient care and satisfaction, but many are not reimbursable, reinforcing the need to obtain fair reimbursement for those services that are. Diligent attention to rules and regulations associated with billing and documentation can help improve patient care and help C-L services become financially viable.

Quality Assurance and Quality Improvement on a Psychiatric Consultation Service

52

Anthony P. Weiss, M.D., M.B.A.
Theodore A. Stern, M.D.

The quality of health care is a hot topic. In an era of increasing accountability throughout our society, it is not surprising that questions about the efficacy and efficiency of our health care system are also being raised. Scrutiny is coming from the three major constituencies (i.e., providers, purchasers/payers, and patients) within the system. Providers (including physicians and nurses) have begun to realize that flaws exist in the current health care delivery system and they have proposed large-scale efforts to improve care.[1] Purchasers and payers (including insurance companies and the government), who are being squeezed during difficult economic times, are demanding to know what they are getting for their money. And finally, patients themselves are now asking questions about their care, with an increasing emphasis on consumerism and advocacy.

In response to these pressures, the quality of health care is increasingly being carefully measured and reported. "Transparency" is the buzzword, with quality dashboards and provider performance report cards becoming commonplace as part of the public reporting efforts on health care quality. In addition, measures of quality are increasingly being tied to reimbursement, whether as part of pay-for-performance (i.e., increased reimbursement for better outcomes) or nonpayment for so-called "never events" (e.g., medical errors, such as wrong-side or wrong-site surgery). Whether or not there is wholesale health care reform, we expect that these early trends will continue to expand.

Interestingly, though the care provided by proceduralists (e.g., surgeons) and hospitalists (e.g., internists) has come under the most scrutiny, the care provided by consultants has to date been off the radar. We suspect this state is only temporary. Given the prevalence of co-morbid medical/surgical and psychiatric illness, the percentage of hospitalized patients who are seen by a psychiatric consultation service (as high as 13% in some settings), and the role consultants have in either reducing or increasing the cost of care (through their ordering of diagnostic tests as well as their impact on length of stay and on re-admissions), we are likely to see increasing efforts to define, to measure, and to report the quality of consulting across all medical disciplines, including psychiatry.

Many physicians will bemoan this prediction, highlighting the innumerable challenges of this endeavor to argue for maintenance of the *status quo*. While we share their concerns about the challenges (and the potential for unintended consequences), we believe there is value in physicians being proactive in outlining the best approach to quality assessment. In so doing we can work to craft measures that are more than just boxes to be checked, but that actually serve to identify added value of the consulting service and to illuminate which aspects of care and the service need improvement. Perhaps more importantly, this type of introspective self-assessment (when coupled with efforts to improve deficiencies in care) has been often cited as a core aspect of medical professionalism.[2]

This chapter represents an initial attempt to illustrate how the quality of a general hospital psychiatry consultation service can be assessed, assured, and improved. To do this we will present the work of the general hospital psychiatrist on the prevailing model of health care quality: the structure/process/outcome triad developed by Dr. Avedis Donabedian.[3]

DONABEDIAN'S MODEL

Donabedian was an epidemiologist and health services researcher who many consider to be the father of the modern health care quality movement. Among his contributions was a simple model that identified three types of interconnected pieces of information (i.e., structure, process, and outcome) from which one could draw inferences about the quality of care delivered.

By structure, he referred to both the material and human resources required to provide health care. By process he referred to the actual activities that comprised care delivery. By outcome he referred to a wide-ranging set of changes (positive or negative) in patients that could be attributed to the processes of care delivered. These three components are not attributes of quality *per se*, but rather they are windows through which quality of care can be viewed and assessed.

The model is elegant in its simplicity; it has stood the test of time as a framework for the assessment of health care quality in a number of settings. Defining exactly how these general concepts apply to a specific aspect of health care (e.g., general hospital psychiatry) has proven more difficult. In addition, the hypothesized linkages between structure, process, and outcome may not always be robust causal connections. Nevertheless, we believe this is a good starting point to guide our discussion (Figure 52–1).

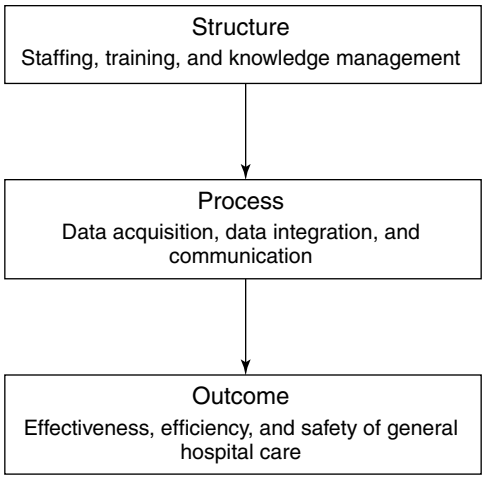

Figure 52–1. Donabedian's quality triad.

STRUCTURAL MEASURES OF CONSULTING QUALITY

A consultation service is only as good as the consultants who comprise it. Unlike other technical areas of medicine, psychiatric consultation is knowledge work, and as such, the key measure of structural quality relates to the human resources (consultation psychiatrists) that form the team. In this regard two questions need to be asked: (1) Is the team well staffed? and (2) Is the team well trained?

Staffing refers to the quantity of psychiatrists that provide coverage to the general hospital (based on recruitment, retention, and full-time equivalents). The size of the roster will depend on multiple factors (e.g., the size of the hospital, the prevailing patient mix, the presence of trainees, the full-time/part-time status of staff, and the referral frequency). Defining "adequate coverage" is certainly up for discussion; no doubt there is a minimum threshold below which the timeliness of consultations becomes an issue and the burden on individual practitioners so substantial as to promote burnout. Beyond the raw number of staff on the service, the turnover rate of psychiatric consultants is another important structural measure of quality. One cannot underestimate the value of in-depth knowledge of the structure and culture of the specific setting in which one is employed—high rates of turnover make it difficult to develop this inside knowledge that is so critical to the framing of recommendations that are actually accepted.

Training refers both to the formal educational and training background of the psychiatrist and his or her actual clinical experience within general hospital psychiatry. The former would include measures such as the percentage of board certified staff, the percentage of staff with subspecialty training in psychosomatic medicine, or the percentage of staff with formal subspecialty certification. The latter refers more to the years of experience, numbers of total cases seen, and markers of expertise in specific domains (such as publication of peer-reviewed articles and chapters). There is evidence that both physician certification[4] and volume of cases seen[5] can be associated with clinical outcome, though to our knowledge these relationships have not yet been established for psychiatry.

One final structural indicator relates to the degree of organizational learning that occurs with experience. This concept, sometimes referred to as "knowledge management," is an important aspect of major management consulting firms (e.g., McKinsey or Boston Consulting Group). How can the consultation service use the combined wisdom and experience of thousands of cases seen over time and bring this to bear on the next consult request? Can the service itself have value beyond the sum of the individuals that comprise it? We believe the answer is yes, but methods of knowledge management within hospital-based consultation services are at present rudimentary when compared to that used by our business colleagues. This may improve with the more widespread use of electronic medical records for inpatient care. Until then, services might consider other aspects of knowledge management, such as the use of daily team rounding, the creation of an anonymous consult registry with "lessons learned," and publication of important observations in peer-reviewed literature.

PROCESS MEASURES OF CONSULTING QUALITY

As outlined in Chapter 2, there are a core set of processes that make up the actual practice of "consultation psychiatry" (see Table 2–1 for example). These processes can be broadly construed under the categories of data gathering (speaking with referring clinician, reviewing the chart, interviewing and examining the patient); data integration (formulating a diagnosis and crafting a plan); and communication (writing and discussing impressions and recommendations). The skill with which we carry out these activities likely influences the outcomes of patients that we are asked to evaluate. It will also influence the service's reputation within the general hospital, in turn influencing the volume of referrals. For high-performing consultation services this can set up a positive reinforcement loop (Figure 52–2) in which a high-quality consult leads to high perceived value, which leads to increasing consultation requests, which leads to increased experience, which when captured leads to greater process skill, and so forth.

Despite the widely acknowledged importance of process excellence in these three domains, they are only rarely, if ever, assessed once a physician has completed his or her

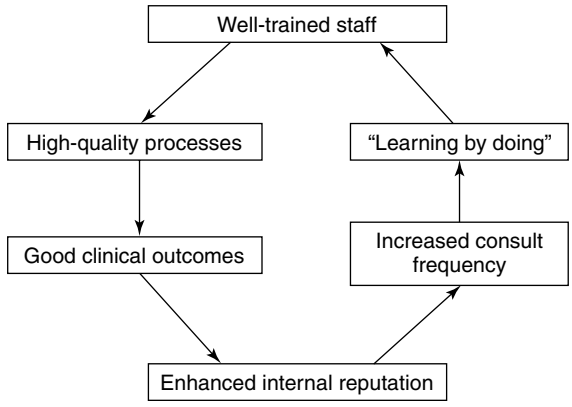

Figure 52–2. Positive feedback loop of high-performing consultation services.

postgraduate training. For example, "How often are we called to account for our review of the old record?" Or, "How often are our efforts in eliciting a history from an intubated patient assessed?" Yet these examples of going beyond the basics are likely key to distinguishing quality with respect to data gathering. Myriad examples could be developed for data integration and communication as well.

Unlike efforts to promote hand washing by staff, the timely use of antibiotics for community-acquired pneumonia, and administration of aspirin after a myocardial infarction (to cite just three examples of process measures within general medicine), there are no national standards for process quality in consultation psychiatry.

OUTCOMES MEASURES OF THE CONSULTANT'S QUALITY

When a well-staffed and trained service implements high-quality processes, good outcomes are bound to occur. Donabedian identified seven domains of outcomes (Clinical, Physiological, Physical/Functional, Psychological, Social, Mortality/Longevity, and Patient Satisfaction) that ran the gamut from enhanced patient understanding of their condition to prolongation of life. Even a cursory glance at these items makes clear that high-quality psychiatric consultation can have a substantial impact on many, if not all, of these outcomes.

In addition, there are a number of patient safety issues that could be addressed by timely and effective psychiatric consultation. Within-hospital suicides, suicide attempts, and staff assaults are a few dramatic and important examples. Other events may include removal of intravenous lines, tubes, or wires by delirious patients. Tracking the frequency of these events on a hospital-wide basis may be a useful marker of the effectiveness of care implemented as a result of a psychiatric consultation. This of course requires a robust and reliable event reporting system, so that bad outcomes (and even "near misses") can be tallied and used as the basis for discussion.

GUIDING PRINCIPLES OF QUALITY MEASUREMENT

We believe there is benefit in measuring the structure, processes, and outcomes associated with a psychiatric consultation service. Through measurement we can better identify the value we add to the mission of the general hospital, serving to justify the expense of maintaining this type of internal consultancy to hospital leadership. It may also enhance the standing of knowledge-based specialties in the eyes of health care purchasers and payers, while working toward equilibrating reimbursement disparities that have long favored our proceduralist colleagues. Most of all, this type of measurement can provide the type of feedback we need to continually improve the quality of the service we provide to patients.

That said, we know full well that these attempts at measurement in and of themselves are potentially costly and time-consuming. All too many measurement efforts in today's health care landscape seem to be nothing more than costly box-checking exercises; they often do little to create actual practice change. To avoid a similar fate we put forward the following three suggestions:

1. Measurements should be devised, conducted, and reviewed by those at the front lines of care, sometimes called clinical microsystems.[6] In this way, those with the greatest knowledge of the care delivery processes and expected outcomes can play the central role in the measurement effort. This type of bottom-up effort is critical in the change process, because it engenders "buy-in" from the beginning, rather than pushing mandates down the throats of providers in a top-down fashion.
2. Measurement cannot be considered a stand-alone process. It must be integrated with quality assurance and quality improvement activities. A quarterly report on the frequency of in-house suicide attempts is meaningless unless it is linked with careful efforts to reduce the rate of occurrence through root cause analysis of reported adverse events (Figure 52–3)[7] and the implementation of rapid cycle change. In addition to formal quality assurance review and specific project-based quality improvement efforts, a wide variety of tools are available (and often underutilized) to promote change within the hospital setting. These include presentations at grand rounds, discussions at case conferences, systematic surveillance for complex cases with early intervention, and supervision with feedback for both trainees and staff.
3. The actual cost of measurement (in time and dollars) should be accounted for, and measurement efforts reassessed periodically to determine whether they are providing an adequate return on this investment. In this way the hospital (or hospital microsystem, such as the consultation psychiatry service) can make certain that quality assessment actually enhances, rather than detracts from, the core capacity of the institution—to provide excellent clinical care.

