Handbook of General Hospital Psychiatry

SIXTH EDITION

Theodore A. Stern, M.D.
Endowed Professor of Psychiatry in the Field of
Psychosomatic Medicine/Consultation
Harvard Medical School;
Professor of Psychiatry, Harvard Medical School;
Psychiatrist and Chief, Psychiatric Consultation Service
Massachusetts General Hospital
Boston, Massachusetts

Gregory L. Fricchione, M.D.
Professor of Psychiatry, Harvard Medical School;
Associate Chief of Psychiatry and Director, Division of Psychiatry and Medicine
Massachusetts General Hospital
Boston, Massachusetts

Ned H. Cassem, M.A., Ph.L., M.D., S.J., B.D.
Professor of Psychiatry, Harvard Medical School;
Psychiatrist
Massachusetts General Hospital
Boston, Massachusetts

Michael S. Jellinek, M.D.
Professor of Psychiatry, Harvard Medical School;
President, Newton Wellesley Hospital
Newton Lower Falls, Massachusetts;
Chief, Child Psychiatry
Massachusetts General Hospital
Boston, Massachusetts

Jerrold F. Rosenbaum, M.D.
Stanley Cobb Professor of Psychiatry, Harvard Medical School;
Psychiatrist-in-Chief
Massachusetts General Hospital
Boston, Massachusetts

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assumes any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contributing Authors

Annah N. Abrams, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Associate Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Menekse Alpay, M.D.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Jonathan E. Alpert, M.D., Ph.D.
Joyce R. Tedlow Associate Professor of Psychiatry, Harvard Medical School; Associate Chief of Psychiatry for Clinical Services, Associate Director, Depression Clinical and Research Program, Massachusetts General Hospital, Boston, Massachusetts

BJ Beck, M.S.N., M.D.
Assistant Clinical Professor, Harvard Medical School; Psychiatrist, Robert B. Andrews Unit, Massachusetts General Hospital, Boston, Massachusetts; Vice President for Medical Affairs, Beacon Health Strategies, Woburn, Massachusetts

Anne E. Becker, M.D., Ph.D., Sc.M.
Associate Professor of Social Medicine, Department of Global Health and Social Medicine; Associate Professor of Psychiatry, Harvard Medical School; Vice Chair, Department of Global Health and Social Medicine, Harvard Medical School; Director, Eating Disorders Clinical and Research Program, Massachusetts General Hospital, Boston, Massachusetts

Eugene V. Beresin, M.A., M.D.
Professor of Psychiatry, Harvard Medical School; Director of Child and Adolescent Psychiatry Residency Training, Massachusetts General Hospital/McLean Hospital; Co-Director, Massachusetts General Hospital Center for Mental Health and Media; Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Mark A. Blais, Psy.D.
Associate Professor of Psychology in Psychiatry, Harvard Medical School; Associate Chief of Psychology, Massachusetts General Hospital, Boston, Massachusetts

Ilana M. Braun, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Director of Cancer-Related Fatigue Clinic, Massachusetts General Hospital, Boston Massachusetts

Rebecca W. Brendel, M.D., J.D.
Assistant Professor of Psychiatry, Harvard Medical School; Assistant Director for Forensic Psychiatry Fellowship Program, Massachusetts General Hospital, Boston, Massachusetts

Megan Moore Brennan, M.D.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

George Bush, M.D., M.M.Sc.
Associate Professor of Psychiatry, Harvard Medical School; Director of Neuroimaging Research, Benson-Henry Institute for Mind-Body Medicine at Massachusetts General Hospital; Assistant Director of Psychiatric Neuroimaging Research, Massachusetts General Hospital, Boston, Massachusetts

Jason P. Caplan, M.D.
Chief of Psychiatry, St. Joseph's Hospital and Medical Center, Phoenix, Arizona; Vice-Chair of Psychiatry, Creighton University School of Medicine, Omaha, Nebraska

Paolo Cassano, M.D., Ph.D.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Ned H. Cassem, M.A., Ph.L., M.D., S.J., B.D.
Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

T. Atilla Ceranoglu, M.D.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital; Child and Adolescent Psychiatry, Massachusetts General Hospital, Shriners Hospitals for Children, Boston, Massachusetts

Lee S. Cohen, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Director, Perinatal and Reproductive Psychiatry Clinical Research Program, Massachusetts General Hospital, Boston, Massachusetts

M. Cornelia Cremens, M.D., M.P.H.
Assistant Professor of Psychiatry, Harvard Medical School; Geriatric Psychiatrist, Massachusetts General Hospital Senior Health Practice, Geriatric Psychopharmacology, Massachusetts General Hospital, Boston, Massachusetts

Cristina Cusin, M.D.
Clinical Fellow in Psychiatry, Harvard Medical School; Resident in Psychiatry, Massachusetts General Hospital/ McLean Hospital, Boston, Massachusetts

Abigail L. Donovan, M.D.
Instructor in Psychiatry, Harvard Medical School; Assistant Psychiatrist and Associate Director, Acute Psychiatry Service, Massachusetts General Hospital, Boston, Massachusetts

Daniel H. Ebert, M.D., Ph.D.
Instructor in Neurobiology, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Lucy A. Epstein, M.D.
Assistant Professor of Clinical Psychiatry, Columbia University, New York, New York

William E. Falk, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Director, Outpatient Geriatric Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Maurizio Fava, M.D.
Professor of Psychiatry, Harvard Medical School; Executive Vice-Chair Department of Psychiatry and Director of the Depression Clinical and Research Program, Massachusetts General Hospital, Boston, Massachusetts

Carlos Fernandez-Robles, M.D.
Instructor in Psychiatry, Harvard Medical School; Attending Psychiatrist, Psychiatry Oncology Service, Psychiatry Consult Service, and Somatic Therapies Service, Massachusetts General Hospital, Boston, Massachusetts

Christine T. Finn, M.D.
Assistant Professor of Psychiatry, Dartmouth Medical School; Director of Emergency Services, Dartmouth Medical School; Assistant Clinical Geneticist, Harvard-Partners Center for Genetics and Genomics, Massachusetts General Hospital, Boston, Massachusetts

Marlene P. Freeman, M.D.
Lecturer in Psychiatry, Harvard Medical School; Psychiatrist, Perinatal and Reproductive Psychiatry, Clinical Research Program, Massachusetts General Hospital, Boston, Massachusetts

Oliver Freudenreich, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Director, First Episode and Early Psychosis Program, Massachusetts General Hospital, Boston, Massachusetts

Gregory L. Fricchione, M.D.
Professor of Psychiatry, Harvard Medical School; Associate Chief of Psychiatry and Director, Division of Psychiatry and Medicine, Massachusetts General Hospital, Boston, Massachusetts

David R. Gastfriend, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Donald C. Goff, M.D.
Professor of Psychiatry, Harvard Medical School; Director, Schizophrenia Program, Massachusetts General Hospital, Boston, Massachusetts

Christopher Gordon, M.D.
Assistant Clinical Professor of Psychiatry, Harvard Medical School; Assistant Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts; Medical Director and Vice President, Clinical Services, Advocates, Inc., Framingham, Massachusetts

Donna B. Greenberg, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Program Director, Psychiatric Oncology, Director, Medical Student Education, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Anne F. Gross, M.D.
Clinical Fellow, Department of Psychiatry, Harvard Medical School; Resident, Department of Psychiatry, Massachusetts General Hospital/McLean Hospital, Boston, Massachusetts

James E. Groves, M.D.
Associate Clinical Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

†Thomas P. Hackett, M.D.
Former Eben S. Draper Professor of Psychiatry, Harvard Medical School; Chief of Psychiatry, Massachusetts General Hospital (1976–1988), Boston, Massachusetts

Stephan Heckers, M.D.
James G. Blakemore Professor in Psychiatry, Chairman, Department of Psychiatry, Vanderbilt University; Psychiatrist-in-Chief, Vanderbilt Psychiatric Hospital, Nashville, Tennessee

David C. Henderson, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Director, Chester M. Pierce, MD Division of Global Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Jeff C. Huffman, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Medical Director, Inpatient Psychiatric Service, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Dan V. Iosifescu, M.D., M.Sc.
Associate Professor of Psychiatry, Harvard Medical School; Director of Translational Neuroscience, Depression Clinical and Research Program and Site Director, Bipolar Trials Network, Massachusetts General Hospital, Boston, Massachusetts

†Deceased.

Esther Jacobowitz Israel, M.D.
Assistant Professor of Pediatrics, Harvard Medical School; Associate Chief, Pediatric Gastroenterology and Nutrition, Massachusetts General Hospital, Boston, Massachusetts

James L. Januzzi, Jr., M.D.
Associate Professor of Medicine, Harvard Medical School; Director, Cardiac Intensive Care Unit and Cardiology Division, Massachusetts General Hospital, Boston, Massachusetts

Michael S. Jellinek, M.D.
Professor of Psychiatry, Harvard Medical School; President, Newton Wellesley Hospital, Newton Lower Falls, Massachusetts; Chief, Child Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Nicholas Kontos, M.D.
Instructor in Psychiatry, Harvard Medical School; Director of Transplantation Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Karsten Kueppenbender, M.D.
Instructor in Psychiatry, Harvard Medical School; Assistant Psychiatrist, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Brian P. Kurtz, M.D.
Clinical Fellow in Psychiatry, Harvard Medical School; Fellow in Child and Adolescent Psychiatry, Massachusetts General Hospital/McLean Hospital, Boston, Massachusetts

Isabel T. Lagomasino, M.D., M.S.H.S.
Assistant Professor of Psychiatry and Behavioral Sciences, University of Southern California, Keck School of Medicine; Director, Adult Psychiatry Residency Training Program, LAC + USC Medical Center, Los Angeles, California

Boris A. Lorberg, M.D.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Bruce J. Masek, Ph.D.
Associate Professor of Psychology (Psychiatry), Harvard Medical School; Clinical Director, Child and Adolescent Outpatient Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Guy Maytal, M.D.
Instructor in Psychiatry, Harvard Medical School; Director, Urgent Care Psychiatry Service, Associate Director, Division of Outpatient Psychiatry,Palliative Care Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

†Edward Messner, M.D.
Associate Clinical Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

David Mischoulon, M.D., Ph.D.
Associate Professor of Psychiatry, Harvard Medical School; Associate Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Anna C. Muriel, M.D., M.P.H.
Instructor in Psychiatry, Harvard Medical School; Clinical Assistant in Psychiatry, Dana Farber Cancer Center, Boston, Massachusetts

George B. Murray, B.S., Ph.L., M.S., M.Sc., M.D., S.J.
Associate Professor of Psychiatry, Harvard Medical School; Senior Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Shamim H. Nejad, M.D.
Instructor in Psychiatry, Harvard Medical School; Director, Adult Burns and Trauma Surgery Psychiatry Consultation, Division of Psychiatry and Medicine, Massachusetts General Hospital, Boston, Massachusetts

Dana Diem Nguyen, Ph.D.
Research Specialist/Director of Operations, Potkin Research, University of California, Irvine, California

Ruta Nonacs, M.D., Ph.D.
Instructor in Psychiatry, Harvard Medical School; Assistant Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Dennis K. Norman, Ed.D.
Associate Professor of Psychology, Harvard Medical School; Chief of Psychology, Massachusetts General Hospital, Boston, Massachusetts

Sheila M. O'Keefe, Ed.D.
Instructor in Psychiatry, Harvard Medical School; Director of Psychology Training, Massachusetts General Hospital, Boston, Massachusetts

Michael W. Otto, Ph.D.
Professor of Psychology; Director, Center for Anxiety and Related Disorders, Boston University, Boston, Massachusetts

Brian A. Palmer, M.D., M.P.H.
Instructor in Psychiatry, Harvard Medical School; Staff Psychiatrist, McLean Hospital, Belmont, Massachusetts

George I. Papakostas, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Director, Treatment-Resistant Depression Studies, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Jennifer M. Park, M.D.
Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts; Walter Reed Army Medical Center, Washington, DC

Lawrence Park, M.A., M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Roy H. Perlis, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Director, Pharmacogenomics Research, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

†Deceased.

Assistant Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Benjamin C. Silverman, M.D.
Clinical Fellow in Psychiatry, Harvard Medical School; Fellow in Medical Ethics, Division of Medical Ethics, Harvard Medical School, Resident, Massachusetts General Hospital/ McLean Hospital Adult Psychiatry; Residency Program, Boston, Massachusetts

Patrick Smallwood, M.D.
Assistant Professor of Psychiatry, University of Massachusetts Medical School; Medical Director, Psychosomatic Medicine and Emergency Mental Health, University of Massachusetts Medical Center, Worcester, Massachusetts

Felicia A. Smith, M.D.
Assistant Professor of Psychiatry, Harvard Medical School; Director, Acute Psychiatry Service, Massachusetts General Hospital, Boston, Massachusetts

Jordan W. Smoller, M.D., Sc.D.
Associate Professor of Psychiatry, Harvard Medical School; Director, Psychiatric Genetics Program in Mood and Anxiety Disorders, and Assistant Vice Chair, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Robert M. Stern, M.D.
Director, Behavioral Health Services and Chair, Department of Psychiatry, Emerson Hospital, Concord, Massachusetts

Theodore A. Stern, M.D.
Endowed Professor of Psychiatry in the Field of Psychosomatic Medicine/Consultation, Harvard Medical School; Professor of Psychiatry, Harvard Medical School; Psychiatrist and Chief, Psychiatric Consultation Service, Massachusetts General Hospital, Boston, Massachusetts

Jonathan R. Stevens, M.D., M.P.H.
Instructor in Psychiatry, Harvard Medical School, Clinical Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts; Child Psychiatrist, North Shore Medical Center, Salem, Massachusetts

Thomas D. Stewart, M.D.
Associate Clinical Professor of Psychiatry, Yale University School of Medicine; Consultant Psychiatrist, Yale New Haven Hospital, New Haven, Connecticut

Frederick J. Stoddard, Jr., M.D.
Associate Clinical Professor of Psychiatry, Harvard Medical School; Chief of Psychiatry, Shriners Burns Hospital; Senior Attending Psychiatrist, Massachusetts General Hospital Burn Service, Boston, Massachusetts

Joan M. Stoler, M.D.
Assistant Professor of Pediatrics, Harvard Medical School; Assistant Pediatrician, Medical Geneticist, Massachusetts General Hospital, Boston, Massachusetts

Paul Summergrad, M.D.
Dr. Francis S. Arkin Professor and Chairman, Department of Psychiatry; Professor of Medicine, Tufts University School of Medicine; Psychiatrist-in-Chief, Tufts Medical Center; Chairman, Tufts Medical Center Physicians Organization, Boston, Massachusetts

Owen S. Surman, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Jennifer J. Thomas, Ph.D.
Clinical and Research Fellow, Harvard Medical School; Massachusetts General Hospital/McLean Hospital, Boston, Massachusetts

Adrienne O. van Nieuwenhuizen, B.A.
Research Coordinator, Depression Clinical and Research Program, Massachusetts General Hospital, Boston Massachusetts

Adele C. Viguera, M.D., M.P.H.
Assistant Professor of Psychiatry, Harvard Medical School; Associate Director, Perinatal and Reproductive Psychiatric Program, Massachusetts General Hospital, Boston, Massachusetts; Staff Psychiatrist; Cleveland Clinic Neurological Institute, Cleveland, Ohio

Betty Wang, M.D.
Instructor in Psychiatry, Harvard Medical School; Assistant Psychiatrist, Massachusetts General Hospital, Boston, Massachusetts

Marlynn Wei, M.D., J.D.
Clinical Fellow in Psychiatry, Harvard Medical School; Adult Psychiatry, Resident at Massachusetts General Hospital/McLean Hospital, Boston, Massachusetts

Avery D. Weisman, M.D.
Professor Emeritus of Psychiatry, Harvard Medical School; Senior Psychiatrist (Retired), Massachusetts General Hospital, Boston, Massachusetts

Anthony P. Weiss, M.D., M.B.A.
Assistant Professor of Psychiatry, Harvard Medical School; Director of Quality Management, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Charles A. Welch, M.D.
Instructor in Psychiatry, Harvard Medical School; Psychiatrist, Director, Somatic Therapies Service, Massachusetts General Hospital, Boston, Massachusetts

Ilse R. Wiechers, M.D., M.P.P.
Clinical Fellow in Psychiatry, Harvard Medical School; Chief Resident, Acute Psychiatry Service, Massachusetts General Hospital, Boston Massachusetts

Marketa M. Wills, M.D.
Clinical Fellow in Psychiatry, Harvard Medical School; Psychiatry Resident, Massachusetts General Hospital, Boston, Massachusetts

Curtis W. Wittmann, M.D.
Instructor in Psychiatry, Harvard Medical School; Attending Psychiatrist, Acute Psychiatry Service, Staff Psychiatrist, Bipolar Clinical Research Program, Massachusetts General Hospital, Boston, Massachusetts

Jonathan L. Worth, M.D.
Instructor in Psychiatry, Harvard Medical School; Urgent Care Psychiatry Clinic, Massachusetts General Hospital, Boston, Massachusetts

Daniel J. Zimmerman, M.D.
Clinical Instructor of Psychiatry, New York University School of Medicine; Inpatient Attending Psychiatrist, Bellevue Hospital Center, New York, New York

Preface

This sixth edition, revised and substantially expanded, was put together by a stalwart group of general hospital psychiatrists. It was designed to help busy practitioners care for patients on medical and surgical floors and in outpatient practices filled by co-morbid medical and psychiatric illness. The chapters, which cover specific illnesses and care settings, were crafted for readability. Moreover, clinical vignettes strategically placed throughout the book were meant to act as a nidus upon which clinical pearls would grow.

Consultation psychiatry, recently minted as a new subspecialty called *psychosomatic medicine*, involves the rapid recognition, evaluation, and treatment of psychiatric problems in the medical setting. Practitioners of psychosomatic medicine must also manage psychiatric reactions to medical illness, psychiatric complications of medical illness and its treatment, and psychiatric illness in those who suffer from medical or surgical illness. Because problems related to the affective, behavioral, and cognitive (the "ABCs") realms of dementia, depression, anxiety, substance abuse, disruptive personalities, and critical illness are faced on a daily basis, emphasis has been placed on successful strategies for their management by the consultant and by the physician of record.

Eight new chapters were added to this edition, and previously written chapters were revised and updated. Additions include discussions of the doctor–patient relationship, the psychiatric interview, sexual disorders and sexual dysfunction, emergency consultations, caring for children when a parent is ill, the rigors of psychiatric practice, quality assurance and quality improvement, and psychiatric research in the general hospital.

This book would not have been possible were it not for the steady hands of our acquisitions editor at Elsevier, Adrianne Brigido, and senior project manager, Cheryl Abbott. At the Massachusetts General Hospital, Judy Byford and Elena Muenzen helped shepherd us through thousands of emails, voice mails, FAXes, and photocopies associated with 54 chapters and scores of authors.

On behalf of the patients who suffer, we hope this edition improves the detection and treatment of psychiatric problems and brings much needed relief.

Nicholas Kontos, M.D.

PSYCHOSOMATIC MEDICINE

A keen interest in the relationship between the psyche and the soma has been maintained in medicine since early times, and certain ancient physicians (such as Hippocrates) have been eloquent on the subject. A search for the precise origins of *psychosomatic medicine* is, however, a difficult undertaking unless one chooses to focus on the first use of the term itself. Johann Heinroth appears to have coined the term *psychosomatic* in reference to certain causes of insomnia in 1818.[1] The word *medicine* was added to *psychosomatic* first by the psychoanalyst Felix Deutsch in the early 1920s.[2] Deutsch later emigrated to the United States with his wife Helene, and both worked at Massachusetts General Hospital (MGH) for a time in the 1930s and 1940s.

Three streams of thought flowed into the area of psychosomatic medicine, providing fertile ground for the growth of general hospital and consultation psychiatry.[3,4] The psychophysiologic school, perhaps represented by the Harvard physiologist Walter B. Cannon, emphasized the effects of stress on the body.[5] The psychoanalytic school, best personified by the psychoanalyst Franz Alexander, focused on the effects that psychodynamic conflicts had on the body.[6] The organic synthesis point of view, ambitiously pursued by Helen Flanders Dunbar, tried with limited success to unify the physiologic and psychoanalytic approaches.[7]

HISTORY

The history of general hospital psychiatry in the United States in general,[8] and consultation–liaison (C-L) psychiatry in particular,[9] has been extensively reviewed elsewhere. For those interested in a more detailed account of both historic trends and conceptual issues of C-L psychiatry, the writings of Lipowski[10–15] are highly recommended.

In years gone by, controversy surrounded the use of the term *liaison* in C-L psychiatry. We believed that using the term *liaison* was confusing and unnecessary. It was confusing because no other service in the practice of medicine employed the term for its consultation activities. In addition, the activity it referred to—to teach nonpsychiatrists psychiatric and interpersonal skills—is done as a matter of course during the routine consultation. The term *liaison*, although still used, has to some extent fallen out of fashion.

In March 2003, the American Board of Medical Specialties unanimously approved the American Board of Psychiatry and Neurology's (ABPN's) issuance of subspecialty certification in psychosomatic medicine. The first certifying examinations were administered in 2005. As of 2009, the completion of an American Board of Medical Specialties–certified fellowship in psychosomatic medicine became mandatory for all who wish to sit for that examination. The achievement of subspecialty status for psychosomatic medicine is the product of nearly 75 years of clinical work by psychiatrists on medical–surgical units, an impressive accumulation of scholarly work contributing to the psychiatric care of general medical patients, and determined intellectual and organizational efforts by the Academy of Psychosomatic Medicine (APM). The latter's efforts included settling on the name *psychosomatic medicine* after *C-L psychiatry* met with resistance from the ABPN during the first application for subspecialty status in 1992.[16] *Psychosomatic medicine* was ultimately felt to best capture the field's heritage and work on mind–body relationships, though there remains controversy over the nebulous boundaries this name implies.[17]

When the history of consultation psychiatry is examined, 1975 seems to be the watershed year. Before 1975, scant attention was given to the work of psychiatrists in medicine. Consultation topics were seldom presented at the national meetings of the American Psychiatric Association. Even the American Psychosomatic Society, which has many

strong links to consultation work, rarely gave more than a nod of acknowledgment to presentations or panels discussing this aspect of psychiatry. Residency training programs on the whole were no better. In 1966, Mendel[18] surveyed training programs in the United States to determine the extent to which residents were exposed to a training experience in consultation psychiatry. He found that 75% of the 202 programs surveyed offered some training in consultation psychiatry, but most of it was informal and poorly organized. Ten years later, Schubert and McKegney[19] found only "a slight increase" in the amount of time devoted to C-L training in residency programs. Today, C-L training is mandated by the ABPN as part of general adult psychiatry training.

Several factors account for the growth of C-L psychiatry in the last quarter of the 20th century. One was the leadership of Dr. James Eaton, former director of the Psychiatric Education Branch of the National Institute of Mental Health (NIMH). Eaton provided the support and encouragement that enabled the creation of C-L programs throughout the United States. Another reason for this growth was the burgeoning interest in the primary care specialties, which required skills in psychiatric diagnosis and treatment. Finally, parallel yet related threats to the viability of the psychiatric profession from third-party payers and nonphysician providers were an incentive to (re-)medicalize the field. Although creation of the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (DSM-III), and increased pharmacotherapy are the two most obvious upshots of this trend,[20,21] an elevated profile for C-L psychiatry also emerged as uniquely tailored to the psychiatrist's skill set. For these reasons, and because of expanding knowledge in neuropsychiatry, consultation work has enjoyed a renaissance.

The origins of organized interest in the mental life of patients at the MGH dates back to 1873, when James Jackson Putnam, a young Harvard neurologist, returned from his grand tour of German departments of medicine to practice his specialty. He was awarded a small office under the arch of one of the famous twin flying staircases of the Bulfinch building. The office was the size of a cupboard and was designed to house electrical equipment. Putnam was given the title of "electrician." One of his duties was to ensure the proper function of various galvanic and faradic devices then used to treat nervous and muscular disorders. It is no coincidence that his office came to be called the "cloaca maxima" by Professor of Medicine George Shattuck. This designation stemmed from the fact that patients whose maladies defied diagnosis and treatment—in short, the "crocks"—were referred to young Putnam. With such a beginning, it is not difficult for today's consultation psychiatrist to relate to Putnam's experience and mission. Putnam eventually became a professor of neuropathology and practiced both neurology and psychiatry, treating medical and surgical patients who developed mental disorders. Putnam's distinguished career, interwoven with the acceptance of Freudian psychology in the United States, is chronicled elsewhere.[22]

In the late 1920s, Dr. Howard Means, chief of medicine, appointed Boston psychiatrist William Herman to study patients who developed mental disturbances in conjunction with endocrine disorders. Herman's studies are hardly remembered today, although he was honored by having a conference room at the MGH named after him.

In 1934, a department of psychiatry took shape when Stanley Cobb was given the Bullard Chair of Neuropathology and granted sufficient money by the Rockefeller Foundation to establish a ward for the study of psychosomatic conditions. Under Cobb's tutelage, the department expanded and became known for its eclecticism and for its interest in the mind–brain relationship. A number of European emigrants fled Nazi tyranny and were welcomed to the department by Cobb. Felix and Helene Deutsch, Edward and Grete Bibring, and Hans Sachs were early arrivals from the continent. Erich Lindemann came in the mid-1930s and worked with Cobb on a series of projects, the most notable being his study of grief, which came as a result of his work with victims of the 1942 Coconut Grove fire.

When Lindemann became chief of the Psychiatric Service in 1954, the Consultation Service had not yet been established. Customarily, the resident assigned to night call in the emergency department saw all medical and surgical patients in need of psychiatric evaluation. This was regarded as an onerous task, and such calls were often set aside until after supper in the hope that the disturbance might quiet in the intervening hours. Notes in the chart were terse and often impractical. Seldom was there any follow-up. As a result, animosity toward psychiatry grew. To remedy this, Lindemann officially established the Psychiatric Consultation Service under the leadership of Avery Weisman in 1956. Weisman's resident, Thomas Hackett, divided his time between doing consultations and learning outpatient psychotherapy. During the first year of the consultation service, 130 consultations were performed. In 1958, the number of consultations increased to 370, and an active research program was organized that later became one of the cornerstones of the overall operation.

By 1960, a rotation through the Consultation Service had become a mandatory part of the MGH residency in psychiatry. Second-year residents were each assigned two wards. Each resident spent 20 to 30 hours a week on the Consultation Service for 6 months. Between 1956 and 1960, the service attracted the interest of fellowship students, who contributed postgraduate work on psychosomatic topics. Medical students also began to choose the Consultation Service as part of their elective in psychiatry during this period. From our work with these fellows and medical students, collaborative research studies were initiated with other services. Examples of these early studies are the surgical treatment of intractable pain,[23,24] the compliance of duodenal ulcer patients with their medical regimen,[25] post-amputation depression in the elderly patient,[15] emotional maladaptation in the surgical patient,[26–30] and the psychological aspects of acute myocardial infarction.[31,32]

By 1970, Hackett, then chief of the Consultation Service, had one full-time (postgraduate year [PGY]-IV) chief resident and six half-time (PGY-III) residents to see consultations from the approximately 400 house beds. A private Psychiatric Consultation Service was begun, to systematize consultations for the 600 private beds of the hospital. A Somatic Therapies Service began and offered electroconvulsive therapy to treat refractory conditions. Three fellows and a full-time faculty member were added to the roster in 1976. Edwin (Ned) Cassem became chief of the

Consultation Service, and George Murray was appointed director of a new fellowship program in psychosomatic medicine and consultation psychiatry. In 1995, Theodore Stern was named chief of the Avery Weisman Psychiatric Consultation Service. Now both fellows and residents take consultations in rotation from throughout the hospital. Our Child Psychiatry Division, composed of residents, fellows, and attending physicians, provides full consultation to the 40 beds of the MGH Hospital for Children.

In July 2002, Gregory Fricchione was appointed director of the new Division of Psychiatry and Medicine, with a mission to integrate the various inpatient and outpatient medical–psychiatry services at the MGH and its affiliates while maintaining the diverse characteristics and strengths of each unit. The division includes the Avery D. Weisman Psychiatry Consultation Service, the MGH Cancer Center, the Psychosocial Oncology Disease Center, the Transplant Consultation Service, the Trauma and Burns Psychiatry Service, the Women's Consultation Service, the Cardiovascular Health Center Service, the Behavioral Medicine Service, and the Spaulding Rehabilitation Hospital's Behavioral and Mental Health Service. Psychiatrists from this division also attend in the human immunodeficiency virus (HIV) outpatient unit and the gastroenterology clinic.

PATIENT CARE, TEACHING, AND RESEARCH

The three functions provided by any consultation service are patient care, teaching, and research.

Patient Care

At the MGH, between 10% and 13% of all admitted patients are followed by a psychiatrist; roughly 3500 initial consultations are performed each year. The problems discovered reflect the gamut of conditions listed in the DSM-IV[33]; however, the most common reasons for consultation are related to depression, delirium, anxiety, substance abuse, character pathology, dementia, somatoform disorders or medically unexplained symptoms, and the evaluation of capacity.

Patients are seen in consultation only at the request of another physician, who must write a specific order for the consultation. When performing a consultation, the psychiatrist, like any other physician, is expected to provide diagnosis and treatment. This includes defining the reason for the consultation; reading the chart; gathering information from nurses and family members when indicated; interviewing the patient; performing the appropriate physical and neurologic examinations; writing a clear clinical impression and treatment plan; ordering or suggesting laboratory tests, procedures, and medications; speaking with the referring physician when indicated; and making follow-up visits until the patient's problems are resolved, the patient is discharged, or the patient dies.

Interviewing style, individual to begin with, is further challenged and refined in the consultation arena, where the psychiatrist is presented with a patient who typically did not ask to be seen and who is often put off by the very idea that a psychiatrist has been called. In addition, the hospital room setting and the threat of acute illness might cause the patient to be either more or less forthcoming than under usual circumstances. The stigma of mental illness and the fear of any illness are universal; they are part of every physician's territory, and each psychiatrist learns to deal with them in a unique way. Residents learn to coax cooperation from such patients by trial and error, by self-understanding, and by observing role models rather than by observing formulas. Essential, however, are interest in the patient's medical situation and an approach that is comparable to that used by a rigorous and caring physician in any specialty. Each consultation can thus be viewed as an opportunity to provide care, to de-stigmatize mental illness, and to de-stigmatize psychiatry by personally representing it, via manner, tone, and examination, as a proper medical specialty.

Teaching

Many consultation psychiatrists believe that teaching psychiatry to medical and surgical house officers cannot be done on a formal basis. When teaching is formalized in weekly lectures or discussion groups, attendance invariably lags. More than 30 years ago, Lindemann, in an attempt to educate medical house officers about the emotional problems of their patients, enlisted the help of several psychiatric luminaries from the Boston area. A series of biweekly lectures was announced, in which Edward and Grete Bibring, Felix and Helene Deutsch, Stanley Cobb, and Carl Binger, among others, shared their knowledge and skills. In the beginning, approximately a fifth of the medical house officers attended. Attendance steadily dwindled in subsequent sessions until finally the psychiatry residents had to be required to attend so as to infuse the lecturers with enough spirit to continue. This might be alleged to illustrate disinterest or intimidation on the part of the nonpsychiatric staff, but we think that such didactics are simply too far removed (geographically and philosophically) from their day-to-day work.

We believe that teaching, to be most effective and reliable, is best done at the bedside on a case-by-case basis. Each resident is paired with an attending physician for bedside supervision, and all new patients are interviewed by our C-L attending staff. Residents teach as well. Medical students, neurology residents, and other visiting trainees are supervised by PGY-III residents, the chief resident, the fellows, and our attending staff. Twice weekly, rounds are held with Stern, the chief resident, and the rest of the service. In 90 to 120 minutes, follow-ups on current cases are presented and discussed, and new cases are presented by the consulting resident.

Before each group of residents begin their 4-month half-time rotation (in July, November, and March), they receive 25 introductory 45-minute lectures on practical topics in consultation (e.g., how to write the note, how to perform the neurologic or neuropsychological examination, the nature of psychotherapy in consultation, ruling out organic causes of psychiatric symptoms, diagnosing delirium and dementia, using psychotropic medications [e.g., psychostimulants, intravenous haloperidol] in the medically ill, assessing decisional capacity, performing hypnosis, and managing functional somatic symptoms). In concert with the orientation lecture series, we provide residents with relevant articles and with an annotated bibliography.[34] The overall curriculum we provide is quite

similar to that recommended by the APM's Task Force on Residency Training in C-L psychiatry.[35]

Fellows attend the rounds of the Fellows Consultation Service, with Murray (director emeritus) and Fricchione (director) presiding three times per week; they see patients at the bedside with senior attending staff including Cassem several times each week. Fellows have an additional 4 hours per week of didactic sessions with Murray on advanced topics of consultation psychiatry, psychosomatic medicine, and neuropsychiatry; they also have individual supervision with Fricchione and the associate fellowship director (John Querques) each week. The Fellowship Program in Consultation Psychiatry, under the leadership of Murray, celebrated its 30th anniversary in 2006; it has trained 99 fellows through June 2009. Many have gone on to direct C-L programs across the United States.

Each resident makes two formal presentations (i.e., a 45-minute review of a topic chosen by the resident, which is elaborated on by a senior discussant for 45 minutes) during the 4-month rotation. These weekly psychosomatic conferences not only produce presentations of high quality but also lead to improved speaking skills, occasional publications, and the beginning of specialized interests and expertise for the resident.[36–45]

In the past, Stern joined medical house staff for work rounds three times a week in the medical intensive care unit, and he ran "autognosis" rounds on a weekly basis from 1979 into the early 2000s.[46] At these rounds, the feelings of the medical house officers toward patients were examined so that patients could be managed more effectively. Since their inception, only two house officers have refused to attend.

Research

Research activity by the Consultation Service, besides answering important questions, builds bridges between medical specialties. When physicians from other services are involved in research planning and when there is dual authorship of published accounts, friendships are firmly bonded, and differences fade. The general hospital population provides such a cornucopia of research material that a consultation service would be lax or unresponsive not to take advantage of it. Many examples are cited in the chapters that follow.[47–56]

Small research projects are the cornerstone of larger ones. So long as generativity is held as a value, research need not be funded through federal or state agencies. Projects can be assigned as such to medical students during their month on the service. They can also be suggested to fellows for more extensive development over the course of the year. What begins as a project with results and conclusions to be presented at psychiatric grand rounds can, over a year, develop into a full-fledged publication. This, in turn, might be the starting point for a larger investigation.

A filing system should be designed to keep potential research materials readily accessible. Systems of computer-based records in consultation services have been described. Strain and associates have devised one of them, and it is now in use in a number of C-L services throughout the United States.[54,55]

Once the direction of the consultation team has been pointed toward research and publication, the results usually fall into line. One of the distressing roadblocks en route to publication is the poor writing skill of many physicians. One or two resource people who can serve as editors and teachers can be of great help. For more than 3 decades, we have held a biweekly writing seminar, in which members submit manuscripts that are reviewed by the seminar group and two senior members of our department (Dr. Stern and the late Mrs. Eleanor Hackett). All efforts seem worthwhile once the printed page is in the author's hand. When a service begins to develop a shelf of publications authored by various members of the team, a pride of accomplishment exists, and this compounds the excitement of the research and stimulates renewed academic effort.

NEW DIRECTIONS

The approval of psychosomatic medicine as a psychiatric subspecialty brings with it changes in many domains of our service. Interestingly, some of these are revivals of older patterns of service provision to various medical domains. Perhaps inevitably, subspecialization invites subsubspecialization. In decades past, particular staff members carved out sectors of the hospital as areas of interest/work (e.g., burns, surgery, medical intensive care, rehabilitation, cardiology, oncology, obstetrics, and gynecology). After a while, the pendulum swung toward a more global, general consultation service. In more recent years, the pendulum has swung back, with more formalized reentry of staff into many of these areas, as well as into some others (e.g., infectious disease, gastroenterology).

Connected with this trend, fueled by a robust literature,[57,58] and codified in the Accreditation Council for Graduate Medical Education requirements for psychosomatic medicine fellowship training is the provision of "outpatient consultation" to primary care settings. Recognizing the importance of this latter approach, we have attempted innovative approaches (e.g., telepsychiatry and urgent care availability) to be of help to our primary care colleagues and to better serve their population of patients in need of psychiatric assistance. All of these endeavors expand potential training experiences and academic opportunities and introduce new logistical challenges to the administration of consultation psychiatry and psychosomatic medicine services.

SUMMARY

From early in medical history, curious physicians have investigated the mysteries of the mind–body relationship, developing a field of study called psychosomatic medicine. The energy of this intellectual enterprise has led to the growth of general hospital psychiatry, initially aided by Rockefeller Foundation funding in 1934, as well as the development of consultation psychiatry, supported through the funding of Eaton's NIMH program in the 1970s and 1980s. A subspecialty of psychiatry called psychosomatic medicine has recently been approved, which recognizes the maturation of the field and the growth that lies ahead.

At each step of the way, the MGH Psychiatric Consultation Service has played an important role. This book, which reviews the essentials of general hospital psychiatry, is a testimony to the caring, creativity, and diligence of those who have come before us.

Approach to Consultation Psychiatry: Assessment Strategies

2

John Querques, M.D.
Theodore A. Stern, M.D.

My emphasis to the residents is: "Now that you've learned a lot about compassion and human dignity … you must learn to be competent," adding "or else." The goals for the trainee are specialty-competence, that is, some specific things about consultation: accountability, commitment, industry, discipline; these are the components that go into the make-up of a professional.

—Ned H. Cassem, M.D.[1]

This chapter provides a practical approach to the assessment of affective, behavioral, and cognitive problems of patients in the general hospital. We first survey the landscape of consultation psychiatry and then identify six broad domains of psychiatric problems commonly encountered in the medical setting. Next, we describe the differences in clinical approach, environment, interactive style, and use of language that distinguish psychiatry in the general hospital from practice in other venues. Then we offer a step-by-step guide to the conduct of a psychiatric consultation. The chapter concludes with a review of treatment principles critical to caring for the medically ill. Throughout this chapter, we emphasize the hallmarks of competence identified by Cassem[1] more than 2 decades ago: accountability, commitment, industry, and discipline.

CATEGORIES OF PSYCHIATRIC DIFFERENTIAL DIAGNOSIS IN THE GENERAL HOSPITAL

The borderland between psychiatry and medicine in which consultation psychiatrists ply their trade can be visualized as the area shared by two intersecting circles in a Venn diagram (Figure 2–1). As depicted in the figure and consistent with the fundamental tenet of psychosomatic medicine (i.e., that mind and body are indivisible), the likelihood that either a psychiatric or a medical condition will have no impact on the other is incredibly slim. Within the broad region of bidirectional influence (the area of overlap in the Venn diagram), the problems most commonly encountered on a consultation–liaison service can be grouped into six categories (modified from Lipowski[2]; see Figure 2–1). Examples of each classification follow.

Psychiatric Presentations of Medical Conditions

An elderly man underwent neurosurgery for clipping of an aneurysm of the anterior communicating artery. A few days after surgery, he became diaphoretic, confused, and agitated and was tachycardic and hypertensive. Because of a history of alcoholism, a diagnosis of alcohol withdrawal delirium was made. He remained confused despite aggressive benzodiazepine treatment. When he later became febrile, a lumbar puncture was done and the cerebrospinal fluid (CSF) analysis was consistent with herpes simplex virus (HSV) infection. His sensorium cleared after a course of acyclovir. *In this case, infection of the central nervous system (CNS) by HSV was heralded by delirium.*

Psychiatric Complications of Medical Conditions or Treatments

Newly diagnosed with human immunodeficiency virus (HIV) infection with a high viral load, a young man without a history of psychiatric illness began treatment with efavirenz, a nonnucleoside reverse transcriptase inhibitor. Within a few days, he experienced vivid nightmares, a known side effect of efavirenz. Over the next several weeks, the nightmares resolved. He continued antiretroviral treatment, but he became increasingly despondent with a full complement of neurovegetative symptoms of major depression. *A chronic, incurable viral illness—whose treatment caused a neuropsychiatric complication—precipitated a depressive episode.*

Psychological Reactions to Medical Conditions or Treatments

A woman with a history of preeclampsia during her first pregnancy was admitted with hypertension in the 38th week of her second pregnancy. Preeclampsia was diagnosed, and she delivered a healthy baby. As she prepared for discharge, and despite her obstetrician's reassurance, she fretted that a hypertensive catastrophe was going to befall her at home. *Pathologic anxiety resulted from an acute obstetric condition.*

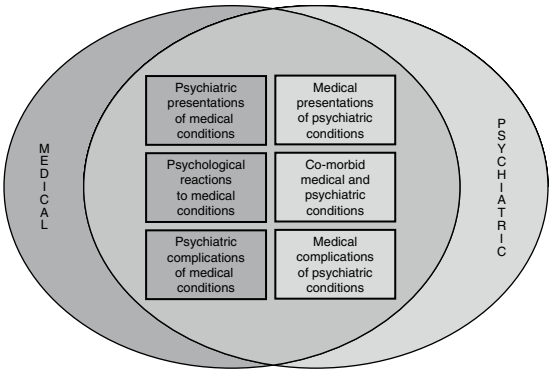

Figure 2–1. A representation of the overlap between medical and psychiatric care.

Medical Presentations of Psychiatric Conditions

A young female graduate student from another country, who for several years had habitually induced vomiting to relieve persistent abdominal pain, presented with generalized weakness and was found to have a serum potassium of 2.2 mEq/L. She had long since been diagnosed with bulimia nervosa, but the psychiatric consultant found no evidence for this disorder and instead diagnosed conversion disorder, construing her chronic abdominal pain as a converted symptom of psychological distress over leaving her family to study abroad. *Conversion disorder presented as persistent abdominal pain*.

Medical Complications of Psychiatric Conditions or Treatments

An obese man with schizophrenia treated with olanzapine (20 mg daily) gained 30 pounds in 6 months. Repeated measurements of fasting serum glucose were more than 126 mg/dL, consistent with a diagnosis of diabetes mellitus. *Treatment with an atypical antipsychotic was complicated by an endocrine condition*.

Co-Morbid Medical and Psychiatric Conditions

A middle-aged man with long-standing obsessive–compulsive disorder (OCD), effectively treated with high-dose fluoxetine, presented with cough, dyspnea, and fever. Chest radiography showed a left lower-lobe infiltrate, consistent with pneumonia. He defervesced after a few doses of intravenous (IV) antibiotics and was discharged to complete the antibiotic course at home. His OCD remained in remission. *Infectious and psychiatric conditions existed independently*.

THE ART OF PSYCHIATRIC CONSULTATION IN THE GENERAL HOSPITAL

Determining where on the vast border between psychiatry and medicine a patient's pathologic condition is located is the psychiatric consultant's fundamental task. As for any physician, his or her chief responsibility is diagnosis. The consultation–liaison psychiatrist is aided in this enterprise by appreciation of four key differences between general hospital psychiatry and practice in other venues: clinical approach, environment, style of interaction, and use of language.

Clinical Approach

A senior psychiatrist at the Massachusetts General Hospital (MGH) and director emeritus of its Psychosomatic Medicine–Consultation Psychiatry Fellowship Program, Dr. George Murray advises his students to think in three ways when consulting on patients: physiological, existential, and "dirty." Each element of this tripartite conceptualization is no more or less important than the other, and the most accurate formulation of a patient's problem will prove elusive without attention to all three.

First, psychiatrists are physicians and, as such, subscribe to the medical model: altered bodily structures and functions lead to disease; their correction through physical means leads to restoration of health. Although allegiance to this model may be impolitic in this era of biopsychosocial holism, the degree of morbidity in general hospitals is ever more acute and the technology brought to bear against it is increasingly more sophisticated.[3] Consultation psychiatrists who fail to keep pace with their medical and surgical colleagues jeopardize their usefulness to physicians and patients alike.

Alongside the physiologic frame of mind, consultation psychiatrists must think existentially; that is, they must nurture a healthy curiosity about the meaning of the illness to their patients at this particular moment in their lives and the circumstances in which their patients find themselves at particular moments in the course of an illness. What does it mean to a burn victim that he was brought by helicopter to a hospital in a neighboring state? What was he thinking during the airlift? Would he have thought differently if an ambulance had brought him to his local hospital? To be curious about such matters, the consulting psychiatrist must first *know* the details of the patient's situation, largely achieved by a careful reading of the chart. For example, ambulance (or helicopter) run sheets and emergency department notes often contain interesting and meaningful data about a patient's mental state in the aftermath of a tragic event. Armed with this information, the consultant can then *ask* the patient what the whole ordeal was like for him or her.

Consultation psychiatrists are wise to maintain a measured skepticism toward patients' and others' statements, motivations, and desires. In other words, they should consider the possibility that the patient (or another informant) is somehow distorting information to serve his or her own agenda. Providers of history can distort the truth in myriad ways, ranging from innocuous exaggeration of the truth to outright lies; their aims are equally legion: money, revenge, convenience, and cover-up of peccadilloes, infidelities, or crimes. For example, the beleaguered mother of a young woman with a borderline personality disorder embellished her daughter's suicidal comments in an effort to secure involuntary commitment for her daughter and respite for herself. By paying attention to his or her own countertransference—his or her personal reading of the limbic music[4]

emanating from the mother–daughter dyad—the psychiatric consultant called in to assess the patient's suicidality ably detected the mother's self-serving distortion and thus avoided unwitting collusion with it. This special case of distortion to remove a relative to a mental or other hospital has been termed the *Gaslight phenomenon*.[5–7] Although thinking "dirty" is merely a realization that people refract reality through the lens of their own personal experience, other health professionals—even some psychiatrists—bristle at even a consideration, let alone a suggestion, that patients and their families harbor unseemly ulterior motives. Consequently, this perspective does not make the consultation psychiatrist many friends; his thinking "dirty" may even earn him or her an unsavory reputation. However, neither an ever-widening social circle nor victory in popularity contests is the consultation–liaison psychiatrist's *raison d'être*—competent doctoring is.

Environment

The successful psychiatric consultant must be prepared to work in an atmosphere less formal, rigid, and predictable than one typically found in an office or a clinic; flexibility and adaptability are crucial. Patients are often seen in two-bedded rooms with nothing but a thin curtain providing only a semblance of privacy; roommates—as well as nurses, aides, dietary personnel, and other physicians—are frequent interlocutors. Cramped quarters are the rule, with IV poles, tray tables, and one or two chairs leaving little room for much else. When family members and other visitors are present, the physician may ask them to leave the room; alternatively, he or she may invite them to stay to "biopsy" the interpersonal dynamics among the family and friends, as was done in the case of the borderline patient described previously. The various alarms and warning signals of medical equipment (e.g., IV pumps, cardiac monitors, and ventilators) and assorted catheters and tubes traveling into and out of the patient's body add to the unique ambiance of the bedside experience that distinguishes it from the quiet comfort afforded by a private office. Perhaps off-putting at first, for the psychiatrist who, as Lewis Glickman in his book on consultation put it (as cited in Cassem[1]), loves medicine and is fascinated with medical illness, the exigencies of life and work in a modern hospital quickly become exciting and ultimately captivating.

Style of Interaction

The adaptability required by these environmental circumstances allows the psychiatric consultant to be more flexible in his or her relations with the patient. For example, psychiatric consultants should permit themselves to crouch at the bedside; lowering themselves to the recumbent patient's level can diminish apprehension and can minimize the inherent power differential between doctor and patient. Shaking hands or otherwise laying on of hands may achieve the same end. Performance of a physical examination provides an excellent opportunity to allay anxiety and dramatically distinguishes consultation work from office-based psychiatry, where any touching of a patient—let alone physical examination—is considered taboo. An offer to make the person more comfortable by adjusting the bed or getting the patient something to drink before beginning the interview goes a long way to building rapport. When the patient is unable to do even these simple things unaided, it is simply a kind, humane gesture. When the patient tends toward the cantankerous and irascible, concern for the patient's comfort may prevent the patient from expelling the consultant from the room. Finally, as a simple matter of respect, one should make every effort to leave the room as one found it (e.g., if towels and sheets are removed from a chair before sitting on it, they should be replaced upon getting up).

Use of Language

Allowance for flexibility also extends to psychiatrists' use of language; they can feel freer than they might in other practice settings to use humor, slang expressions, and perhaps even foul language. All of these varieties of verbal expression create a temporarily jarring juxtaposition between the stereotypical image of the austere, reserved physician and the present one; defenses may be briefly disabled just long enough to connect with the truth and allow connection with the patient. For example, in a technique taught by Murray, the psychiatrist raises a clenched fist in front of an angry but anger-phobic patient and asks him, "If you had one shot, where would you put it?" In this case, the sight and sound of a "healer" in boxer's pose inquiring about placement of a "shot" creates a curious, or even humorous, incongruity that disarms the patient's defenses and allows an otherwise intolerable emotion (anger) to emerge (if it is there in the first place).

A variant of this maneuver, substitution of a verbal expression of anger for the physical one, is also possible. For example, a 30-year-old man with leukemia refractory to bone-marrow transplantation was admitted with graft-versus-host disease. His mother and sister kept a near-constant vigil at his bedside. When he refused to eat and to talk to his family and the nurses, the psychiatrist was summoned. Quickly sizing up the situation, the consultant said to the young man, "It must be a pain to have your mother constantly hovering over you." The patient grinned slightly and answered in the affirmative. Use of a foul expression of the same sentiment would predictably have achieved a more robust response.

Lack of the formal arrangements of office-based psychiatric practice makes such techniques permissible in the general hospital, often to the delight of residents, who sometimes feel unnecessarily constrained in their interpersonal comportment and in whom even a little training unfortunately does much to limit their natural spontaneity.

THE PROCESS OF PSYCHIATRIC CONSULTATION IN THE GENERAL HOSPITAL

With this general overview of the art of consultation, we next outline the step-by-step approach to the actual performance of a psychiatric consultation. Table 2–1 summarizes the key points elaborated in the following text.

Speak Directly with the Referring Clinician

The consultative process begins with the receipt of the referral. With experience, the sensitive consultant begins to formulate preliminary hypotheses even at this early

TABLE 2–1 Procedural Approach to Psychiatric Consultation

Speak directly with the referring clinician.
Review the current and pertinent past records.
Review the patient's medications.
Gather collateral data.
Interview and examine the patient.
Formulate a diagnosis and management plan.
Write a note.
Speak directly with the referring clinician.
Provide periodic follow-up.

stage. For example, he or she recognizes a particular unit within the hospital or an individual physician and recollects previous consultations that originated from these sources. In addition, he or she may discern a difference in the way this consultation request was communicated compared with the form of previous requests. In a form of parallel process, this alteration in the usual routine—even if subtle and only in retrospect—often reflects something about the patient. Throughout the consultative process, these crude preliminary hypotheses thus formed are refined and ultimately either accepted or rejected. The continual revision of previous theories as additional data become available is a fundamental process in consultation–liaison psychiatry as it is in the whole of medicine.

The reason for the consultation stated in the request might differ from the real reason for the consultation. The team might accurately sense a problem with the patient but not capture it precisely. In some cases, they may be quite far afield, usually when the real reason for the consultation is difficulty in the management of a hateful patient.[8] It is up to the consultant to identify the core issue and ultimately address it in the consultation. Practically speaking, a special effort to contact the consultee is not usually required, because, in general, in the course of reading the chart or reviewing laboratory data, one encounters a member of the team and can inquire then about the consultation request.

Review the Current and Pertinent Past Records

A careful review of the current medical record is indispensable to a thorough and comprehensive evaluation of the patient. Perhaps no other element of the consultative process requires as much discipline as this one. The seasoned consultant is able to accomplish this task quite efficiently, knowing fruitful areas of the chart to mine. For example, nursing notes often contain behavioral data often lacking from other disciplines' notes; a well-written consultation provided by another service can provide a general orientation to a case, although the consultant must take care not to propagate error by failing to check primary data himself or herself. Other bountiful areas of the chart include notes written by medical students (who tend to be the most thorough of all), physical and occupational therapists (for functional data), and speech pathologists (for cognitive data). In reading the chart, the focus of the psychiatric consultant's attention varies according to the nature of the case and the reason for the consultation. In cases in which sensorium is altered, for example, careful note of changes in level of awareness, behavior, and cognition should be made, especially as they relate to changes in the medical condition and treatment.

Review the Patient's Medications

Regardless of the particulars of a case, detailed evaluation of medications, paying special attention to those recently initiated or discontinued, is always in order. For example, in the vignette presented previously, knowledge that the HIV-positive man had recently initiated treatment with efavirenz was key to accurately diagnosing the cause of his nightmares. Important medications the patient might have taken before admission, including those on which he may be physiologically dependent (e.g., benzodiazepines and narcotic analgesics), might inadvertently have been excluded from his current regimen. Patients who have been transferred among various units in the hospital may be at particular risk of such inadvertent omissions. In cases in which mental status changes resulting from withdrawal phenomena top the differential diagnosis, careful construction of a timeline of the patient's receipt of psychoactive agents is often the only way to identify the problem. In much the same way as infectious-disease specialists chart the administration of antibiotics in relation to culture results and dermatologists plot newly prescribed medications against appearance of rashes, the psychiatric consultant tabulates mental status changes, vital signs, and dosages of psychoactive medications to clarify the diagnostic picture. Such a procedure exemplifies the industry and discipline required of the competent consultant.

Gather Collateral Data

The gathering of collateral information from family, friends, and outpatient treaters is no less important in consultation work than in other psychiatric settings. For several reasons (e.g., altered mental status, denial, memory impairment, and malingering), patients' accounts of their history and current symptoms are often vague, spotty, and unreliable. Although data from other sources is therefore vital, the astute psychiatrist recognizes that their information, too, may be distorted by the same factors and by selfish interests, as already described. Consultation psychiatrists must guard against accepting any one party's version of events as gospel and must maintain an open mind in collecting a history informed from many angles.

Interview and Examine the Patient

Next follows the interview of the patient and performance of a mental status examination, in addition to relevant portions of the physical and neurologic examinations. We discussed earlier the differences between patient encounters in the general hospital and those in other venues.

A detailed assessment of cognitive function is not necessary in all patients. If there is no evidence that a patient has a cognitive problem, a simple statement to the effect that no gross cognitive problem is apparent is sufficient. However, even a slight hint that a cognitive disturbance is present should trigger performance of a more formal screen. We recommend the Folstein Mini-Mental State

Examination (MMSE)[9] for this purpose and supplement this test with others that specifically target frontal executive functions (e.g., clock drawing, Luria maneuvers, and cognitive estimations). Any abnormalities that turn up on these bedside tests should be comprehensively evaluated by formal neuropsychological testing. It is convenient if a psychologist—especially one trained specifically in neuropsychology—is affiliated with the consultation service. Conversely, if a patient is obviously inattentive, we would argue that performance of the MMSE (or similar tests) is not indicated, because one can predict a priori poor performance resulting from the subject's general inattention to the required tasks.

The consultant should at the very least review the physical examinations performed by other physicians. This does not, however, preclude doing his or her own examination of relevant systems, including the CNS, which, unless the patient is on the neurology service or is known to have a motor or a sensory problem, has likely been left unexamined. A number of physical findings can be discerned simply by observation: pupillary size (which is noteworthy with opioid withdrawal or intoxication); diaphoresis, either present (from fever or from alcohol or benzodiazepine withdrawal) or absent (associated with anticholinergic intoxication); and adventitious motor activity (e.g., tremors, tremulousness, or agitation). Vital signs are especially relevant in cases of substance withdrawal, delirium, and other causes of agitation. Primitive reflexes (e.g., snout, glabellar, and grasp), deep-tendon reflexes, extraocular movements, pupillary reaction to light, and muscle tone are among the key elements of the neurologic examination that the psychiatrist often checks.

Formulate a Diagnosis and Management Plan

Any physician's tasks are twofold: diagnosis and treatment. This dictum is no different for the psychiatrist, whether in the general hospital or elsewhere. To arrive at a diagnosis, laboratory testing comes after history and examination. By the time a psychiatric consultation is requested, most hospitalized patients have already undergone extensive laboratory testing, including comprehensive metabolic panels and complete blood cell counts; these should be reviewed. In constructing the initial parts of a management plan, the psychiatric consultant should attend to diagnostics and specifically consider each of the tests listed in Table 2–2, which we review presently. Therapeutic strategies are discussed in a later section.

Toxicology screens of both serum and urine are required any time a substance-use disorder is suspected and in cases of altered sensorium, intoxication, or withdrawal.

Well known by every student of psychiatry, syphilis, thyroid dysfunction, and deficiencies of vitamin B_{12} and folic acid are always included in an exhaustive differential diagnosis of virtually every neuropsychiatric disturbance. Although it is certainly possible that these conditions can *cause* any manner of psychiatric perturbation (e.g., dementia, depression, mania), more commonly these ailments coexist with other conditions, which together *contribute* to psychiatric disturbances. Although blood tests and treatments for these diseases are relatively easily accomplished, these tests should not be recommended reflexively in every case but only when a specific reason dictates (e.g., anemia for vitamin testing).

TABLE 2–2 Laboratory Tests in Psychiatric Consultation

- Toxicology
  - Serum
  - Urine
- Serology
  - RPR test
  - VDRL test
- TSH (thyrotropin)
- Vitamin B_{12} (cyanocobalamin)
- Folic acid (folate)
  - EEG
  - CSF analysis
- Neuroimaging
  - CT
  - MRI

CSF, Cerebrospinal fluid; *CT*, computed tomography; *EEG*, electroencephalography; *MRI*, magnetic resonance imaging; *RPR*, rapid plasma reagin; *TSH*, thyroid stimulating hormone; *VDRL*, Venereal Disease Research Laboratory.

For purposes other than evaluation of acute intracranial hemorrhage, cerebral magnetic resonance imaging (MRI) is preferred to computed tomography. MRI provides higher resolution and greater detail, particularly of subcortical structures of interest to the psychiatrist. A thorough consultation is incomplete without a reading of the actual radiology report of the study; merely reviewing the telegraphic summary in a house officer's progress note is insufficient, because important findings are often omitted. For example, an MRI scan that shows no abnormalities other than periventricular white matter changes is invariably recorded as "normal" or as showing "no acute change." Although periventricular white matter changes are not acute and their significance is arguable, they are certainly not normal and they should be documented in a careful psychiatric consultation note. They may be evidence of an insult that forms a substrate for depression or dementia and may be a predictive sign of sensitivity to usual dosages of psychotropic medications.

Electroencephalography (EEG) can be particularly helpful to document the presence of generalized slowing in patients thought by their primary physicians to have a functional problem. Such indisputable evidence of electric dysrhythmia often puts a sudden end to the primary team's skepticism. In cases of suspected complex partial seizures, depriving the patient of sleep the night before the EEG increases the likelihood that he or she will sleep during the test; against a background of slow activity in the sleeping state, any spikes or sharp waves indicating seizure activity will be more easily detected. Continuous EEG and video monitoring or ambulatory EEG monitoring may be necessary to catch aberrant electric activity. As with neuroimaging reports, the consultant psychiatrist must read the EEG report himself or herself; nonpsychiatrists commonly equate absence of "organized electrographic seizure activity" with normality, even though focal slowing may be evidence of seizure activity.

CSF analysis is often overlooked by psychiatrists and other physicians. However, it should be considered in cases

of altered mental status with fever, leukocytosis, or meningismus and when causes of beclouded consciousness are not obvious. In some cases (e.g., in the vignette of the man with HSV presented previously), some conditions initially considered causative are not, and the true culprit is identified only after a lumbar puncture is performed.

Any suspicion of a somatoform disorder (especially conversion disorder) should trigger referral for psychological testing with the Minnesota Multiphasic Personality Inventory (MMPI) or the shorter Personality Assessment Inventory. For example, MMPI results of the young female graduate student described previously may demonstrate the conversion (or psychosomatic) V pattern of marked elevations on the hypochondriasis and hysteria scales and a normal or slightly elevated result on the depression scale. These pencil-and-paper tests can also be useful in assessments of psychological contributions to pain. Projective testing (e.g., Rorschach inkblots) is more common in outpatient venues.

Write a Note

The psychiatric consultation note should be a model of clear, concise writing with careful attention to specific, practical diagnostic and therapeutic recommendations. Several reviews of this topic are available.[10,11] If the stated reason for the consultation differs from the consultee's more fundamental concern, both should be addressed in the note. If the referring physician adopts the consultant's recommendations, he or she should be able to transcribe them directly onto the order sheet or into computerized order-entry systems. "Note wars," criticism of the consultee, accusations of shoddy work, pejorative labels, and jargon should all be avoided. If the consultee chooses a diagnostic or therapeutic course equally appropriate to the consultant's suggested choice, an indication of agreement is more prudent than rigid insistence on the psychiatrist's preference. The consultant should avoid prognostication (e.g., "This patient will probably have decision-making capacity after his infection has resolved" or "This patient will likely need psychiatric hospitalization after he recovers from tricyclic antidepressant toxicity"). Such forecasts do not evince confidence in the consultant's skill if they prove inaccurate, may be invoked by the consultee even when they no longer apply, and are unnecessary if routine follow-up is provided (see later).

Speak Directly with the Referring Clinician

The consultative process is not complete without contact, either by phone or in person, with the referring physician or other member of the patient's team, especially if the diagnosis or recommended intervention warrants immediate attention.

Provide Periodic Follow-Up

The committed consultant sees the patient as often as is necessary to treat him or her competently, and the consultant holds himself or herself accountable for tracking the patient's clinical progress, following up on laboratory tests, refining earlier diagnostic impressions, and modifying diagnostic and treatment recommendations. The consultation comes to an end only when the problem for which the consultant was called resolves, any other concerns identified by the consultant are fully addressed, or the patient is discharged or dies. Rarely do any of these outcomes occur after a single visit, making repeated visits the rule and availability, even at inopportune times, crucial. However, the consultant is not obligated to continue consulting on a case when his or her recommendations are clearly being ignored.[12] In these cases, it is appropriate to sign off. Although clinical nurse specialists, nurse practitioners, physician assistants, and case managers may be available to locate psychiatric beds and secure insurance coverage for inpatient psychiatric stays for patients who require them, the psychiatric consultant should be ready and able to perform these duties.

PRINCIPLES OF PSYCHIATRIC TREATMENT IN THE GENERAL HOSPITAL

As in other practice settings, in the general hospital, psychiatric treatment proceeds along three fronts: biological, psychological, and social.

Biological Management

When prescribing psychopharmaceuticals for medically ill patients taking other medications, the consultant must be aware of pharmacokinetic profiles, drug–drug interactions, and adverse effects. These topics are considered in depth in Chapter 34.

Pharmacokinetic Profiles

Pharmacokinetics refers to a drug's absorption, distribution, metabolism, and excretion. Because an acutely medically ill patient might not be able to take medications orally, absorption is a primary concern in the general hospital setting. Often in such situations (e.g., in an intubated patient), a nasogastric tube is in place and medications can be crushed and administered through the nasogastric tube. However, if one is not in place, the psychiatric consultant is obliged to consider medications that can be given intramuscularly, intravenously, or in suppository form. In addition, orally disintegrating formulations may be available (e.g., mirtazapine, olanzapine, risperidone).

Many psychotropic medications are metabolized in the liver and excreted through the kidneys. Thus impaired hepatic and renal function can lead to increased concentrations of parent compounds and pharmacologically active metabolites. This problem is readily overcome by using lower initial doses and by performing slower titration. However, concern for metabolic alterations in medically ill patients should not justify use of homeopathic doses for indeterminate durations, because most patients ultimately tolerate and require standard regimens.

Drug–Drug Interactions

Many psychopharmaceuticals are metabolized by the cytochrome P450 isoenzyme system; many also inhibit various isoforms in this extensive family of hepatic enzymes, and the metabolism of many is, in turn, inhibited by other classes of medication, thus creating fertile ground for drug–drug interactions in patients taking several medications. This

topic is reviewed extensively in Chapter 34. Psychiatric consultants should also be aware that cigarette smoking induces the metabolism of many drugs. When patients are hospitalized and thus stop or curtail smoking, serum concentrations of these drugs (e.g., clozapine) increase, and propensity for adverse effects thus also increases.

Adverse Effects

Depending on the practice venue, the profile of adverse effects of concern to the psychiatrist varies. For example, the likelihood that tricyclic antidepressants will cause dry mouth and sedation may be of more concern in the outpatient setting than in the general hospital, where concern about the cardiac-conduction and gut-slowing effects will likely be of greater importance in patients recovering from myocardial infarction or bowel surgery. Traditional neuroleptics—often relegated to the second line in otherwise healthy patients with psychosis—may be preferable to the atypical agents in general medical settings, where patients with obesity, diabetes mellitus, and dyslipidemia may be seen for the complications of these conditions (e.g., myocardial infarction, stroke, and diabetic ketoacidosis).

TABLE 2–3 Personality Assessment and Management in the General Hospital

PERSONALITY TYPE	MAJOR TRAITS	REACTION TO ILLNESS	RECOMMENDED STRATEGIES
Dependent	Craves special attention Expects services on demand Requires constant reassurance	Perceived abandonment generates feeling of helplessness Increased anxiety prompts more demands	Express desire to provide comprehensive care Make minor concessions if possible
Obsessive	Values detail and order Becomes anxious with uncertain outcomes Well defended against fear and pain	Illness represents threat to self-control Need for certainty and control prevents questioning of staff, thus increasing anxiety	Provide ample information, using and defining medical terms Ally with patient's desire for mastery Allow patient to participate in medical decisions
Histrionic	Prematurely trusts others Uses repression, denial, and avoidance Dramatizes feelings	Illness represents threat to masculinity or femininity	Recognize patient's grace under pressure Omit details in reassuring patient
Masochistic	Plays the martyr role Seems to enjoy suffering Feels unappreciated	Illness represents deserved punishment Illness is welcomed as form of suffering Lack of recognition of martyr status risks noncompliance	Appreciate patient's suffering Recommend treatment as an additional burden that will aid others
Paranoid	Is suspicious, wary, and guarded Readily feels slighted Bickers when feeling persecuted	Illness represents an external assault Medical interventions generate suspicions and fear of harm	Inform patient completely about tests and treatments Acknowledge difficulty of illness
Narcissistic	Requests and receives help with difficulty Strives to appear smart, strong, and superior Fears dependence	Illness challenges self-esteem and superior stance Efforts to appear effectual and strong are redoubled	Recognize patient's strengths and knowledge Allow patient to participate in medical decisions Expect gaps in history, because more illness connotes weakness
Schizoid	Is aloof, uninvolved, and detached Prefers solitary occupations	Illness requires contact with caregivers Rejection risk spurs greater withdrawal	Recognize preference for isolation Minimize intrusions Assure patient of interest and concern

In Rippe JM, Irwin RS, Alpert JS et al, editors: *Intensive care medicine*, ed 2, Boston, 1991, Little, Brown, pp 1906–1916.