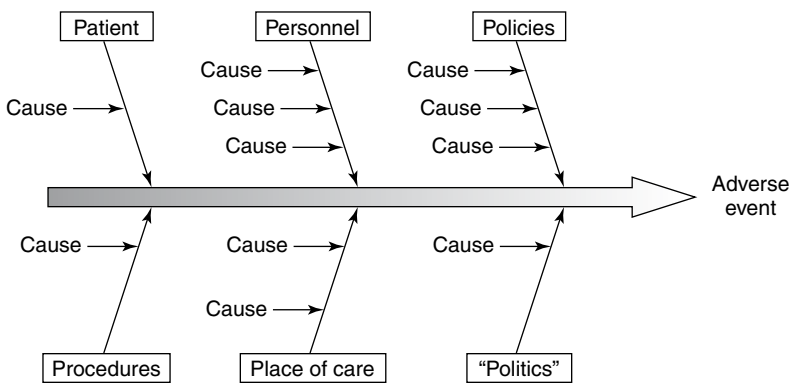

Figure 52–3. Ishikawa ("fishbone") diagram to identify root causes of adverse events.

CONCLUSION

Over the past half-century psychiatric consultation in the general hospital has advanced from a novelty to a full-fledged medical subspecialty. As part of this coming of age the time has come to not simply ask—"Do you have a psychiatric consultation service?," but rather "How good is the psychiatric consultation service at your institution?" This question is posed to initiate introspection by all who are involved in this field. Only through considering that we can and must do better for our patients will improvement be possible.

Psychiatric Research in the General Hospital

53

Adrienne O. van Nieuwenhuizen, B.A.
Dan V. Iosifescu, M.D., M.Sc.

The goal of this chapter is to highlight the importance of pursuing research in the context of a busy clinical psychiatry department. This chapter is also intended as a primer for the clinician who is interested in research activities but has minimal experience with clinical research. So, why should a busy clinician consider pursuing research? First, research is necessary. Without research studies, psychiatric treatment would be limited to old treatments or treatments that lack empirical validation. Clinical research is the only way to accumulate the evidence necessary to practice evidence-based medicine. We need clinical research to push the boundaries of what we know, and to evaluate new definitions of disorders or the efficacy of new treatments. However, a great deal of clinical research is published each year, and we already have a hard time keeping up with new results. This brings us to our second point: Why is it important for clinicians to be involved in research? The answer is that clinicians are in direct contact with the existing unmet clinical needs of their patients. Therefore, they are in the best position to know which research is most needed and which research topics will have the most profound impact on the field. Pure scientists are more likely to pursue topics of great intellectual complexity but of less direct practical importance.

Although it is true that clinical experience is crucial for the planning and prioritizing of clinical research, the reverse is also true. Involving ourselves in the research process is great training for our clinical work. Research requires us to be critical and iconoclastic; it trains us to pay attention not only to the results but also to the details. Thus, we are better able to evaluate the strength of the evidence and to differentiate between high-quality and poor-quality research. The former should be trusted and may justify changes in our clinical practice, whereas the latter should not be trusted; at best, it may serve as a rationale for further studies.

Engaging in research also serves to demystify the process. Clinicians are frequently reluctant to refer patients to research studies out of concern that such studies may involve ineffective treatments and use subjects as "guinea pigs." When engaged in research studies, clinicians can experience first hand the elaborate planning required of a research trial that aims for the highest level of protection of participants, as well as the extensive evaluations in research that are on par with the very best of clinical encounters.

We will next describe the most significant parts of a research study, the most common types of research, and the steps that must be gone through, from the first outline of a research idea to the publication of the research results.

THE RESEARCH QUESTION AND PLANNING THE STUDY

Pursuing an intriguing clinical observation or anecdote is one of the best ways to choose a research question. The topic of interest might be as general as the prevalence of depression after myocardial infarction and the relationship between these two illnesses. Alternatively, it might be the relationship between depression and a much rarer condition, such as depression associated with a mitochondrial disorder. It is important to choose an innately compelling research question, as this is the best defense possible when coping with the trials and tribulations inherent in research. Designing, implementing, and completing a study can be tedious, so a deep, personal interest in the research question is necessary to push through the challenges that will inevitably arise.

Once a potential research question has been identified, the next task is to meticulously define each aspect of the question. Conducting a thorough review of the literature relating to the research question is essential and is best done by searching the National Library of Medicine PubMed database (www.ncbi.nlm.nih.gov/pubmed) for related articles. If the literature search reveals that similar research has already been done, learning about the methods used and the suggestions for further research will be helpful for designing a new study. Familiarity with the relevant literature is also important for describing how the proposed research would differ from what has already been done, and what important research question it would address. These arguments will be invaluable when submitting the research proposal for approval by funding agencies and ethics committees.

To study depression in patients who have had a myocardial infarction, the particular phenomena that are of interest must be operationally defined. Depression and cardiovascular disease encompass broad fields of research, so the research question must be narrowed to a specific subtopic in this field (e.g., prevalence, risk factors, or outcomes with a particular intervention). On the other hand, almost any research project can be undertaken on the association of depression with mitochondrial myopathy, encephalopathy, or lactic acidosis with stroke-like episodes syndrome, as very few reports exist on this topic. The rarity of this disorder is a mixed blessing for researchers, as it entails significant challenges for recruitment.

Defining the research topic begins with the currently accepted gold standard, the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR). The DSM manual was originally drafted for

research purposes, but its influence now reaches far beyond the research world. If the research question involves a narrower subtype of disorders that is not yet defined in the DSM (such as pathologic grief), appropriate and validated scales should be selected to operationally define and assess this subtype.

The next step is to specify the clinical population of interest. Naturally, this will be constrained by one's access to such patients (see Recruitment, under Executing the Study, later). Access to potential research subjects is often gained through clinical care contacts or from research collaborators. Some of the common population parameters that must be specified include the age range, exclusionary co-morbid disorders, the minimum and maximum number of treatments a patient may have failed (e.g., a patient who has not responded to two or more treatments may be different from a treatment-naive patient in ways that are clinically important), and exclusionary concomitant medications. Defining the study's population requires determining how many subjects are needed and can be feasibly recruited; this, in turn, requires taking into account drop-out rates and noncompliance rates (these are best based on similar clinical trials that have recently been conducted nearby). Necessary considerations for planning an adequate sample size are discussed later (see Statistical Methods later).

Once all aspects of the research question have been clearly defined, measures must be chosen that can quantify these concepts. Possible types of research measures range from clinical research scales to electroencephalograms to neuroimaging assessments. One useful exercise is to imagine the study proceeding exactly according to plan, and then to review the hypothetical data that would confirm the study's hypotheses. What findings would confirm these hypotheses? Will the research scales' individual item scores be analyzed, or only the scales' total scores? Confronting these questions early will benefit the study database's design greatly. The importance of carefully designing a database tailored to the study's objectives *before* initiating enrollment cannot be overemphasized (see Choosing the Research Tools, later).

The design of the study should minimize two common methodological flaws. The first involves clinical reliability in a study. *Reliability* refers to raters' consistency in determining whether to include patients in the study, and their agreement in measuring symptom severity. Two raters scoring the answers of the same patient with the same research scale and yet producing very different scores would signal a potential problem with reliability. The second common weakness relates to *validity*—the study's ability to correctly target the symptoms or illness of interest. The symptoms or illness must be very clearly defined to avoid inadvertently assessing *other* symptoms or illnesses. For example, an assessment of depression that is limited to questions about difficulties with concentration and lack of motivation might assess cognitive deficits just as much as depression, and therefore this measure would have poor validity. These concerns highlight an important issue: One of the many challenges in research is the tension between (1) the desire to purify the subject population as much as possible, to minimize variability related to other patient characteristics (i.e., to compare apples with apples) and (2) the need for results to be generalizable to the larger population (as accomplished by including patients of different genders, of different ethnic and racial backgrounds, and with multiple associated co-morbid conditions).

Although designing a study solely on these theoretical considerations is ideal, in reality the research question is often shaped, at least in part, by more practical considerations. These may include the resources of one's hospital, department, or clinical practice; access to research funds directly or indirectly through colleagues; and the physical and financial limitations of the target population's ability to participate in research.

TYPES OF PSYCHIATRIC STUDIES

Once the research question has been determined, it is possible to choose the type of clinical research that best suits it. In prospective studies, the data are collected after the selection of subjects. In contrast are retrospective studies, in which a population of interest is identified (e.g., all depressed adults with co-morbid anxiety admitted in a 6-month period), and then data already collected for clinical purposes are reviewed for the parameters of interest (e.g., how many of the depressed adults received additional psychopharmacologic treatment for their anxiety). Although retrospective studies are easier and cheaper, they are limited to data already collected, and thus to the variability in the quality and completeness of such data over time. Some research questions are specific enough to make the choice between prospective and retrospective design a moot point (e.g., the rate of mortality in Revolutionary War soldiers would clearly require a retrospective study), but most research questions can be explored using several different approaches. The discussion of study types that follows is meant to serve as an introduction to some of the different options, but they are not necessarily mutually exclusive. For example, prospectively acquired data on the effects of one intervention can be compared to already-gathered, retrospective data on the effects of another intervention. This design is not ideal, as these two sets of data probably differ with regard to more than just the type of intervention, but this may be the only ethical option when the new therapy under investigation appears strikingly superior to all other therapies.

Retrospective Studies

Case-control studies are usually conducted retrospectively, via chart reviews. Cases are selected from subjects affected by the illness of interest, and controls are selected from individuals not affected by that illness.

Literature reviews can yield a qualitative and a quantitative product. If a review article is written summarizing all the publications on a particular topic in the literature, the literature is qualitatively reviewed.

Meta-analyses can be conceptualized as quantitative literature reviews, but they represent a major genre of research in their own right. A meta-analysis requires quantitatively reviewing all the studies that have been conducted on a certain disorder, following specific rules for statistical analysis of such data. The large sample size amassed by aggregating studies in a meta-analysis can reveal better-substantiated conclusions than those that small, individual

studies can detect. Although up to 10,000 clinical trials are published in English-language journals every year, their small sample sizes lead to many contradictory conclusions. In contrast, the results of meta-analyses are often consistent with those of clinical trials with very large sample sizes, so this study design may provide a faster and cheaper means of obtaining conclusive data on the safety and efficacy of new therapies.

Epidemiologic Studies

Epidemiologists interested in mental health study the causes and prevalences of various psychopathologies in well-defined populations. Most epidemiologic studies are cross sectional, and their purpose is often to determine the prevalence of a disorder at a specific point in time. Alternatively, some epidemiologic studies follow a population over an extended period; these are known as longitudinal epidemiologic studies.

Cohort studies are mostly done via longitudinal epidemiologic studies. Research subjects are chosen on the basis of whether they were exposed to a certain condition at a specific point in time. Longitudinal data (such as symptoms, diagnoses, and mortality rates) are then collected over time to determine the clinical consequences of the initial exposure. These studies can be conducted prospectively or retrospectively; the former naturally allow greater control over what data are collected, whereas the latter have the advantage of being faster and cheaper.

Prospective Studies

Prospective clinical trials gained popularity in the mid-1900s as a means of comparing the feasibility and efficacy of various therapeutic agents. Clinical trials can range from those on a very small scale (such as single case reports) to those on a very large scale (such as international, multisite clinical trials). In the process of developing a novel treatment, the scale of the study often correlates with the phase of the investigational product (see The Phases of Drug or Device Development, later). For example, phase I studies are always small, as safety is at issue, whereas phase III studies are often very large, because comparing the efficacy of potentially similar therapeutic agents requires well-powered studies.