Psychological Management

Psychological management of the hospitalized medically ill patient begins—as does all competent treatment—with diagnosis, in this case, personality diagnosis. That is, the psychiatric consultant first appraises the patient's psychological strengths and vulnerabilities. Armed with this psychological balance sheet, the psychiatrist then uses this information therapeutically in how he or she phrases questions and comments to the patient and describes the patient to the medical and nursing staff. Several schemas have been developed to aid in such a personality assessment.[8,13,14] Groves's formulation is reviewed in Chapter 38; Table 2–3 summarizes Kahana and Bibring's approach.

The consultant must realize that the patient may find the psychiatrist the only outlet available to vent his or her feelings about treatment in the hospital. This is an appropriate function of the consultant—and, in fact, may be the tacit reason for the consultation. Relieved of his or her feelings, often hostile and at odds with the team's treatment efforts, the patient is thus better able to work with the team.

Social Management

Psychiatric consultants may be called on to help make decisions about end-of-life care (e.g., do-not-resuscitate and do-not-intubate orders), disposition to an appropriate living situation (e.g., home with services, assisted-living residence, skilled nursing facility, or nursing home), short-term disability, probate guardianship for a patient deemed clinically unable to make medical decisions for himself or herself, and involuntary psychiatric commitment. For patients who are agitated and thereby place themselves and others in harm's way, the consultant may recommend the use of various restraints (e.g., Posey vests, mitts [to prevent removing IV and other catheters], soft wrist restraints, and leather wrist and ankle restraints) and constant observation.

SUMMARY

Regardless of the practice setting, the basics of competent psychiatric care remain the diagnosis of affective, behavioral, and cognitive disturbances and their treatment by pharmacologic, psychological, and social interventions. The psychiatrist in the general hospital applies these fundamentals while remaining *accessible* to the consultee and to the patient, *adaptable* to the exigencies of the hospital environment, and *flexible* in clinical approach and interpersonal style. The consultation psychiatrist adheres to the tenets of competent doctoring: accountability, commitment, industry, and discipline.

The Doctor–Patient Relationship

3

Christopher Gordon, M.D.
Margot Phillips, M.D.
Eugene V. Beresin, M.A., M.D.

The doctor–patient relationship—despite all the pressures of managed care, bureaucratic intrusions, and other systemic complications—remains one of the most profound partnerships in the human experience; in it, one person reveals to another his or her innermost concerns, in hope of healing.[1,2] In this deeply intimate relationship, when we earn our patients' trust, we are privileged to learn about fears and worries that our patients may not have shared—or ever will share—with another living soul; patients literally put their lives and well-being in our hands. For our part, we hope to bring to this relationship technical mastery of our craft, wisdom, experience, and humility as well as our physicianly commitment to stand by and with our patient—that is, not to be driven away by any degree of pain, suffering, ugliness, or even death itself. We foreswear our own gratification, beyond our professional satisfaction and reward, to place our patients' interests above our own. We hope to co-create a healing relationship, in which our patients can come to understand with us the sources of suffering and the options for care and healing, and to partner with us in the construction of a path toward recovery.

In clinical medicine the relationship between doctor and patient is not merely a vehicle through which to deliver care. Rather, it is one of the most important aspects of care itself. Excellent clinical outcomes—in which patients report high degrees of satisfaction, work effectively with their physicians, adhere to treatment regimens, experience improvements in the conditions of concern to them, and proactively manage their lives to promote health and wellness—are far more likely to arise from relationships with doctors that are collaborative and in which patients feel heard, understood, respected, and included in treatment planning.[3–6] On the other hand, poor outcomes—including noncompliance with treatment plans, complaints to oversight boards, and malpractice actions—tend to arise when patients feel unheard, disrespected, or otherwise out of partnership with their doctors.[7–9] Collaborative care not only leads to better outcomes but also is more efficient than noncollaborative care in achieving good outcomes.[10,11] The relationship matters.

An effective doctor–patient relationship may be more critical to successful outcomes in psychiatry (because of the blurred boundaries between the conditions from which patients suffer and the sense of personhood of the patients themselves) than it is in other medical specialties. In psychiatry, more than in most branches of medicine, there is a sense that when the patient is ill, there is something wrong with the person as a whole, rather than that the person has or suffers from a discrete condition. Our language aggravates this sense of personal defectiveness or deficiency in psychiatric illness. We tend to speak of "being depressed" or "being bipolar" as if these were qualities of the whole person rather than a condition to be dealt with. Even more hurtfully, we sometimes speak of people as "borderlines" or "schizophrenics" as if these labels summed up the person as a whole. This language, together with the persistent stigma attached to mental illness in our culture, amplifies the shame and humiliation that patients may experience in any doctor–patient interaction[12] and makes it even more imperative that the physician work to create a safe relationship.

Moreover, if we seek to co-create a healing environment in which the patient feels understood (as a basis for constructing a path toward recovery), psychiatry more than any other branch of medicine requires us to attend thoughtfully to the whole person, even to parts of the person's life that may seem remote from the person's areas of primary concern. This is especially salient in the general hospital, where a patient's medical problem may cause clinicians to overlook critically important aspects of the person's current relationships and social environment, from long-standing psychological issues, and from the person's spiritual life and orientation. Much of the time, these psychological, social, or spiritual aspects shed a bright light on the nature of the person's distress (Figure 3–1). There must be time and space in the doctor–patient relationship to know the person from several perspectives[13]: in the context of the person's biological ailments and vulnerabilities; in the setting of the person's current social connections, supports, and stressors; in the context of the person's earlier psychological issues; and in the face of the person's spirituality.[14]

UNIQUE ASPECTS OF THE DOCTOR–PATIENT RELATIONSHIP IN THE GENERAL HOSPITAL

In the general hospital, the doctor–patient relationship has several unique features. To begin with, a medical problem is usually the cornerstone of doctor–patient encounters. This simple fact has several key consequences.

First, the relationship occurs in the context of a complex interplay of psychiatric and medical symptoms and illnesses (see Figure 2–1) that may each stem from a variety of etiologies; the doctor–patient relationship must assess and attempt to address each of these domains.

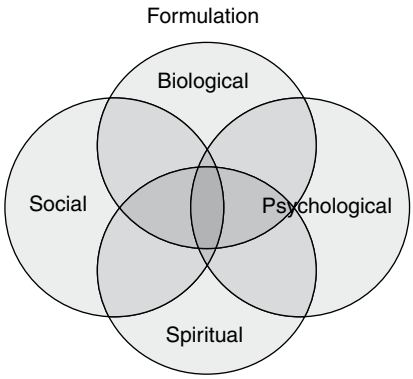

Figure 3–1. Graphic representation of frameworks that facilitate an understanding of the patient.

Second, the dynamics of power and trust in the doctor–patient relationship may be different than in outpatient settings. In the hospital patients usually have not asked for a meeting with a psychiatrist, nor do they understand why they should have done so. For instance, a psychiatrist may be called to evaluate a patient who is refusing treatment or who has developed hallucinations after a cholecystectomy. The context of care affects the patient's willingness and ability to engage in a relationship with a psychiatric physician. Doctors must be mindful of patient autonomy—which is typically strained by illness—and strive to maintain a patient-centered approach.

Third, the presence of a primary medical or surgical team changes a dyadic relationship into a complex doctor–patient–doctor triad. Both sets of physicians and the patient can feel pulled in different directions when there is disagreement about treatment. Physicians and patients alike tend to categorize illness and treatments as "medical" and "psychiatric." [15] Successful doctor–patient relationships collaborate in the service of patient care (Figure 3–2).

Fourth, the hospital environment challenges privacy, space, and time and hinders the clinical encounter. For example, assessing whether a patient who is losing weight after a stroke is depressed may be especially difficult because of barriers to communication. The hospital roommate may have visitors who interrupt or inhibit the patient from expressing himself or herself, or the patient may have intrinsic barriers to communication (e.g., an aphasia or intubation). Clinicians who practice in the general hospital should be aware of the unique aspects of providing care in this setting and tailor their clinical approach accordingly. Chapter 2 reviews some differences in approach, language, and style that may be applicable to care in the general hospital. Ultimately, regardless of setting, the doctor–patient relationship is at the core of the clinical encounter. The following sections will explore provision of patient-centered care, conduct of the clinical interview, and creation of a clinical formulation and treatment plan; all of them are facilitated by a therapeutic doctor–patient relationship.

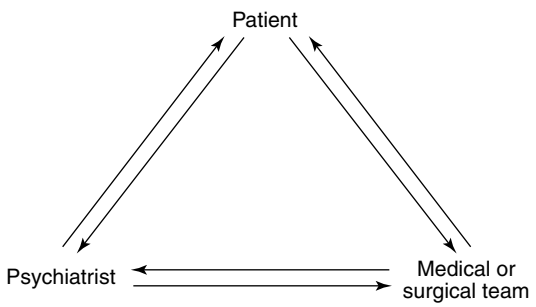

Figure 3–2. Patient–doctor relationships in the general hospital.

THE OPTIMAL HEALING ENVIRONMENT: PATIENT-CENTERED CARE

Although cultural factors limit the validity of this generalization, patients generally prefer care that centers on their own concerns; addresses their perspective on these concerns; uses language that is straightforward, is inclusive, and promotes collaboration; and respects the patient as a fully empowered partner in decision-making.[16–18] This model of care may be well denoted by the term *patient-centered care*[10,19,20] or, even better, *relationship-centered care*. In *Crossing the Quality Chasm*, the Institute of Medicine identified person-centered practices as key to achieving high-quality care that focuses on the unique perspective, needs, values, and preferences of the individual patient.[21] Person-centered care involves a collaborative relationship in which two experts—the practitioner and the patient—attempt to blend the practitioner's knowledge and experience with the patient's unique perspective, needs, and assessment of outcome.[18,22,23]

In relationship-centered practice, more than patient-centered practice, the physician does not cede decision-making authority or responsibility to the patient and family but rather enters into a dialogue about what the physician thinks is best. Most patients and families seek a valued doctor's answer to the question (stated or not), "What would you do if this were your family member?" This transparent and candid collaboration conveys respect and concern. Enhanced autonomy involves a commitment to know the patient deeply, to respect the patient's wishes, to share information openly and honestly (as the patient desires), to involve others at the patient's direction, and to treat the patient as a partner (to the greatest extent possible).

In patient-centered care, there is active management of communication to avoid inadvertently hurting, shaming, or humiliating the patient through careless use of language or other slights. When such hurt or other error occurs, the practitioner apologizes clearly and in a heartfelt way to restore the relationship.[24]

The role of the physician in patient-centered care is one of an expert who seeks to help a patient co-manage his or her health to whatever extent is most comfortable for that particular person. The role is not to cede all important decisions to the patient.[21,25]

The patient-centered physician attempts to accomplish six goals (Table 3–1).[26] First, the physician endeavors to create conditions of welcome, respect, and safety so that the patient can reveal his or her concerns and perspective. Second, the physician endeavors to understand the patient as a whole person, listening to both the "lyrics" and the "music" of what is communicated. Third, the physician confirms and demonstrates his or her understanding

TABLE 3–1 Six Goals of Patient-Centered Care[26]

- Create conditions of safety, respect, and welcome.
- Seek to understand the patient's perspective.
- Confirm an understanding of the problem(s) via direct communication.
- Synthesize information into diagnoses and problem lists.
- Formulate and share thoughts about the illness.
- Negotiate a plan of action with the patient.

through direct, nonjargonistic language to the patient. Fourth, if the physician successfully establishes common ground on the nature of the problem as the patient perceives it, an attempt is made to synthesize these problems into workable diagnoses and problem lists. Fifth, through the use of technical mastery and experience, a path is envisioned toward healing, and it is shared with the patient. Finally, together, the physician and patient can then negotiate the path that makes the most sense for this particular patient.

Through all of this work, the physician models and cultivates a relationship that values candor, collaboration, and authenticity; it should be able to withstand and even welcome conflict, as a healthy part of human relationships.[25] In so doing, the physician–patient partnership forges a relationship that can withstand the vicissitudes of the patient's illness, its treatment, and conflict in the relationship itself. In this way, the health of the physician–patient relationship takes its place as an important element on every problem list, to be actively monitored and nurtured as time passes.

Physician Practice in Patient-Centered Care

Physicians' qualities have an impact on the doctor–patient relationship. These qualities support and enhance—but are not a substitute for—technical competence and cognitive mastery. Perhaps most important is a quality of mindfulness,[27] as described by Messner,[28] acquired through a process of constant autognosis, or self-awareness. Mindfulness appreciates that a person's emotional life (i.e., of both the physician and the patient) has meaning and importance and deserves our respect and attention. Mindfulness involves acceptance of feelings in both parties without judgment and with the knowledge that feelings are separate from acts. It also enhances an awareness of our ideals, values, biases, strengths, and limitations—again, in both the patient and doctor.

Mindfulness, which springs from Buddhist roots,[29] has offered wisdom to the practice of psychotherapy (e.g., helping patients tolerate unbearable emotions without action and helping clinicians tolerate the sometimes hideous histories their patients share with them).[30] It helps physicians find a calm place from which to build patient relationships.[31] Mindfulness also counsels us to be compassionate, without a compulsion to act on feelings. This quality is an invaluable asset to consultation psychiatrists in the general hospital, particularly with difficult patients who evoke strong emotions in medical and surgical teams. Thus the physician can be informed by the wealth of his or her inner emotional life, without being driven to act on these emotions; this can serve as a model for the relationship with the patient.

Empathy (the ability to imagine a patient's perspective, express genuine care and compassion, and communicate understanding back to the patient) is another important quality for physicians.[32] Stated differently, empathy involves "identifying a patient's emotional state accurately, naming it, and responding to it appropriately."[33] Studies have shown that physician empathy promotes more complete history-taking, enhances patient satisfaction, and improves adherence to treatment.[32,34] Conversely, simple reassurance without empathic exploration of the patient's concerns has been linked to increased visits and cost.[35] Empathy may even decrease medical–legal risk;[36] one study by Ambady and colleagues suggested that surgeons' tone of voice corresponded to malpractice rates.[37]

Communication of empathy can be achieved by both verbal and nonverbal means. Listening, establishing eye contact, expressing emotion (e.g., through facial expressions and body language, such as leaning forward, and modulating the tone of voice) are several components of empathy. Other personal qualities in the physician that promote healthy and vibrant relationships with patients include humility, genuineness, optimism, good humor, candor, a belief in the value of living a full life, and transparency in communication.[38]

Important communication skills include the ability to elicit the patient's perspective, help the patient feel understood, explain conditions and options using clear and nontechnical language, generate input and consensus about paths forward in care, acknowledge difficulty in the relationship without aggravating it, welcome input and even conflict, and work through difficulty.[39–41]

One of the most important ingredients of successful doctor–patient relationships (and one that is in terribly short supply) is time.[42] There is simply no substitute for or quick alternative to sitting with a person and taking the time to get to know that person in depth, in a private setting free from intrusions and interruptions. In the general hospital, where there are frequent interruptions, this scenario may seem impossible. However, most physicians know that patients want our full and undivided attention.

COLLABORATION AROUND HISTORY-TAKING

One major goal of an initial interview is to generate a database that will support a comprehensive differential diagnosis. However, there are other overarching goals, including demystifying and explaining the process of collaboration, finding out what is troubling and challenging the patient, co-creating a treatment path to address these problems, understanding the person as a whole, encouraging the patient's participation, welcoming feedback, and modeling a mindful appreciation of the complexity of human beings (including our inner emotional life).[43,44] At the end of the history-taking—or to use more collaborative language, after building a history with the patient[45]—a conversation should be feasible about paths toward healing and the patient's and doctor's mutual roles in that process (in which the patient feels heard, understood, confident in the outcome, and committed to the partnership).

In the general hospital, the psychiatric interview may stem from a request from the medical or surgical team.

In this case, it may be tempting to view the interview as serving the primary medical or surgical team. However, the fundamental goals and principles of the interview remain the same. Chapter 4 provides an approach to the key components of the content of a psychiatric interview. Chapter 2 discusses the approach to performing a psychiatric consultation in the general hospital.

Effective Clinical Interviewing

Effective skills and traits for clinical interviewing include friendliness, warmth, a capacity to help patients feel at ease in telling their stories, and an ability to engage the person in a mutual exploration of what is troubling him or her. Demystification of the clinical encounter, by explaining what we are doing before we do it and by making our thinking as transparent and collaborative as possible, promotes good interviews.[46] Similarly, pausing often to ask the patient if we understand clearly or seeking the patient's input and questions promotes bidirectional conversations (rather than one-sided interrogation) and can yield deeper information.[47]

One useful technique involves offering to tell the patient what we already know about him or her. For example, "I wonder if it would be helpful if I told you what Dr. Smith mentioned to me when she called to refer you to me? That way, if I have any information wrong, you could straighten it out at the outset." In the emergency department, in which we usually have a chart full of information, or when doing consultations on medical–surgical patients, this technique allows us to "show our cards" before we ask the patient to reveal information about himself or herself. Moreover, by inviting correction, we demonstrate at the outset that we value the person's input. Last, this technique allows us to put the person's story in neighborly, nonpathological language, setting the stage for the interview to follow. For example, if the chart reveals that the person has been drinking excessively and may be depressed, we can say, "It looks like you have been having a hard time recently," leaving to the patient the opportunity to fill in details.[48]

Having opened the interview, the doctor remains quiet to make room for the person to tell his or her story, encouraging (with body language, open-ended questions, and other encouragement) the person to say more. The temptation to jump too early to closed-ended symptom checklists should be eschewed. One study of 73 recorded doctor–patient encounters revealed that doctors interrupted patients after an average of 18 seconds and did not allow them to complete their opening statement in 69% of cases.[49] We should venture to listen deeply, to both the words and the music.

After a reasonable amount of time, it is often helpful for the physician to summarize what he or she has heard and to establish whether he or she understands accurately what the patient is trying to say. Saying "Let me see if I understand what you are saying so far" is a good way of moving to this part of the interview. In reflecting back to the patient our summary of what we have heard, careful use of language is important. Whenever possible, use of inflammatory or otherwise inadvertently hurtful language should be avoided ("So it sounds like you were hallucinating and perhaps having other psychotic symptoms") in favor of neighborly, neutral language ("Sounds like things were difficult—did I understand you to say you were hearing things that troubled you?"). Whenever possible, it is preferable to use the exact words that the patient has used to describe his or her emotional state. For example, if the person says, "I have been feeling so tired, just so very, very tired—I feel like I have nothing left," and we say, "It sounds as if you have been exhausted," we may or may not convey to the person that we have understood them; however, if we say, "You have been just so terribly tired," it is more likely that the person will feel understood.

One measure of rapport comes from getting the "nod"—that is, simply noticing if in the early stages of the interview, the patient is nodding at us in agreement and otherwise giving signs of understanding and of feeling understood.[46] If the nod is absent, it is a signal that something is amiss—either we have missed something important, have inadvertently offended the person, have failed to explain our process, or have otherwise derailed the relationship. A clinical interview without the nod is an interview in peril. Often a simple apology if a person has been kept waiting or an acknowledgment of something in common ("Interesting—I grew up in Maryland, too!") can go a long, long way toward creating connection and rapport.

Having established a tone of collaboration, identified the problem, and gotten the nod, the next area of focus is the history of present illness. Letting the person tell his or her story is important when eliciting the history of present illness. For many people, it is a deeply healing experience merely to be listened to in an empathic and attuned way.[48] It is best to listen actively (by not interrupting and by not focusing solely on establishing the right diagnosis) and to make sure to "get it right" from the patient's point of view. When the physician hypothesizes that the patient's problem may be more likely to be in the psychological or interpersonal realm, it is especially important to give the patient a chance to share what is troubling him or her in an atmosphere of acceptance and empathy. For many people it is a rare and healing experience to be listened to attentively, particularly about a subject that may have been a source of private suffering for some time.

In taking the history of present illness, under the pressure of time, the physician may erroneously rely too heavily on symptom checklists or ask a series of closed-ended questions to rule in or rule out a particular diagnosis (e.g., major depression). Doing this increases the risk of prematurely closing off important information that the patient might otherwise impart about the social or psychological aspects of the situation.

Having sketched in the main parameters of the person's history of the current issue, it may be wise to inquire about the last time the patient felt well with respect to this problem: the earliest symptoms recollected; associated stresses, illnesses, and changes in medications; attempts to solve the problem and their effects; and how the person elected to get help for the problem at the present time. This may be a time to summarize, review, and request clarification.

As the interviewer moves to different sections of the history, he or she may want to consider explaining what he or she is doing and why: "I'd like now to ask some questions about your psychiatric history, if any, to see if anything like this has happened before." This guided interviewing tends

to demystify what the interviewer is doing and to elicit collaboration.[46,50] Chapter 4 discusses each component of the psychiatric interview in more detail.

The social and developmental history offers a rich opportunity for data-gathering in the social and psychological realms. Where the person grew up, what family life was like, what culture the person identifies with, how far the person advanced in school, what subjects the person preferred, and what hobbies and interests the person has are all fertile lines of pursuit. Marital and relationship history, whether the person has been in love, who the person admires most, and who has been most important in the person's life are even deeper probes into this aspect of the person's experience. A deep and rapid probe into a person's history can often be achieved by the simple question, "What was it like for you growing up in your family?"[51] Spiritual orientation and practice (e.g., whether the person ever had a spiritual practice and, if so, what happened to change it) fit well into this section of the history.[52]

The formal mental status examination continues the line of inquiry that was begun in the history of present illness (i.e., the symptom checklists to rule in or rule out diagnostic possibilities and to ask more about detailed signs and symptoms to establish pertinent positives and negatives in the differential diagnosis).

An extremely important area, and one all too frequently given short shrift in diagnostic evaluations, is the area of the person's strengths and capabilities. As physicians, we are trained in the vast nosology of disease and pathology, and we admire the most learned physician as one who can detect the most subtle or obscure malady; indeed, these are important physicianly strengths, to be sure. But there is regrettably no comparable nosology of strengths and capabilities. Yet, in the long road to recovery it is almost always the person's strengths on which the physician relies to make a partnership toward healing. It is vitally important that the physician note these strengths and let the person know that the physician sees and appreciates them.[45]

Sometimes strengths are obvious (e.g., high intelligence in a young person with a first-break psychosis or a committed and supportive family surrounding a person with recurrent depression). At other times, strengths are more subtle or even counterintuitive—for example, seeing that a woman who cuts herself repeatedly to distract herself from the agony of remembering past abuse has found a way to live with the unbearable; to some extent this is true, and this is a strength. Notable, too, may be her strength to survive, her faith to carry on, and other aspects of her life (e.g., a history of playing a musical instrument, a loving concern for children, a righteous rage that galvanizes her to make justice in the world). Whatever the person's strengths, we must note them, acknowledge them, and remember them. An inability to find strengths and capacities to admire in a patient (alongside other attributes that may be a great deal less admirable) is almost always a sign of countertransference malice and bears careful thought and analysis.

Finally, a clinical diagnostic interview should always include an opportunity for the patient to offer areas for discussion: "Are there areas of your life that we have not discussed that you think would be good for me to know about?" or "Are there things we have mentioned that you'd like to say more about?" or "Is there anything I haven't asked you about that I should have?"

PLANNING THE PATH FORWARD: CREATING A CLINICAL FORMULATION

Having heard the patient's story, the physician next formulates an understanding of the person that can lead to a mutually developed treatment path. A formulation is not the same thing as a diagnosis. A diagnosis describes a condition that can be reasonably delineated and described to the person and that implies a relatively foreseeable clinical course; usually it implies options of courses of treatment. As important as a diagnosis is in clinical medicine, a diagnosis alone is insufficient for effective treatment planning and is an inadequate basis for work by the doctor–patient dyad.

In psychiatry one method for creating a formulation is to consider each patient from a bio-socio-psycho-spiritual perspective, thinking about each patient from each of four perspectives.[14] The first of these is biological: Could the person's suffering be due, entirely or in part, to a biological condition of some sort (either from an acquired condition [such as hypothyroidism] or a genetic "chemical imbalance" [such as some forms of depression and bipolar disorder])? The second model is social: Is there something going on in the person's life that is contributing to his or her suffering, such as an abusive relationship, a stressful job, a sick child, or financial trouble? The third model is psychological: Although this model is more subtle, most patients will acknowledge that practically everyone has baggage from the past, and sometimes this baggage contributes to a person's difficulties in the present. The fourth model is spiritual: Although this model is not relevant for all people, sometimes it is very important. For people who at one point had faith but lost it or for whom life feels empty and meaningless, conversation about the spiritual aspects of their suffering sometimes taps into important sources of difficulty and sometimes into resources for healing.[52]

These four models—biological "chemical imbalances," current social stressors, psychological baggage, and spiritual issues—taken together provide an excellent framework for understanding most people (see Figure 3–1). One of the beauties of this method is that these models are not particularly pathologizing or shame-inducing. On the contrary, they are normalizing and emphasize that all of us are subject to these same challenges. This opens the way to collaboration.

Whereas the biological, social, and spiritual models are fairly easy to conceptualize, the formulation of psychological issues can seem particularly daunting to physicians and to patients alike, given that every person is dizzyingly complex. It can seem almost impossible to formulate a psychological perspective of a person's life that is neither simplistic and jargon-ridden nor uselessly complex (and often jargon-ridden). A useful method for making sense of the psychological aspects of the person's life is to consider whether there are recurrent patterns of difficulty, particularly in important relationships as the person looks back on his or her life.[14] The most useful information when assessing this model is information about the most important relationships in this person's life (in plain, nontechnical terms—not only current important relationships, for which we need to

assess current social function, but also past important relationships). In this way, for example, it may become clear that the person experienced his relationship with his father as abusive and hurtful and has not had a relationship with any other person in authority since then that has felt truly helpful and supportive. This information in turn may shed light on the person's current work problems and illuminate some of the person's feelings of depression.

Underlying our inquiry regarding whether there may be significant recurrent patterns in the person's life that shed light on his or her current situation is the critical notion that these patterns almost always began as attempts to cope and represent creative adaptations or even strengths. Often, these patterns—even when they involve self-injury or other clearly self-destructive behaviors—began as creative solutions to apparently insoluble problems. For example, self-injury may have represented a way of mastering unbearable feelings and may have felt like a way of being in control while remaining alive under unbearable circumstances. It is important that the doctor appreciate that most of the time these self-defeating behaviors began as solutions and often continue to have adaptive value in the person's life. If we fail to appreciate the creative, adaptive side of the behavior, the person is likely to feel misunderstood, judged harshly, and possibly shamed.

Practically everyone finds the four models understandable and meaningful. Moreover, and importantly, these four models avoid language that overly pathologizes the person, and they use language that tends to universalize the patient's experience. This initial formulation can be a good platform for a more in-depth discussion of diagnostic possibilities. With this framework the differential diagnosis can be addressed from a biological perspective, and acute social stressors can be acknowledged. The diagnosis and treatment can be framed in a manner consistent with the person's spiritual orientation. Fleshing out the psychological aspects can be more challenging, but this framework creates a way of addressing psychological patterns in a person's life and his or her interest in addressing them and ability to do so.

TREATMENT PLANNING

Having a good formulation as a frame for a comprehensive differential diagnosis permits the doctor and the patient to look at treatment options (including different modalities or even alternative therapies or solutions not based in traditional medicine). It is possible from this vantage point to look together at the risks and benefits of various approaches, as well as the demands of different approaches (the time and money invested in psychotherapy, for example, or the side effects that are expectable in many medication trials). The sequence of treatments, the location, the cost, and other parameters of care can all be made explicit and weighed together.

This approach also is effective in dealing with situations in which the physician's formulation and that of the patient differ, so that consultation and possibly mediation can be explored.[14] For example, the physician's formulation and differential diagnosis for a person might be that the person's heavy drinking constitutes alcohol abuse or possibly dependence and that cessation from drinking and the active pursuit of sobriety is a necessary part of the solution to the patient's chronic severe anxiety and depression. The patient, on the other hand, may feel that if the doctor were offering more effective treatment for his anxiety and depression, he would then be able to stop drinking. An explicit formulation enables the patient and the doctor to see where and how they disagree and to explore alternatives. For example, in the case cited the physician could offer to meet with family members with the patient, so both could get family input into the preferred solution; alternatively, the physician could offer the patient a referral for expert psychopharmacological consultation to test the patient's hypothesis.

TABLE 3–2 Strategies to Build the Doctor–Patient Relationship

- Encourage the patient to tell his or her story.
- Explain the process of the clinical encounter at the outset.
- Use open-ended questions early in the interview.
- Elicit the patient's understanding of the problems.
- Summarize information and encourage the patient to correct any misinformation.
- Look for the "nod" as an indication of collaboration.
- Provide transitional statements when moving to new sections of the history.
- End the interview with an opportunity for the patient to add or correct information.
- Formulate according to the bio-psycho-social-spiritual model.
- Share your formulation with the patient and negotiate a plan for treatment.

In either case, however, the use of an explicit formulation in this way can identify problems and challenges early in the evaluation phase and can help the physician avoid getting involved in a treatment under conditions that make it likely to fail. Mutual expectations can be made clear (e.g., the patient must engage in a 12-step program, get a sponsor, and practice sobriety for the duration of the treatment together), and the disagreement can be used to forge a strong working relationship, or the physician and patient may agree not to work together.

The formulation and differential diagnosis are of course always in flux, as more information becomes available and the doctor and patient come to know each other more deeply. Part of the doctor's role is to welcome and nurture, to change, and to promote growth, allowing the relationship to grow as part of the process (Table 3–2).[14]

OBSTACLES AND DIFFICULTIES IN THE DOCTOR–PATIENT RELATIONSHIP

Lazare and colleagues[23] pioneered the patient's perspective as a customer of the health care system. Lazare[12] subsequently addressed the profound importance of acknowledging the potential for shame and humiliation in the doctor–patient encounter and most recently has written a treatise on the nature and power of true, heartfelt apology.[24] Throughout his work, Lazare has addressed the inevitable occurrence of conflict in the doctor–patient relationship (as in all important human relationships) and offered wise counsel for negotiating with the patient as a true partner to find creative solutions.[53]

Conflict and difficulty may arise from the very nature of the physician's training, language, or office environment. Physicians who use overly technical, arcane, or obtuse language distance themselves and make communication difficult. Physicians may lose sight of how intimidating, arcane, and forbidding medical practice—perhaps especially psychiatry—can appear to the uninitiated, unless proactive steps toward demystification occur. Similarly, overreliance on so-called objective measures, such as symptom checklists, questionnaires, tests, and other measurements, may speed diagnosis but alienate patients from effective collaboration. More insidious may be assumptions regarding the supposed incapacity of psychiatric patients to be full partners in their own care. Hurtful, dismissive language or a lack of appreciation for the likelihood that a patient has previously experienced hurtful care may damage the relationship.[15] Overly brief, symptom-focused interviews that fail to address the whole person, as well as his or her preferences, questions, and concerns, are inadequate foundations for an effective relationship.

Conflict may also arise from the nature of the problem to be addressed. In general, patients are interested in their illness—how they experience their symptoms, how their health can be restored, how to ameliorate their suffering—whereas physicians are often primarily concerned with making an accurate diagnosis of an underlying disease.[54] Moreover, physicians may erroneously believe that the patient's chief complaint is the one that the patient gives voice to first, whereas patients often approach their doctors warily, not leading with their main concern, which they may not voice at all unless conditions of safety and trust are established.[55] Any inadvertent shaming of the patient makes the emergence of the real concern all the less likely.[12]

Physicians may misunderstand a patient's readiness to change and assume that once a diagnosis or problem is identified, the patient is prepared to work to change it. In actuality, a patient may be unable or unwilling to acknowledge the problem that is obvious to the physician or, even if able to acknowledge it, may not be prepared to take serious action to change it. Clarity about where the patient is in the cycle of change[56,57] can clarify such misunderstanding and help the physician direct his or her efforts at helping the patient become more ready to change, rather than fruitlessly urging change to which the patient is not committed. Similarly, physicians may underestimate social, psychological, or spiritual aspects of a person's suffering that complicate the person's willingness or ability to partner with the physician toward change. A deeply depressed patient, for example, whose sense of shame and worthlessness is so profound that the person feels that he or she does not deserve to recover, may be uncooperative with a treatment regimen until these ideas are examined in an accepting and supportive relationship.