Randomized controlled trials are the most common and are the gold standard of studies for the evaluation of the efficacy and safety of a new therapy. These trials always include a control group (either placebo or an accepted treatment), and the decision of whether a subject receives the investigational drug or a control is made by randomization. Randomization is the random assignment of research subjects to one of several preselected treatments, usually by a computer program. The goal of randomization is to reduce the risk of biased assignment (e.g., enrolling patients who are more likely to improve in one of the treatment groups). Although clinical trials represent the most common kind of prospective study, they are generally very costly and there may be ethical issues associated with the use of control treatment. (See What Is a Randomized, Placebo-Controlled, Double-Blind Clinical Trial later.) Another disadvantage of this type of trial is the possible ethical issue associated with the use of a control treatment (see discussion on placebos, later).

Crossover designs are used in studies that assign half the subjects to the control group and half to the treatment group, and then switch the two groups. Typically, half the subjects might be assigned to treatment A, and half to treatment B; at the midpoint of the study, all the subjects are switched to the treatment they have not received, so that the first group receives treatment B and the second group receives treatment A. This design has the advantage of reducing the number of patients required, as each group serves as its own control and as the control for the other group. One complication of the design is that the first treatment may sometimes have lasting effects that could influence the measurements in the second half of the study. Also, data from subjects who drop out during the study are difficult to compare, because they did not complete both treatments. On a much smaller scale, the crossover design can be applied with one or several subjects, in the form of an intensive, repeated single-case design. In this case, each subject is his or her own control, and there is no averaging of data. Because the intensive single-case design does not involve many subjects, there can be one crossover, or two or more crossovers (e.g., the subject experiences the side effect on treatment A, then no side effect on placebo, and then the side effect again on treatment A, which stops again while on placebo). This can be done in a nonblinded, single-blind, or double-blind fashion. The benefit of repeated single-case designs is that one is left with a very well documented case in which one treatment can be shown to be more efficacious than another.

Case-control studies can sometimes be conducted prospectively as well. Subjects recruited as cases are affected by the illness of interest, whereas controls are unaffected by that illness (but may be affected by another).

AN IN-DEPTH LOOK AT PROSPECTIVE CLINICAL TRIALS

What Is a Randomized, Placebo-Controlled, Double-Blind Clinical Trial?

Randomized, placebo-controlled, double-blind clinical trials are frequently encountered in psychiatric literature. These are the three elements of modern clinical trials.

Randomization: The purpose of clinical trials is often to investigate the efficacy of a particular treatment. This is often accomplished by giving an active treatment to half the subjects in a study and giving the other half a placebo treatment. The term *randomization* refers to the technique used to assign patients to either the active group or the placebo group. The consequence of randomization is that every patient entering a clinical trial has an equal chance of being assigned to any treatment group. As discussed previously, the role of randomization is to reduce selection bias. In a *simple randomization*, each time a subject is enrolled in a trial, a computer program randomly assigns him or her to one of the treatment groups. This leaves open the risk that an important variable could be unequally represented between the groups. For example, if a clinical trial is investigating a potential anxiolytic and the recruitment includes subjects with co-morbid depression, it would be important to ensure that the drug and placebo groups have equal numbers of subjects with co-morbid depression

(as these subjects could be more treatment refractory). Stratification allows the researcher to specify the variables that should be equally distributed, such as gender, co-morbid diagnosis, and age range. Simple randomization alone does not ensure that the groups will be homogeneous, as all the subjects with co-morbid depression could accidentally end up in one group, so stratification allows active manipulation of assignment to avoid such an outcome. However, stratification reduces the statistical power of the study, and there are limits on the numbers of strata that are feasible.

Ethically and scientifically, randomization cannot be used unless the investigators view all treatments as equally favorable. This means that current clinical evidence cannot favor one treatment in the study over another treatment in the study. It would be unethical for an investigator to know that a certain treatment was superior therapeutically, and yet still expose half (or more) of the subjects to an alternative (inferior) treatment. Also, if the treatment had already been demonstrated to be superior, there would be no point in pursuing the research. This is different from a researcher's intuition or desire to believe that a certain treatment might be superior. Some patients enrolled in clinical trials secretly hope they will be exposed to the "real" (i.e., active) treatment as opposed to a placebo (conceptualized as ineffective); the investigator should be able to explain there is not sufficient evidence to suggest that any treatment is superior. If the investigator does not believe that statement, or if the current literature does not support it, the study should not be conducted in the first place.

Placebo: The placebo is another key element in most modern clinical trials. Placebos have been included in medication, surgery, device, and even psychotherapy studies. For studies examining the effectiveness of a certain medication, placebos are often inert pills containing no pharmacologically active compound. In studies assessing the efficacy of a device, the placebo may involve sham applications of the device, in which the patient receives the application of the device but a key component is disabled. Psychotherapy studies may involve generic interactions with patients without making use of formal psychotherapy or enrolling subjects on a wait list. Thus, the objective is for the subjects to be incapable of detecting whether they are receiving active treatment or placebo. The placebo effect is very significant in most psychiatric illnesses, so many psychiatric studies make use of a placebo control. The use of placebo in psychiatric research is hotly debated. Some researchers maintain that for a disease where active treatments have already been approved and are considered efficacious, new medications should be approved only on the basis of equivalence with existing treatments. However, when ineffective treatments might have been approved or are in widespread use, demonstrating that new treatments are as effective as the old ones is not very useful. Only a placebo can measure the true magnitude of the nonpharmacologic healing effect of the clinical and research interaction.

Use of a placebo helps to clarify the real magnitude of clinical improvement associated solely with the active treatment. If a study comparing two active treatments measures a 35% response rate for both treatments, the investigators might conclude that roughly a third of patients improved due to pharmacologic effects. Including a placebo control might reveal that the placebo group had a 30% response rate, which could lead to the alternative conclusion that the patient–doctor relationship and interactions may have been responsible for most of the improvement.

Blinded-trials: Like randomization, double-blinding is a strategy to further homogenize the characteristics of active group and placebo group so as to improve the likelihood that the main difference is in the treatment that is received. A clinical trial can be an open trial, a single-blind trial, or a double-blind trial. In an open trial, clinicians, subjects, and research staff are all aware of the treatment received by the subject. This very closely resembles standard clinical practice. In a single-blind study, one of the parties involved in the research is blinded. The subject could be blinded, while the rest of the research team is aware of what the subject is receiving. Many clinicians dislike this situation, as it can erode the trust and alliance usually present in the doctor–patient relationship. Alternatively, the clinical rater might be blinded, while the subject and study clinician both know which treatment the subject is receiving. In a double-blind study, the clinician, study rater, and subject all are naive as to which treatment the subject is receiving. Double-blind trials reduce the chance that the data collected will be influenced by clinician or subject bias, but the risk is not completely eliminated. Positive or negative changes in patients may suggest which treatment they are receiving. For example, if the treatment being studied is known to cause dry mouth, the clinician may suspect that the subject reporting the side effect is receiving the active treatment. However, patients receiving placebo may also report side effects similar to those expected with the active treatment, as they are led to expect the possibility of a specific group of side effects. This highlights the importance of including a placebo arm, as it reveals the possibility that not all side effects observed are a consequence of the pharmacologic effects of the active treatment. It can be helpful to assess the clinician's and the patient's intuition or expectation regarding which treatment was administered. This may reveal a correlation between extent of improvement and the expectation regarding the treatment received.

When a trial makes use of blinding, questions about the nature and timing of the unblinding inevitably arise. If all the subjects were enrolled at the same time, it may be feasible to unblind them when they simultaneously finish the trial. However, most clinical trials enroll subjects over a long period of time, and this complicates the issue. If patients are unblinded whenever they finish the study, the risk is that the research staff and current and future subjects will be unblinded. For example, if all the patients who were on active treatment had complained of increased appetite, staff and future subjects may associate increased appetite with active treatment. The alternative to unblinding patients in long trials can be equally challenging, as it requires arranging follow-up care without making use of information regarding treatment assignment during the study. If patients have experienced significant improvement during the trial, it will be unclear which intervention they should continue receiving (placebo or medication). These issues must be clearly thought out and resolved by the clinician before initiating the trial.

The Phases of Drug or Device Development

A medication or device under development passes through four phases of investigation. Because studies in these phases involve investigating the novel use of a medication or device, these studies require an Investigational New Drug (IND) application form to be submitted to the U.S. Food and Drug Administration (FDA) (the form can be found on the FDA website). Phase I is initiated when an agent has successfully demonstrated some safety and efficacy in animals. At this point, an investigator (usually the pharmaceutical company) can apply for permission from the FDA via an IND to explore the tolerability and safety of the agent in humans. If the results are positive for these criteria, phase II studies may be initiated, with a larger number of subjects than phase I; this time, the objectives are to determine whether the agent can demonstrate any therapeutic efficacy and to suggest the range of effective doses. If the results are once again positive, phase III trials may be initiated. These include classic, large, randomized, double-blind, placebo-controlled studies, and they can result in the approval of a new medication or device. Once a treatment has successfully passed phase III, phase IV trials may be undertaken to explore the treatment's safety and efficacy for other populations, or for the treatment of other disorders.

IMPORTANT SUBTYPES OF CLINICAL TRIALS

The following subtypes of clinical trials come with their own set of challenges and benefits. These categories are not necessarily mutually exclusive; for example, biological markers (via neuroimaging) can be explored and correlated with psychological assessments (via computer tasks).

Biological Markers

A number of biological variables (metabolic, endocrine, neurologic, and genetic) have been investigated as potential diagnostic markers for psychiatric illness or as predictors of treatment outcome. The diagnosis of most psychiatric illnesses relies primarily or exclusively on subjective information. Objective biological markers would be very helpful in increasing the inter-clinician agreement (reliability) for certain psychiatric diagnoses. Moreover, partial or inadequate response to treatments is common in many psychiatric disorders. Nonresponse to treatments is associated with disability and higher medical costs, and partial response is associated with higher relapse and recurrence rates. The absence of clinical or biological predictors of treatment outcome that can guide treatment selection for major depressive disorder is frustrating to both clinicians and patients, as the patient's suffering is extended through ineffective treatment trials. Moreover, the choice of next-step strategies after a failed trial is not clear, especially because some patients do well with a medication even if they previously failed another medication in the same class.

Metabolic studies: Many studies have focused on the changes in brain and body metabolism that occur with psychiatric illnesses. Other studies have focused on the increased associations with obesity, diabetes, dyslipidemia, and other metabolic abnormalities in relation to psychiatric illness or to the treatments used.

Endocrine studies: Dysfunctions in multiple endocrine glands (e.g., thyroid, adrenal, gonads) have been associated with psychiatric illness as well as the side effects of specific treatments.

Imaging studies: Structural neuroimaging studies have investigated changes in brain morphology in patients with psychiatric illness. Functional neuroimaging studies (single-photon emission computed tomography, positron emission tomography, and functional magnetic resonance imaging) allow investigators to observe the functionality of specific brain areas by measuring blood flow and metabolic rates. These can be compared between subjects and controls or within subjects before and after treatment, to understand changes in brain function associated with treatment effects. Magnetic resonance spectroscopy studies allow investigators to perform an *in vivo* chemical analysis by measuring brain levels of key neurochemicals. Such studies may also reveal the metabolic effects of treatments.

Genetics studies: Genetic research has been very successful in the past decade in associating candidate genes with many important psychiatric disorders. Because of the large numbers of genes under investigation, such trials are very large and expensive. It is hoped that genetic research may reveal the specific biological pathways that are involved in psychiatric illnesses. A separate area of investigation is pharmacogenomics, the study of variations in the efficacy of pharmacologic treatments in relation to genetic predisposition. It is possible that certain populations may be more responsive to specific treatments and that genetic information may lead to personalized medicine, through which the most susceptible individuals are identified, and patients receive the pharmacologic treatment most effective for them. Another area of investigation is genetic epidemiology, which studies the causes, rates, and treatments of illnesses in families. This type of research uses genetic and clinical information about as many individual members of a family as possible to determine the relative influences of the environment and genes on each individual's risk for developing an illness. Geneticists also seek to determine which genes and single nucleotide polymorphisms are associated with a particular illness. Mathematical models are used to assess all of these possible factors, and to weigh their predictive importance, as well as to model possible relationships between different variables.

Psychological Assessments

Some studies focus on, or include, assessments of psychological features (e.g., cognitive deficits, mood traits and mood reactivity, associative thinking, reward response). For example, a subject's cognitive function may be first assessed before they receive treatment for their psychosis and then again after several months of treatment. Alternatively, mood reactivity might be compared between patients with unipolar depression and psychotic depression in order to study psychological differences between these two clinical populations. Such studies may focus on psychological characteristics and function with certain disorders, or on changes in psychological measures in relation to treatment. Increasing use has been made of computer tasks for assessing patients, particularly for assessing their cognitive function.

Treatment Studies

Inpatient unit: Research on an inpatient psychiatric unit comes with its own set of advantages and disadvantages. One of the advantages to this research environment is that a steady stream of symptomatic patients is guaranteed. The disadvantage is that patients are often admitted to inpatient units only when their symptoms are particularly difficult to treat, and therefore they require acute, intensive treatment. This challenge can be dealt with by tailoring research studies to the inpatient population. If mood disorders co-morbid with substance use is the most common diagnosis for patients admitted to a unit, designing research for this population will greatly aid recruitment. Another challenge is the unpredictability of admission and discharge. Patients are generally kept on a unit only as long as their need meets the level of care of inpatient hospitalization, and because current lengths of stay are short, most patients would be discharged within a week of enrolling in a study. If possible, studies should be designed to have inpatient–outpatient status flexibility, so that patients can continue to participate in the study even after they are discharged. Finally, it is very important to assess whether these subjects have the capacity to provide informed consent and thus are voluntarily consenting to a study. This can be particularly difficult when patients are admitted to the hospital against their will.

Neurotherapeutic studies: Recently, there has been an explosion of studies on neurotherapeutic interventions. These include electroconvulsive therapy, vagus nerve stimulation, repetitive transcranial magnetic stimulation, and deep brain stimulation. Although some have suffered from stimatizing media coverage (e.g., electroconvulsive therapy) or have had controversy surrounding their efficacy (e.g., vagus nerve stimulation, repetitive transcranial magnetic stimulation), a growing body of literature supports the use of such treatments. As these means of treating psychiatric illnesses become more common, further research will be needed.

Natural remedies: Over the past few decades, natural or alternative remedies have become dramatically more popular in the United States and worldwide. Increasing numbers of patients now ask whether they might benefit from natural treatments, and many patients will visit a variety of practitioners, including herbalists, naturopaths, and other healers, in addition to physicians. Because natural remedies are readily available over the counter, many individuals choose to self-medicate without professional supervision. Frequently used treatments that have benefited from positive research in psychiatric disorders include St. John's wort *(Hypericum)*, *S*-adenosylmethionine, the omega-3 fatty acids, *Ginkgo biloba*, L-methylfolate, and acupuncture. The benefits and liabilities of herbal remedies and other natural treatments are still largely unclear. Medical research has historically overlooked this area, and nutraceutical companies do not routinely fund studies on these medications. The public has the unfortunate misconception that just because something is called natural, it is safe. Natural medications, with the exception of homeopathic remedies, are not generally regulated by the FDA. Consequently, optimal dosages for these medications are poorly established, as are the active ingredients, contraindications, drug–drug interactions, and potential toxicities. Additional research in this field is needed.

Psychotherapy studies: Psychotherapy research has a reputation for being particularly challenging, but it is also filled with opportunities for novel research because many important questions remain to be addressed. One of the biggest challenges involves clearly defining and standardizing the psychotherapeutic intervention. Although ensuring that patients are all receiving the same pharmacologic agent in a psychopharmacologic study is fairly straightforward, ensuring standardized interventions in a psychotherapy trial is much more challenging, because psychotherapists' therapeautic techniques may vary greatly. One way this challenge has been overcome is by using psychotherapy treatment manuals, in which the psychotherapy protocol is extensively detailed. A second challenge is the difficulty of designing a placebo-control arm. Again, this is relatively straightforward in psychopharmacologic studies, where an inactive pill can be used. In psychotherapy, attempts at simulating the placebo condition have included use of nontreatment groups, wait lists for treatment groups, and talk sessions in which topics of therapeutic importance are avoided. A third challenge in psychotherapy research is that various psychotherapies and placebos have a high rate of response, which means that much larger studies are needed to detect meaningful differences. Again, this is more feasible in psychopharmacologic studies, where larger enrollment is less costly in time for the research clinician.

Several recent studies have combined pharmacologic interventions and psychotherapy (e.g., comparing patients receiving a medication with patients receiving a medication plus psychotherapy). This combination addresses some of the challenges mentioned, and it is likely to be an area of continued research in the future.

Alternative support studies: Another domain for research relates to studies of collaborative care or culturally sensitive support for patients. Studies of collaborative care have been developed to assess whether the assistance of a mental health clinician (such as a social worker) can be effective in boosting mental health services in the primary care setting. Studies on culturally sensitive support examine the effects of tailoring clinical care to patients' cultural backgrounds.

CHOOSING THE RESEARCH TOOLS

Which tools? Choosing the best research tools, including a study's clinical rating scales, is a very important process. It requires determining which assessments will best measure the constructs of interest, how often they should be completed, and who should be responsible for administering them. As mentioned earlier (see The Research Question and Planning the Study), it is important to ensure that reliability and validity are maintained when choosing the most appropriate study tools. Reliability can be improved by thoroughly training raters in the use of the study's scales, and by establishing a clear protocol for the ratings. For example, some scales direct raters to "rate up" whenever more than one answer could fit a subject. In addition, it is important to assess test–retest reliability as well as interrater reliability. Validity can be improved by clearly defining the symptoms or disorder of interest. For example,

studies on traumatic brain injury have resulted in many conflicting findings, some of which may result from differences in the severity of the brain trauma in each case (e.g., severe versus mild), or from different etiologies of the brain injuries.

The first step is to choose rating scales that match the research question and have been validated for the population of interest. For most major psychiatric diagnoses, there is a wide range of scales to choose from—from fully structured rating scales that leave the rater little discretion in making an assessment, to semistructured and open-ended assessments that give the clinician a fair amount of flexibility in how to proceed with the assessment. The degree of structuring will probably depend on who is responsible for doing the assessments (see later). Next, a clear plan should be designed for entering the data into the study database, and for regular quality-control sessions. This is much easier when the initial assessments are entered on a computer in real time, so that no data transcription from paper forms to computer files is necessary. Entering data directly into a computer program immediately reveals problems with data quality (such as items not completed by the clinician or patient). Ensuring data quality can improve the study's power, whereas attempting to conduct analyses for a study where significant amounts of the data are missing is much more challenging.

Used by whom? The delegation of responsibility for clinical assessments will depend on which scales are used, as staff with less clinical experience can be trained to complete fully structured rating scales, whereas scales with less structure may be better left to experienced clinicians. Raters with limited clinical experience may adhere more closely to rating protocols, whereas seasoned clinicians may be more likely to override rating guidelines in favor of their own clinical judgment. Regardless of the raters' degree of experience, it is also necessary to determine whether one clinician will be responsible for all of a patient's ratings, or whether different clinicians will rotate in assessing a patient. Having the subject always rated by the same clinician can improve the reliability of the ratings. On the other hand, rotating the clinicians ensures that an individual clinician's rating biases are averaged out. For example, clinicians on an inpatient psychiatric unit will be accustomed to more severe symptoms and may therefore underrate moderate depression symptoms; including clinicians less accustomed to severe presentations can balance this out. Rotating clinicians also reduces the risk that patient improvement will be the result of a powerful therapeutic alliance rather than the more generalized aspects of the studys intervention.

Because clinical assessments may be biased for a variety of reasons, several checks and balances have been developed for assessing patients' symptoms. The most common alternative source of assessment is the subject himself or herself. Self-rated scales reduce the risk that the patient is revealing only the symptoms he or she is comfortable sharing verbally with a clinician. Patient-completed scales also reduce the risk that a clinician might score them in such a way as to ensure enrollment of the patient into the study.

Another source of assessment is off-site monitoring. External rating consultants can be employed to verify the screening or study assessments completed by the clinician. For example, if the clinician-rated scores of a patient achieve the symptom severity needed for a study, an off-site rater then conducts the ratings a second time to verify that the required symptom severity is in fact present. Off-site self-rated assessments can also be done by interactive voice recognition. Patients call an automated program and answer a series of self-rated questions. The interactive voice recognition system can then confirm whether the required degree of symptom severity is present.

EXECUTING THE STUDY

Recruitment: Finding funding for a study may be the number one challenge in research, but meeting recruitment goals is often a close second. It is easy to underestimate the difficulty of enrolling patients, and this is why larger grants often require some pilot data to demonstrate the feasibility of the study. Finding out what the no-show and dropout rates are for local research clinics can provide a good forecast of the challenges ahead. Funding agencies often require regular updates (e.g., on the number of potential subjects screened, the number enrolled, and the number completed). Some institutions, such as the National Institutes of Health (NIH) and the local institutional review board (IRB), require a breakdown of enrollment according to gender, race, and ethnicity. Recruitment requires constant attention, so weekly meetings with study staff to review successes and challenges with enrollment can be helpful. These meetings should track the enrollment rate and attempt to identify factors responsible for increases or decreases in enrollment. It can also be helpful to meet with clinicians working with the clinical population of interest, as these clinicians can refer patients for study participation. If recruitment is much slower than expected, it will be necessary to assess whether the study will still have enough statistical power to draw meaningful results and conclusions. If this does not appear to be the case, the remaining options include requesting a no-cost extension from the funding agency to achieve adequate recruitment, modifying some of the exclusion criteria (as long as this is not too detrimental to the study's validity), providing more compensation for participation in the study, or, if all else fails, making significant changes to the protocol and objectives of the study.

The informed consent process: Clinical research has had its dark moments both internationally and in the United States, so ethics committees were developed to review all clinical research. (For more information on working with IRBs, see Regulatory Responsibilities, later.) Requiring informed consent from study subjects is probably the most significant measure IRBs have implemented to reduce the risk of unethical research. Informed consent forms are written documents that clearly explain, in simple, accessible language, what the study involves, and the risks and possible benefits of participating in the study. This form should clearly state how the study will differ from standard clinical care, what the alternatives are to participating in the study (e.g., receiving clinical care through other means), under what circumstances the subject may be withdrawn from the study, and the subject's right to withdraw from the study at any time. If the study involves randomization and use of placebos, these concepts must also be clearly explained. Once the subject has had a chance to learn about the study and to ask questions, the subject and clinician can then sign

the informed consent form and proceed with the screening visit. If the nature of the study, or the risks and benefits of participating in the study, change during a subject's participation, the subject should sign a revised consent form, to ensure that fully informed consent has been acquired for the current study.

Submitting protocols and consent forms to the IRB may seem tedious, and this process is often a source of delays in starting a study, but a clear understanding of the IRB's goals and concerns can help reduce these delays. Two sources of information should be consulted when drafting consent forms. First, there are federal regulations on requirements for consent forms, and these are detailed in the Department of Health and Human Services' general requirements for informed consent, in 45 CFR 46.116 (see www.hhs.gov/ohrp/humansubjects/guidance/45cfr46.htm). Second, most institutions' review boards provide clear instructions for all required study documents, particularly for drafting consent forms.

There is ongoing debate about the informed consent procedure, how best to acquire consent, and which subjects do not have the necessary capacity to provide informed consent. However, there are some generally accepted thoughts on this issue. The NIH's Office for Protection from Research Risks identifies mentally disabled persons as needing additional safeguards to protect them when participating in research. There are no federal regulations on the specific nature of the safeguards, however, so the key is to determine whether the population is at risk for lacking capacity, and then to proceed with the consent procedure accordingly. When a study is recruiting patients with severe dementia, a guardian or proxy will need to provide the informed consent, and the subject will need to provide assent. In intermediate cases, such as studies on a bipolar disorder, subjects with severe mania may not be able to provide informed consent, so an assessment of symptom severity should accompany the consent procedure to ensure there is capacity for consent.