Conflict may arise, too, over the goals of the work. Increasingly, mental health advocates and patients promote recovery as a desired outcome of treatment, even for severe psychiatric illness. Working toward recovery in schizophrenia or bipolar disorder, which most psychiatrists regard as lifelong conditions that require ongoing management, may seem unrealistic or even dishonest.[58]

It may be useful for physicians to be aware that the term *recovery* is often used in the mental health community to signify a state analogous to recovery from alcoholism or other substance abuse.[59] In this context, one is never construed to be a recovered alcoholic but rather a recovering alcoholic—someone whose sobriety is solid; who understands his or her condition and vulnerabilities well; who takes good care of himself or herself; and who is ever alert to risks of relapse, to which the person is vulnerable for his or her entire life.

In a mental health context, *recovery* similarly connotes a process of reclaiming one's life, taking charge of one's options, and stepping out of the position of passivity and victimization that major mental illness often entails, particularly if it involves involuntary treatment, stigmatization, or downright oppression. From this perspective, recovery means moving beyond symptomatic control of the disease to having a full life of one's own design (including work, friends, sexual relationships, recreation, political engagement, spiritual involvement, and other aspects of a full and challenging life).

Other sources of conflict in the doctor–patient relationship may include conflict over methods of treatment (a psychiatrist, perhaps, who emphasizes medication to treat depression to the exclusion of other areas of the patient's life, such as a troubled and depressing marriage), over the conditions of treatment (e.g., the frequency of interactions or access to the physician after hours), or over the effectiveness of treatment (e.g., the psychiatrist believes that antipsychotic medications restore a patient's function, whereas the patient believes the same medications create a sense of being drugged and "not myself").[18]

In these examples, as in so many challenges on the journey of rendering care, an answer may lie not solely in the doctor's offered treatment, nor in the patient's resistance to change, but in the vitality, authenticity, and effectiveness of the doctor–patient relationship.

CONCLUSION

The doctor–patient relationship is a key driver of clinical outcomes—both in promoting desired results and in preventing adverse outcomes. An effective doctor–patient relationship involves both parties in co-creating a working relationship that is reliable, effective, and durable. The doctor–patient relationship in the general hospital has several unique features, including limited privacy, the interplay of medical and psychiatric illness, and the interplay of relationships among the psychiatrist, the patient, and the medical or surgical team. The relationship promotes good outcomes by creating an empowered, engaged, and active partnership with patients who feel heard and accurately understood by their physicians. Successful relationships require physicians to practice a welcoming stance, participatory decision-making, and mindfulness about both the patient's and the physician's inner lives. Especially in psychiatry, the physician must understand and relate to the patient as a whole person, which requires both accurate diagnosis and formulation, blending biological, social, psychological, and spiritual perspectives. Conflict is an inevitable aspect of all important relationships and, properly managed, can deepen and strengthen them. In the doctor–patient relationship, conflict can arise from many sources and can either derail the relationship or provide an opportunity to improve communication, alliance, and commitment.

4 The Psychiatric Interview

Eugene V. Beresin, M.A., M.D.
Margot Phillips, M.D.
Christopher Gordon, M.D.

The purpose of the initial psychiatric interview is to build a relationship and a therapeutic alliance with an individual or a family, to collect, organize, and synthesize information about present and past thoughts, feelings, and behaviors. The relevant data derive from several sources: observing the patient's behavior with the examiner and with others present (including medical staff); attending to the emotional responses of the examiner; obtaining pertinent medical, psychiatric, social, cultural, and spiritual history (using collateral resources if possible); and performing a mental status examination. The initial evaluation should enable the practitioner to develop a clinical formulation that integrates biological, psychological, and social dimensions of a patient's life and establish provisional clinical hypotheses and questions—the differential diagnosis—that need to be tested empirically in future clinical work.

A collaborative review of the formulation and differential diagnosis can provide a platform for developing (with the patient) options and recommendations for treatment, taking into account the patient's amenability for therapeutic intervention.[1] Finally, the interview must generate a relationship both with the patient and with the primary medical or surgical team as the basis of future collaboration for treatment.

Few medical encounters are more intimate and potentially frightening and shameful than the psychiatric examination.[2] As such, it is critical that the examiner create a safe space for the kind of deeply personal self-revelation required.

Several methods of the psychiatric interview are examined in this chapter. These methods include the following: promoting a healthy and secure attachment between doctor and patient that promotes self-disclosure and reflection and lends itself to the creation of a coherent narrative of the patient's life; appreciating the context of the interview that influences the interviewer's clinical technique; establishing an alliance around the task at hand and fostering effective communication; collecting data necessary for creating a formulation of the patient's strengths and weaknesses, a differential diagnosis, and recommendations for treatment, if necessary; educating the patient about the nature of emotional, behavioral, and interpersonal problems and psychiatric illnesses (while preparing the patient for a psychiatric intervention, if indicated and agreed on, and setting up arrangements for follow-up); using special techniques with children, adolescents, and families; understanding difficulties and errors in the psychiatric interview; and documenting the clinical findings for the medical record and communicating with other clinicians involved in the patient's care.

LESSONS FROM ATTACHMENT THEORY, NARRATIVE MEDICINE, AND MINDFUL PRACTICE

"I'm the spirit's janitor. All I do is wipe the windows a little bit so you can see for yourself."
Godfrey Chips, Lakota Medicine Man[3]

Healthy interactions with "attachment figures" in early life (e.g., parents) promote robust biological, emotional, and social development in childhood and throughout the life cycle.[4] The foundations for attachment theory are based on research findings in cognitive neuroscience, genetics, and brain development, and they indicate an ongoing and lifelong dance between an individual's neural circuitry, genetic predisposition, brain plasticity, and environmental influences.[5] Secure attachments in childhood foster emotional resilience[6] and generate skills and habits of seeking out selected attachment figures for comfort, protection, advice, and strength. Relationships based on secure attachments lead to effective use of cognitive functions, emotional flexibility, enhancement of security, assignment of meaning to experiences, and effective self-regulation.[5] In emotional relationships of many sorts, including the student–teacher and doctor–patient relationships, there may be many features of attachment present (such as seeking proximity, or using an individual as a "safe haven" for soothing and as a secure base).[7]

What promotes secure attachment in early childhood, and how may we draw from this in understanding a therapeutic doctor–patient relationship and an effective psychiatric interview? The foundations for secure attachment for children (according to Siegel) include several attributes ascribed to parents[5] (Table 4–1).

We must always be mindful not to patronize our patients and to steer clear of the paternalistic power dynamics that could be implied in analogizing the doctor–patient relationship to one between parent and child; nonetheless, if we substitute "doctor" for "parent" and similarly substitute "patient" for "child," we can immediately see the relevance to clinical practice. We can see how important each of these elements is in fostering a doctor–patient relationship that is open, honest, mutual, collaborative, respectful, trustworthy, and secure. Appreciating the dynamics of secure attachment also deepens the meaning of "patient-centered" care. The medical literature clearly indicates that good outcomes

TABLE 4–1 Elements That Contribute to Secure Attachments

- Communication that is collaborative, resonant, mutual, and attuned to the cognitive and emotional state of the child.
- Dialogue that is reflective and responsive to the state of the child. This creates a sense that subjective experience can be shared, and allows for the child "being seen." It requires use of empathy, "mindsight," and an ability to "see," or be in touch with, the child's state of mind.
- Identification and repair of miscommunications and misunderstandings. When the parent corrects problems in communication, the child can make sense of painful disconnections. Repair of communication failures requires consistent, predictable, reflective, intentional, and mindful caregiving. The emphasis here is on mindfulness and reflection. Mindfulness in this instance is an example of a parent's ability for self-awareness, particularly of his or her emotional reactions to the child and the impact of his or her words and actions on the child.
- Emotional communication that involves sharing feelings that amplify the positive and mitigate the negative.
- Assistance in the child's development of coherent narratives that connect experiences in the past and present, creating an autobiographical sense of self-awareness (using language to weave together thoughts, feelings, sensations, and actions as a means of organizing and making sense of internal and external worlds).

and patient satisfaction involve physician relationship techniques that center on reflection, empathy, understanding, legitimization, and support.[8,9] Patients reveal more about themselves when they trust their doctors, and trust has been found to relate primarily to behavior during clinical interviews[9] rather than to any preconceived notion of competence of the doctor or behavior outside the office.

Particularly important in the psychiatric interview is the facilitation of a patient's narrative. The practice of narrative medicine involves an ability to acknowledge, absorb, interpret, and act on the stories and struggles of others.[10] Charon[10] describes the process of listening to patients' stories as a process of following the biological, familial, cultural, and existential thread of the situation. It encompasses recognizing the multiple meanings and contradictions in words and events; attending to the silences, pauses, gestures, and nonverbal cues; and entering the world of the patient, while simultaneously arousing the doctor's own memories, associations, creativity, and emotional responses—all of which are seen in some way by the patient.[10] Narratives, like all stories, are co-created by the teller and the listener. Storytelling is an age-old part of social discourse that involves sustained attention, memory, emotional responsiveness, nonverbal responses and cues, collaborative meaning-making, and attunement to the listener's expectations. It is a vehicle for explaining behavior. Stories and storytelling are pervasive in society as a means of conveying symbolic activity, history, communication, and teaching.[5] If a physician can assist the patient in telling his or her story effectively, reliable and valid data will be collected and the relationship solidified. Narratives are facilitated by authentic, compassionate, and genuine engagement.

A differential diagnosis detached from the patient's narrative is arid; even if it is accurate it may not lead to an effective and mutually designed treatment path. By contrast, an accurate and comprehensive differential diagnosis that is supported by an appreciation of the patient's narrative is experienced by both patient and physician as more three-dimensional, more real, and more likely to lead to a mutually created and achievable plan, with which the patient is much more likely to "comply."

Creating the optimal conditions for a secure attachment and the elaboration of a coherent narrative requires mindful practice. Just as the parent must be careful to differentiate his or her emotional state and needs from the child's and be aware of conflicts and communication failures, so too must the mindful practitioner. Epstein[11] noted that mindful practitioners attend in a nonjudgmental way to their own physical and mental states during the interview. Their critical self-reflection allows them to listen carefully to a patient's distress, to recognize their own errors, to make evidence-based decisions, and to stay attuned to their own values so that they may act with compassion, technical competence, and insight.[11]

Self-reflection is critical in psychiatric interviewing. Reflective practice entails observing ourselves (including our emotional reactions to patients, colleagues, and illness); our deficits in knowledge and skill; our personal styles of communicating; our responses to personal vulnerability and failure; our willingness or resistance to acknowledge error, to apologize, and to ask for forgiveness; and our reactions to stress. Self-awareness allows us to be aware of our own thinking, feelings, and action while we are in the process of practicing. By working in this manner, a clinician enhances his or her confidence, competence, sensitivity, openness, and lack of defensiveness—all of which assist in fostering secure attachments with patients, and help them share their innermost fears, concerns, and problems.

THE CONTEXT OF THE INTERVIEW: FACTORS INFLUENCING THE FORM AND CONTENT OF THE INTERVIEW

All interviews occur in a context. Awareness of the context may require modification of clinical interviewing techniques. There are four elements to consider: the setting, the situation, the subject, and the significance.[12]

The Setting

Patients are exquisitely sensitive to the environment in which they are evaluated. There is a vast difference between being seen in an emergency department (ED), on a medical floor, on an inpatient or partial hospital unit, in a psychiatric outpatient clinic, in a private doctor's office, in a school, or in a court clinic. In the ED or on a medical or surgical floor, space for private, undisturbed interviews is usually inadequate. Such settings are filled with action, drama, and hospital personnel who race around. ED visits may require long waits and contribute to impersonal approaches to patients and negative attitudes towards psychiatric patients. For a patient with borderline traits who is in crisis, this can only create extreme frustration and exacerbate chronic fears of deprivation, betrayal, abandonment,

aloneness, and regression.[13] For these and for higher functioning patients, the public nature of the environment and the frantic pace of the emergency service may make it difficult for the patient to present personal, private material calmly. It is always advisable to ask the patient directly how comfortable he or she feels in the examining room, and to try to ensure privacy and a quiet environment with minimal distractions.

The setting must be comfortable for the patient and the physician. If the patient is agitated, aggressive, or threatening, it is always important to calmly assert that the examination must require that everyone is safe and that we will only use words and not actions during the interview. Hostile patients should be interviewed in a setting in which the doctor is protected. In some instances, local security may need to be called to ensure safety.

The Situation

Many individuals seek psychiatric help because they are aware that they have a problem. Given the limitations placed on psychiatrists by some managed care panels, access to care may be severely limited. It is not unusual for a patient to present to an ED in crisis after having called multiple psychiatrists, only to find that their practices are all filled. The frustrating process of finding a psychiatrist sets the stage for some patients to either disparage the field and the health care system, or to idealize the psychiatrist who has made the time for the patient. In either case, much goes on before the first visit that may significantly affect the initial interview. To complicate matters, the evaluator needs to understand previous experience with psychiatrists and psychiatric treatment. Sometimes a patient had a negative experience with another psychiatrist—perhaps the result of a mismatch of personalities, a style that was ineffective, a treatment that did not work, or other problems. Many will wonder about a repeat performance. In all cases, in the history and relationship building, it is propitious to ask about previous treatments (e.g., what worked and what did not, and particularly how the patient felt about the psychiatrist). There should be reassurance that this information is held in confidence, though in a hospital setting the clinician should discuss that information may be shared with the medical or surgical team.

Other patients may come reluctantly or even with great resistance. Many arrive in the ED at the request or demand of a loved one, friend, colleague, or employer because of behaviors deemed troublesome. The patient may deny any problem or simply be too terrified to confront a condition that is bizarre, unexplainable, or "mental." Some conditions are ego-syntonic, such as anorexia nervosa. A patient with this eating disorder typically sees the psychiatrist as the enemy—as a doctor who wants to make her "get fat." For resistant patients, it is often very useful to address the issue at the outset. With an anorexic patient referred by her internist and brought in by family, one could begin by saying, "Hi, Ms. Jones. I know you really don't want to be here. I understand that your doctor and family are concerned about your weight. I assure you that my job is first and foremost to understand your point of view. Can you tell me why you think they wanted you to see me?" Another common situation with extreme resistance is the individual with alcohol abuse who is brought in by a spouse or friend (and clearly not ready to stop drinking). In this case you might say, "Good morning, Mr. Jones. I heard from your wife that she is really concerned about your drinking, and your safety, especially when driving. First, let me tell you that neither I nor anyone else can stop you from drinking. That is not my mission today. I do want to know what your drinking pattern is, but more than that, I want to get the picture of your entire life to understand your current situation." Extremely resistant patients may be brought involuntarily to an emergency service, often in restraints, by police or ambulance, because they are considered dangerous to themselves or others. It is typically terrifying, insulting, and humiliating to be physically restrained. Regardless of the reasons for admission, unknown to the psychiatrist, it is often wise to begin the interview as follows: "Hi, Ms. Carter, my name is Dr. Beresin. I am terribly sorry you are strapped down, but the police and your family were very upset when you locked yourself in the car and turned on the ignition. They found a suicide note on the kitchen table. Everyone was really concerned about your safety. I would like to discuss what is going on, and see what we can do together to figure things out."

In the general hospital, a physician is commonly asked to perform a psychiatric evaluation on a patient who is hospitalized on a medical or surgical service with symptoms arising during medical or surgical treatment. These patients may be delirious and have no idea that they are going to be seen by a psychiatrist. This was never part of their agreement when they came into the hospital for surgery, and no one may have explained the risk of delirium. Some may be resistant, others confused. Other delirious patients are quite cognizant of their altered mental status and are extremely frightened. They may wonder whether the condition is going to continue forever. For example, if we know a patient has undergone abdominal surgery for colon cancer, and has been agitated, sleepless, hallucinating, and delusional, a psychiatric consultant might begin, "Good morning, Mr. Harris. My name is Dr. Beresin. I heard about your surgery from Dr. Rand and understand you have been having some experiences that may seem kind of strange or frightening to you. Sometimes after surgery, people have a reaction to the procedure or the medications used that causes difficulties with sleep, agitation, and mental confusion. This is not unusual, and it is generally temporary. I would like to help you and your team figure out what is going on and what we can do about this." Other requests for psychiatric evaluation may require entirely different skills, such as when the medical team or emergency service seeks help for a family who lost a loved one.

In each of these situations, the psychiatrist needs to understand the nature of the situation and to take this into account when planning the evaluation. In the aforementioned examples, only the introduction was addressed. However, when we see the details (discussed next) about building a relationship and modifying communication styles and questions to meet the needs of each situation, other techniques might have to be employed to make a therapeutic alliance. It is always helpful to find out as much ancillary information as possible before the interview. This may be done by talking with the medical team and primary care physicians, by looking in an electronic medical record or patient chart, and by talking with family, friends, or professionals (such as police or emergency medical technicians).

The Subject

Naturally, the clinical interview needs to take into account features of the subject (including age, developmental level, gender, and cultural background, among others). Moreover, one needs to determine "who" the patient is. In families, there may be an identified patient (e.g., a conduct-disordered child or a child with chronic abdominal pain). However, the examiner must keep in mind that psychiatric and medical syndromes do not occur in a vacuum. Although the family has determined an "identified patient," the examiner should consider that, when evaluating the child, all members of the environment need to be part of the evaluation. A similar situation occurs when an adult child brings in an elderly demented parent for an evaluation. It is incumbent on the evaluator to consider the home environment and caretaking, in addition to simply evaluating the geriatric patient. In couples, one or both may identify the "other" as the "problem." An astute clinician remains neutral (i.e., does not "take sides") and allows each person's perspective to be clarified.

Children and adolescents require special consideration. Though they may, indeed, be the "identified patient," they are embedded in a home life that requires evaluation; the parent(s) or guardian(s) must help administer any prescribed treatment (e.g., psychotropic or behavioral). Furthermore, the developmental level of the child needs to be considered in the examination. Young children may not be able to articulate what they are experiencing. For example, an 8-year-old boy who has panic attacks may simply throw temper tantrums and display oppositional behavior when asked to go to a restaurant. Although he may be phobic about malls and restaurants, his parents simply see his behavior as defiance. When asked what he is experiencing, he may not be able to describe palpitations, shortness of breath, fears of impending doom, or tremulousness. However, if he is asked to draw a picture of himself at the restaurant, he may draw himself with a scared look on his face and with jagged lines all around his body. Then when specific questions are asked, he is able to acknowledge many classic symptoms of panic disorder. Chapter 42 will address the evaluation of children in greater detail.

Evaluation of adolescents raises additional issues. While some may come willingly, others are dragged in against their will. In this instance, it is very important to identify and to empathize with the teenager: "Hi, Tony. I can see this is the last place you want to be. But now that you've been hauled in here by your folks, we should make the best of it. Look, I have no clue what is going on, and don't even know if you are the problem! Why don't you tell me your story?" Teenagers may indeed feel like hostages. They may have *bona fide* psychiatric disorders or may be stuck in a terrible home situation. The most important thing the examiner must convey is that the teenager's perspective is important, and that this will be looked at, as well as the parent's point of view. It is also critical to let adolescents, as all patients, know about the rules and limits of confidentiality. Many children think that whatever they say will be directly transmitted to their parents. Surely this is their experience in school. However, there are clear guidelines about adolescent confidentiality, and these should be delineated at the beginning of the clinical encounter. Confidentiality is a core part of the evaluation, and it will be honored for the adolescent; it is essential that this be communicated to them so they may feel safe in divulging very sensitive and private information without fears of repercussion. Issues such as sexuality, sexually transmitted diseases, substance abuse, and mental health are protected by state and federal statutes. There are, however, exceptions; one major exception is that if the patient or another is in danger by virtue of an adolescent's behavior, confidentiality is waived.[14]

The Significance

Psychiatric disorders are commonly stigmatized and subsequently are often accompanied by profound shame, anxiety, denial, fear, and uncertainty. Patients generally have a poor understanding of psychiatric disorders, either from lack of information, myth, or misinformation from the media (e.g., TV, radio, and the Internet).[15] Many patients have preconceived notions of what to expect (bad or good), based on the experience of friends or family. Some patients, having talked with others or having searched online, may be certain or very worried that they suffer from a particular condition, and this may color the information presented to an examiner. A specific syndrome or symptom may have idiosyncratic significance to a patient, perhaps because a relative with a mood disorder was hospitalized for life, before the deinstitutionalization of people with mental disorders. Hence, he or she may be extremely wary of divulging any indication of severe symptoms lest lifelong hospitalization result. Obsessions or compulsions may be seen as clear evidence of losing one's mind, having a brain tumor, or becoming like Aunt Jessie with a chronic psychosis.[12] Some patients (based on cognitive limitations) may not understand their symptoms. These may be normal, such as the developmental stage in a school-age child, whereas others may be a function of mental retardation, Asperger syndrome, or cerebral lacunae secondary to multiple infarcts following embolic strokes.

Finally, there are significant cultural differences in the way mental health and mental illness are viewed. Culture may influence health-seeking and mental health–seeking behavior, the understanding of psychiatric symptoms, the course of psychiatric disorders, the efficacy of various treatments, or the kinds of treatments accepted.[16] Psychosis, for example, may be viewed as possession by spirits. Some cultural groups have much higher completion rates for suicide, and thus previous attempts in some individuals should be taken more seriously. Understanding the family structure may be critical to the negotiation of treatment; approval by a family elder could be crucial in the acceptance of professional help.

ESTABLISHING AN ALLIANCE AND FOSTERING EFFECTIVE COMMUNICATION

Studies of physician–patient communication have demonstrated that good outcomes flow from effective communication; developing a good patient-centered relationship

is characterized by friendliness, courtesy, empathy, and partnership building, and by the provision of information. Positive outcomes have included benefits to emotional health, symptom resolution, and physiological measures (e.g., blood pressure, blood glucose level, and pain control).[17–20]

In 1999 leaders and representatives of major medical schools and professional organizations convened at the Fetzer Institute in Kalamazoo, Michigan, to propose a model for doctor–patient communication that would lend itself to the creation of curricula for medical and graduate medical education, and for the development of standards for the profession. The goals of the Kalamazoo Consensus Statement[21] were to foster a sound doctor–patient relationship and to provide a model for the clinical interview. The key elements of this statement are summarized in Table 4–2, and are applicable to the psychiatric interview.

TABLE 4–2 Building a Relationship: The Fundamental Tasks of Communication

- Elicit the patient's story while guiding the interview by diagnostic reasoning.
- Maintain an awareness that feelings, ideas, and values of both the patient and the doctor influence the relationship.
- Develop a partnership with the patient and form an alliance in which the patient participates in decision-making.
- Work with patients' families and support networks.

Open the Discussion

- Allow the patient to express his or her opening statement without interruption.
- Encourage the patient to describe a full set of concerns.
- Maintain a personal connection during the interview.

Gather Information

- Use both open- and closed-ended questions.
- Provide structure, clarification, and a summary of the information collected.
- Listen actively, using verbal and nonverbal methods (e.g., eye contact).

Understand the Patient's Perspective

- Explore contextual issues (e.g., familial, cultural, spiritual, age, gender, and socioeconomic status).
- Elicit beliefs, concerns, and expectations about health and illness.
- Validate and respond appropriately to the patient's ideas, feelings, and values.

Share Information

- Avoid technical language and medical jargon.
- Determine if the patient understands your explanations.
- Encourage questions.

Reach Agreement on Problems and Plans

- Welcome participation in decision-making.
- Determine the patient's amenability to following a plan.
- Identify and enlist resources and supports.

Provide Closure

- Ask if the patient has questions or other concerns.
- Summarize and solidify the agreement with a plan of action.
- Review the follow-up plans.

BUILDING THE RELATIONSHIP AND THERAPEUTIC ALLIANCE

All psychiatric interviews must begin with a personal introduction and establish the purpose of the interview; this helps create an alliance around the initial examination. The interviewer should attempt to greet the person warmly and use words that demonstrate care, attention, and concern. Note-taking and use of computers should be minimized and, if used, should not interfere with ongoing eye contact. The interviewer should indicate that this interaction is collaborative, and that any misunderstandings on the part of patient or physician should be immediately clarified. In addition, the patient should be instructed to ask questions, interrupt, and provide corrections or additions at any time. The time frame for the interview should be announced. In general, the interviewer should acknowledge that some of the issues and questions raised will be highly personal, and that if there are issues that the patient has real trouble with, he or she should let the examiner know. Confidentiality should be assured at the outset of the interview. If the psychiatrist is meeting a hospitalized patient at the request of the primary medical or surgical team, this should be stated at the outset.

These initial guidelines set the tone, quality, and style of the clinical interview. An example of a beginning is, "Hi, Mr. Smith. My name is Dr. Beresin. It is nice to meet you. Your surgeon, Dr. Jones, asked me to meet with you because he is concerned that you haven't eaten or taken any of your medications since you've been in the hospital. I would like to discuss some of the issues or problems you are dealing with so that we can both understand them better, and figure out what kind of assistance may be available. I will need to ask you a number of questions about your life, both your past and present, and if I need some clarification about your descriptions I will ask for your help to be sure I 'get it.' If you think I have missed the boat, please chime in and correct my misunderstanding. Some of the topics may be highly personal, and I hope that you will let me know if things get a bit too much. We will have about an hour to go through this, and then we'll try to come up with a reasonable plan together. I do want you to know that everything we say is confidential. Do you have any questions about our job today?" This should be followed with an open-ended question about the reasons for the interview.

One of the most important aspects of building a therapeutic alliance is helping the patient feel safe. Demonstrating warmth and respect is essential. In addition, the psychiatrist should display genuine interest and curiosity in working with a new patient. Preconceived notions about the patient should be eschewed. If there are questions about the patient's cultural background or spiritual beliefs that may have an impact on the information provided, on the emotional response to symptoms, or on the acceptance of a treatment plan, the physician should note at the outset that if any of these areas are of central importance to the patient, he or she should feel free to speak about such beliefs or values. The patient should have the sense that both doctor and patient are exploring the history, life experience, and current symptoms together.

For many patients, the psychiatric interview is probably one of the most confusing examinations in medicine. The psychiatric interview is at once professional and profoundly intimate. We are asking patients to reveal parts of their life they may only have shared with extremely close friends, a spouse, clergy, or family, if anyone. And they are coming into a setting in which they are supposed to do this with a total stranger. Being a doctor may not be sufficient to allay the apprehension that surrounds this situation; being a trustworthy, caring human being may help a great deal. It is vital to make the interview highly personal and to use techniques that come naturally. Beyond affirming and validating the patient's story with extreme sensitivity, some clinicians may use humor and judicious self-revelation. These elements are characteristics of healers.[22]

An example should serve to demonstrate some of these principles. A 65-year-old deeply religious woman was seen to evaluate delirium following cardiac bypass surgery. She told the psychiatric examiner in her opening discussion that she wanted to switch from her primary care physician, whom she had seen for more than 30 years. As part of her postoperative delirium, she developed the delusion that he may have raped her during one of his visits with her. She felt that she could not possibly face him, her priest, or her family, and she was stricken with deep despair. Although the examiner may have recognized this as a biological consequence of her surgery and postoperative course, the patient's personal experience spoke differently. She would not immediately accept an early interpretation or explanation that her brain was not functioning correctly. In such a situation, the examiner must verbally acknowledge her perspective, seeing the problem through her eyes, and helping her see that he or she "gets it." For the patient, this was a horrible nightmare. The interviewer might have said, "Mrs. Jones, I understand how awful you must feel. Can you tell me how this could have happened, given your longstanding and trusting relationship with your doctor?" She answered that she did not know, but that she was really confused and upset. When the examiner established a trusting relationship, completed the examination, determined delirium was present, and explained the nature of this problem, they agreed on using haloperidol to improve sleep and "nerves." Additional clarifications could be made in a subsequent session after the delirium cleared.

As noted earlier, reliable mirroring of the patient's cognitive and emotional state and self-reflection of one's affective response to patients are part and parcel of establishing secure attachments. Actively practicing self-reflection and clarifying one's understanding helps to model behavior for the patient, as the doctor and patient co-create the narrative. Giving frequent summaries to "check in" on what the physician has heard may be very valuable, particularly early on in the interview, when the opening discussion or chief complaints are elicited. For example, consultation was requested after a 22-year-old woman who was hospitalized for emergency surgery refused to go to a rehabilitation facility. During the course of the psychiatric interview, the physician elicited a history of obsessive–compulsive symptoms during the past 2 years that led her to be housebound. The interviewer said, "So, Ms. Thompson, let's see if I get it. You have been stuck at home and cannot get out of the house because you have to walk up and down the stairs for a number of hours. If you did not 'get it right,' something terrible would happen to one of your family members. You also noted that you were found walking the stairs in public places, and that even your friends could not understood this behavior, and they made fun of you. You mentioned that you had to 'check' on the stove and other appliances being turned off, and could not leave your car, because you were afraid it would not turn off, or that the brake was not fully on, and again, something terrible would happen to someone. And you said to me that you were really upset because you knew this behavior was 'crazy.' How awful this must be for you! Did I get it right?" The examiner should be sure to see both verbally and nonverbally that this captured the patient's problem. If positive feedback did not occur, the examiner should attempt to see if there was a misinterpretation, or if the interviewer came across as judgmental or critical. One could "normalize" the situation and reassure the patient to further solidify the alliance by saying, "Ms. Thompson, your tendency to stay home, stuck, in the effort to avoid hurting anyone is totally natural given your perception and concern for others close to you. I do agree, it does not make sense, and appreciate that it feels bizarre and unusual. I can see why it would be upsetting to have to wait any longer to return home. I think we can better understand this behavior, and later I can suggest ways of coping and maybe even overcoming this situation through treatments that have been quite successful with others. However, I do need to get some additional information. Is that OK?" In this way, the clinician helps the patient feel understood—that anyone in that situation would feel the same way, and that there is hope. But more information is needed. This strategy demonstrates respect and understanding and provides support and comfort, while building the alliance.

DATA COLLECTION: BEHAVIORAL OBSERVATION, THE MEDICAL AND PSYCHIATRIC HISTORY, AND MENTAL STATUS EXAMINATION

Behavioral Observation

There is a lot to be learned about patients by observing them before, during, and after the psychiatric interview. It is useful to see how the patient interacts with support staff of the clinic and with family, friends, or others who accompany him or her to the appointment. In the interview one should take note of grooming, the style and state of repair of clothes, mannerisms, normal and abnormal movements, posture and gait, physical features (such as natural deformities, birth marks, cutting marks, scratches, tattoos, or piercings), skin quality (e.g., color, texture, and hue), language (including English proficiency, the style of words used, grammar, vocabulary, and syntax), and nonverbal cues (such as eye contact and facial expressions). All these factors contribute to a clinical formulation.

The Medical and Psychiatric History

Table 4–3 provides an overview of the key components of the psychiatric history.

Presenting Problems

The interviewer should begin with the presenting problem using open-ended questions. The patient should be encouraged to tell his or her story without interruptions. Many times the patient will turn to the doctor for elaboration, but it is best to let the patient know that he or she is the true expert and that only he or she has experienced this situation directly. It is best to use clarifying questions throughout the interview. For example, "I was really upset and worked up" may mean one thing to the patient and something else to an examiner. It could mean frustrated, anxious, agitated, violent, or depressed. Such a statement requires clarification. So, too, does a comment such as "I was really depressed." Depression to a psychiatrist may be very different for a patient. To some patients, depression means aggravated, angry, or sad. It might be a

momentary agitated state or a chronic state. Asking more detailed questions not only clarifies the affective state of the patient, but also transmits the message that he or she knows best and that a real collaboration and dialogue is the only way we will figure out the problem. In addition, once the patient's words are clarified it is very useful to use the patient's own words throughout the interview to verify that you are listening.[23]

When taking the history, it is vital to remember that the patient's primary concerns may not be the same as the physician's. For example, although the examiner may be concerned about escalating mania due to high-dose steroids, the patient may be more concerned about her husband's unemployment and how this is making her agitated and sleepless. The psychiatrist may be called to consult on managing the steroid-induced mania, whereas the patient may be focused on how the psychiatrist may help her and her husband cope with family finances. In this case, her concerns should be validated. Additionally, the consultant should gently redirect her attention to her hospitalization and indicate that he is concerned about her inability to sleep and level of emotional intensity. If the patient feels the clinician and she are on the same page, this will facilitate the interview and enable the clinician to get a more detailed history and establish a diagnosis of mania. It is always useful to ask, "What are you most worried about?"

In discussing the presenting problems, it is best to avoid a set of checklist questions, but one should cover the bases to create a differential diagnosis based on the *Diagnostic and Statistical Manual*, *Fourth Edition*, *Text Revision* (DSM-IV-TR). It is best to focus largely on the chief complaint and presenting problems and to incorporate other parts of the history around this. The presenting problem is the reason for a referral and is probably most important to the patient, even though additional questions about current function and the past medical or past psychiatric history may be more critical to the examiner. A good clinician, having established a trusting relationship, can always redirect a patient to ascertain additional information (such as symptoms not mentioned by the patient, and the duration, frequency, and intensity of symptoms). Also, it is important to ask how the patient has coped with the problem and what is being done personally or professionally to help it. One should ask if there are other problems or stressors, medical problems, or family issues that exacerbate the current complaint. This is particularly relevant for patients who are hospitalized, because the period of hospitalization can have profound repercussions on a patient's emotional stability, family, finances, and future. After a period of open-ended questions about the current problem, the interviewer should ask questions about mood, anxiety, and other behavioral problems and how they affect the presenting problem.