The screening visit: Only after the informed consent procedure has been completed can any other study-related procedures be completed at the screening visit. This visit often includes completing clinician-rated and self-rated scales to determine whether the subject meets criteria for enrollment. Completing these scales also provides useful baseline information for the subject, which can then be compared to their ratings during and after the intervention. It is important to keep detailed information on the participants who were scheduled for a screen, which ones showed up for the screen visit, which ones provided consent, and, of those, which ones met the study criteria. These data can reveal obstacles to enrollment (such as particular exclusion criteria) and which referral sources are particularly fruitful. Some institutions, including the NIH, require detailed information on how many subjects granted consent, how many were not eligible, why, and so on.

The baseline visit: Some studies also include a baseline visit. The primary aim of the baseline visit is to ensure that the subject meets the inclusion criteria for a certain period (the interval between screen and baseline), rather than solely at the screening visit. In some cases, participating in the screen itself can cause significant clinical improvement, so assessing a patient a second time at baseline can improve the likelihood that changes observed during the study result from the intervention and are not a nonspecific effect.

Further visits: After the screen and baseline visits, the rest of the visits are often similar to one another. Subjects may be scheduled for a predetermined number of visits, but in some cases the length of their participation is determined by the speed of their clinical improvement. Clear criteria should be in place specifying at what points subjects should leave a study. Ideally, most subjects will leave when they have completed all of the study procedures, but other circumstances can also necessitate leaving a study. Possible grounds for withdrawing subjects from a study include failure to see improvement in the patient's condition, worsening of the patient's condition, the development of suicidal ideation or intent, and nonadherence to study protocol.

Nonadherence, a common phenomenon in psychiatric studies, is a complex issue. It is helpful to define the required dosage adherence for participation in a trial; many protocols require that subjects take at least 80% of the medication or therapy specified in the protocol. If adherence is a major concern, studies can include a lead-in phase, with participation limited to subjects who adhere to the protocol in that phase. Taking the time to fully explain the study and the importance of compliance can greatly boost adherence. Making study participation as painless as possible is also helpful (e.g., by reducing wait times, maintaining a positive and patient attitude toward subjects, and being responsive to their concerns and frustrations).

Although several steps can be taken to address adherence, struggles to enroll perfectly adherent subjects are reminiscent of the desire to enroll a very "pure" sample. Pursuing purity may mean sacrificing generalizability, so a careful compromise should be struck between these two ideals. In any case, regardless of what is done to mediate adherence rate, careful documentation on adherence should be maintained. This can be done by having participants maintain drug diaries in which they note the medication they consumed each day, and study coordinators can request that any leftover medication be returned to them so as to track adherence rates.

Final visit: Subjects should be reminded in advance that their final visit is approaching, so that completion of the study does not come as an unpleasant surprise. The final visit should be carefully planned, particularly because subjects often have ambivalent feelings about ending their participation. If the study is unblinded at this point, the unblinding should be done in a thoughtful manner; if unblinding will not yet take place, the protocol should specify how to appropriately refer subjects to follow-up care.

Concluding the study: Once the study is completed, the focus quickly turns to analyzing the results, and to publishing a manuscript that details the study's findings in a peer-reviewed journal. There is an ethical obligation to funding agencies, subjects, and the clinical community to share the study's findings in a timely manner. The investigators are also interested in publishing as quickly as possible, as this will influence their ability to secure future research opportunities.

WRITING THE PROTOCOL

Once the details have been determined, formally drafting the protocol should be relatively straightforward. The protocol may initially be drafted for submission to the IRB or to a funding agency, or perhaps for simultaneous submission to both. Although there may be some variation in different organizations' preferences for protocol style and organization, most protocols are expected to review the same basic information. Regardless of where it is being submitted, the key to a good protocol is to make it as detailed as possible, thereby eliminating ambiguity and the risk of different interpretations of the protocol.

Many protocols start by describing the study's *hypotheses and objectives*. These include the primary set of hypotheses as well as any secondary hypotheses of interest. This section is meant to outline the purpose of conducting the study. Next, the *background and rationale* for the study explain and support the hypotheses based on the existing literature. The importance of the study's research question should be defended, including relevant theory and current empirical data. A general literature review should be provided, highlighting what information is still missing and how the proposed study will address this void. The background section is greatly strengthened if a pilot study has been done, as this reassures the reviewer that the study is feasible. The study's *population* should be described, with details on how many subjects will be enrolled and whether the study will take place at one or multiple sites. For clinical drug trials in adult populations, 18 to 65 years is a typical age range for subject inclusion, but this is adjusted depending on the focus of the study. Other inclusion and exclusion criteria should also be clearly detailed and justified. As previously discussed, the desire for a pure sample must be balanced with the generalizability of the study. This tension should be carefully and realistically considered when the study is being designed. If overly stringent criteria are set, the planned enrollment may not be feasible. In such circumstances, inclusion criteria may need to be relaxed at some point over the course of a study, but increasing the study population's heterogeneity may then require achieving an even greater sample size to draw meaningful conclusions.

The protocol should also clearly discuss what data will be collected during the study, and when. This involves detailing all of the study elements described earlier (see Executing the Study). The protocol should also review the same issues addressed in the consent form, including ways in which the study protocol differs from standard of care, the risks and benefits of participating in the study, measures that will be taken to reduce risks to subjects (including steps taken to protect subjects' privacy), the circumstances under which participants may need to be withdrawn from the study for their own protection or for the integrity of study data, and how the study is being funded. An explanation should also be given as to how the data will be monitored, who will have responsibility for monitoring the data and any adverse events, and how the study will be analyzed.

FUNDING

Once a clear protocol exists, the most challenging aspect of a grant application has been addressed. Some grants require all of the information discussed earlier, whereas smaller grants often require less information, such as a brief one- to two-page description of the study. It is helpful to find out from colleagues and mentors what some common sources of funding are in the field of interest. Additional information can be obtained from an Internet search, as most foundations or institutions aiming to fund research have searchable websites with detailed information for research applicants. It is important to read the information provided about the key areas of research focus for each institution, as proposals are more likely to get funded if they are in line with the sponsor's research interests. A university's or hospital's research administration office should also have a database of the existing funding opportunities (or those successfully used by other researchers). Smaller foundations tend to have more narrowly defined research interests and can provide only small grants, but those can be very helpful for funding the initial (pilot) projects required to secure funding for larger studies. Larger organizations such as the NIH have grant awards specifically designed to assist new clinicians in developing their research skills. There are also research training awards and research fellowships to assist new researchers in developing experience and training. Institutions vary with respect to what study costs they are able to assist with, so it is important to find this out when drafting the budget, and to contact the home institution's grants office to find out what institutional costs must be accounted for (e.g., overhead fees and IRB fees). Most funding agencies include salaries for study staff, as well as study materials, tests, or devices, among the supported costs.

Pharmaceutical companies or device manufacturers are a source of potential funding, as most have programs for Investigator-Initiated Trials that can support small- to medium-size studies (usually involving the pharmaceutical product or device manufactured by the company, but sometimes also funding more general research in the disease area of interest). The contact between the academic investigator and the pharmaceutical company is usually mediated by the company's medical science liaison for the specific geographic area. Investigator-Initiated Trials are designed and conducted by the investigator, not by the research staff at the pharmaceutical company. Thus, the research should prevent concerns that studies may be biased toward finding and reporting results that are favorable to the sponsor. Research contracts should specify that the academic investigator has the right to publish the data generated as part of the study (while usually having to give advance notice to the company regarding the results).

The very large clinical studies sponsored by the NIH tend to be led by senior investigators and typically require pilot data for the grant application. Thus, they would not be immediately available to new investigators. The large studies sponsored by pharmaceutical or device companies (usually during phases II and III of drug or device development) tend to be designed and conducted by researchers from the industrial sponsor, usually in close consultation with experts at the FDA and with academic experts in the field.

REGULATORY RESPONSIBILITIES

It is usually preferable to submit research protocols to the IRB after funding is secured, as the study may not be feasible in the absence of such funding. However, some studies

may be done without external funding. After having decided on all the details and after having written up at least some of them for a funding agency, drafting and submitting the required protocols, consent forms, and other forms for the IRB should be fairly easy. Because IRBs are particularly concerned about the safety of clinical subjects, some sections may need to be added to the protocol, or expanded upon, to fully address this. It is advisable to seek guidance from a mentor or another investigator familiar with the IRB, at least for the initial submission of the study for IRB approval. Once this has been approved, communication with the IRB will continue throughout the study. Any adverse events or requests for amending the protocol should be submitted to the IRB as they arise, and an annual review of the progress to date and problems that have arisen should be submitted in advance of the study's yearly expiration date.

Study sponsors (foundations, federal agencies, or commercial companies) have their own reporting requirements. Amendments that affect the design of the study, reports of serious adverse events, and annual updates must be submitted to the study's sponsors, have to be approved by the study sponsors, as do annual updates. Detailed records on the subjects enrolled, any adverse events, any subject discontinuation, and any changes to the protocol must be maintained to meet these reporting requirements.

STATISTICAL METHODS

It is beyond the scope of this chapter to provide a detailed presentation of statistics. We want, however, to emphasize the importance of statistical methods at every step of planning, conducting, or reporting the results of a research study. A statistician or a researcher with extensive statistical experience should be involved from the very first stages of designing a study. Waiting until the end of the study may lead to significant study design or execution errors that could have been prevented and are difficult or impossible to correct at a late stage.

The first concept to consider in the study design phase is the *statistical power* of the study. There are two major types of statistical errors in regards to a clinical trial. The type I error (alpha, α) is the probability of a false-positive result (i.e., finding a difference when in reality none exists). The type II error (beta, β) is the probability of a false-negative result (i.e., finding no difference when one exists in reality). Studies are designed to minimize these two errors to acceptable levels. Frequently, α is arbitrarily chosen as 0.05. Beta (β) and the commonly used "statistical power" ($1-\beta$) are dependent on alpha, on the number of subjects in the study, and on the magnitude of the expected difference to be detected. It is not only possible but also very important at the beginning of the study to estimate the number of subjects required to detect a difference between the groups of subjects studied. Such a computation can be performed with several statistical software packages. Not doing this computation exposes researchers to the risk of performing an underpowered study (i.e., one in which there is a very low chance of detecting a difference, even if such a difference does exist). Performing an underpowered study is scientifically wrong, and it might even be unethical because it exposes research subjects to risks related to the study intervention when there is an insufficient chance that the study can provide useful results.

Although a final statistical analysis is conducted once the study is over, the importance of designing a database and choosing statistical analyses before starting the study cannot be overemphasized. With a database already established, study data can be entered as they are collected, revealing quickly whether the rating scales are being scored completely and correctly. In real-life situations, some of the data will be missing, either because subjects do not complete the study or because forms are lost or incomplete. If data are not checked, there is a serious risk that only after the study is completed will it be discovered that too many data points are missing for any conclusions to be drawn from the study. A plan for dealing with missing data can help prevent some avoidable data losses, and it should include statistical rules for when the losses are not avoidable. Also, creating the database in advance often reveals ambiguities in the study protocol that can then be resolved before enrolling patients.

Investigators should know before they start analyzing data which analyses will be performed and why they were chosen. Many good statistical software packages are available (e.g., SPSS, Stata, SAS); the choice rests with the investigators and should be based on their intimate knowledge of the study and the data to be analyzed. Investigators should be fluent in the basics of statistical methods, even when they collaborate with statisticians. The data analysis methods have to be matched to the research questions and to the data collected. For example, the investigator will have to choose between methods used to compare data (e.g., gender or diagnosis) such as the chi-square test, and tests aimed for continuous data (e.g., symptom severity or age). Some tests allow comparison of only the main variables (*t* tests), whereas others allow correction of the analysis for differences between groups in other secondary variables (e.g., analysis of variance [ANOVA] or linear regression). For example, in a study comparing clinical improvement after antidepressants A and B, ANOVA can be used to test the difference between the two treatment groups while correcting for baseline depression scores, age, and gender (used as co-variables). Variables that are not normally distributed, or comparisons between groups with low numbers of subjects, require nonparametric methods (e.g., the Mann–Whitney *U* test).

The first analysis reported for any study is the one that answers the main question of the research, and it includes all randomized patients. When further analyses are reported, it must be clear why those were performed, which patients were excluded, and what corrections for multiple comparisons were performed. Although by convention a type I error ($\alpha = 0.05$) is considered acceptable for most clinical studies, performing many comparisons in the same subject increases the chance of type I errors. The value of α will need to be adjusted to avoid false-positive results.

PUBLISHING RESEARCH RESULTS

The first rules of good scientific writing are those of any good writing: be clear, be concise, and focus on the essentials. The aim is to present the data in detail and to make the complexities understandable to clinician readers who may not be familiar with the specific methods used in the study.

The typical research paper presenting original data has four parts. The *introduction* summarizes the research done before the current study and justifies the study being conducted. A common mistake made by junior researchers is to write the introduction as an extensive review of the entire field of research; this can be confusing and should be avoided. The introduction should highlight primarily the research hypothesis that started the study, as based on the literature. If an extensive review is desirable, it could be written as a separate review paper. The *methods* section describes in detail all the components of the study, as previously discussed in this chapter. By the end of the study, the methods section should be mostly written, as all the steps have already been planned, documented, and implemented. The *results* section is the most important; it includes all important results, tables, and figures. Presenting too many results can confuse readers and overshadow the important ones; secondary results and figures can be left as an Internet-only supplement (an option now offered by many journals). The *discussion* targets the research presented and the way it agrees, completes, or contradicts previously published results. The focus is on the current results, their importance, and their relationship with the pre-existing published data. A paragraph summarizing the limitations of the study is also advisable and helps the reader evaluate the quality of the data and the conclusions presented. When writing the conclusions, authors should avoid bold statements or extrapolations, especially when study limitations (e.g., low numbers of subjects and imperfect methods) may not justify such categorical statements.

Several aspects are important when deciding where to submit the paper. First, the author needs to find the publications that are most likely to be interested in publishing the research topic. The impact factor of the journal (a measure of how many of the published papers are cited in the literature) should also be considered, but this should not be the sole determining factor. Once a journal is targeted, its instructions for authors should be reviewed for specific requirements (e.g., length, format, specific sections). Ignoring such requirements can lead to a negative first impression from reviewers. After the peer review is complete, authors are frequently faced with critical reviews, formulated as requests for revision or as outright rejections. When asked to revise, the author should carefully read the critiques and edit the paper on the basis of their substance, providing a point-by-point, detailed list of all modifications. When faced with rejection, the author should avoid taking it as a personal failure, choose a more appropriate journal, and reshape the report for this other publication, incorporating suggested changes from the previous reviews.

CONCLUSION

We have stressed the importance of clinical research and summarized common research methods and pitfalls. Research involves a compromise between ideal conditions and feasible conditions. Quality research requires intelligence and innovation while designing the study, and then enduring enthusiasm and meticulous attention to detail while executing it. All this effort, however, is justified by the final result: our ability to better understand psychiatric disorders and validate new, more efficacious methods of treating them. Thus, clinical research is a fundamental part of our efforts to help our patients, now and in the future.

The formal introduction of psychiatric services into general hospitals in the 1930s and their subsequent growth have been among the most important institutional developments that have affected modern American psychiatric practice. Psychiatric units in general hospitals have proliferated since 1934, when 96% of psychiatric beds were under government control and generally found in state or veterans' hospitals.[1–5] Consultation, outpatient, and emergency psychiatric services in general hospitals have grown dramatically during this period as well.[6–8] Including data on the admission of patients to general medical services for primary psychiatric illness, it has been estimated that general hospitals provide nearly 60% of all inpatient psychiatric care in the United States.[9–12]

Reviews of the growth in general hospital psychiatry have often attempted to define its proper role. Commentators about these issues have generally split into two groups. The social-reformist group has seen the development of general hospital psychiatry as a function of its social position. General hospital psychiatry emerged in this view because it was seen as the setting in which mental illness could be treated in a more open manner, replacing custodial state hospital care. The general hospital's proximity to family and community resources was perceived as a central therapeutic element in this clinical efficacy.[11–15] Psychiatric wards should be therapeutic communities, and psychiatric consultants should be standard-bearers for a biopsychosocial model of illness, who would educate physicians to this new style of medical practice.[16,17]

The medical group, especially Hackett,[6] emphasized the links to medicine as central to the identity and growth of general hospital psychiatry. These authors stressed the development of psychopharmacology and the need for consultation services for patients with serious medical illness.[18–20] Institutional expressions of this perspective include the development of medical–psychiatric units, psychiatric consultation services stressing the medical care of patients rather than the education of caregivers, and the growing use of neurobiological discoveries in many areas of psychiatric practice.[21,22] The development of a sophisticated psychiatric pharmacopoeia, new insights into the molecular biology of psychiatric illness, and this handbook are a testimony to the correctness of this latter point of view.

This chapter reviews the forces that are currently affecting general hospital psychiatry and its major responses: medical/psychiatry units, consultation–liaison (C-L) services, psychiatric neuroscience, and psychiatry within integrated medical delivery systems.

FORCES AFFECTING GENERAL HOSPITAL PSYCHIATRY

Forces that contribute to change within contemporary general hospital psychiatry include intense economic pressures to reduce costs, restrictions on access to health care by insurers, new theoretical models within psychiatry, larger populations in need of psychiatric care, geographic areas underserved by psychiatric care, and privatization of public mental health care.

Controlling Health Care Costs

Attempts to control health care expenditures in the United States abound. Faced with the largest economic crisis of the past hundred years and fierce international competition, the pressures applied by government and industry to reduce these expenditures have been unrelenting.[23–26] These economic pressures have led to significant changes in the way expenditures for health care services have been controlled and have prompted reforms and proposed overhauls in health care insurance and delivery systems. For psychiatric services, negative operating margins threaten their viability, particularly in general hospital settings, making them vulnerable to downsizing or closure.[27]

In the 1980s and 1990s, the growth of health maintenance organizations (HMOs) and prepaid health plans, including capitation and other forms of health care financing that shift risk to providers, were among mechanisms that attempted to reduce the duration of hospitalization and the cost of health care. The net effect of these changes has been to shorten hospital stays for all classes of medical and psychiatric patients and to increase the acuity of illness necessary to allow admission to the general hospital.[28,29]

The growth of carve-outs (the removal of contracts for psychiatric services from the rest of medical services so that they are independently bid on and separately managed) has been one of the most difficult developments affecting general hospital psychiatry. These carve-out arrangements are particularly pernicious for medical psychiatry, placing newer and more competitive pressures on services and limiting the quality of care. In this model, psychiatry is divorced from primary care. Patients are not allowed to be cared for

by psychiatrists who in the past were well-known colleagues of primary care physicians (PCPs), and thus patients often face interruptions in basic psychiatric care.[30,31] In addition, carve-out models falsely assume that the medical and psychiatric needs of patients are distinct (both clinically and fiscally)—often to the detriment of patient care and leading to even higher costs in the end.[32,33]

In response to the ongoing economic pressures and public dissatisfaction with the availability and cost of medical care,[34] legislation in the United States has aimed to reform the health care system. In 2008, the federal government enacted mental health parity legislation designed to require equal insurance benefits for medical and psychiatric services by 2010.[35] The impact of this change has yet to be determined, but it has shown the potential to improve outpatient psychiatric follow-up in acute depressive episodes or after inpatient hospitalizations, without substantial increases in costs.[36–38] Mental health parity carries the potential to counteract the effects of carve-out models noted earlier, but only if the full costs associated with psychiatric disorders are understood and payment and care models allow care to be provided in an integrated way.

Movements toward health care reform and universal health care continue to gain momentum.[39–42] In 2006, Massachusetts became the first state in the United States to enact near-universal health care legislation.[43–47] Through expansions in the state Medicaid program, creation of income-related subsidies for health insurance, reform of the insurance market, and required mandates for both individuals and employers to participate in the program, Massachusetts aimed to insure between 90% and 95% of its previously uninsured population within 3 years of implementation. Although the long-term effects and viability of these changes remain uncertain, the short-term positive results have included increased enrollment in health insurance plans (e.g., the uninsured rate for working adults fell by nearly one half, with 93% insured 1 year after implementation), improved access to routine and preventive medical care, and decreased out-of-pocket costs for consumers, who reported less difficulty paying medical bills. The reform has produced negative outcomes as well, including higher-than-anticipated costs and increased unmet needs for health care, likely due in part to the large pool of newly insured patients entering the already overcrowded market of individuals looking for (and struggling to find) an available health care provider.[48]

In 2008, the United States presidential election focused heavily on health care reform, including the promise of accessible health insurance for all Americans.[49,50] It is not yet clear how such programs might be implemented or how they would affect the delivery of psychiatric care.

In the context of proposed health care reforms, the idea of patient-centered medical homes has the potential to reunite psychiatry and medical care under the same roof. Adapted from models of pediatric care, a patient-centered medical home is a comprehensive and personalized primary care setting, focused on accessibility, continuity, compassion, cultural sensitivity, evidence-based treatments, commitment to quality and safety, and coordinated or integrated care; it is an approach and attitude toward care, rather than a specific location. The medical home can provide patients with preventive care and a first contact in the medical system, decreasing acute care utilization rates and associated costs at the same time as improving the quality of care.[51]

Coordinated care in a medical home would ease referrals for mental health care, a process currently limited by insurance as discussed earlier. Smith and Sederer[51] have proposed the related idea of a mental health home: Mental health clinicians working with patients with severe mental illness would function as generalists, providing accountable, continuous, compassionate, and evidence-based care, coordinated with behavioral, medical, and rehabilitation service providers, including primary care providers, inpatient teams, day treatment programs, intensive case managers, assertive community treatment teams, housing services, and addictions specialists, among others.[52] A mental health home would not be a new form of psychiatric care delivery (e.g., similar characteristics to community mental health centers), but it would mark a return to the comprehensive, coordinated, and better-quality services of the past that existed before carve-outs and cost-cutting led to currently fragmented systems of mental health care and would meet the need to include the provision of some medical services to psychiatric patients where they receive their mental health care.

New Treatments and New Technologies

The development of new treatments and technologies has some roots in the development of effective psychopharmacologic agents in the mid 1950s.[7] Medications previously used in other areas of medicine have been used to treat psychiatric illness. Psychopharmacologic evaluation and treatment are often a focus of psychiatric hospitalization, especially for patients not safely treated outside of the hospital.

The efficacy of these new agents has also increased the emphasis on accurate diagnosis in psychiatry. Semistructured diagnostic interviews and rating scales have targeted observable elements in psychiatric illness.[53] Newer neuroimaging techniques, such as magnetic resonance imaging (MRI) or positron emission tomography (PET) scanning, have revealed evidence of previously unsuspected abnormalities, such as enlarged lateral ventricles in patients with schizophrenia or abnormal white matter in elderly patients with affective illness.[54] Studies using these technologies have begun to define fundamental neurobiological abnormalities underlying major psychiatric disorders. The combined effect of these changes is to make psychiatric care even more focused on neuromedical diagnostic evaluation, on medical care, and on psychopharmacologic management. Reflecting this shift at Massachusetts General Hospital (MGH), our psychiatric residents receive cross-specialty training by psychiatrists, neurologists, and neuropsychologists working on the same team so as to best provide them with a psychiatric education including neuroscience, neuroanatomy, neuroimaging, neuropsychopharmacology, and genetics, among other collaborative disciplines ideally suited to lead future developments in the understanding of the brain.[55,56]

New Populations in Psychiatric Treatment

Changing populations have also affected the focus and organization of general hospital psychiatric care. This happened, in part, due to the willingness of general hospital

psychiatrists to care for a broader range of patients: elderly patients, demented patients, patients with concomitant medical and psychiatric illness, patients with substance-related disorders, and patients with other neurobehavioral disorders. Psychiatrists are now established caregivers in intensive care and critical care settings.