A key part of the assessment of the presenting problem should be a determination of safety. Questions about suicide, homicide, domestic violence, and abuse must be included in the review of the current situation. Finally, one should ascertain how motivated the patient is for getting help and how the patient is faring in personal, family, social, and professional life. Without knowing more, since this is early in the interview, the examiner should avoid offering premature reassurance, but provide support and encouragement for therapeutic assistance that will be offered in the latter part of the interview.

Past Psychiatric History

After the initial phases of the interview, open-ended questions may shift to more focused questions. In the past psychiatric history, the interviewer should inquire about previous DSM-IV-TR Axis I and II diagnoses (including the symptoms of each, partial syndromes, how they were managed, and how they affected the patient's life). A full range of treatments, including outpatient, inpatient, and partial hospital care, should be considered. One should assess whether the patient has ever considered or attempted suicide. If so, ask what prompted the attempt, when it occurred, what means were used, and what the consequences were. In addition, one should also assess self-harm behaviors (such as cutting, burning, or intentional recklessness). It is most useful to ask what treatments, if any, were successful, and if so, in what ways. By the same token, the examiner should ask about treatment failures. This, of course, will contribute to the treatment recommendations provided at the close of the interview. This may be a good time in the interview to get a sense of how the patient copes under stress. What psychological, behavioral, and social means are employed in the service of maintaining equilibrium in the face of hardship? It is also wise to focus not just on coping skills, defenses, and adaptive techniques in the face of the psychiatric disorder, but also on psychosocial stressors in general (e.g., births, deaths, loss of jobs, problems in relationships, and problems with children). Discerning a patient's coping style may be highly informative and contribute to the psychiatric formulation. Does the patient rely on venting emotions, on shutting affect off and wielding cognitive controls, on using social supports, on displacing anger onto others, or on finding productive distractions (e.g., plunging into work)? Again, knowing something about a person's style of dealing with adversity uncovers defense mechanisms, reveals something about personality, and aids in the consideration of treatment options. For example, a person who avoids emotion, uses reason, and sets about to increase tasks in hard times may be an excellent candidate for a cognitive-behavioral approach to a problem. An individual who thrives through venting emotions, turning to others for support, and working to understand the historical origins of his or her problems may be a good candidate for psychodynamic psychotherapy, either individual or group.

Past Medical History

A number of psychiatric symptoms and behavioral problems are secondary to medical conditions, to the side effects of medications, and to drug–drug interactions (including those related to over-the-counter medications). The past medical history needs to be thorough and must include past and current medical and surgical conditions, past and current use of medications (including vitamins, herbs, and nontraditional remedies), use of substances (e.g., tobacco, alcohol, and other drugs [past and present]),

an immunization and travel history, pregnancies, menstrual history, a history of hospitalizations and day surgeries, accidents (including sequelae, if any), and sexual history (including use of contraception, abortions, history of sexually transmitted diseases, and testing for the latter). For hospitalized patients, assessment should include a thorough review of the patient's current hospital course, relevant laboratory test results and imaging studies, medication changes, and history from nurses, doctors, and social workers.

Review of Systems

By the time the examiner inquires about the past medical history and the review of systems, a checklist type of questioning is adopted in lieu of the previous format of interviewing. It is useful to elicit a complete review of systems following the medical history. A number of undiagnosed medical disorders may be picked up in the course of the psychiatric interview. For instance, night sweats, weight loss, and easy bruising in an elderly man with apathy may signify a malignancy that could be mistaken for depression. Many patients do not routinely see their primary care physician, and psychiatrists have a unique opportunity to consider medical conditions and their evaluation in the examination. Although not a formal part of the interview, laboratory testing is a core part of the psychiatric examination. Though this chapter refers to the interview, the review of systems may alert the clinician to order additional laboratory tests and consult the primary care physician about medical investigations.

Family History

The fact that many illnesses run in families requires an examiner to ask about the family history of medical, surgical, and psychiatric illnesses, along with their treatments.

Social and Developmental History

The developmental history is important for all psychiatric patients, but especially for children and adolescents, because prevention and early detection of problems may lead to interventions that can correct deviations in development. The developmental history for early and middle childhood and adolescence should include questions about developmental milestones (e.g., motor function, speech, growth, and social and moral achievements), family relationships in the past and present, school history (including grade levels reached and any history of attention or learning disabilities), friends, hobbies, jobs, interests, athletics, substance use, and any legal problems. Questions about adult development should focus on the nature and quality of intimate relationships, friendships, relationships with children (e.g., natural, adopted, products of assisted reproductive technology, and stepchildren), military history, work history, hobbies and interests, legal issues, and financial problems. Questions should always be asked about domestic violence (including a history of physical or sexual abuse in the past and present).

The social history should include questions about a patient's cultural background, including the nature of this heritage, how it affects family structure and function, belief systems, values, and spiritual practices. Culture can inform a patient's explanatory model of an illness for which he or she is hospitalized and may affect his or her interactions with medical staff. Questions should be asked about the safety of the community and the quality of the social supports in the neighborhood, the place of worship, or other loci in the community.

Assessing social factors (such as the availability of housing and primary supports) is of vital importance for hospitalized patients. For instance, knowing that a depressed patient is in danger of being evicted from her apartment while in the hospital is critical in performing an adequate safety assessment.

Use of Collateral Information

In addition to the patient interview, it is quite useful to obtain collateral information. Patients may have impaired insight into their behavior, so talking to other important people in the patient's life (such as a spouse or partner, siblings, children, parents, friends, and clergy) can yield important clinical information. For example, a patient who appears paranoid and mildly psychotic may deny such symptoms or not see them as problems. To understand the nature of the problem, its duration and intensity, and its impact on function, others may need to be contacted (with informed consent, of course). This applies to many other conditions, particularly substance abuse, in which the patient may deny the quantity used and the frequency of effects of substances on everyday life.

In the general hospital, several factors (e.g., delirium, confusion, dementia, pain, or sedation) can limit the patient's ability to give a full history. Collateral information is especially important in these cases. With the patient's permission, one should perform a thorough review of the medical chart. Medical personnel (including nurses, social workers, physical therapists, and primary care physicians) can provide data about the patient's symptoms and course. Moreover, they may know the patient over several years and have a useful perspective of the patient's attitudes toward illness and coping style.

Obtaining consent to contact others in a patient's life is useful not only for information gathering, but for the involvement of others in the treatment process, if needed. For children and adolescents, this is absolutely essential, as is obtaining information from teachers or other school personnel.

The Mental Status Examination

The mental status examination is part and parcel of any medical and psychiatric interview. Its traditional components are indicated in Table 4–4. Most of the data needed in this model can be ascertained by asking the patient about elements of the current problems. Specific questions may be needed for the evaluation of perception, thought, and cognition. Most of the information in the mental status examination is obtained by simply taking the psychiatric history and by observing the patient's behavior, affect, speech, mood, thought, and cognition.

Perceptual disorders include abnormalities in sensory stimuli. There may be misperceptions of sensory stimuli, known as *illusions*, for example, micropsia or macropsia (objects that appear smaller or larger, respectively, than they are). Phenomena such as this include distortions of external stimuli (affecting the size, shape, intensity, or

TABLE 4–4 The Mental Status Examination

General appearance and behavior: grooming, posture, movements, mannerisms, and eye contact
Speech: rate, flow, latency, coherence, logic, and prosody
Affect: range, intensity, lability
Mood: euthymic, elevated, depressed, irritable, anxious
Perception: illusions and hallucinations
Thought (coherence and lucidity): form and content (illusions, hallucinations, and delusions)
Safety: suicidal, homicidal, self-injurious ideas, impulses, and plans
Cognition:
- Level of consciousness
- Orientation
- Attention and concentration
- Memory (registration, recent and remote)
- Calculation
- Abstraction
- Judgment
- Insight

sound of stimuli). Distortions of stimuli that are internally created are hallucinations and may occur in one or more of the following modalities: auditory, visual, olfactory, gustatory, or kinesthetic.

Thought disorders may manifest with difficulties in the form or content of thought. Formal thought disorders involve the way ideas are connected. Abnormalities in form may involve the logic and coherence of thinking. Such disorders may herald neurological disorders, severe mood disorders (e.g., psychotic depression or mania), schizophreniform psychosis, delirium, or other disorders that impair reality testing. Examples of formal thought disorders are listed in Table 4–5.[24,25]

Disorders of the content of thought pertain to the specific ideas themselves. The examiner should always inquire about paranoid, suicidal, and homicidal thinking. Other indications of disorder of thought content include delusions, obsessions, and ideas of reference (Table 4–6).[25]

TABLE 4–5 Examples of Formal Thought Disorders

- **Circumstantiality:** a disorder of association with the inclusion of unnecessary details until one arrives at the goal of the thought
- **Tangentiality:** use of oblique, irrelevant, and digressive thoughts that do not convey the central idea to be communicated
- **Loose associations:** jumping from one unconnected topic to another
- **Clang associations:** an association of speech without logical connection dictated by the sound of the words rather than by their meaning; it frequently involves using rhyming or punning
- **Perseveration:** repeating the same response to stimuli (such as the same verbal response to different questions) with an inability to change the responses
- **Neologism:** made-up words; often a condensation of different words; unintelligible to the listener
- **Echolalia:** persistent repetition of words or phrases of another person
- **Thought-blocking:** an abrupt interruption in the flow of thought, in which one cannot recover what was just said

TABLE 4–6 Disorders of Thought Content

- **Delusions:** fixed, false, unshakable beliefs
- **Obsessions:** persistent thoughts that cannot be extruded by logic or reasoning
- **Idea of reference:** misinterpretation of incidents in the external world as having special and direct personal reference to the self

TABLE 4–7 Categories of the Mental Status Examination

- **Orientation:** for example, to time, place, person, and situation
- **Attention and concentration:** for example, remembering three objects immediately, in 1 and 3 minutes; spelling "world" backward; performing digit span; and serially subtracting 7 from 100
- **Memory:** registration, both recent and remote
  - Registration is typically a function of attention and concentration
  - Recent and remote memory are evaluated by recalling events in the short and long term
- **Calculations**
- **Abstraction:** assessed by the patient's ability to interpret proverbs or other complex ideas
- **Judgment:** evaluated by seeing if the patient demonstrates an awareness of personal issues or problems, and provides appropriate ways of solving them
- **Insight:** an assessment of self-reflection and an understanding of one's condition or the situation of others

The cognitive examination includes an assessment of higher processes of thinking. This part of the examination is critical for a clinical assessment of neurological function, and is useful for differentiating focal and global disorders, delirium, and dementia. The traditional model assesses a variety of dimensions (Table 4–7).[26]

Alternatively, the Mini-Mental State Examination[27] may be administered (Table 4–8). This instrument is commonly used to assess dementia. One large study revealed a sensitivity of 87% and specificity of 82% of diagnosing dementia with a cutoff score of 24 out of 30 points. Use of this instrument cannot make the diagnosis of a mild dementia or focal neurological deficits. Its value may also be limited by the patient's educational level and primary language. Finally, the instrument is often invalid in the presence of delirium or other processes that impair attention and concentration.[28]

SHARING INFORMATION AND PREPARING THE PATIENT FOR TREATMENT

The conclusion of the psychiatric interview requires summarizing the symptoms and history and organizing them into a coherent narrative that can be reviewed and agreed on by the patient and the clinician. This involves recapitulating the most important findings and explaining the meaning of them to the patient. It is crucial to obtain an agreement on the clinical material and the way the story holds together for the patient. If the patient does not concur

with the summary, the psychiatrist should return to the relevant portions of the interview in question and revisit the topics that are in disagreement.

This part of the interview should involve explaining one or more diagnoses to the patient (their biological, psychological, and environmental etiologies), as well as a formulation of the patient's strengths, weaknesses, and style of managing stress. The latter part of the summary is intended to help ensure that the patient feels understood. The next step is to delineate the kinds of approaches that the current standards of care would indicate are appropriate for treatment. If the diagnosis is uncertain, further evaluation should be recommended to elucidate the problem or co-morbid problems. This might require one or more of the following: further laboratory evaluation; medical, neurologic, or pediatric referral; psychological or neuropsychological testing; use of standardized rating scales; or consultation with a specialist (e.g., a psychopharmacologist or a sleep disorders or substance abuse specialist).

Education about treatment should include reviewing the pros and cons of various options. This is a good time to dispel myths about psychiatric treatments, either pharmacotherapy or psychotherapy. Both of these domains have significant stigma associated with them. For patients who are prone to shun pharmacotherapy (not wanting any "mind-altering" medications), it may be useful to "medicalize" the psychiatric disorder and note that common medical conditions involve attention to biopsychosocial treatment.[12] For example, few people would refuse medications for treatment of hypertension, even though it may be clear that the condition is exacerbated by stress and lifestyle. The same may be said for the treatment of asthma, migraines, diabetes, and peptic ulcers. In this light, the clinician can refer to psychiatric conditions as problems of "chemical imbalances"—a neutral term—or as problems with the brain, an organ people often forget when talking about "mental" conditions. A candid dialogue in this way, perhaps describing how depression or panic disorder involves abnormalities in brain function, may help. It should be noted that this kind of discussion should in no way be construed or interpreted as pressure—rather as an educational experience. Letting the patient know that treatment decisions are collaborative and patient-centered is absolutely essential in a discussion of this order.

A similar educational conversation should relate to the use of psychotherapies. Some patients disparage psychotherapies as "mumbo jumbo," lacking scientific evidence. In this instance, discussion can center around the fact that scientific research indicates that experience and the environment can affect biological function. An example of this involves talking about how early trauma affects child development, or how coming through an experience in war can produce posttraumatic stress disorder, a significant dysfunction of the brain. Many parents will immediately appreciate how the experiences in childhood affect a child's mood, anxiety, and behavior, though they will also point out that children are born with certain personalities and traits. This observation is wonderful because it opens a door for a discussion of the complex and ongoing interaction among brain, environment, and behavior.

THE EVALUATION OF CHILDREN AND ADOLESCENTS

Psychiatric disorders in children and adolescents will be discussed elsewhere in this book. In general, children and adolescents pose certain unique issues for the psychiatric interviewer. First, a complete developmental history is required. For younger children, most of the history is taken from the parents. Rarely are young children seen initially apart from parents. Observation of the child is critical. The examiner should notice how the child relates to the parents or caregivers. Conversely, it is important to note whether the adult's management of the child is appropriate. Does the child seem age appropriate in terms of motor function and growth? Are there any observable neurological impairments? The evaluator should determine whether speech, language, cognition, and social function are age appropriate. If possible, the examiner should provide toys for the evaluation in the emergency department or hospital ward. Collateral information from the pediatrician and schoolteachers is critical to verify or amplify parental and child-reported data.

Adolescents produce their own set of issues and problems for the interviewer.[29] A teenager may or may not be accompanied by a parent. However, given the developmental processes that surround the quests for identity and separation, the interviewer must treat the teen with the same kind of respect and collaboration as with an adult. The issue and importance of ensuring confidentiality have been mentioned previously. The adolescent also needs to hear at the outset that the interviewer would need to obtain permission to speak with parents or guardians, and that any information received from them would be faithfully transmitted to the patient.

Although all the principles of attempting to establish a secure attachment noted previously apply to the adolescent, the interview of the adolescent is quite different from that of an adult. Developmentally, teenagers are capable of abstract thinking and are becoming increasingly autonomous. At the same time, they are struggling with grandiosity that alternates with extreme vulnerability and self-consciousness and managing body image, sexuality and aggression, mood lability, and occasional regression to dependency—all of which makes an interview and relationship difficult. The interviewer must constantly consider what counts as normal adolescent behavior and what risk-taking behaviors, mood swings, and impulsivity are pathological. This is not easy, and typically teenagers need a few initial meetings for the clinician to feel capable of co-creating a narrative—albeit a narrative in progress. The stance of the clinician in working with adolescents requires moving in a facile fashion between an often-needed professional authority figure and a big brother or sister, camp counselor, and friend. The examiner must be able to know something about the particular adolescent's culture, to use humor and exaggeration, to be flexible, and to be empathic in the interview, yet not attempt to be "one of them." It is essential to validate strengths and weaknesses and to inspire self-reflection and some philosophical thinking—all attendant with the new cognitive developments since earlier childhood.

DIFFICULTIES AND ERRORS IN THE PSYCHIATRIC INTERVIEW

Dealing with Sensitive Subjects

A number of subjects are particularly shameful for patients. Such topics include sexual problems, substance abuse and other addictions, financial matters, impulsive behavior, bizarre experiences (such as obsessions and compulsions), domestic violence, histories of abuse, and symptoms of psychosis. Some patients will either deny or avoid discussing these topics. In this situation, nonthreatening, gentle encouragement and acknowledgment of how difficult these matters are may help. If the issue is not potentially dangerous or life-threatening to the patient or to others, the clinician may omit some questions known to be important in the diagnosis or formulation. If it is not essential to obtain this information in the initial interview, it may be best for the alliance to let it go, knowing the examiner or another clinician may return to it as the therapeutic relationship grows.

In other situations that are dangerous (such as occurs with suicidal, homicidal, manic, or psychotic patients), in which pertinent symptoms must be ascertained, questioning is crucial no matter how distressed the patient may become. In some instances when danger seems highly likely, transfer to a psychiatric hospital may be necessary for observation and further exploration of a serious disorder. Similarly, an agitated patient who needs to be assessed for safety may need sedation, restraints, or eventual transfer to a psychiatric hospital to complete a comprehensive evaluation, particularly if the cause of agitation is not known and the patient is not collaborating with the evaluative process.

Disagreements about Assessment and Treatment

There are times when a patient disagrees with a clinician's formulation, diagnosis, and treatment recommendations. Or the disagreement may be between the patient and the medical staff, with the psychiatrist in the challenging position of the intermediary. In either case, it is wise to listen to the patient and hear where there is conflict. This can serve to reestablish the alliance. It also may diffuse the

TABLE 4–9 Common Errors in the Psychiatric Interview

- Premature closure and false assumptions about symptoms
- False reassurance about the patient's condition or prognosis
- Defensiveness around psychiatric diagnoses and treatment, with arrogant responses to myths and complaints about psychiatry
- Omission of significant parts of the interview, due to theoretical bias of the interview (e.g., mind–body splitting)
- Recommendations for treatment when diagnostic formulation is incomplete
- Inadequate explanation of psychiatric disorders and their treatment, particularly not giving the patient multiple options for treatment
- Minimization or denial of the severity of symptoms, due to overidentification with the patient; countertransference phenomenon (e.g., as occurs with treatment of a "very important person" [VIP] in a manner inconsistent with ordinary best practice, with a resultant failure to protect the patient or others)
- Failure to establish a genuine, empathic rapport (e.g., by using brusque language, tone, or body posture)
- Use of an angry or dismissive style in response to a patient who is guarded or hostile
- Inadvertently shaming or embarrassing a patient, and not offering an apology

patient's need to defend himself or herself against what he or she may perceive as doctors "ganging up" on him or her. Then, the evaluator should systematically review what was said and how he or she interpreted the clinical findings. The patient should be encouraged to correct misrepresentations. Sometimes clarification will help the clinician and patient come to an agreement. At other times, the patient may deny or minimize a problem. In this case additional interviews may be necessary. It is sometimes useful to involve a close relative or friend, if the patient allows this. If the patient is a danger to self or others, however, protective measures will be needed, short of any agreement. If there is no imminent danger, explaining one's clinical opinion and respecting the right of the patient to choose treatment must be observed. It may also be necessary to work with the medical team to reach a compromise that takes into consideration the patient's goals and wishes when they differ from that of the medical team.

Errors in Psychiatric Interviewing

Common mistakes made in the psychiatric interview are provided in Table 4–9.

CONCLUSION

The purpose of the psychiatric interview is to establish a therapeutic relationship with the patient to collect, organize, and synthesize data that can become the basis for a formulation, differential diagnosis, and treatment plan. A fundamental part of establishing this relationship is fostering a secure attachment between doctor and patient, in order to facilitate mutual and open communication, to correct misunderstandings, and to help the patient create a cohesive narrative of his or her past and present situation. Interviews in the general hospital require modification in techniques in order to take into account four elements of the context: the setting, the situation, the subject, and the significance. Data collection should include behavioral observation, medical and psychiatric history, and a mental status examination.

The clinician should conclude the interview by summarizing the findings and the formulation, seeking agreement with the patient, and negotiating appropriate follow-up arrangements. All clinicians should be aware of difficulties in the psychiatric interview (such as shameful topics and disagreements about assessment or treatment). Common errors in an interview include premature closure and false assumptions about symptoms, false reassurance about a patient's condition, defensiveness around psychiatric diagnosis and treatment, maintenance of a theoretical bias about mental health and illness, inadequate explanations about psychiatric disorders and their treatment, minimization of the severity of symptoms, and inadvertent shaming of a patient without offering an apology.

Functional Neuroanatomy and the Neurologic Examination

5

Anthony P. Weiss, M.D., M.B.A.
Stephan Heckers, M.D.

The brain is a complex and mysterious organ. Sealed away in its cranial vault, it is immune from the poking, prodding, visualizing, and auscultating that are central to the examination of other organs. The assessment of the brain and its peripheral extensions requires an indirect approach, one that evaluates the integrity of its functional capacity. Because there are many faculties associated with the brain, this functional assessment is lengthy and complex. One component of this evaluation is the neurologic examination, which can intimidate medical students and seasoned physicians alike. As a result, the neurologic examination is all too often omitted by the busy clinician, with the entire examination summarized as "grossly intact."

For the psychiatric consultant, the neurologic examination is an important component of every patient evaluation for several reasons. First, psychiatric symptoms (affective, behavioral, or cognitive) may result directly from underlying neurologic damage (e.g., stroke causing mood lability). It is the associated sensory and motor findings on examination that will uncover the root cause of these symptoms. Second, psychiatric symptoms are commonly seen in the context of neurologic disorders (e.g., depression in Parkinson's disease). In some cases, the psychiatric symptoms predate or predominate over the other features of the illness; a thorough examination by the psychiatrist may therefore lead to early recognition and treatment. Third, knowledge of the neurologic examination is crucial for distinguishing real neurologic deficits from simulated deficits associated with conversion disorders or malingering. The consultation psychiatrist is often called on to clarify this diagnostic dilemma. Finally, the psychiatrist must be aware of the numerous ways in which psychotropic medications can affect the sensory and motor systems of the brain (e.g., by causing dystonias and other movement disorders) and must be capable of assessing the severity of these adverse effects.

In this chapter, we hope to provide the consulting psychiatrist with both a theoretical and a pragmatic framework for the neurologic examination. First, we introduce a systematic overview of functional neuroanatomy, examining at a basic level the actual role of the nervous system in the human, and providing a simplified approach to the otherwise unimaginable complexity of billions of interconnected neurons. Then, we provide an outline for the neurologic examination itself, discussing the rationale for each component and providing a few clinically relevant pointers. By enumerating the main components of the standard examination and by attempting to relate them to the anatomic constructs developed herein, we hope to provide an organization to help in both the understanding and the recollection of each aspect of the examination.

FUNCTIONAL NEUROANATOMY

Why do we have a nervous system? What is the reason for its complexity in humans? By addressing these questions we gain a greater understanding not only of the nervous system as a whole but also of its component parts.

At its most basic level, the nervous system allows us to interact with the external world, serving as a bridge between the environment and our internal mental and physical worlds. Put another way, the nervous system allows us to respond in some fashion to environmental stimuli. In simpler organisms, there is little or no gap between stimulus and response, allowing little or no variability of response to a specific stimulus. In humans, however, there is a large evaluation step, which allows a carefully chosen response to a stimulus, one that may be influenced by the situational context.

Using an information-processing model, we can map these concepts in three distinct steps: *input* of sensory information through perceptual modules, the internal integration and *evaluation* of this information, and the production of a *response*. These steps are carried out by four main anatomic systems in the brain: the *thalamus*, the *cortex*, the *medial temporal lobe*, and the *basal ganglia* (Figure 5–1).

Sensory organs provide information about physical attributes of incoming information. Details of physical attributes (e.g., temperature, sound frequency, color) are conveyed through multiple segregated channels in each perceptual module. Information then passes through the thalamus, which serves as the gateway to cortical processing for all sensory data. Specifically, it is the relay nuclei (ventral posterior lateral, medial geniculate, and lateral geniculate) that convey sensory information from the sensory organs to the appropriate area of primary sensory cortex (i.e., S1, A1, or V1) (Figure 5–2).

The first step in the integration and evaluation of incoming stimuli occurs in unimodal association areas of the cortex, where physical attributes of one sensory domain are linked together. A second level of integration is reached in multimodal association areas, including regions in the parietal lobe and prefrontal cortex, which link together the physical attributes from different sensory domains. A third

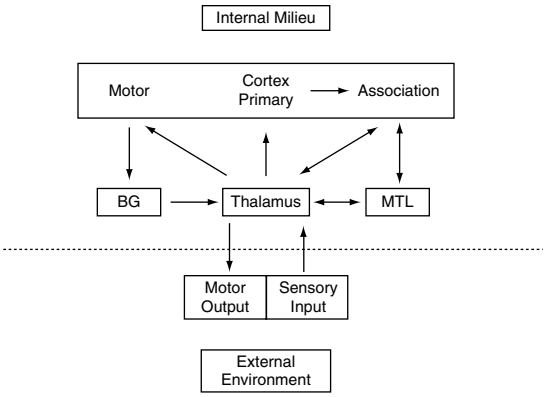

Figure 5–1. Basic circuitry of information processing. BG, basal ganglia; MTL, medial temporal lobe.

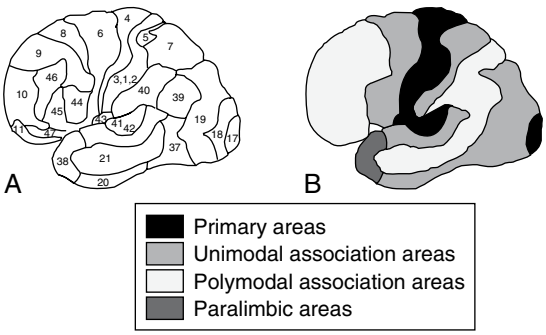

Figure 5–2. Functional role of areas in the human cerebral cortex. **A,** Map of cytoarchitectonic areas according to Brodmann. The parcellation of the cortical mantle into distinct areas is based on the microscopic analysis of neurons in the six layers of the cortex. **B,** Map of functional areas according to Mesulam. The primary sensory areas (visual = area 17; auditory = areas 41, 42; somatosensory = areas 3, 1, 2) and the primary motor area 4 are indicated in *black*. The association areas, dedicated to one stream of information processing (visual = areas 18, 19, 20, 37; auditory = area 22; somatosensory = areas 5, 7, 40; motor = areas 6, 44), are indicated in *dark gray*. The polymodal association areas, where all sensory modalities converge, are indicated in *light gray*. The temporal pole is part of the paralimbic areas, which occupy large regions on the medial surface of the brain (i.e., cingulate cortex and parahippocampal cortex). **A** from Brodmann K: *Vergleichende lokalisationslehre der grosshirnrinde in ihren prinzipien dargestellt auf grund des zellenbaues,* Leipzig, Germany, 1909, JA Barth; **B** from Mesulam M-M: *Principles of behavioral neurology,* Philadelphia, 1985, FA Davis.

level of integration is provided by input from limbic and paralimbic regions of the brain, including the cingulate cortex and regions of the medial temporal lobe (hippocampus and amygdala). It is at this third level of integration that the brain creates a representation of experience that has the spatiotemporal resolution and full complexity of the outside world, imbued with emotion and viewed in the context of prior experience. Evaluation and interpretation involve the comparison of new information with previously stored information and current expectations or desires. This allows the brain to classify information as new or old, or as threatening or nonthreatening.

Based on the result of evaluation and interpretation, the brain then creates a response, most often through motor action. The regions involved in generating this response include the motor cortex, the motor nuclei of the thalamus, the basal ganglia, and the cerebellum. The basal ganglia, which include the striatum (made up of the caudate and the putamen) and the globus pallidus, are charged with integrating and coordinating this motor output. The striatum receives input from the motor cortex, and it projects to the globus pallidus. The globus pallidus in turn relays the neostriatal input to the thalamus. The thalamus then projects back to the cortical areas that gave rise to the corticostriatal projections, thereby closing the cortico-striato-pallido-thalamo-cortical loop. This loop is thought to be the means by which motor control is enacted; damage to regions in this loop leads to disorders such as Parkinson's disease and Huntington's disease.

THE NEUROLOGIC EXAMINATION

The neurologic examination is a set of steps designed to probe the input, integration/evaluation, and output domains of information processing. We provide here an overview of the examination, using this framework. Our aim is to demystify the examination by presenting the rationale for its component parts. The examination presented here is not all-encompassing; see standard texts of neurology for complete details.

Input

Sensory information enters the central nervous system (CNS) by two routes: spinal nerves and cranial nerves. The former handle tactile information presented to the body, and the latter handle tactile information presented to the face and each of the remaining special senses (vision, hearing, smell, and taste).

Peripheral Sensory Examination

Peripheral sensation allows tactile exploration of our environment. Even the most thorough examiner could not test every square inch of the body for intact sensation, nor would this be necessary. Knowledge of the full sensory examination is important for the patient with a focal sensory complaint (see other texts for detailed information on peripheral nerve examination[1–9]). The main sensory modalities include the following:

Pain: Tested by pinprick (using disposable sterile pins)

Temperature: Tested by touching the skin with a cold metal object (e.g., a tuning fork)

Light touch: Tested by simply brushing the patient's skin with your hand or a moving wisp of cotton

Vibration sense: Tested by applying a "buzzing" tuning fork to the distal lower extremities

Proprioception: Best tested by Romberg's maneuver (which can be assessed during gait observation). Ask the patient to stand with the feet as close together as possible while still maintaining stability. Then ask the patient to close the eyes (ensure the patient that you will not let him or her fall). The patient with poor proprioception will begin to sway and lose balance after closing the eyes.

Sensory Cranial Nerves (I, II, V, VII, VIII)

Five cranial nerves serve an input function and are known as sensory cranial nerves, to distinguish them from those that play a motor/output or dual sensorimotor role (Table 5–1).

Olfactory Nerve (Cranial Nerve I)

Testing of the first cranial nerve is almost uniformly neglected, and the entire cranial nerve examination is often described as "II-XII within normal limits." This notation indicates little regard for the first cranial nerve, and it communicates little about the individual features of the examination.

The first cranial nerve runs along the orbital surface of the frontal lobe, an area that is otherwise clinically silent. Lesions in this area (e.g., a frontal lobe meningioma) may produce unilateral anosmia, occasionally as a sole symptom. Routine testing of smell is therefore quite important. A small vial of coffee provides a simple and convenient method for testing smell. The nostrils should be tested separately.

Optic Nerve (Cranial Nerve II)

The optic nerve and its posterior radiations run the entire length of the brain and produce different patterns of symptoms and signs depending on where they are compromised. A thorough visual examination can therefore be quite informative. It involves five components:

Funduscopic examination: The optic nerve is the only nerve that can be visualized directly. The physician should take advantage of this in assessing its integrity. A good funduscopic examination also reveals much about the systemic vascular system, and it is a critical guide to the presence of increased intracranial pressure.

Visual acuity: Testing of visual acuity (i.e., the actual strength of vision) is frequently ignored in the adult patient. This is unfortunate because poor vision can profoundly impair a patient's ability to function and is often reversible with corrective lenses or surgery. Acuity should be assessed in each eye while the patient is wearing current corrective lenses.

Pupillary measurement: Pupillary size represents the delicate balance between sympathetic and parasympathetic input to the ciliary muscles of the eye. The presence of abnormally large or small pupils reflects an imbalance and may be an important sign of disease or toxicity. Similarly, an inequality in pupillary size (anisocoria) can be an important hallmark of a severe intracranial pathologic condition. Each pupil should be measured in millimeters, with measurements clearly documented for future reference.

Pupillary reaction: The direct and consensual pupillary reaction to light, and the near reaction (accommodation), should be tested routinely. This assesses any damage in the afferent and efferent pathways that compose the pupillary response. A penlight and close observation are all that are necessary.