New patient populations, including patients with drug-induced illness and those with human immunodeficiency virus (HIV)-related illness, have emerged that have required psychiatric care. Acquired immunodeficiency syndrome (AIDS) has now been recognized to have significant psychological, psychiatric, and neuropsychiatric sequelae. The capacities of the medical–psychiatric unit are an important resource for the response to the HIV epidemic.[57–59]

At the same time, new medical technologies, although sometimes life-saving, have in some instances put patients at risk for psychiatric morbidity. For example, undergoing cardiac electrophysiologic studies, having an automatic implantable cardioverter defibrillator (AICD) implanted, and then having it discharge appears to lower the threshold for panic or phobic anxiety and for posttraumatic stress disorder (PTSD).[60]

Changing Relationship with State Hospital Systems

Another factor that has affected the use and demographics of general hospital inpatient services has been the attempt to increase the admission of patients previously cared for in state hospital systems.[61–64]

Medical–Psychiatric Units

The development of medical–psychiatric units has represented an important conceptual shift in general hospital inpatient psychiatric care.[65–76]

The development of the medical–psychiatric concept has been, in some measure, a response to the limitations of the therapeutic milieu model.[67–76] The medical–psychiatric unit established the appropriate medical role of the attending physician. Where traditional units required attendance at group meetings as a condition for admission, patients on medical–psychiatric units might be so ill (e.g., with catatonia, feeding tubes, central lines, or severely psychotic behavior) that they might not be able to leave their bed, let alone their room. Patients with severe medical–psychiatric illness, excluded from traditional general hospital units, became the *raison d'être* of medical–psychiatric units. Such populations require traditional medical rounds, physical examinations, and the use of active treatments (such as psychopharmacologic agents). The role of the general hospital psychiatric unit, as it transitioned into a medical–psychiatric unit, became more medically traditional. Patients needed to receive an active medical intervention to get well. Community activities were relatively de-emphasized, and a normative medical hierarchy was approximated.[65,66,73,74]

Models

Kathol and others[77–80] have described a typology of medical–psychiatric units that has been useful in defining levels of medical–psychiatric acuity and the physical and staff organization to manage such services appropriately. Kathol defined four types of medical psychiatry units; type I and II units are traditional psychiatric units without medical capacity and standard medical units respectively, and types III and IV units are medical–psychiatry units proper. They differ predominantly in the severity of medical illness for which they can care. Both types III and IV units can care for patients needing intravenous fluids or medications, blood products, hemodialysis, peritoneal dialysis, or the care of other acute medical conditions. Type IV units are usually staffed by both internists and psychiatrists. These units can care for patients with high medical acuity (up to, but not including, patients who might require admission to the intensive care unit). Patients on such units may include those with significant congestive heart failure and co-morbid depression, delirium while undergoing chemotherapy, or peri-transplantation issues.

All medical–psychiatry units require cross-training of nursing and medical staff to allow the provision of high-quality care for patients with co-morbid acute medical and psychiatric illness. Psychiatrists on such units need to be able to provide general medical care and to collaborate with medical consultants. This conjoint care should include in-house internists for medical emergencies and possibly hired internal medicine consultants. Some units have handled this by hiring directors who are board certified in both psychiatry and either internal medicine or neurology or by maintaining medical and psychiatric physicians in a co-attending model.

In an environment that tends to carve out psychiatric care from medical care, close attention needs to be paid to define how medical–psychiatry units are reimbursed. To the extent that such units can shorten the overall length of stay (LOS) for patients with combined medical and psychiatric illness, they may be fiscally advantageous, especially in a capitated environment. For example, patients with complicated co-morbid psychiatric and medical conditions treated on type IV units have been shown to have enhanced psychiatric improvement compared to similar patients on general internal medicine wards and shorter length of inpatient stays than would have occurred with the traditional sequential approach to care (i.e., inpatient medical admission followed by transfer for inpatient psychiatric admission).[80]

As medical–psychiatry services become more oriented to acute symptomatic care, a variety of outpatient, partial hospital, and holding facilities are being created to decrease the need for hospitalization and to provide for the longer-term psychological, social, and medical rehabilitation of psychiatric patients. It is clear that medical–psychiatric units need to be closely integrated with such outpatient and partial hospital facilities to allow medical–psychiatry units to be used for patients in need of acute care; moreover, this will facilitate shorter admissions and successful operation within integrated delivery systems.

Psychosomatic Medicine and Consultation-Liaison Psychiatry

Kornfeld[81] has written an elegant review on the impact of C-L psychiatry on medical care in general hospitals. He surveyed, among others, the major contributions of Hackett and Cassem, Frasure-Smith, and Reich in psychocardiology; his own team in helping to understand

why some patients want to sign out against medical advice; Sutherland, Holland, Oken, and Spiegel in psychooncology; Abrams, Denour, Levy, and Viederman in psychonephrology; Robinson in poststroke syndromes; Perry in HIV care; and Musselman on the relationship between interferon and depression. He then recounted the effects of C-L psychiatry on cost-benefit analyses, medical teaching, clinical ethics, end-of-life care, and clinical genetics. He concluded that psychosomatic medicine through C-L psychiatry has substantially influenced medical practice for the better, and he predicted that the field will flourish especially as medicine becomes increasingly technological. Indeed, formal added qualifications in the subspecialty field of psychosomatic medicine are now available from the American Board of Medical Specialties and fellowship programs in psychosomatic medicine are now accredited by the Accreditation Council for Graduate Medical Education, signifying the maturation of this subspecialty.

Here at MGH, advances in the psychopharmacology of medical psychiatry patients are worth noting. The use of intravenous (IV) haloperidol for agitated delirium, the use of methylphenidate for depression in medically ill patients, and the first-line use of IV lorazepam for catatonic states were pioneered and then advocated by MGH consulting psychiatrists; these have become part of standard medical practice.[82–84]

Alert and well-trained consulting psychiatrists will continue to make key contributions to our understanding of pathophysiology and therapeutics. More and more will be learned from clinical experience and from research about how the visceral paralimbic and limbic brain influences human disease processes, and vice versa. Take the functional gastrointestinal disorders, for example. Up to 50% of all patients who present with gastrointestinal complaints have no known pathophysiologic basis for their complaints or have complaints that are out of proportion to their physiologic abnormalities.[85] In the future, the intricate interrelationship between the intrinsic enteric nervous system of the gut and the extrinsic peripheral and central nervous systems will be better understood, thereby improving our ability to manage these painful and costly disorders. Consulting psychiatrists have the skill set and knowledge of both the brain and the body to make major contributions in this effort.

In an environment of cost-cutting in the general hospital, consulting psychiatrists also play important roles on multidisciplinary teams, identifying and taking care of the medical inpatients with the highest utilization, specifically, those who commonly have psychiatric co-morbidity.[86] The drive toward shorter hospital stays has propelled research into ways of identifying high-utilizers of medical and psychiatric care at the time of admission and of minimizing their impact on the health care system.[87–92] Using screening instruments and red flags at the time of admission (e.g., based on physician and nurse predictions, disease or treatment type, frequency of doctor visits, number of medications, noncompliance, mobility, frailty, negative health behaviors, and biopsychosocial stressors, among others), multidisciplinary teams can identify high-utilizers early in their hospital stay and provide them with complex care coordination and case management in an effort to improve their quality of care and to prevent obstacles to discharge (such as lack of a safe home, lack of family or social support, lack of insurance, and dementia and need for guardianship, among others).

Characteristically, the high-utilizers tend to have multiple chronic medical and psychiatric co-morbidities and are best served by integrated interdisciplinary care. Here at MGH, a multidisciplinary medical team called *Team 5* has been established with full-time medical, C-L psychiatry, and case management staff specialized in treating medical inpatients at risk for long LOS (defined as longer than 20 days, compared to the hospital's average LOS of less than 6 days). Team 5 admits medical inpatients (directly and as transfers from other inpatient teams) at risk for long LOS, identified by a number of characteristics, including psychosocial stressors, substance abuse, and previous failed discharge plans, among others similar to those described earlier.[93] In 2007, Team 5 discharged more than one third of the high-utilizers before day 20 and allowed 200 additional inpatient medical admissions during the fiscal year.

Outpatient Psychosomatic Medicine and Consultation–Liaison Psychiatry

As general hospitals shorten medical admissions and shift more care to observation, nonacute settings, and ambulatory settings, traditional inpatient C-L activities will need to shift as well. In many cases, this will require locating these services within PCP groups.

Approximately 6% of all patients receive psychiatric services within the general medical sector. In addition, other patients who present for medical care have undiagnosed or undertreated psychiatric or substance-abuse disorders. In situations in which PCPs are financially at risk for all medical services, the ability of outpatient C-L psychiatrists to offset unneeded medical utilization will be important in reducing the cost of care and improving outcome.

The co-location of psychiatrists who are able to provide immediate consultation to PCPs in a variety of non-inpatient settings, while caring for patients in the specialty care sector, will be important for the further development of medical psychiatry. Medical psychiatrists are also performing teleconsultations (i.e., telepsychiatry) and using computer-based systems to provide immediate consultations to a larger network of PCPs and their patients at risk.

Telepsychiatry permits psychiatrists with specialized knowledge to reach previously underserved populations, especially in geographic areas lacking available psychiatric care, and has been shown to be as effective as in-person sessions for psychiatric and psychosomatic consultation, as well as to assess and treat conditions ranging from depression and obsessive–compulsive disorder to schizophrenia.[94–100] Patients enrolled in studies of telepsychiatry have reported equal satisfaction with in-person treatments. Teleconsultation services allow PCPs to consult with psychiatrists in real time, while their patients are still in their office.

In Massachusetts, for example, pediatricians can access child psychiatry consultation services through the state-funded Massachusetts Child Psychiatry Access Project (MCPAP).[100] MCPAP provides all pediatricians in the state with timely, cost-free access to child psychiatry consultation and can assist with transitioning to ongoing behavioral health care. Composed of teams of child psychiatrists, social

workers, and care coordinators and coordinated through regional hospitals (psychiatric departments) including ours, MCPAP can provide live telephone consultation to pediatricians (available via a paging system), referrals to follow-up mental health care, and educational activities for pediatricians. With 96% of pediatricians in Massachusetts enrolled in MCPAP as of June 2008, this service has helped meet the psychiatric needs of children and adolescents across the state.

PSYCHIATRIC NEUROSCIENCE

Looking forward to the future of psychiatry, in the best tradition of the medical model, pathophysiology-based diagnostic entities will be ascertained through history and examination, as well as more direct tests of brain structure and function (e.g., neuroimaging tests) and by probes of genotype. Thus, the diagnostic process and classification system in psychiatry will inevitably evolve in tandem, incorporating contemporary advances in psychiatric neuroscience.[101]

The emergence of contemporary neuroimaging techniques has provided a new class of information, allowing characterization of regional brain activity or chemistry in time and in three dimensions of space.[102] Investigators have come to realize that psychiatric diseases are not simply reducible to a three-dimensional map of generic regional brain dysfunction. Rather, neuroimaging will help to characterize pathophysiology in terms of dysfunctional distributed networks and provide for multidimensional assessments of computational deficits at any given locus.

Psychiatric neuroscience in the 21st century will continue to rely heavily on neurotransmitter pharmacology, as well as on the newly found power of neuroimaging methods, to establish phenotypes at the level of the brain. This will accompany a progressive focus on molecular biology, which is necessary to understand the genetic and epigenetic bases of resiliencies and selected vulnerabilities, as well as the presynaptic and postsynaptic and second-messenger processes that mediate neural health and dysfunction.