Confrontational visual fields: As noted previously, the visual system runs from the retina to the occipital cortex, involving a substantial area of the CNS. Lesions anywhere along this pathway lead to visual field cuts. Importantly, the patient is almost never aware of this abnormality of vision; careful testing is therefore required to elucidate it. Sit directly in front of the patient, and have him or her look into your eyes. The eyes should be tested separately by bringing an object

TABLE 5–1 The Cranial Nerves

NUMBER	NAME	SENSORY (INPUT), MOTOR (OUTPUT), OR BOTH?	FUNCTION
I	Olfactory	Sensory	Olfaction
II	Optic	Sensory	Vision
III	Oculomotor	Motor	Innervation of extraocular musculature
IV	Trochlear	Motor	Innervation of extraocular musculature
V	Trigeminal	Both	Facial sensation + innervation of muscles of mastication
VI	Abducens	Motor	Innervation of extraocular musculature
VII	Facial	Motor	Taste + innervation of muscles of facial expression
VIII	Vestibulocochlear	Sensory	Hearing + balance
IX	Glossopharyngeal	Both	Taste + innervation of stylopharyngeus muscle
X	Vagus	Both	Parasympathetic innervation + innervation to muscles of larynx and pharynx
XI	Spinal accessory	Motor	Innervation of the sternocleidomastoid and trapezius muscles
XII	Hypoglossal	Motor	Innervation of tongue

(e.g., a pin or a wiggling finger) into each visual quadrant. For the patient who is unable to cooperate in this fashion, simply having him or her count fingers displayed in each quadrant is another option.

Trigeminal Nerve (Cranial Nerve V)

The sensory component of the trigeminal nerve provides tactile sense to the face. As with sensory testing in general (see earlier), testing sensory integrity of the face can be a frustrating exercise if the examiner insists on precision. Unless the patient has a specific sensory complaint (e.g., a numb chin or facial pain), thorough testing of all sensory modalities is probably unnecessary. Testing light touch (by stroking the face with your fingers) or temperature sensitivity (using a cold metal tuning fork) is usually adequate. Asking the patient to quantify the degree of difference (e.g., "If this side is a dollar, how much is this side?") is generally not fruitful. Simply asking, "Does this feel normal on both sides?" saves time and will generally detect any abnormalities worth further investigation.

The trigeminal nerve also provides the input for the corneal reflex, the direct and the consensual blink seen in response to corneal irritation. Although testing for the corneal reflex can be helpful in localization of brainstem dysfunction (usually in the comatose patient), it is unfortunately both nonspecific and insensitive. It is therefore not done routinely.

Facial Nerve (Cranial Nerve VII)

The sensory component of the facial nerve (chorda tympani) transmits taste from the anterior two thirds of the tongue, running from the taste buds to the nucleus of the tractus solitarius in the medulla. Testing this aspect of the facial nerve involves the application of a sweet, sour, or salty solution (via a cotton-tipped swab) to the outstretched tongue. The yield of this component of the examination in the patient without specific gustatory complaints is minimal.

Acoustic Nerve (Cranial Nerve VIII)

In addition to its role in the maintenance of equilibrium (via the vestibular branch), the eighth cranial nerve is the primary input channel for auditory information. The acoustic nerve carries information from the hair cells in the organ of Corti, traveling through the internal auditory meatus to the pontomedullary junction of the brainstem. For the consulting psychiatrist, the examination of auditory function can be kept to a cursory check, but it should be included, particularly in geriatric patients. Rubbing fingers together near the ear may bring out high-pitched hearing deficits, a finding typically associated with presbycusis.

Integration and Evaluation

Even the simplest unicellular organisms have means by which they can sense and react to the environment. These responses are automatic and limited; the same stimulus results in the same response regardless of context. A number of these automatic or reflexive responses can be tested in the human, and some of them were discussed as part of the sensory evaluation (e.g., the pupillary light reflex and the corneal reflex). Three additional sets of reflexes are commonly probed in a standard neurologic examination:

Proprioceptive reflexes: Proprioceptive reflexes, also known as deep tendon reflexes (DTRs), are based on the simple reflex arcs that are activated by stretching (or tapping). Because they are influenced by the descending corticospinal tracts, DTRs can provide important information on the integrity of this pathway at several levels. The reader is probably familiar with the methods used to elicit the five major DTRs: biceps, triceps, brachioradialis, quadriceps (knee), and Achilles (ankle). The grading of each reflex is on a four-point scale, with a score of 2 (2+) designated as normal.

Nociceptive reflexes: Nociceptive reflexes are based on reflex arcs located in the skin (rather than muscle tendons) and are therefore elicited by scratching or stroking. These include the abdominal reflexes, cremasteric reflex, and anal wink, none of which is extensively used clinically. The major nociceptive reflex of clinical value is the plantar reflex. Stroking the sole of the foot should elicit plantar flexion of the toes. Babinski's sign, marked by an extensor response (i.e., dorsiflexion) of the toes, often with fanning of the toes and flexion of the ankle, is seen in pyramidal tract disease. It has become one of the most famous eponymic signs in medicine.

Primitive reflexes (release reflexes): Primitive reflexes are present at birth but disappear in early infancy. Their reappearance later in life is abnormal and often reflects frontal lobe disease. They include the grasp reflex (stroking the patient's palm leads to an automatic clutching of your finger between his thumb and index finger), the glabellar reflex (cessation of the natural blink response in response to repetitive tapping on the forehead), and the snout reflex (gentle tapping over the patient's upper lip causes a puckering of the lips). Note that this may also elicit a suck response, or a turning of the head toward the stroking stimulus (root reflex).

The Mental Status Examination

The brains of higher mammals, particularly the human, have the added capacity to integrate sensory information across domains, to evaluate this information, and to react in a manner consistent with past experience, current context, or future expectations. The ability to use these higher-level faculties is often considered part of the mental status examination. For routine purposes, the following four components compose an adequate examination. It is important that these components, unlike other features of the neurologic examination, be done in order, because basic functions must be intact to perform more complex tasks.

Level of consciousness: Consciousness lies on a continuum from full alertness to coma. Although the two extremes are generally obvious, the middle ground of attentional deficit can be subtle. Because inattention is a hallmark of delirium (an acute confusional state), a common and emergent medical condition, attention should be tested in all patients. Sustained attention is also a critical component for all other cognitive functions. Some common tests of attention include "serial 7s" (ask the patient to subtract 7 from 100 and to then continue to serially subtract 7 from the remainder) and digit span (have the patient repeat a randomly presented list of digits [a normal capacity is between five and seven digits], or have the patient spell a five-letter word [e.g., *world*] backward).

Language: Language is the means by which we present our thoughts to each other. Like other cognitive functions, language can be extraordinarily complex, with entire texts of aphasiology dedicated to its study. In general, the following three simple questions allow the examiner to draw valid conclusions about language in the individual patient (Figure 5–3):

- Is the language *fluent* or *nonfluent?* Independent of the actual words, does the speech sound like a language? Loss of the normal inflection and spacing of normal speech leads to nonfluent language production.
- Is *comprehension* normal or abnormal? Does the patient seem to understand what you are saying? A request to complete a one-step to three-step command (although complex commands may test more than just receptive language function) best assesses this. Asking simple yes-or-no questions (e.g., Were you born in Mexico? or Are we in the kitchen?) is another common method.
- Is *repetition* normal or abnormal? Have the patient repeat a phrase such as "no ifs, ands, or buts." This particular phrase is quite sensitive, given the difficulty of repeating conjunctions.

Memory: Memory function is generally divided into the following three components:

- *Immediate recall* is the ability to hold information long enough to use it (e.g., remembering a phone number given by the operator long enough to dial it). Immediate recall is heavily dependent on attention and is tested by both digit span and phrase repetition. Asking the patient to repeat three named items (e.g., piano, monkey, and blue) is another commonly used method.
- *Short-term memory* involves the ability to store information for later use. Asking the patient to reproduce the three previously named items after a span of 2 to 5 minutes is a common test.
- *Long-term memory* involves the recall of past events. This is nearly impossible to test accurately at the bedside, because the examiner is rarely privy to details of remote events from the patient's life. Asking about well-known national events or people (e.g., How did JFK die?) depends on the age and educational background of the patient. Accurate assessment often requires a standardized battery of questions available in full neuropsychological testing.

Basic Aphasiology

Type	Repetition	Comprehension	Speech
Gobal	Impaired	Impaired	Nonfluent
Wernicke's	Impaired	Impaired	Fluent
Broca's	Impaired	Intact	Nonfluent
Conduction	Impaired	Intact	Fluent
Transcortical			
Motor	Intact	Intact	Nonfluent
Sensory	Intact	Impaired	Fluent

Figure 5–3. Differential diagnosis of the main types of aphasias.

Visual-Spatial Skills

Writing: Ask the patient to write his or her name, address, and a sentence about the weather. Look for grammatical errors, as well as errors in spacing and overall presentation.

Clock-drawing: Have the patient fill in a circle with numbers in the form of a clock; when completed, ask the patient to set the hands at 10 minutes to 2. Abnormalities can occur in planning (e.g., manifested by poor spacing between numbers) or in positioning of the hands (with a style that reflects being stimulus-bound) that may belie a frontal lobe lesion. Complete absence of detail on one side of the clock (usually the left side) may represent a hemineglect syndrome associated with a (right) parietal lobe lesion.

Output

Although there are many potential responses to environmental stimuli, including subtle changes in the internal hormonal or neurochemical milieu, most often the response requires some type of motor output. The examination of this output can be divided into a motor (or muscular) component and a coordination component.

Motor (III, IV, VI, XI, XII) and Sensorimotor (V, VII, IX, X) Cranial Nerves

These cranial nerves are responsible for motor function in the head and neck and are tested by examining the functionality of the muscles they subserve. For example, cranial nerves III, IV, and VI innervate the extraocular muscles that allow the eye to scan its environment. They are therefore tested by examining the range of eye movement in all directions (by having the patient track one's finger). The role and testing of other cranial nerves are listed in Table 5–1.

Motor Examination

There are three aspects evaluated in the motor examination: muscle tone, muscle bulk, and muscle strength. The three aspects may be affected separately. *Motor tone* refers to the resistance of a limb to passive movement through its normal range of motion. To examine for tone, one can have the patient fully relax the arms and legs to allow you to determine the degree of stiffness during passive motion. An increased level of tone, noted by rigidity or spasticity, is an important finding that may belie an upper motor neuron or extrapyramidal lesion (as in, e.g., parkinsonism).

Muscle atrophy is an important sign of lower motor neuron disease. Assessment of muscle bulk can be extraordinarily difficult, even for the seasoned clinician, because of natural variations in body habitus and the role of weightlifting or exercise (i.e., "bulking up"). Muscles that are unaffected by weightlifting or exercise (e.g., the facial muscles or the intrinsic muscles of the hand) may therefore provide the best estimate of overall muscle bulk.

In testing muscle strength, it is impractical (and unnecessary) to test each of the several hundred muscles in the human body. Should the patient have a focal motor complaint, knowledge of major muscle groups in the proximal and distal limbs becomes important. Muscle strength is graded from 0 (no motion) to 5 (normal strength).

Observation of gait is an excellent screening test for the patient without focal weakness. If the patient is able to rise briskly and independently from a seated position and

walk independently, gross motor deficits can be confidently ruled out. The ability to walk on one's heels and toes further ensures distal lower-extremity strength. Gait must be tested in all patients, particularly in older adults, for whom a fall can be a life-threatening event.

Coordination

Coordination reflects the ability to orchestrate and control movement, and it is crucial in the translation of movement into productive activity. Although the cerebellum probably plays the lead role in motor coordination, several other structures (e.g., the basal ganglia and red nucleus) are also clearly involved.

Walking is an extraordinarily complex motor skill that requires significant coordination of the trunk and limbs. Its complexity makes it an ideal screening test for coordination ability. Humans have a particularly narrow base when standing upright; with any degree of incoordination (ataxia), the patient needs to widen the base to remain upright. Balance becomes even more difficult when other sensory information is removed, forming the basis for Romberg's maneuver. The sensitivity of screening is further increased by having the patient walk heel-to-toe (as on a tightrope). The ability to do this smoothly and quickly rules out any major impairment in coordination.

Diadochokinesia refers to the alternating movements made possible by the paired nature of agonist and antagonist muscle activity in coordinated limb movement. Abnormalities of this function are given the lengthy label *dysdiadochokinesia* and are detected by several simple maneuvers, including finger-to-nose, heel-to-shin, and rapid alternating movements (rapid pronation or supination of the forearm [e.g., screwing in a light bulb], finger tapping, or toe tapping). Having the patient tap out a rhythm is an excellent way to assess coordination ability. With cerebellar damage, the rhythm is poorly timed, with emphases in the wrong places.

CONCLUSION

The brain is an organ that is unmatched in its eloquence. Unlike the anginal grip of cardiac disease or the choking dyspnea of respiratory dysfunction, illness of the brain can send many different messages. Deciphering these messages using the neurologic examination can be complex and at times bewildering. This should not discourage the practicing psychiatrist from using the examination described in this chapter as a routine part of every patient evaluation.

6 Limbic Music

George B. Murray, B.S., Ph.L., M.S., M.Sc., M.D., S.J.
Nicholas Kontos, M.D.

"Limbic Music" is a strange title for a chapter in a handbook of psychiatry in the general hospital. However, it is meant to be clinically relevant. This chapter is primarily heuristic. Some license is taken with philosophic assumptions not adequately substantiated, there are arguable statements, and the anatomy and physiology on which this structure is based may change, although probably not in a major way, in the coming years. Mesulam[1] mentions that the concept of the limbic system has ebbed and flowed to fit the preference of individual authors. This is another case of it. It is hoped that the use of *limbic music* will aid the clinician in assessing the affective component in the patient.

In academic institutions, the limbic system has historically played the ugly stepsister to the cerebral hemispheres and the arousal system. Several factors might account for this. First, the limbic system is difficult to reach within the brain; one has to traverse much cortex to get to it. Second, the limbic system is not a neatly discrete structure; some, such as Brodal,[2] would say that it does not exist as a system at all. A third factor, not usually stated, but detectable in casual discussion, is that the limbic system does not subserve "higher function" and as a result has the bias associated with it as mediating "lower functions" in humans. Academics usually pride themselves not on their pro-football muscles but on their higher functions, and they therefore do not usually feel that the study of the "lower functions" (the four Fs) in human beings is an especially worthy, clean, intellectual, and liberalizing endeavor.

MIND–BRAIN

First, let us briefly review some aspects of the mind–body arena. *Psychobiology* was a word coined by Adolph Meyer to compress and unite the concept of mind–brain. Those of us who had an interest in the mind–brain connection thought that this concept of psychobiology would contain the kernel that would dispel the problems involved with mind–brain. Unfortunately, after carefully reading Meyer's works, we find that kernel is still difficult to attain. In today's iteration of the tradition of psychosomatic medicine, a word again tries to compress the two ideas of mind and brain (and the rest of the body) into one word, implying a unity therein. As one reads the literature in this area and discusses the term with experts in the field, one finds much left to be desired for an understanding of the relationship of mind to brain and vice versa – especially for the kind of understanding that the pragmatic and action-oriented physician needs in his or her daily work. Psychosomatic concepts may be quite interesting, and even true, in themselves, but as a collected fund of knowledge, they do not allow the physician to do much.

On the other hand, there is a certain animosity among psychosomaticists directed toward those who would split humans into mind and brain. In traditional philosophic thinking, there are two core poles: realism and idealism. Those with a more idealistic bent strive for global unity, tend to dislike fractionation and atomization, tend to charge the realists with disuniting and reducing everything to its smallest biological parts (i.e., realists are practitioners of reductionism). The charge goes on to say that in reductionism what one reduces and gets rid of is, in fact, mind. The idealist smiles when the charge is made that the realist has a mindless brain only; however, when the idealist is charged with having a brainless mind (as a subject of study) the smile turns to a frown.

The culprit for this great supposed split between brain and mind is usually thought to be Descartes. His most famous treatise, *Discourse on the Method of Rightly Conducting the Reason and Seeking for Truth in the Sciences*,[3] outlined his philosophic approach to using methodical doubt in obtaining philosophic proof by the use of reason alone.

One often hears the phrase *Cartesian dualism*, and it is presupposed that Descartes, in isolating the mind from the body to study it more specifically, in fact initiated the great disunion of mind and brain.[4] We submit that it was primarily Descartes' followers who pragmatically operated on the premises of a split between brain and mind. Because Descartes is often quoted and rarely read, it is not difficult to see why he has been blamed for dualism. Descartes operated in no way differently than, for example, a heart surgeon does today. Heart surgeons isolate their interests and bear their intensity on how they may best make an intervention on the physiologic function of a failing heart, and they do not pay much attention to the gastrointestinal system, the endocrine system, and so forth. Similarly, Descartes set his intensity on the mind and did not, in fact, negate the importance of the body, just as the heart surgeon would not negate the importance of the endocrine system and the fact that humans live by all of their physiologic systems as well as mind. Although Descartes' criteria of clarity and distinctness of ideas led him to emphasize a real distinction between mind and body—soul and body to him—he still did not accept the idea that the soul (mind) is just lodged in the body. What he does say in his *Objections*

and Replies to Objections is "Mind and body are incomplete substances, viewed in relation to the man who is the unity which they form together."[5]

Most psychiatrists use the term *Cartesian dualism* in a pejorative sense, as if to castigate someone for not being an idealistic upholder of "holism." Most persons interested in psychosomatic medicine have an interest in how the body can influence the mind and how the mind can influence the body, but there have been no clear, distinct theories that settle this question to everyone's satisfaction.

We submit here that a partial key to the understanding of the mind–brain or mind–body meld is the limbic system. The limbic system can be considered in the Cartesian manner as part mind and part body. Mind consists of many things: intellect, imagination, affect, cognition, and motivation, among others. There is no one definition of *mind* that satisfies everybody. If the neocortex is more "intellectual," certainly the limbic system is more effectual. In fact, it is often stated that the limbic system is the substratum of emotion in humans and other animals.

HISTORY OF THE LIMBIC SYSTEM

The history of the development of the concept of the limbic system is important in psychiatry. Of the many names in the history of its development, four stand out: Broca, Papez, MacLean, and Nauta.

Paul Broca (1824–1880), a French surgeon, founded the Societé d'Anthropologie in Paris in 1859 (the year Darwin's *On the Origin of Species by Means of Natural Selection* was published). In 1861, a patient named Laborgne came under Broca's care. Laborgne had aphasia for 21 years; all he could say was "tan-tan-tan." After his death, a postmortem examination was carried out, and Broca found a softened area in the left frontal cortex, now described as *Brodmann's area 44* and more popularly known as *Broca's area*.[6] In the medical sciences, Broca is best known for his work in aphasia. (Laborgne's brain is extant, housed in L'École de Medicine in Paris, as is Broca's brain.)

Broca is less well known as an author of a remarkable 113-page monograph on the comparative neuroanatomy of mammals.[7] The title of this monograph is *Des Circonvolutions Cérébrals*. This work was published in Revue d'Anthropologie in 1878, two years before Broca's death. The monograph is a fascinating comparative neuroanatomic study of mammals and contains drawings of what the author called the *great limbic lobe* (*limbic* meaning *border*). What Broca called the *great limbic lobe* includes today the cingulate gyrus, retrosplenial cortex, and parahippocampal gyrus (gyrus fornicatus).

Neuroanatomic knowledge progressed with its characterizations of nuclei and connections, but there was no stimulating discussion of the limbic lobe until 1937, when James Papez published his classic paper, "A Proposed Mechanism of Emotion."[8] Papez (1883–1958) was a 1911 graduate of the University of Minnesota Medical School; at the time of writing the paper cited, he was a neuroanatomist at Cornell University Medical School when it was still in Ithaca, New York. When he published the paper, it did not create much stir. According to MacLean,[9] Papez wrote this paper because of some ongoing discussion in England on the subject; Papez thought that the discussion did not reflect the tradition of emotion and neuroanatomic structures already known, and thus he elaborated the idea of the limbic structures subserving the emotions.

From this paper came the popular name of the *Papez circuit* (Figure 6–1). This circuit was so called because Papez himself hypothesized that a neuroimpulse could leave the hippocampus via the fornix, travel up the fornix under the corpus callosum, and traverse the septal area into

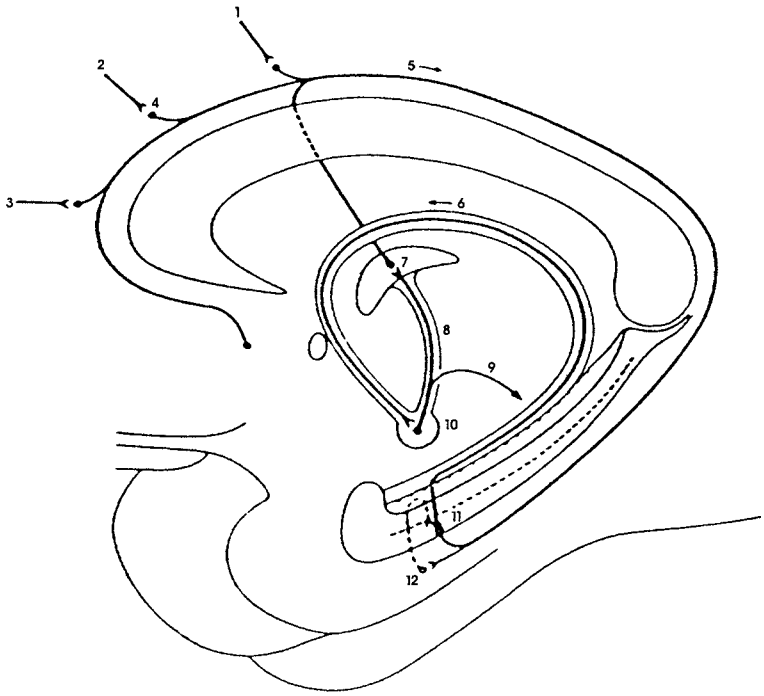

Figure 6–1. The Papez circuit. *1,* Brodmann areas 6 and 8; *2,* area 9; *3,* areas 10 and 11; *4,* area 24; *5,* cingulum; *6,* fornix; *7,* anterior nucleus of the thalamus; *8,* mamillothalamic tract; *9,* mamillotegmental tract; *10,* mamillary body; *11,* subiculum; *12,* area 28. *(From Nieuwenhuys SR, Voogd J, Van Huijzen CHR:* The human central nervous system, *New York, 1979, Springer-Verlag.)*

the mamillary bodies. At the mamillary bodies, a synaptic connection would be made to the anterior nucleus of the thalamus and then it would radiate up onto more primitive cortex, the cingulate gyrus. This impulse would then be captured at the level of the cingulate gyrus, be returned in a neurobundle, the cingulum, and be brought down and again entered into the hippocampus.[10] He did not include the amygdala in this circuit.

Papez postulated that this circuit was the basis for the feeling of emotions in humans. The cingulate gyrus in particular, not a neocortical structure, but composed of archicortex and mesocortex, allows a human to "know" that he or she is having his or her present feelings.

There was not much stir until 1947 when Paul MacLean ran across Papez's paper in the library at Massachusetts General Hospital. At this time, MacLean was a U.S. Public Health Service fellow. MacLean, with Stanley Cobb as his mentor, was making electroencephalographic recordings of the mesobasal structures of the brain in patients with temporal lobe epilepsy. Discussion with Cobb about the significance of the Papez circuit resulted in MacLean's visiting Papez (accomplished with Cobb's help).

After his discussion with Papez, MacLean wrote a paper entitled "Psychosomatic Disease and the 'Visceral Brain': Recent Developments Bearing on the Papez Theory of Emotion."[11] MacLean used the term *visceral brain* because he wanted to communicate the notion of "gut feeling." In those years, for the most part, this area of the brain was called the *rhinencephalon*, or the *nose brain*. It turned out that *visceral brain* did not catch the wind and soar effectively either.

In 1952, after further research, MacLean published another paper entitled "Some Psychiatric Implications of Physiological Studies on the Frontotemporal Portion of the Limbic System (Visceral Brain)."[12] This was the first use of the term *limbic system*. This concept did catch the wind, and it soars today as a concept for structures that subserve emotion in humans.

Walle J. H. Nauta, a neuroanatomist at Massachusetts Institute of Technology, was instrumental both in his own meticulous work and in influencing his students in careful delineation and expansion of the limbic system. In tracking down frontal lobe connections to the limbic system, he effectively expanded it forward. Connections to the midbrain indicate an expansion of the limbic concept backward or "downstream."[13,14] One of Nauta's students, Lennart Heimer, has further tracked and extended the limbic system's connections into the basal forebrain, including his ventral striatum and an extended amygdala.[15]

More important, the limbic system can serve as an integrating concept for the clinical side of psychiatry and neurology. Various approaches to the study of the limbic system can be taken: morphologic,[16] evolutionary,[17] polymodal,[1] or an overview.[18] Perhaps Nauta gave us the most contemporary view: a look at emotions and their anatomy.[19]

PSYCHOLOGISTS' VIEWS

There has been disagreement about the impact of the limbic system on the field of cognitive psychology. Some say emotion is partially independent of cognition; others say that emotions are the products of cognition. It is our position that although emotions (mediated by the limbic system) are usually conjoined with cognition, they can stand on their own without prior cognitive process. The psychologist Richard Lazarus, maintaining that emotions are the products of cognitions, said:

> *Recent years have seen a major change in the way psychologists view emotion—the rediscovery that emotions are products of cognitive processes. The emotional response is elicited by an evaluative perception in lower animals, and in humans by a complex cognitive appraisal of the significance of events for one's well-being.*[20]

The psychologist Robert Zajonc elaborated a position seemingly more in accord with how the limbic system functions:

> *Only a few years ago, I published a rather speculative paper entitled "Feeling and thinking" (Zajonc, 1980).*[21] *. . . In this paper I tried to make an appeal for more concentrated study of affective phenomena which have been ignored for decades, and at the same time to ease the heavy reliance on cognitive functions for the explanation of affect. The argument began with the general hypothesis that affect and cognition are partially independent systems and although they ordinarily function conjointly, affect could be generated without a prior cognitive process. It could, therefore, at times precede cognition in a behavioral chain.*[22]

Zajonc also believes that there exists a form of cognitive imperialism, wherein there is a disdain for affect and only the cognitive is considered to be of priority in higher animals. His position on the secondary nature of cognition recalls William James's supposition that:

> *We feel sorry because we cry, angry because we strike, afraid because we tremble, and not that we cry, strike, or tremble, because we are sorry, angry, or fearful, as the case may be. Without the bodily states following on the perception, the latter would be purely cognitive in form, pale, colourless, destitute of emotional warmth.*[23]

At the same time, Zajonc anticipates contemporary ideas such as Porges's polyvagal theory[24] and interoception[25] where limbic activation and perception of bodily states precede and influence conscious responses and experiences. Sperry has shown movies of split brain subjects who had had corpus callosotomies for intractable epilepsy. In one film, the contents of a slide were flashed into the right cortex of a woman's brain, and, of course, she could not speak about it because there is no Broca's area in the right cortex. Every slide flashed into her left cortex only was described adequately in words; in the pictures flashed to her right cortex only, the left brain chattered on in a manner not relevant to the slide shown to the right mute brain. At one point, a risqué slide was shown to the right brain and the woman flushed and showed other aspects of autonomic arousal, for example, rapid respirations, increased systolic blood pressure, increased pulse rate. Not surprisingly, her left brain did not know why. All the left brain said was "Oh my! That's something isn't it!" Even though the left brain did not know what was occurring and the right brain did, the limbic system also "knew" what was occurring to have the affectual engagement of the autonomic system. It became clear that many things can happen affectually without all of the neocortex being aware of what is going on.

EMOTIONAL VALENCE

Humans' intellects are often not formally conscious of much that goes on within them. This is no great insight to psychotherapists who emphasize the unconscious. Kihlstrom[26] stated, "People may reach conclusions about events—for example, their emotional valence—and act on these judgments without being able to articulate the reasoning by which they were reached." Behavioral activity can tell us often about the inner state of another or ourselves. For example, dogs have a visible "limbicometer," their tails. Whether a dog's tail wags or not, with what frequency, and with what vigor all tell us about the dog's feelings.

Probably the closest thing to a limbicometer in humans is the smile. In this context, a smile is the limbic recognition of reality before it is fully understood by intellect (neocortex). If someone smiles and is asked why he or she smiled or what made him or her smile, that person often cannot specify or gives an intellectual response not derived from the present smile-reality.

The traditional view of affective coloring on incoming sensory material has been that the incoming sensory signals went to thalamic relay nuclei and therein radiated to sensory receiving areas as, for example, occipital visual Brodmann area 18. From there, over many synapses, the now-modified signal went to subcortical (limbic) regions, which attached an emotional tone to the signal (schematized in Figure 6–1). It is now clear, mainly through the work of LeDoux,[27] that pathways exist from sensory receptors that bypass the neocortex and wend straight to the limbic system, specifically, the amygdala (Figure 6–2). If this bypass exists in humans, it could reshape current thinking about how the affective processing of incoming sensory material can be an unconscious function of the brain.

For example, amygdala activation was noted in white subjects exposed to unfamiliar African American faces (but not unfamiliar white faces), independent of their conscious expression of race attitudes.[28] Further, the amygdala activation correlated with indirect measures of physiologic states of alarm (e.g., a startle response). No doubt, the "high-minded" cortex steers us away from some undesirable thoughts and behaviors, but for good and for ill it shares the helm with the limbic system far more than some would like to think.

The limbic system is involved with motivation, attention, emotion, and memory. It can also be looked at in an animal way or a human way. In a cavalier fashion, it is often said that the limbic system mediates the four Fs—fear, food, fight, and fornication. This is a view from the Olympian hill of the cerebral cortex. A more noble formulation is that the limbic system mediates gender role, territoriality, and bonding.[29] For example, as far as territoriality is concerned, the limbic system mediates how one feels about family, rights, "keep off the grass," and other areas that have a spatial or relational component. In bonding, the limbic system mediates strongly how one bonds to one's spouse, family, parents, country, flag, and religion—in sum, loyalty. If this is true, most of the actions performed daily are already set limbically before humans neocortically intellectualize, and these three elements constitute much of the work of the psychiatrist.

The neocortex, with Broca's area, is the substrate for the lyrics or the words of what one thinks and feels. The limbic system has no Broca's area, has no words, but is the locus of the music of one's affect. Psychiatric interviewers hear what people verbalize, but often much more important is what one sees, what one feels, and what one hears as the affective music or tune from the person interviewed.

AMYGDALA

Some general agreement exists that the amygdala is concerned with motivation in the organism. The classic view is that the amygdala attaches motivational significance to the information elaborated by the neocortex.[30] Kagan and colleagues[31] considered increased arousal in the amygdala to be a contributor to shyness in childhood and social avoidance in adults. The late Pierre Gloor of Montreal, following his experience with implanted electrodes in the human limbic system, proposed that:

> *the site where this [the coalescence of experimental mechanisms] occurs is the limbic system, and in particular the amygdala. Visual and auditory perceptual data are first analyzed in the appropriate areas of the temporal neocortex. . . . Finally, the information is conveyed to the amygdala where affective tone is attached to it. I would like to suggest that this involvement of affect is necessary to make a perception or memory emerge into consciousness, thus enabling it to be experienced as an event one is living or has lived through.*[32]

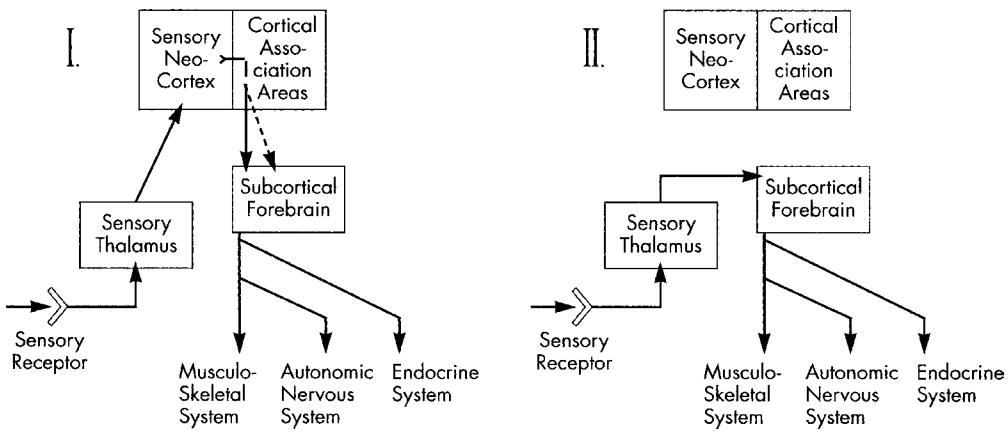

Figure 6–2. I, The traditional perceptual process. **II,** A recently found variant of the perceptual process. *(Modified from LeDoux JE:* Sensory systems and emotion: a model of affective processing, *Integr Psychiatry, 4:237–248, 1986.)*

Therefore, according to this proposal, it is primarily the amygdala and its role in affect that affects the brain's consciousness of the material. Thus, the limbic system is responsible for what enters into consciousness—a long noble step from the four Fs.

A crude analogy may be helpful in how the neocortex and limbic system might work in the human. If one views a slide of Death Valley, one perceives that slide neocortically in the primary visual area pretty much the same as all other humans do. Limbically, however, one could have at least two different feeling states on seeing the slide. One could have a subtitle or label at the bottom of the slide reading "the sparse grandeur of the West," or at the other end of the spectrum one could label the Death Valley slide as "the devil's fiery hell." The limbic system supplies the personalized affective tone when information is perceived or recalled.

HIPPOCAMPUS

The hippocampus has been termed, by O'Keefe and Nadel,[33] a *cognitive map*. The importance of the hippocampus in memory is well known since the hippocampectomies in the patient H.M., who after this surgery, and right up to his recent death, was unable to lay down new memories.[34] Knowing one's place in the world, both internally and externally, appears to be another function of the hippocampus.