Implications for Psychiatric Treatment in the General Hospital

Developing valid and reliable predictors of treatment response will enhance treatment efficacy. If such predictors can be gleaned from easily accessible clinical information (e.g., age, gender, and constellation of symptoms), this would be most cost-effective. However, it may be that the most powerful predictors of treatment response will be ascertained via more fine-grained probes of brain function, such as those obtained via neuroimaging or pharmacogenomic laboratory testing. Already, brain-imaging studies have produced preliminary findings that suggest that particular brain activity profiles predict antidepressant and anti-obsessional responses to medication.[103–104] Such predictors of treatment response will be most important in the context of candidate treatments that are of long duration, high cost, or great risk (e.g., anti-obsessional medication trials, electroconvulsive therapy [ECT], or neurosurgical treatment).[105] Reliable predictors of bad outcomes can be just as valuable as reliable predictors of treatment success. Pharmacogenomic blood tests, for example, may soon offer the possibility of predicting adverse reactions (such as agranulocytosis from clozapine or metabolic syndrome from antipsychotics) before treatment is initiated.[106]

New Concepts in Somatic Therapies

As we discover the core pathophysiology of particular diseases, optimal therapies might include a capacity to direct medications to specific cell types or brain regions. It is difficult to know whether or not transplantation methods will evolve into useful interventions for psychiatric conditions. To date, this strategy has been adopted as a means to compensate for gross degeneration, such as in Parkinson's disease.[107]

Advances in psychiatric neurosurgical treatments have accelerated over the past decade. Vastly different from the crude free-hand lobotomies of the mid-20th century, much-refined stereotactic procedures have emerged in the last 25 years, culminating in noninvasive ablative radiosurgical applications using the gamma knife.[108] Developed initially for the treatment of epilepsy, vagus nerve stimulation (VNS) received approval from the U.S. Food and Drug Administration (FDA) in 2005 as an adjunctive treatment for treatment-resistant depression in patients who have failed multiple trials of antidepressant medication.[109] Deep brain stimulation methods have been adapted for use in psychiatric conditions, receiving FDA approval for treating severe, intractable cases of obsessive-compulsive disorder (OCD) in 2009. Paralleling advances in surgical treatment for Parkinson's disease, deep brain stimulation promises the potential for adjustable and reversible means of modulating brain function and hence ameliorating psychiatric symptoms, including depression and cognitive impairment, among others.[110]

Over the next decade, the promise of transcranial magnetic stimulation as an alternative to ECT for treatment-resistant depression will continue to be rigorously tested.[111–113] In 2008, the FDA passed the first approval of a transcranial magnetic stimulation device for treatment-resistant depression in patients who had failed one trial of antidepressant medication. Although it is appealing to propose that localized, noninvasive brain stimulation could provide advantages in terms of efficacy and adverse effects (compared to ECT), this remains a source of uncertainty, debate, and research. Certainly, advances in our understanding of pathophysiology will help guide the study of this potential treatment modality.

BUILDING INTEGRATED DELIVERY SYSTEMS

It will become progressively more important that occupation of general hospital psychiatric beds be increasingly focused on cases that require highly integrated medical and psychiatric care, because these units carry inherently higher direct and indirect costs, which are often poorly compensated by current public and private payers. Given that the general hospital sector admits the largest number of acute psychiatric patients, it will be important to evolve a care system that can link such units across regions to free-standing psychiatric hospitals for patients who require

inpatient care but are without such complex clinical needs. This will be essential as a matter of cost efficiency given the lower costs of freestanding hospitals. Due to the unique demands for consultation and emergency services in general hospitals, as well as the close linkage to other physicians, cost and reimbursement systems supporting the entire system of care will be critical. Free-standing psychiatric hospitals should become progressively better positioned to offer efficient, high-quality specialty psychiatric services by virtue of greater numbers of beds that can be specialized. Further, care within modern free-standing psychiatric hospitals must evolve to incorporate the best practices and influences of medical psychiatry, including the direct provision of some general and specialty medical services, and to become progressively evidence-based in their treatment models.[27] This would help address one of the major reasons for the shift to general hospital psychiatry units, namely that psychiatry, as practiced in free-standing facilities, had distanced itself from the rest of medicine in the 19th and for most of the 20th centuries.

Managed care organizations (MCOs) are able to lower costs in part by controlling where the large number of patients they insure will receive care. In an environment in which the supply of hospital services (e.g., inpatient beds) is high and the demand for services is dropping (as in managed care), prices for care (e.g., hospital *per diems*) decline. In response to this concentration of buying power by payers, providers have formed integrated delivery systems.

The growth of integrated delivery systems allows the creation of a balance between the payers and providers. Also, integrated delivery systems allow the management of care to be returned to providers. Many integrated delivery systems organize around PCP groups or physician–hospital organizations. Such integrated delivery systems often place PCPs at financial risk (in a gatekeeper role) and discourage excessive care by specialists and hospitals.

How does medical psychiatry fare within these integrated delivery systems? In large measure, it depends on the available conditions in given localities. In some areas, separate psychiatric or behavioral health integrated delivery systems may be strong. If these are also areas where carve-out models of care are prominent among payers, the task facing medical psychiatrists may be more complex and difficult. Psychiatrists in these circumstances might need to fight a two-front war—building relationships with primary care while competing for carve-out contracts and internally reintegrating care. Given that a significant percentage of all primary care visits are psychiatric, psychiatrists need to be actively involved in creating integrated delivery systems and in educating payers, PCPs, and others about the suboptimal nature of disaggregated care. The development of medical or mental health homes, as discussed earlier, may be one future solution to fragmentation of care, but only if payment systems become more flexible and the full impact of psychiatric illness on medical costs is well understood.

MEDICAL PSYCHIATRY IN A MANAGED ENVIRONMENT

Medical psychiatrists have to struggle with a variety of tensions regarding how to provide effective care in the context of managed care.

As discussed earlier, medical–psychiatry units are under intense pressure to reduce hospital LOS. Often, clinicians must explain to cost-conscious reviewers why their patients who have recently been suicidal require continued hospitalization or why their elderly patients cannot safely receive the rest of their ECT on an ambulatory basis. MCOs, operating within a carve-out model (and thus eager to shift costs) might ask why they should pay for the care of a patient with post-stroke depression. When conflicts arise with reviewers, physicians should request a formal review by a physician who is board certified in psychiatry. Such physicians often have greater latitude in allowing extended stays for patients with complex medical–psychiatric illness. In other situations, patients might fall under a catastrophic case definition, which might allow greater flexibility of care.

National managed care benchmarks for average LOS or for days of inpatient care per 1000 covered members can reflect distinctly different psychiatric populations. It is important for clinical and administrative leadership in general hospitals to be aware of this population variability before agreeing to contract benchmarks or payments that can compromise patient care.

The efficacy of a medical–psychiatry service that operates in a carve-out environment requires careful education of payers, administrators, clinical leadership, and the general physician community. Because psychiatric illness is common in the primary care setting and because effective care requires the availability of psychiatric services, the lower cost of a mental health carve-out may be both short-lived and illusory, especially in a capitated environment. Unless these groups are aware of the impact of carve-out models, they will not be able to prevent the exclusion of psychiatrists from contracts or the erosion of clinical standards.

INTERNATIONAL MOVEMENT TOWARD PSYCHOSOMATIC MEDICINE

Most of the discussion has centered on the development of and challenges facing medical psychiatry (and general hospital psychiatry) in American psychiatric practice. In the 21st century, the economic pressures faced by psychiatry have worldwide significance in a global marketplace where historical and geographical divisions between countries grow increasingly irrelevant; however, each country's response to the pressures varies based on the systems of health care delivery in place, such as a traditionally employer-based insurance system in the United States versus a government-funded national health plan in the United Kingdom.

In spite of such differences, the international community has supported movements toward improving mental health care, particularly with efforts toward removing the stigma of mental illness, strengthening the human rights of persons with mental illness, acknowledging the worldwide burden of mental illness, and highlighting the inseparable relationship between psychiatric and medical illness. In a series of articles in *The Lancet*, representatives of the Lancet Global Mental Health Group called for a scaling up of evidence-based care for mental illness across the globe, especially in low-income and middle-income countries.[114–118] This advocacy followed from World Health Organization

research that identified mental disorders as a substantial contributor to the burden of disease worldwide, accounting for 13.5% of all disability-adjusted life-years (DALYs: the sum of years lived with disability plus years of life lost).

From the perspective of medical psychiatry, the *Lancet* articles highlight the bidirectional intersection between mental and physical illness: Mental and physical disorders are risk factors for and consequences of one another, and their co-morbid occurrence leads to significantly greater decrements in health than from one or more of the conditions alone and to resultant increases in health care costs. For example, Prince and colleagues[115] analyzed the relationships between mental disorders and health conditions (e.g., heart disease, stroke, diabetes, HIV/AIDs, malaria, tuberculosis, and infant mortality), and produced models to predict the public health effects of extending evidence-based treatments of mental illness: Treating 50% of maternal depression in Pakistan might prevent 13,800 cases of infant stunting and save nearly $2 million per year.[115]

No matter the type of health care system in place, the costs of fragmented health care are felt across the globe, including as a substantial barrier to expanding the availability of psychiatric care. As highlighted by the *Lancet* series, medical psychiatrists need to play an essential role in guiding the integration of psychiatric care into primary health care as a means of improving global psychiatric services. Such efforts will require close attention to the deep levels of stigma that surround psychiatric illness, especially in more traditional cultures, and the need to place the care of mental illness on a strong evidence and biomedical basis. Medical psychiatrists are ideally suited to act as trainers, supervisors, researchers, advocates, and leaders for this process.

SUMMARY AND CONCLUSIONS

As we face the future, we can anticipate continuing pressures on general hospital services that will require local, national, and international responses. It is unlikely that pressures to decrease LOS, to admit only sicker patients, or to respond to the competition inherent in managed care will diminish. In some locations, general hospitals may be asked to assume more responsibilities for state hospital care. It is likely that overall economic pressures will require a coherent system of care that might, with local variations, include private psychiatric hospitals, state hospitals, and outpatient and partial hospital functions as well as integration with the general medical care system. General hospital inpatient services might have to offer involuntary locked care or other specialized psychiatric units and emphasize attending physician involvement and daily walk-rounds. Developments in the neurosciences are likely to enhance the role of medical–psychiatry physician leadership.

The decision about how much general hospital psychiatric services should specialize will be affected by the range of psychiatric and medical services available in a particular area. Affiliation agreements between private and general hospital units, as well as the types of general hospital units in a community, will also affect these decisions. As pressures intensify from large managed care contracts to provide extensive integrated systems of care, general hospital psychiatric services may be forced to provide specialty medical–psychiatric or psychiatric services for more severely ill populations. Such networking arrangements could create fiscal risks for the care of patients with combined medical and psychiatric illness because these patients might not be easily discharged into available aftercare resources. When constructing integrated systems, we need to attend to the continuity of care and minimize the number of transitions between providers.

The concept of the general hospital developed in the 19th and early 20th centuries in response to advances in medical science, urbanization, and economic forces that surrounded the practice of medicine.[119] It was not until the early 1930s that a similar movement in psychiatry began, bringing psychiatry into the general hospital. Beginning in the 1930s,[120] general hospital psychiatry was poised for the rapid growth of the post-war years that was to make it the dominant institution in American psychiatry.

The entry of psychiatry into the general hospital meant more than a change of locale. It meant a shift from a "moral" to a medical model of psychiatric illness. It was a shift from methods of investigation and treatment that ran counter to the ethos of the general hospital and academic medicine to methods that were consonant with it. Psychiatry's entry into the general hospital brought it closer to the thinking of medicine, which was transforming illness into a treatable and comprehensible phenomenon.

The period that lies ahead will provide great opportunities for general hospital psychiatry in training, models of clinical care, and medical–psychiatric treatment and research. Advances in neurobiology and psychopharmacology, as well as the broadening clinical population of general hospital psychiatry, will make it the setting in which the most sophisticated and comprehensive psychiatric care can and should take place. In this era of growing efficacy and research, attention to these opportunities and to the pressures outlined herein is crucial for the further development and viability of medical psychiatry, of general hospital psychiatry, and of psychiatry as a whole.