Because humans are an altricial species—the infant undergoes much maturation after birth—there is a relatively enormous openness to environmental influence compared to the nonaltricial species. Some fibers to the hippocampus do not mature for years after birth. Although "the wires and the juices" have much to do in setting the individual's emotional life, it is this long maturation process that allows culture, teaching, and so forth to shape that emotional life.

CLINICAL ASPECT OF THE LIMBIC SYSTEM

At the bedside, one can use the Frank Jones story to screen for neuropsychiatric impairment. The supposition here is that the neocortex is usually affected in many conditions earlier and more severely than the limbic system. Let us say that the psychiatrist has been called because there is suspicion of a postoperative acute confusional state. One of the things the psychiatrist can do is say to the patient, "Now, how does this strike you? I have a friend, Frank Jones, whose feet are so big he has to put his pants on over his head."

Usually, one of three responses is provided by patients. The type 1—or normal—response occurs when the limbic system is grossly intact. The patient will smile or chuckle. The chuckle indicates that the patient appreciates the incongruity, and when the patient is asked, "Can he do it?" the patient usually says something like, "No, it's goofy…. The crotch—he can't go up on both sides," meaning that the patient also has intellectual insight.

The type 2 answer usually indicates that the limbic system is intact, but the neocortex is impaired. In this situation, the patient usually smiles and laughs and gives the limbic music that there's something funny to the story. However, when asked, "Can he do it?" the patient will usually say something like, "Well, whatever you say," or "Well, if he tries hard enough." This type 2 patient appreciates the incongruity but does not have intellectual insight.

The type 3 response indicates that both the limbic system and the neocortex are impaired. After hearing the story the patient does not smile, shows no facial quizzicalness, and gives no special limbic response at all. When one asks, "Can he do it?" the unsmiling answer usually is something like, "Well, doctor, he must have to have special shoes but sure he can." This patient neither appreciates the incongruity nor has intellectual insight. The patient has limbic and neocortical confusion, suggesting a more advanced or widespread pathologic process.

From a diagnostic point of view, the Frank Jones story is nonspecific, but rather sensitive.[35] Its value lies also in its vivid display of how the patient processes and responds to the world.

Quietly confused hospitalized patients are often seen after surgery. The treating physician often does not recognize that the patient has an impairment of higher cortical function. The impairment is usually missed because the patient is alert and gets along well with the physician. The patient smiles and says he or she is doing okay, but if the patient is pressed to say exactly where he or she is, or what year it is, the patient does not know. The limbic system, even without neocortical clarity, can take humans quite far in everyday life, and that is probably what really gets us through the day. That is, the limbic system and not the higher intellectual activity of the neocortex, save for the primary motor and sensory areas, is where most human mental activity occurs. Much resistance to this notion exists, especially from intellectuals, theologians, humanists, and others who, perhaps unconsciously, have a bias against the limbic system because it mediates those raw, crude, baser elements of humans: that is, the emotions.

CASE 1

One of us (GBM) was once asked to see a patient in the Massachusetts Eye and Ear Infirmary for presumed hysterical blindness. She had had an extensive work-up that included visual evoked potentials; no clinical findings were found to support an organic lesion. Unfortunately, the diagnosis of a conversion disorder is often made without primary data for the diagnosis, but only with secondary, substantive corollary data from the psychosocial realm. This woman had quite a bit of psychosocial perturbation having to do with a violent husband and an appearance in court. In fact, the day she was seen, she was to have appeared in court against her husband, but "unfortunately" she was hospitalized.

During the interview she looked away from me. Gradually, I moved in front of her again as I continued talking and noticed that her eyes gradually moved off to the other side, looking away from me again. I continued to do this, moving in front of her gaze several times; each time she shifted her gaze. I performed the usual test of threatening her eyes with my hand. She did not blink. I then moved in front of her gaze and as I continued to speak I put both of my hands on the side of my head, contorted my face, and wiggled my fingers as children do. (The incongruity of finger wiggling and serious physician's voice should evoke some response in the normal patient.) There was a brief, slight smile on her lips, and her eyes shifted away again. I repeated this maneuver

several times, and each time it was apparent that the patient revealed a small smile, which immediately disappeared. Then it was clear: This woman sees.

My interpretation of what happened was that the patient perceived in the occipital cortex my funny business with the hands and screwing-up of my face but heard in her auditory cortex a serious physician's voice. Before she could employ "neocortical squelch," her limbic system assigned a valence[32] to the incongruity of voice and pantomime, thus activating, presumably, the nucleus accumbens— the limbic basal ganglion[36]—and evoking a slight accumbens smile that appeared just beyond her immediate neocortical control.

CASE 2

One of us (NK) was once asked to see a man soon after an opiate overdose. He was large and muscular, wearing a bandana and Harley Davidson t-shirt and with abundant elaborate and somewhat macabre tattoos. He participated in the interview for only a few minutes and then quickly lapsed into a state of apparent unconsciousness when we got down to the details of his overdose and his choice of drug. He was unresponsive to voice, to loud voice, to shaking of shoulder, and all this seemed quite incongruent with his initial level of alertness. Because he looked like a man who knew how to take and to administer physical pain, I chose another route to test alertness before moving on to nail bed pressure or sternal rub. Taking a step back, I said in a slightly raised voice, "Now this is just strange. I don't know if you are really out of it or if you're just f***king with me." The patient sprang up to a seated position and angrily but affectedly shouted "Well I never!"

Yes he had, of course, as was already obvious from a casual scan of the images and words on his arms. But his limbic system would not allow my alpha-male posturing to go unchallenged, and it overrode his cortically controlled "coma." Menace ensued, but I intentionally ended the alpha male struggle via nature's nonlethal limbic means: neck-baring.[37] The patient agreed that I "would not be doing you any favors if I kept my suspicions about you a secret *just because I'm scared of you*."

CONCLUSION

There are several points to emphasize. The use of the term *limbic system* here is not a hard, scientific usage; it partakes of metaphor. The limbic system can be helpful in understanding the so-called rift between mind and body. The stuff of clinical psychiatry is primarily mediated by the limbic system and not by the nonsensory structures of the neocortex. *Limbic music* is a term that denotes the existential, clinical raw feel emanating from the patient. It is a truer rendering of the patient's clinical state than is articulate speech. Limbic music never lies.

7 Psychological and Neuropsychological Assessment

Mark A. Blais, Psy.D.
Sheila M. O'Keefe, Ed.D.
Dennis K. Norman, Ed.D.

The intent of this chapter is to increase clinicians' knowledge of psychological and neuropsychological assessment. This will be accomplished by reviewing the scientific basis of psychological instruments, the major categories of psychological tests, and the application of these instruments in clinical assessment. The chapter also briefly touches on issues related to the ordering of psychological testing and understanding of assessment reports. The material contained in this chapter should allow clinicians to better use psychological and neuropsychological assessments in the care of patients.

Psychological tests must be reliable and valid. Reliability represents the repeatability, stability, or consistency of a subject's test score. Reliability is usually represented as a correlation coefficient ranging from 0 to 1.0. Research instruments can have reliabilities in the low .70s, whereas clinical instruments should have reliabilities in the high .80s to low .90s. A number of reliability statistics are available for evaluating a test. For example, internal consistency measures the degree to which items in a test function in the same manner, and test–retest reliability shows the consistency of a test score over time. Interrater reliability measured by the Kappa statistic reflects the degree of agreement among raters, usually corrected for chance. Unreliability, or error, can be introduced into a test score by variability in the subject (changes in the subject over time), the examiner, or the test (given with different instructions).

Validity is a more complex concept and a hard property to demonstrate. The validity of a test reflects the degree to which the test actually measures the construct it was designed to measure. Measures of validity are usually represented as correlation coefficients ranging from 0 to 1.0. Multiple types of validity data are required before a test can be considered valid. Content validity assesses the degree that an instrument covers the full range of the target construct, and predictive validity indicates how well a test predicts future occurrences of the target variable. It is important to realize that no psychological test is universally valid. Tests are considered valid or not valid for a specific purpose. The validity of psychological tests is comparable to that of most routine diagnostic tests used in medicine.

TYPES OF PSYCHOLOGICAL TESTS

Test of Intelligence

Matarazzo states, "Intelligence…is the aggregate or global capacity of the individual to act purposefully, to think rationally, and to deal effectively with the environment."[1] This definition demonstrates what the tests of intelligence measure (adaptive function) and that measured intelligence quotient (IQ) can provide important information, particularly with regard to treatment planning. In fact, measured IQ has been shown to account for approximately 25% of life success. The Wechsler tests are the most commonly used IQ tests; they cover almost the whole life span. The series starts with the Wechsler Preschool and Primary Scale of Intelligence (for ages 4 to 6 years), progresses to the Wechsler Intelligence Scale for Children-IV (for ages 5 to 16 years), and ends with the Wechsler Adult Intelligence Scale-IV (for ages 16 to 89 years).[2–4] A new abbreviated version of the Wechsler IQ test is now available (Wechsler Abbreviated Scale of Intelligence [WASI]).[5] All the Wechsler scales provide three major IQ tests scores: the full scale IQ, verbal IQ (VIQ), and performance IQ (PIQ). All three IQ scores have a mean of 100 and standard deviations (SDs) of 15. These statistical features mean that a 15-point difference between a subject's VIQ and PIQ is both statistically and clinically meaningful. Table 7–1 presents an overview of the IQ categories.

The Wechsler IQ tests are composed of 10 or 11 subtests that were developed to tap into two primarily intellectual domains, verbal intelligence (as measured by Vocabulary, Similarities, Arithmetic, Digit Span, Information, and Comprehension) and nonverbal visual–spatial intelligence (as measured by Picture Completion, Digit Symbol, Block Design, Matrix Reasoning, and Picture Arrangement). Empirical studies have suggested that the Wechsler subscales can be reorganized into three cognitive domains: verbal ability, visual–spatial ability, and attention and concentration (which is assessed by the Arithmetic, Digit Span, and Digit Symbol subtests). All the Wechsler subtests have a mean score of 10 and an SD of 3. Given this statistical feature, we know that if two subtests differ by 3 or more scaled score points, the difference is significant. All IQ scores and

TABLE 7–1 IQ Categories with Their Corresponding IQ Scores and Percentile Distribution

IQ CATEGORIES		
FULL SCALE IQ SCORE	**CATEGORIES**	**NORMAL DISTRIBUTION PERCENTILE**
≥ 130	Very superior	2.2
120-129	Superior	6.7
110-119	High average	16.1
90-109	Average	50.0
80-89	Low average	16.1
70-79	Borderline	6.7
≤ 69	Extremely low	2.2

IQ, Intelligence quotient.

subtest scaled scores are adjusted for age. It is important to understand that IQ scores represent patients' ordinal position, their percentile ranking as it were, on the test relative to the normative sample. These scores do not represent a patient's innate intelligence, and there is no good evidence that they measure a genetically determined intelligence. They do, to a considerable degree, reflect the patient's current level of adaptive function.

At times it is difficult to sort out whether dysfunction in affect, behavior, or cognition can be primarily assessed with psychological instruments of psychiatric consultation or whether they require neuropsychological assessment. Requests for psychological assessment might be conveyed as follows:

Please conduct a psychological assessment on Ms. B, a 28-year-old, right-handed, single attorney to help determine "if Ms. B was really depressed and suicidal or just character-disordered."

When the emergency department physician found her to be mildly confused and disoriented, Ms. B was admitted to the medical service. By the next morning, her mental status had improved; however, she continued to complain of extreme back pain and made vague suicidal statements. A pain workup and psychiatric consultation were both ordered.

Ms. B got into frequent struggles with the nursing staff over the hospital's smoking rules. A review of the medical chart revealed that she had graduated from a prestigious university and law school and was employed at a large legal firm. She had developed severe back pain secondary to multiple equestrian injuries that occurred while riding competitively in college. She had received various diagnoses for her pain, and she had failed to respond to several medication trials, surgery, and one stay on an inpatient pain rehabilitation unit. Ms. B's current medications included diazepam 5 mg bid, amitriptyline 100 mg qhs, and oxycodone–acetaminophen (Percocet) one tablet qhs. The pain service consultant was unsure about the diagnosis. The psychiatric consultant found her to be guarded (with regard to her mood and the level of her suicidal ideation). She reported no history of depression or suicide attempts; later that same day, Ms. B completed a brief but fairly comprehensive psychological assessment.

The test battery for Ms. B consisted of several tests, including the WASI (which was given first); it was followed by the Rorschach inkblot test, four Thematic Apperception Test (TAT) cards, and the Personality Assessment Inventory (PAI). The WASI was selected for its brief administration time (20 to 30 minutes) and its ability to provide accurate IQ data (assessing cognitive function). The Rorschach was selected as the second test to be administered for two reasons: Given Ms. B's guardedness, projective test data seemed crucial for the personality assessment, and it was felt that the novelty of the Rorschach might help maintain Ms. B's involvement in the assessment. A self-report test of psychopathology was desired, but it seemed likely that Ms. B would neither complete one nor portray herself in an exceedingly favorable light. The PAI was selected for use because of its shorter length (344 items) and its ability to be scored with a short form of the test using only the first 160 items. Also, the PAI contains a number of treatment planning scales that can provide important information.

Ms. B's assessment was conducted in her semiprivate room. Although this was not an ideal situation, hospital evaluations are commonly performed in this fashion. Surprisingly, Ms. B completed all of the testing without complaint or fuss. The WASI data assessed the quality and consistency of her cognitive function. Her WASI scores were full scale IQ 102, VIQ 120, and PIQ 87. The WASI data can be thought of as providing an estimate of the patient's current best possible level of function. Her visual–spatial skills were weak relative to her verbal ability. In general, Ms. B's cognitive functioning was not as effective as one might have assumed, given her verbal abilities and her level of education. The VIQ > PIQ difference of an 18-point split could have represented either a long-standing learning disability (somewhat less likely given her strong high school, college, and law school performance) or cognitive disruption secondary to depression, pain, the effects of her current medications, or a combination thereof.

The Rorschach revealed Ms. B's implicit psychological function. The Rorschach depression index was positive and suggested either current depression or a propensity to depressive experiences. The suicide constellation was negative. Although her adaptive psychological resources were adequate, situational stress was overwhelming her ability to cope. Her affective experience was dominated by helplessness, painful internalized affect, and unmet dependency–nurturance needs. Together these findings suggested a possible depression resulting from situational factors. She was not psychotic, but her thinking was overpersonalized and idiosyncratic. The experience of anger also decreased her reasoning and judgment. She had an immature, self-centered personality style and a narcissistic character style. She did not process her feelings but instead tried to minimize them through intellectualization or externalize them (projection).

The PAI could be considered to provide a picture of her explicated psychological world. The PAI profile was valid. She reported minimal psychopathology. Her mean elevation on the 10 clinical scales was only 53 (T-score, well within the range of nonpatients), suggesting either that she was experiencing little overt distress or that she was reluctant to express emotional pain. Either way, she did not appear to others, including her caregivers, to

be psychologically impaired. She reported mild clinical depression (T-score = 71) and excessive concern about her physical function (T-score = 85). Further, on clinical interview her excessive physical complaints and concerns overshadowed her depressive symptoms. A grandiose sense of self, consistent with the pronounced signs of a narcissistic character style on the Rorschach, was also indicated by one of the PAI subscales. On the treatment consideration scales, she indicated minimal interest in psychologically oriented treatments, a perception of high levels of social stress, and minimal suicidal ideation (T-score = 54).

Impressions and recommendations: Overall the assessment strongly suggested the presence of a clinical depression. Depression was likely masked to some extent by both the patient's focus on her physical function (the back pain) and her inability or unwillingness to express her emotional pain. As a result, her depression was likely more significant and disruptive to her function than she was reporting. In addition, character issues (Axis II pathology) in the form of an immature self-centered view of the world and narcissistic character traits complicated Ms. B's treatment. Ms. B's function was greatly reduced because of both her depression and her situational stressors. These stressors affected both her emotional and intellectual function. Her ability to organize, plan, and initiate coping strategies was limited. As such, the advisability of her immediate return to full-time employment needed to be carefully reviewed. Her caregivers may have overestimated her level of function because of her strong verbal communication skills. On testing she did not appear to be actively suicidal (either on the self-report or projective tests). However, given her state of being emotionally overwhelmed and depressed and her reduced coping ability, Ms. B should be considered at an increased risk (over and above being depressed) for impulsive self-harm. Her safety should be monitored closely. Her psychotherapy, which will be challenging given her personality style, should first focus on practical efforts to improve her coping and function. Once her function stabilizes, the therapy focus might profitably expand to include her interpersonal style.

Tests of Personality, Psychopathology, and Psychological Function

Objective psychological tests, also called *self-report tests*, are designed to clarify and quantify a patient's personality function and psychopathology. Objective tests use a patient's response to a series of true/false or multiple-choice questions to broadly assess psychological function. These tests are called *objective* because their scoring involves little speculation. Objective tests provide excellent insight into how patients see themselves and how they want others to see and treat them. Self-report tests allow the patient to directly communicate their psychological difficulties to their caregivers.

The Minnesota Multiphasic Personality Inventory–2 (MMPI-2)[6] is a 567-item true/false, self-report test of psychological function. It was designed to provide an objective measure of abnormal behavior, basically to separate subjects into two groups (normal and abnormal) and then to further categorize the abnormal group into specific classes.[7] The MMPI-2 contains 10 clinical scales that assess major categories of psychopathology and 3 validity scales designed to assess test-taking attitudes. MMPI-2 validity scales are (L) lie, (F) infrequency, and (K) correction. The MMPI-2 clinical scales include (1) Hs—hypochondriasis, (2) D—depression, (3) Hy—conversion hysteria, (4) Pd—psychopathic deviate, (5) Mf—masculinity–femininity, (6) Pa—paranoia, (7) Pt—psychasthenia, (8) Sc—schizophrenia, (9) Ma—hypomania, and (10) Si—social introversion. More than 300 new or experiential scales have also been developed for the MMPI-2. MMPI raw scores are transformed into T-scores; a T-score greater than or equal to 65 indicates clinical levels of psychopathology. The MMPI-2 is interpreted by determining the highest two or three scales, called a code type. For example, a 2–4–7 code type indicates the presence of depression (scale 2), impulsivity (scale 4), and anxiety (scale 7), along with the likelihood of a personality disorder (PD).[7]

The Millon Clinical Multiaxial Inventory–III (MCMI-III) is a 175-item true/false, self-report questionnaire designed to identify both symptom disorders (Axis I conditions) and PDs.[8] The MCMI-III is composed of 3 modifier indices (validity scales), 10 basic personality scales, 3 severe personality scales, 6 clinical syndrome scales, and 3 severe clinical syndrome scales. One of the unique features of the MCMI-III is that it attempts to assess both Axis I and Axis II psychopathology simultaneously. The Axis II scales resemble but are not identical to the Axis II disorders given in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). Given its relatively short length (175 items versus 567 for the MMPI-2), the MCMI-III has an advantage in the assessment of patients who are agitated, whose stamina is significantly impaired, or who are just suboptimally motivated.

The PAI[9] is one of the newest objective psychological tests available. The PAI uses 344 items and a 4-point response format (false, slightly true, mainly true, and very true) to make 22 nonoverlapping scales. These 22 scales include 4 validity scales, 11 clinical scales, 5 treatment scales, and 2 interpersonal scales. The PAI covers a wide range of Axis I and Axis II psychopathology and other variables related to interpersonal function and treatment planning (including suicidal ideation, resistance to treatment, and aggression). The PAI possesses outstanding psychometric features and is an ideal test for broadly assessing multiple domains of relevant psychological function.

A subject's response style can have an impact on the accuracy of his or her self-report. Validity scales are incorporated into all major objective tests to assess the degree to which a response style may have distorted the findings. The three main response styles are careless or random responding (which may indicate that someone is not reading or cannot understand the test), attempting to "look good" by denying pathology, and attempting to "look bad" by overreporting pathology (a cry for help or malingering).

Projective tests of psychological function differ from objective tests in that they are less structured and require more effort on the part of the patient to make sense of, and to respond to, the test stimuli. As a result, the patient has a greater degree of freedom to demonstrate his or her own unique personality characteristics. Projective tests are more like problem-solving tasks, and they provide us with insights into a patient's style of perceiving, organizing, and responding to external and internal stimuli. When data

from objective and projective tests are combined, they can provide a fairly complete picture or description of a patient's range of function.

The Rorschach inkblot test[10] consists of 10 cards that contain inkblots (five are black and white; two are black, red, and white; and three are various pastels), and the patient is asked to say what the inkblot might be. The test is administered in two phases. First, the patient is presented with the 10 inkblots one at a time and asked, "What might this be?" The patient's responses are recorded verbatim. In the second phase, the examiner reviews the patient's responses and inquires where on the card the response was seen (known as *location* in Rorschach language) and what about the blot made it look that way (known as the *determinants*). For example, a patient responds to Card V with "A flying bat." The practitioner asks, "Can you show me where you saw that?" The patient answers, "Here. I used the whole card." The practitioner asks, "What made it look like a bat?" The patient answers, "The color, the black made it look like a bat to me." This response would be coded as follows:

Wo FMa.FC'o A P1.0.

The examining psychologist reviews these codes rather than the verbal responses to evaluate the patient's performance. Rorschach "scoring" has been criticized for being subjective. However, over the last 20 years, Exner[11] has developed a Rorschach system (called the *Comprehensive System*) that has demonstrated acceptable levels of reliability. For example, inter-rater Kappas of .80 or better are required for all Rorschach variables reported in research studies. Rorschach data are particularly valuable for quantifying a patient's reality contact and the quality of his or her thinking.

The TAT is useful in revealing a patient's dominant motivations, emotions, and core personality conflicts.[12] The TAT consists of a series of 20 cards depicting people in various interpersonal interactions. The cards were intentionally drawn to be ambiguous. The TAT is administered by presenting 8 to 10 of these cards, one at a time, with the following instructions: "Make up a story about this picture. Like all good stories, it should have a beginning, a middle, and an ending. Tell me how the people feel and what they are thinking." Although there is no standard scoring method for the TAT (making it more of a clinical technique than a psychological test proper), when a sufficient number of cards are presented, meaningful information can be obtained. Psychologists typically assess TAT stories for emotional themes, level of emotional and cognitive integration, interpersonal relational style, and view of the world (e.g., whether it is seen as a helpful or hurtful place). This type of data can be particularly useful in predicting a patient's response to psychotherapy.

Psychologists sometimes use projective drawings (freehand drawings of human figures, families, houses, and trees) as a supplemental assessment procedure. These are clinical techniques rather than tests because there are no formal scoring methods. Despite their lack of psychometric grounding, projective drawings can sometimes be very revealing. For example, psychotic subjects may produce a human figure drawing that is transparent and shows internal organs. Still, it is important to remember that projective drawings are less reliable and less valid than the tests reviewed in this chapter.

NEUROPSYCHOLOGICAL ASSESSMENT

The request for neuropsychological testing might be framed as follows:

Please perform a neuropsychological evaluation on Mr. A, a 20-year-old, right-handed, white single male, to assess his current cognitive function, to establish a baseline profile, to aid in diagnosis, and to guide treatment. Help figuring out whether his current problems are a result of psychiatric or neurologic conditions would be greatly appreciated.

Mr. A was recently discharged from a psychiatric unit, where he was being treated for schizophrenic symptoms that included hallucinations (in multiple perceptual systems) and dysregulated behavior. He was on the medical service for treatment of diabetic ketoacidosis. Despite a long history of psychiatric and emotional problems (including a diagnosis of attention-deficit/hyperactivity disorder at the age of 9 and visual hallucinations that first developed at the age of 16), he has completed some college courses. During his mid- to late teens, he was treated with a variety of antidepressants and antianxiety agents. Antipsychotics were started in the past year. Two years before this admission, he sustained a closed head injury (CHI) in a motor vehicle accident. A question has arisen as to whether he has residual cognitive deficits resulting from the CHI. Although he denied use of substances within the past 4 months, he had regularly smoked marijuana, taken hallucinogenic mushrooms, and used inhalants.

Mr. A's evaluation included a review of his recent hospital discharge summary, an interview with Mr. A and his mother, and a discussion with his outpatient treaters. The following tests were also administered: WASI, Wechsler Memory Scale–IV (WMS-IV), Trails A & B, Boston Naming Test, Hooper Visual Organization Test, Rey-Osterrieth Complex Figure, Stroop Color Word Test, Digit Vigilance, and PAI. Mr. A cooperated fully with the evaluation. Overall, his performance appeared to be a valid reflection of his current behavior and level of function. All the psychological tests were valid and interpretively useful. His WASI IQ scores were as follows: Full Scale IQ 76 (borderline range fifth percentile), VIQ 83 (low average range, thirteenth percentile), and PIQ 68 (second percentile). Age-adjusted scaled scores earned during this assessment were as follows:

VERBAL	SCALED SCORE	PERFORMANCE	SCALED SCORE
Vocabulary	8	Block design	5
Similarities	10	Matrix reasoning	6

Further analysis of Mr. A's WASI performance indicated a likely substantial decline from his premorbid level of function. Even if his estimated premorbid IQ had been just average (100), his current measured IQ has fallen 1.5 SDs. As such, the quality of his current function had also likely dropped substantially. Furthermore, his WASI profile revealed a significant 15-point difference between his VIQ and PIQ, favoring the former. A difference of this magnitude was unexpected and indicated that his nonverbal abilities suffered more of a decline than his verbal/language-based abilities. Because nonverbal intellectual abilities are typically associated with right-hemisphere function, these findings pointed to a relative inefficiency in his right hemisphere.

Memory Function: His performance on the WMS-IV was generally consistent with the WASI findings. His logical memory score (recalling a just-read paragraph) was at the fifty-seventh percentile on immediate recall (better than would have been expected given his current VIQ), and it fell to the eighteenth percentile after a 30-minute delay (more consistent with his measured IQ). However, the quality of his memories was not as good as the percentile scores suggest. On this test credit was given for any detail of a story recalled, and no credit was lost if the details were recalled out of order or if errors were introduced into the stories. Mr. A's recall of these two stories was disjointed, and some facts were misrepresented. His functional verbal memory was likely less adequate than his test scores suggested. His visual memory (ability to recall designs) fell at the twelfth percentile on immediate recall and at the eighteenth percentile after a 30-minute delay. Although weaker than his verbal memory scores, his recall of visual material was consistent with his current measured (nonverbal) PIQ. However, the quality of his visual memories was also quite poor. His pattern of memory scores again pointed to possible greater right-hemisphere dysfunction.

Language: On the Boston Naming Test, he was able to correctly name 52 items (out of 60) spontaneously. This score was just slightly below the level expected for his age. However, when provided with a phonemic cue, he was able to improve his score to a 58 (out of 60). This degree of improvement suggested some mild word retrieval problems. He was able to comprehend complex instructions, suggesting that his receptive language skills were intact. His reading and writing abilities were not formally tested.

Visual–Spatial: Mr. A performed weakly, but inconsistently, on tests of visual–spatial function. His performance on the WASI Block Design subtest was weak (scaled score of 5), and he frequently broke the "gestalt" of the design he was trying to copy. On the Hooper Visual Organization Test, he obtained a score of 24, which was on the border of normal and impaired. However, his copy of the Rey Complex Figure was basically accurate. His inconsistent performance across these tests (all thought to tap basically the same function) suggested that fluctuations in his level of attention and motivation accounted for some of his poor performance.

Executive Function: On tests that tapped his ability to use abstract reasoning and to plan and change his behavior on the basis of external feedback, Mr. A again performed inconsistently. On the Trail Making Test Part B, a test that required him to draw a line that alternately connected numbers and letters in increasing order, he made three impulsive errors suggesting problems with inhibition of his behavior. Yet on the Stroop Color Word Test, he scored at the expected level. Again, it is likely that alterations in his attention and motivation contributed to his inconsistent performance on these tasks that were thought to tap into frontal lobe function.

Emotional Function: The patient's PAI profile revealed elevations on the depression and schizophrenia scales. All three of the depression subscales (cognitive, affective, and physiological) were elevated (indicating a strong likelihood of major depression), as were all three schizophrenia subscales (psychotic experiences, social isolation, and thought disorder).

Mr. A likely suffers from both a mood disorder and a psychotic condition. However, it is not clear whether these are independent conditions. Mr. A also reported having a stimulus-seeking personality style and little motivation for psychological treatment. Both of these features will complicate his treatment.

Impressions and Recommendations: The neuropsychological evaluation revealed three principal findings: (1) Mr. A's overall functional capacity (efficiency of his function) was greatly reduced from his premorbid level. (2) There were some consistent findings that point to a greater relative decline in right-hemisphere function. (3) However, most of the areas tested revealed inconsistent findings that likely reflect minute-to-minute fluctuations in his attention, concentration, and level of motivation. The overall profile appears most consistent with the types of cognitive deficits usually associated with schizophrenia and also point to a possible independent (but mild) problem that affects his right-hemisphere function. Perhaps this mild right-hemisphere impairment is a residual effect resulting from his CHI. Still, the majority of difficulties seen on this testing (and likely in his daily function) appear related to his psychiatric condition (schizophrenia).

Neuropsychological function assessment is a relatively recent development within applied psychology. In fact, it is only in the last 2 or 3 decades that neuropsychology has become established as a clinical specialty. Neuropsychologists assess brain–behavior relationships using standardized psychological instruments. The main goal of a neuropsychological evaluation is to relate a patient's test performance to both the status of his or her central nervous system and real-world functional capacity. In addition to assessing general intelligence, a complete neuropsychological assessment evaluates five major cognitive abilities: attention and concentration, language (expressive and receptive), memory (immediate and delayed), visual–spatial intelligence, and executive function and abstract thinking. This assessment is similar to the mental status examination used in neurology; it differs mainly in that it provides a deeper, more comprehensive, and better-quantified assessment. The application of a battery of tests covering these major cognitive areas allows for a broad assessment of the patient's strengths and deficits and provides some indication as to how these strengths and deficits will affect real-world adaptation.

Types of Neuropsychological Assessment

The Halstead-Reitan (H-R) Battery is the oldest standardized neuropsychological assessment battery currently in use. The H-R Battery is an elaborate and time-intensive set of neuropsychological tests. Analysis of an H-R Battery is almost exclusively quantitative. The H-R profile is interpreted at four levels: an impairment index (a composite score reflecting the subject's overall performance), lateralizing signs, localizing signs, and a pattern analysis for inferences of causal factors.[13] The Boston process approach to neuropsychological assessment is a newer and more flexible style of neuropsychological assessment.[14] The Boston process approach starts with a small core test battery (usually containing one of the Wechsler IQ tests); subsequently, hypotheses regarding cognitive deficits are developed on

the basis of the patient's performance. Other instruments are administered to test and refine these hypotheses about the patient's cognitive deficits. The Boston approach focuses on both the quantitative and qualitative aspects of a patient's performance. By *qualitative*, we mean the manner or style of the patient's performance, not just the accuracy. In fact, reviewing how a patient failed an item can be more revealing than knowing which items were missed. In this way the Boston approach reflects an integration of features from behavioral neurology and psychometric assessment.

Many neuropsychologists use a composite battery of tests in their day-to-day clinical work. A composite battery is usually composed of an IQ test (one of the Wechsler scales) and a number of selected tests matched to the patient and to the disorder being evaluated. Here we review some of the specific neuropsychological tests that might be used to compose a battery or to assess specific cognitive functions. For a description of these tests, see Spreen and Strauss.[15]

Attention and concentration are central to most complex cognitive processes; therefore it is important to adequately measure these functions in a neuropsychological test battery. In fact, some patients who complain of memory disorders turn out to have impaired attention and concentration rather than pure memory dysfunction. Tests of attention and concentration include Trail Making Test Parts A & B and the mental control subtests of the WMS-IV and the WAIS-IV digit span, digit symbol, and arithmetic subtests. It is important to assess language from a number of perspectives, including simple word recognition, reading comprehension, verbal fluency, object-naming ability, and writing. Frequently used measures of language function are the WAIS Verbal IQ subtests, the Boston Naming Test, the Verbal Fluency Test, Reading (word recognition and reading comprehension), and Written Expression (a writing sample). The accurate measurement of reading ability (often using the North American Adult Reading Test) can provide an estimation of premorbid intelligence and allow the examiner to gauge the degree of overall cognitive decline. The assessment of memory is extremely important in a neuropsychological battery because impaired memory is both a major reason for referral and a strong predictor of poor treatment outcome. An evaluation of memory should cover both visual and auditory memory systems, measure immediate and delayed recall, assess the pattern and rate of new learning, and explore for differences between recognition (memory with a retrieval cue) and unaided recall. The WMS-IV[4] is one of the primary memory inventories. Like the Wechsler IQ scales, this memory test is well standardized. The WMS-IV produces major memory scores that have a mean of 100 with an SD of 15. The memory subscales all have a mean of 10 and an SD of 3. These statistical properties allow for a detailed evaluation of memory function. In fact, the most recent revision of the Wechsler IQ and Memory Scales was jointly normed, allowing for more meaningful comparisons between IQ and memory. The Three Shapes and Three Words Memory Test[16] is a less demanding test of verbal (written) and nonverbal immediate and delayed memory. Unfortunately, it is not well normed. Visual–spatial tests (usually with a motor component—drawing) help evaluate right-hemisphere functions in most (right-handed) adults. Because these deficits are nonverbal (sometimes called *silent*), they are often overlooked in briefer nonquantitative cognitive evaluations. Tests that tap visual–spatial function include the Rey-Osterrieth Complex Figure, the Hooper Visual Integration Tests, the Draw-a-Clock Test, and the Performance IQ subtests of the WAIS. *Executive function* refers to higher-order cognitive processes, such as judgment, planning, logical reasoning, and the modification of behavior on the basis of external feedback. All these functions are thought to be associated with the frontal and prefrontal lobes and are extremely important for effective real-world function. One of the most frequently used tests of executive function is the Wisconsin Card Sorting Test (WCST), which requires the patient to match 128 response cards to one of four stimulus cards using three possible dimensions (color, form, and number). While the patient matches these cards, the only feedback he or she receives is the response "right" or "wrong." After 10 consecutive correct matches, the matching rule shifts to a new dimension (unannounced) and the patient must discover the new rule. One of the primary scores from the WCST is the number of perseverative errors committed (a perseverative error is scored when the patient continues to sort to a dimension despite clear feedback that the strategy is incorrect). Other tests of executive functioning include the Booklet Format Category Test, the Stroop Color Word Test, and the similarities and comprehension subtests of the WAIS (tapping abstract reasoning).

Typically, neuropsychologists are interested in both the absolute magnitude of patients' performance (how well they performed in comparison with the test's norms) and any differences between the two body sides (the left–right discrepancies). Tests of motor function include the Finger Tapping Test (the average number of taps per 10 seconds with the index finger of each hand) and a test of grip strength (using the hand dynamometer). Sensory tests include Finger Localization Tests (naming and localizing fingers on the subject's and examiner's hand) and Two-Point Discrimination and Simultaneous Extinction Test (measuring two-point discrimination threshold and the extinction or suppression of sensory information by simultaneous bilateral activation).

It is becoming more evident that many psychiatric conditions are associated with cognitive impairment. Therefore a complete neuropsychological assessment should also include a self-report test of psychopathology, such as the MMPI-2. Including such a test in the battery allows the neuropsychologist to assess the possible contribution of psychopathology to the cognitive profile. One of the main advantages of neuropsychological assessment is the ability to compare a patient's performance to that of a normative sample. This allows the physician to determine how well the patient performed relative to a comparison group. However, the usefulness of neuropsychological test data can be limited by the quality of such norms. Unfortunately, the quality of norms varies greatly from test to test. Tests such as the Wechsler IQ and Memory Scales have excellent norms, whereas other frequently used tests (e.g., Boston Naming Test) have more limited norms. With regard to older adults, it is most helpful to have age- and education-adjusted norms because both these variables have a substantial mediating effect on the normal (age-appropriate) decline of cognitive function.

A number of brief neuropsychological assessment tools are used in clinical practice. Brief assessment tools are not a substitute for a comprehensive neuropsychological assessment, but they can be useful as screening instruments or when patients cannot tolerate a complete test battery. One such brief test is the Dementia Rating Scale–2 (DRS-2).[17] This test provides a brief but reasonable assessment of the major areas of cognitive function (attention, memory, language, reasoning, and construction). The test employs a screening methodology in evaluating these cognitive domains; the patient is first presented with a moderately difficult item, and if that item is passed, the rest of the items in that domain are skipped (with the examiner moving on to the next domain). However, if the screening item is failed, then a series of easier items are given to more fully evaluate the specific cognitive ability.

The DRS-2 is a useful tool for assessing patients 55 and older who are suspected of having dementia of the Alzheimer's type (DAT). It takes between 10 and 20 minutes to administer, and it provides six scores. The total score and the scores from the Memory and Initiation/Perseveration subscales have been useful in the identification of patients with DAT. The DRS was designed to have a deep floor. This means that the test contains many items that tap low levels of function and allow the test to track patients as their function declines. This quality makes the DRS a useful tool for monitoring patients with DAT along the course of their illness.

The differentiation of depression from dementia in older adults is the most common neuropsychological referral question. Depression in older adults is often accompanied by mild cognitive deficits, making the diagnostic picture somewhat confused with that of early dementia. By evaluating the profile of deficits obtained across a battery of tests, a neuropsychologist can help distinguish between these two illnesses. For example, depressed patients tend to have problems with attention, concentration, and memory (new learning and retrieval), whereas patients with early dementia have problems with delayed recall memory (encoding) and word-finding or naming problems. Both groups of patients can display problems with frontal lobe/executive function. However, the function of the depressed patient often improves with cues or suggestions about strategies; this typically does not help patients with dementia. Although this general pattern does not always hold true, it is this type of contrasting performance that allows neuropsychological assessment to aid differential diagnosis.

Whether a patient is capable of living independently is a complex and often emotionally charged question. Neuropsychological test data can provide one piece of the information needed to make a reasonable medical decision in this area. In particular, neuropsychological test data regarding memory function (both new learning rate and delayed recall) and executive function (judgment and planning) have been shown to predict failure and success in independent living. However, any neuropsychological test data should be thoughtfully combined with information from an occupational therapy evaluation, assessment of the patient's psychiatric status, and input from the family (when available) before rendering any judgment about a patient's capacity for independent living.

Neuropsychological assessment has a role in the diagnosis and treatment of adults and children with attention-deficit disorder (ADD). However, as in the question of independent living status, it provides just a piece of the data necessary for making this diagnosis. The evaluation of ADD should include a detailed review of academic performance, including report cards and school records. When possible, living parents should also be interviewed for their recollections of the patient's childhood behavior. The neuropsychological evaluation should focus on measuring intelligence, academic achievement (expecting to see normal or better IQ with reduced academic achievement), and multiple measures of attention and concentration (with tests of passive, active [shifting], and sustained attention). Although the neuropsychological testing profile might aid in the diagnosis of ADD in adulthood, the diagnosis is usually based on historic data. The neuropsychological test data or profile is often more useful in helping the patient, family, and treater understand the impact of ADD on the patient's current cognitive abilities, as well as ruling out co-morbid disorders (e.g., learning disabilities, which are very common in ADD).

Neuropsychological assessments can often aid in treatment planning for patients with moderate to severe psychiatric illness. Although this aspect of neuropsychological testing is somewhat underutilized at present, in the years to come this may prove to be the most beneficial use of these tests. Neuropsychological assessment benefits treatment planning by providing objective data (a test profile) regarding the patient's cognitive skills (deficits and strengths). The availability of such data can help clinicians and family members develop more realistic expectations about the patient's functional capacity.[18] This can be particularly helpful for patients suffering from severe disorders, such as schizophrenia. The current literature indicates that neuropsychological deficits are more predictive of long-term outcome in schizophrenic patients than are either positive or negative symptoms.

OBTAINING AND UNDERSTANDING TEST REPORTS

Referring a patient for an assessment consultation should be like referring a patient to any professional colleague. Psychological and neuropsychological testing cannot be done "blind." The psychologist will want to hear relevant information about the case and will explore with the referring practitioner what questions need to be answered (this is called the referral question). On the basis of this case discussion, the psychologist will select an appropriate battery of tests designed to obtain the desired information. It is helpful if the referrer prepares the patient for the testing by reviewing with him or her why the consultation is desired and telling him or her that it will likely take 3 or more hours to complete. The referrer should expect the psychologist to evaluate the patient in a timely manner and provide verbal feedback, a "wet read," quickly. The written report should follow shortly thereafter (inpatient reports should be produced within 48 hours and outpatient reports should be available within 2 weeks).

The psychological assessment report is the written statement of the psychologist's findings. It should be understandable and should plainly state and answer the referral

question(s). The report should contain relevant background information, a list of the tests used in the consultation, a statement about the validity of the results and the confidence the psychologist has in the findings, a detailed integrated description of the patient, and clear recommendations. It should contain raw data (e.g., IQ scores) as appropriate to allow for meaningful follow-up testing. To a considerable degree, the quality of a report (and the assessment consultation) can be judged from the recommendations provided. A good assessment report should contain a number of useful recommendations. The referrer should never read just the summary of a test report; this leads to the loss of important information, because the whole report is really a summary of a very complex consultation process.

In contrast to the written report from a personality assessment, the written neuropsychological testing report tends to be less integrated. The test findings are provided and reviewed for each major area of cognitive function (intelligence, attention, memory, language, reasoning, and construction). These reports typically contain substantial amounts of raw data to allow for meaningful retesting comparison. However, the neuropsychological assessment report should provide a brief summary that reviews and integrates the major findings and also contains useful and meaningful recommendations. As with all professional consultations, the examining psychologist should be willing to meet with the referrer and/or the patient to review the findings.

Diagnostic Rating Scales and Laboratory Tests

8

Joshua L. Roffman, M.D.
Benjamin C. Silverman, M.D.
Theodore A. Stern, M.D.

Although the interview and the mental status examination compose the primary diagnostic tools in psychiatry, the use of standardized rating scales and laboratory tests provides important adjunctive data. In addition to ruling out medical and neurological explanations for psychiatric symptoms, the quantitative instruments described in this chapter play important clinical roles in clarifying disease severity, identifying patients who meet subsyndromal criteria within a particular diagnosis, assessing response to treatment, and monitoring for treatment-related side effects. Rating scales are similarly applied in research studies to enroll patients and are often developed initially for this purpose.

DIAGNOSTIC RATING SCALES

Diagnostic rating scales (or rating instruments) translate clinical observations or patient self-assessments into objective measures. Clinically, rating scales can screen for individuals who need treatment, evaluate the accuracy of a diagnosis, determine the severity of symptoms, or gauge the effectiveness of a given intervention. In clinical research, rating scales ensure the diagnostic homogeneity of subject populations, essentially helping to define phenotypic categories, and assess outcomes of study interventions. Ideal rating instruments in both settings should demonstrate good reliability (i.e., the ability to relate consistent and reproducible information) and validity (i.e., the ability to measure what they intend to measure). Although clinician-administered instruments are generally more reliable and valid, self-completed patient instruments are less time-consuming and more readily utilized. In either case, careful consideration should be given to the clinical meanings and consequences of their results, as well as to cultural factors that could affect performance. The following sections summarize commonly used rating scales for general psychiatric diagnosis as well as specific disorders and treatment-related conditions.

GENERAL PSYCHIATRIC DIAGNOSTIC INSTRUMENTS

The Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), (SCID)[1,2] is the most commonly used clinician-administered diagnostic instrument in psychiatry. An introductory segment relies on open-ended questions to elucidate demographic, medical, and psychiatric histories, as well as medication use. The remainder employs standardized questions in nine modules that reflect DSM-IV, criteria for most major Axis I disorders: mood episodes, psychotic symptoms, psychotic disorders, mood disorders, substance use, anxiety, somatoform disorders, eating disorders, and adjustment disorders. Based on patient responses, the rater determines the likelihood that criteria for a DSM-IV diagnosis will be met. The SCID is reliable but time-consuming; for this reason, it is used primarily in research. The derivative SCID-clinical version (SCID-CV) provides a simplified format more suitable for clinical use. A similar, but more compact and easily administered, structured diagnostic interview is the Mini International Neuropsychiatric Interview (MINI).[3] Also administered by the clinician, the MINI uses "yes/no" questions that cover the major Axis I disorders, as well as antisocial personality disorder and suicide risk. Following administration of a diagnostic instrument, the seven-point Clinical Global Improvement (CGI) scale may be used to determine both severity of illness (CGI-severity [S]) and degree of improvement following treatment (CGI-improvement [I]).[4] On the CGI-S, a score of 1 indicates normal, whereas a score of 7 indicates severe illness; a 1 on the CGI-I corresponds to a high degree of improvement, whereas a 7 means the patient is doing much worse.

Mood Disorders

Considered the "gold standard" for evaluating the severity of depression in clinical studies, the Hamilton Rating Scale for Depression (HAM-D)[5] may be used to monitor the patient's progress during treatment, after the diagnosis of major depression has been established. This clinician-administered scale exists in several versions, ranging from 6 to 31 items; answers by patients are scored from 0 to 2 or 0 to 4 and tallied to obtain an overall score. Standard scoring for the 17-item HAM-D-17 instrument, frequently used in research studies, is listed in Table 8–1. A decrease of 50% or more in the HAM-D score is often considered to indicate a positive treatment response, whereas a score of 7 or less is considered equivalent to a remission. The HAM-D was developed before publication of the DSM-III and does not evaluate more recent criteria for depression (e.g., anhedonia); it also favors somatic signs and symptoms and can miss atypical symptoms, such as overeating and oversleeping.

TABLE 8–1 Scoring the HAM-D

SCORE	INTERPRETATION
0–7	Not depressed
7–15	Mildly depressed
15–25	Moderately depressed
>25	Severely depressed

HAM-D, Hamilton Rating Scale for Depression.

The Montgomery-Asberg Depression Rating Scale (MADRS) is a 10-item clinician-administered scale, designed to be particularly sensitive to antidepressant treatment effects in patients with major depression.[6] The HAM-D and the MADRS are well correlated with each other, with the MADRS sampling a smaller symptom set, but including anhedonia and concentration difficulties not collected in the HAM-D. The MADRS provides a short but reliable scale, optimized for rapid clinical use.

The Beck Depression Inventory (BDI)[7] is a widely used 21-item patient self-rating scale that can be completed in a few minutes. Scores on the BDI can be used both as a diagnostic screen and as a measure of improvement over time. For each item, patients choose from among four answers, each corresponding to a severity rating from 0 to 3. The correlation between total scores and the severity of depression is provided in Table 8–2. Although easy to administer and to score, the BDI also excludes atypical neurovegetative symptoms.

Fewer rating scales have been designed to assess mania. Two instruments for assessing manic symptoms, the Manic State Rating Scale (MSRS)[8] and Young Mania Rating Scale (Y-MRS)[9] have been designed for use on inpatient units; they demonstrate high reliability and validity. Whereas the 26-item MSRS gives extra weight to grandiosity and to paranoid–destructive symptoms, the Y-MRS examines primarily symptoms related to irritability, speech, thought content, and aggressive behavior. Neither scale has been as extensively evaluated for reliability and validity as have its counterparts geared toward depression. Newer scales, such as the Bipolar Depression Rating Scale (BDRS), have been designed to capture episodes of bipolar depression, focusing more on mixed symptoms than the above noted studies designed for unipolar depression.[10]

Psychotic Disorders and Related Symptoms

Instruments for assessing psychotic symptoms are nearly always administered by clinicians. Two of the broader and more frequently used instruments are the Brief Psychiatric Rating Scale (BPRS)[11] and Positive and Negative Syndrome Scale (PANSS).[12] The BPRS was designed to address symptoms common to schizophrenia and other psychotic disorders, as well as severe mood disorders with psychotic features. Items assessed include hallucinations, delusions, and disorganization, as well as hostility, anxiety, and depression. The test is relatively easy to administer and takes about 20 to 30 minutes. The total score, often used to gauge the efficacy of treatment, provides a global assessment and therefore lacks the ability to track subsyndromal items (e.g., positive versus negative symptoms). Alternatively, the PANSS includes separate scales for positive and negative symptoms, as well as a scale for general psychopathology. The PANSS requires more time to administer (30 to 40 minutes); related versions for children and adolescents are available.

TABLE 8–2 Scoring the BDI

SCORE	INTERPRETATION
0–7	Normal
7–15	Mild depression
15–25	Moderate depression
>25	Severe depression

BDI, Beck Depression Inventory.

More focused attention to positive and negative symptoms characterize the Scale for the Assessment of Positive Symptoms (SAPS)[13] and the Scale for the Assessment of Negative Symptoms (SANS),[14] respectively. The 30-item SAPS is organized into domains that include hallucinations, delusions, bizarre behavior, and formal thought disorder; the 20-item SANS covers affective flattening and blunting, alogia, avolition-apathy, anhedonia-antisociality, and attentional impairment. The scales are particularly useful to document specific target symptoms and measure their response to treatment, but their proper administration requires more training than do the global scales.

The proclivity of neuroleptics to induce motoric side effects has driven the creation of standardized rating scales to assess these treatment-related conditions. The Abnormal Involuntary Movement Scale (AIMS)[4] is the most widely used scale to rate tardive dyskinesia. Ten items evaluate orofacial movements, limb–truncal dyskinesias, and global severity on a 5-point scale; the remaining two items rule out contributions of dental problems or dentures. The Barnes Akathisia Rating Scale[15] evaluates both objective measures of akathisia, as well as subjective distress related to restlessness. Both scales are administered easily and rapidly and may be used serially to document the effects of chronic neuroleptic use or changes in treatment.

Anxiety Disorders

A variety of rating scales are available to assess anxiety symptoms as well as specific anxiety disorders (e.g., panic disorder, social phobia, obsessive–compulsive disorder [OCD], posttraumatic stress disorder [PTSD], and generalized anxiety disorder [GAD]). Two of the more frequently used scales, both clinically and for research purposes, are described here: the Hamilton Anxiety Rating Scale (HAM-A)[16] and Yale-Brown Obsessive Compulsive Scale (Y-BOCS).[17,18] The HAM-A provides an overall measure of anxiety, with particular focus on somatic and cognitive symptoms; worry, which is a hallmark of GAD, receives less attention. The clinician-administered scale consists of 14 items and, when scored, does not distinguish specific symptoms of a specific anxiety disorder. A briefer 6-item version, the Clinical Anxiety Scale, is also available. The most widely used scale for assessing severity of OCD symptoms, the Y-BOCS, is also clinician-administered and yields global as well as obsessive and compulsive subscale scores. Newer self-report and computer-administered versions have compared favorably to the clinician-based gold standard. The Y-BOCS has proven useful both in initial assessments and as a longitudinal measure.

Attention Disorders

Rating scales for attention disorders in children are numerous and include clinician-administered instruments, along with self-reports and scales completed by teachers, parents, and other caregivers.[19] Current (DSM-IV) diagnostic criteria for attention-deficit/hyperactivity disorder (ADHD) in children and adolescents require impairment across multiple settings, necessitating a multi-informant assessment. The Conners Rating Scales are the most popular and well researched of the DSM-IV–based rating scales and exist in several versions, including parent and teacher questionnaires, an adolescent self-report scale, and both full and abbreviated length scales.[20] The full scale is limited in use by its length (20-30 minutes to administer), but it provides a large normative base and well tested reliability. Completed by parents or teachers, the ADHD Rating Scale-IV (ADHD RS-IV) derives directly from DSM-IV symptom criteria and provides a faster (5-10 minutes), reliable screening that can help to identify children in need of additional evaluation and monitor treatment effects in children treated for ADHD.[21] The Adult ADHD Self-Report Scale (ASRS) is an 18-item self-rating scale focusing on difficulties with concentration, organization, and psychomotor restlessness.[22] The checklist takes about 5 minutes to complete and can alert the treating clinician of the need for a more in-depth interview and assessment. A 6-item screening tool, taken out of the full ASRS, provides a rapid (less than 2 minutes) method for screening general clinic populations.

Substance Abuse Disorders

The CAGE Questionnaire (Table 8–3)[23] is a brief, clinician-administered tool used to screen for alcohol problems in many clinical settings. CAGE is an acronym for the four "yes/no" items in the test, which requires less than 1 minute to administer. "Yes" answers to two or more questions indicate a clinically significant alcohol problem (sensitivity has been measured at 0.78 to 0.81, specificity at 0.76 to 0.96), and positive screening suggests the need for further evaluation. The Alcohol Use Disorders Identification Test (AUDIT) is a 10-item questionnaire designed to detect problem drinkers at the less severe end of the spectrum, prior to the development of alcohol dependence and associated medical illnesses and major life problems from drinking.[24] The AUDIT can quickly screen for hazardous alcohol consumption (sensitivity 0.92 and specificity 0.94) in outpatient settings and permit early intervention and treatment for alcohol-related problems, often before the brief CAGE questions would be positive. A widely used scale to assess past or present clinically significant drug-related diagnoses, the Drug Abuse Screening Test (DAST)[25] is a 28- or 20-item self-administered instrument that takes several minutes to complete. If the subject answers "yes" to five or more questions, a drug abuse disorder is likely. The instrument includes consequences related to drug abuse (without being specific about the drug); it is most useful in settings where drug-related problems are not the patient's chief complaint.

TABLE 8–3 The CAGE Questionnaire

C	Have you ever felt you should **C**ut down on your drinking?
A	Have people **A**nnoyed you by criticizing your drinking?
G	Have you ever felt bad or **G**uilty about your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (**E**ye opener)?

Cognitive Disorders

Cognitive scales are useful for screening out organic causes for psychopathological conditions and can help the clinician determine whether more formal neuropsychological, laboratory, or neuroimaging work-ups are warranted. It is important to consider the patient's intelligence, level of education, and literacy before interpreting results. The Folstein Mini-Mental State Examination (MMSE) (Table 8–4)[26] is used ubiquitously in diagnostic interviews as well as to follow cognitive decline over time in neurodegenerative disorders. The MMSE is administered by the clinician. It includes items that test orientation to place (state, county, town, hospital, and floor) and time (year, season, month, day, and date), registration and recall of three words, attention and concentration (serial 7s or spelling the word *world* backward), language (naming two items, repeating a phrase, understanding a sentence, following a three-step command), and visual construction (copying a design). The total score ranges from 0 to 30, with a score of 24 or lower indicating possible dementia. Although highly reliable and valid, the MMSE demonstrates less sensitivity early in the course of Alzheimer's disease and other dementing disorders, and pays little attention to executive function. In clinical practice, the MMSE is often supplemented by clock drawing and Luria maneuvers to more fully assess frontal function.

The clock drawing test is a simple, bedside assessment of general cognitive dysfunction.[27] When asked to draw a clock face with the hands set to a specified time (e.g., 10 minutes to 2), the patient must demonstrate several cognitive processes, including auditory comprehension of the instructions, access to the semantic representation of a clock,

TABLE 8–4 Scoring the MMSE

5 points	Orientation to state, country, town, hospital, floor
5 points	Orientation to year, season, month, day, date
3 points	Registration of three words
3 points	Recall of three words after 5 minutes
5 points	Serial 7s or spelling *world* backward
2 points	Naming two items
1 points	Understanding a sentence
1 points	Writing a sentence
1 points	Repeating "No *if's*, *and's*, or *but's*"
3 points	Following a three-step command
1 points	Copying a design
30 points	Total

Adapted from Folstein MF, Folstein SE, McHugh PR: "Mini-mental state": a practical method for grading the cognitive state of patients for the clinician, *J Psychiatr Res* 12:189–198, 1975.

planning ability, and visual–spatial and visual–motor skills, to successfully complete the task. Although performance can be assessed informally, several structured scoring measures have been described in the literature.[27–29]

Earlier detection of neurodegenerative disorders can be achieved with the Mattis Dementia Rating Scale (DRS).[30] Administered by a trained clinician, the DRS consists of questions in five domains: attention, initiation and perseveration, construction, conceptualization, and memory. Subscale items are presented hierarchically, with the most difficult items presented first; if the subject can perform these correctly, many of the remaining items in the section are skipped and scored as correct. The total score ranges from 0 to 144 points. In addition to early detection, the DRS can be used in some cases to differentiate dementia that results from different neuropathological conditions, including Alzheimer's disease, Huntington's disease, Parkinson's disease, and progressive supranuclear palsy. We refer the reader to Chapter 11 in this text for additional details on the work-up, assessment, and quantification of dementia.

LABORATORY TESTS

Although primary diagnoses in psychiatry are based on clinical phenomenology, physical examination and laboratory studies are often essential to rule out organic causes in the differential diagnosis for psychiatric symptoms.[31,32] Consideration should be given to dysfunction in multiple organ systems, toxins, malnutrition, infections, vascular abnormalities, neoplasm, and other intracranial problems (Table 8–5 organizes many of these using the mnemonic VICTIMS DIE). Certain presentations are especially suggestive of an organic cause, including onset after the age of 40 years, history of chronic medical illness, or a precipitous course. Laboratory tests are also important for following serum levels of certain psychiatric medications and for surveillance for treatment-related side effects. The following sections describe routine screening tests as well as specific serum, urine, cerebrospinal fluid (CSF), and other studies that are considered in the determination of the differential diagnosis and in treatment monitoring. The use of electroencephalography and neuroimaging studies is also described later in this chapter vis-à-vis diagnosis of neuropsychiatric conditions.

Routine Screening

The decision to order a screening test should take into account its ease of administration, the likelihood of an abnormal result, and the clinical implications of abnormal results (including management). Although no clear consensus exists about which tests to order in a routine screening battery for new-onset psychiatric symptoms, in practice routine screening tests include the complete blood cell (CBC) count; serum chemistries including electrolytes, glucose, calcium, magnesium, phosphate, and tests of renal function; erythrocyte sedimentation rate; and levels of vitamin B_{12}, folate, thyroid-stimulating hormone, and rapid plasma reagin (RPR). Often urine and serum toxicology screens, liver function tests (LFTs), and urinalysis are added as well.

TABLE 8–5 Organic Causes for Psychiatric Symptoms, Recalled by the Mnemonic VICTIMS DIE

Vascular	Multi-infarct dementia
	Other stroke syndromes
	Hypertensive encephalopathy
	Vasculitis
Infectious	Urinary tract infection and urosepsis
	Acquired immunodeficiency syndrome
	Brain abscess
	Meningitis
	Encephalitis
	Neurosyphilis
	Tuberculosis
	Prion disease
Cancer	Central nervous system tumors (primary or metastatic)
	Endocrine tumors
	Pancreatic cancer
	Paraneoplastic syndromes
Trauma	Intracranial hemorrhage
	Traumatic brain injury
Intoxication/withdrawal	Alcohol or other drugs
	Environmental toxins
	Psychiatric or other medications (side effects or toxic levels)
Metabolic/nutritional	Hypoxemia
	Hyper/hyponatremia
	Hypoglycemia
	Ketoacidosis
	Uremic encephalopathy
	Hyper/hypothyroidism
	Parathyroid dysfunction
	Adrenal hypoplasia (Cushing's syndrome)
	Hepatic failure
	Wilson's disease
	Acute intermittent porphyria
	Pheochromocytoma
	Vitamin B_{12} deficiency
	Thiamine deficiency (Wernicke–Korsakoff syndrome)
	Niacin deficiency (pellagra)
Structural	Normal pressure hydrocephalus
Degenerative	Alzheimer's disease
	Parkinson's disease
	Huntington's disease
	Pick's disease
Immune (autoimmune)	Systemic lupus erythematosus
	Rheumatoid arthritis
	Sjögren's syndrome
Epilepsy	Partial complex seizures/ temporal lobe epilepsy
	Postictal or intraictal states

Psychosis and Delirium

Evaluation of new-onset psychosis or delirium must include a full medical and neurological work-up; potential causes for mental status changes include central nervous system (CNS) lesions, infections, intoxication, medication effects, metabolic abnormalities, and alcohol or benzodiazepine withdrawal (Table 8–6 organizes the life-threatening causes of delirium, using the mnemonic WWHHHHHIMPS).[33] If an organic causal agent is not clearly established by virtue of the history, physical examination, and the screening studies listed previously, additional testing should include an electroencephalogram (EEG) and neuroimaging. Blood or urine cultures should be sent if there is suspicion for a systemic infectious process. Lumbar puncture is indicated (once an intracranial lesion and elevated intracranial pressure have been ruled out) if patients present with fever, headache, photophobia, or meningeal symptoms; in addition to sending routine CSF studies (e.g., opening pressure, appearance, Gram stain, culture, cell counts, and levels of protein and glucose), depending on the clinical circumstances, consideration should also be given to specialized markers (e.g., antigens for cryptococcus, herpes simplex virus, Lyme disease, and other rare forms of encephalitis, including paraneoplastic syndromes, autoimmune encephalitides, and prion diseases; acid-fast staining; and cytological examination for leptomeningeal metastases). With appropriate clinical suspicion, other tests to consider include serum heavy metals (e.g., lead, mercury, aluminum, arsenic, and copper), ceruloplasmin (which is decreased in Wilson's disease), and bromides.

Patients receiving certain antipsychotic medications (e.g., thioridazine, droperidol, pimozide, and ziprasidone [as well as haloperidol when high-dose intravenous administration is required for the treatment of agitated delirious patients]) should have a baseline electrocardiogram (ECG) as well as periodic follow-ups to monitor for QTc prolongation. Serum levels of antipsychotics can be useful both as a measure of compliance and to monitor for drug interactions (e.g., carbamazepine can decrease haloperidol levels).[34] The atypical antipsychotic clozapine causes agranulocytosis in 1% to 2% of patients taking the medication, necessitating weekly CBC testing for the first 6 months. At the initiation of treatment, a patient must have a white blood cell count (WBC) units of greater than 3500 cells/mm^3 and an absolute neutrophil count (ANC) greater than 2000 cells/mm^3. If treatment proceeds without interruption (i.e., with laboratory values remaining above these thresholds), CBC testing can be spaced to biweekly testing after 6 months and to monthly after 1 year of treatment. If the WBC or ANC drops significantly (by more than 3000 or 1500 cells/mm^3 respectively), or in the case of mild leukopenia (WBC 3000 to 3500 cells/mm^3) or granulocytopenia (ANC 1500 to 2000 cells/mm^3), the patient should be monitored closely and have biweekly CBCs checked. In the case of moderate leukopenia (WBC 2000 to 3000 cells/mm^3) or granulocytopenia (ANC 1000 to 1500 cells/mm^3), treatment should be interrupted, CBCs checked daily until abnormalities resolve, and the patient may be re-challenged with clozapine in the future. If the WBC drops below 2000 cells/mm^3 or the ANC drops below 1000 cells/mm^3, clozapine should be permanently discontinued (i.e., patients should not be challenged in the future). In this case, the patient may need inpatient medical hospitalization with required daily CBCs. Physicians and pharmacists who dispense clozapine must report laboratory values through national registries. As an aside, if a patient on clozapine develops signs of myocarditis, treaters should immediately check the WBC, troponin, and an ECG; interrupt treatment with clozapine; and refer the patient for medical evaluation.

Other adverse neuropsychiatric side effects of antipsychotic medications include the risk of seizure, changes in prolactin levels, and the onset of neuroleptic malignant syndrome (NMS). A baseline EEG can be helpful in patients taking more than 600 mg/day of clozapine because of an increased incidence of seizures at higher doses. Patients taking typical antipsychotics and risperidone should have prolactin levels checked if they manifest galactorrhea, menstrual irregularities, or sexual dysfunction. NMS should be suspected in patients who develop high fever, delirium, muscle rigidity, and elevated serum creatine phosphokinase levels while taking antipsychotic medications.

Finally, it is becoming increasingly clear that antipsychotic medications, particularly second-generation antipsychotics, are associated with weight gain and the development of metabolic syndrome. This is particularly concerning in patients with schizophrenia, who are more likely to be overweight or obese than the general population. Consensus guidelines recommend baseline and routine monitoring of weight, body mass index, waist circumference, blood pressure, and fasting glucose and lipid profiles.[35,36]

Hypoperfusion/hypoxia of the brain
Hypoglycemia
Hyper/hypothermia
Intracranial process/infection
Metabolic/meningitis
Poisons
Status epilepticus

Mood Disorders and Affective Symptoms

Although depressive symptoms often reflect a primary mood disorder, they may also be associated with a number of medical conditions, including thyroid dysfunction, folate deficiency, Addison's disease, rheumatoid arthritis, systemic lupus erythematosus, pancreatic cancer, Parkinson's disease, and other neurodegenerative disorders. Clinical suspicion for any of these disorders should drive further laboratory testing, in addition to the routine screening battery listed previously. First-break manic symptoms warrant especially careful medical and neurological evaluation, and patients who present with these symptoms often receive a laboratory work-up analogous to that described previously for a new-onset psychosis.

Patients who receive pharmacotherapy for mood disorders often require serum levels of the drug being prescribed (and its metabolite) to be checked periodically, as well as baseline and follow-up screening for treatment-induced organ damage. Tricyclic antidepressants (TCAs) can cause cardiac conduction abnormalities, including prolongation of the PR, QRS, or QT intervals; patients taking TCAs should have a baseline ECG to assess for conduction delays, especially if they have a history of pathologic cardiac conditions. TCA levels are useful in several clinical situations, including when the patient reports side effects at low doses, in geriatric or medically ill patients, when there is a question of compliance, or in an urgent clinical situation that requires rapid achievement of therapeutic levels (e.g., in a severely suicidal patient). Steady state levels are usually not achieved for 5 days after starting the medication or changing the dose; TCA trough levels should be obtained 9 to 12 hours after the last dose. No guidelines support routine checking of blood levels once a stable maintenance dose has been achieved, except in the noted circumstances or with changes in the clinical picture.

Lithium, a remarkably effective drug for bipolar disorder, has a bevy of adverse effects spanning numerous organ systems. Lithium can induce adverse effects on the thyroid gland, the kidney, and the heart, as well as cause a benign elevation of the WBC count; accordingly, baseline and follow-up measures of the CBC count with a differential, serum electrolytes, blood urea nitrogen (BUN), creatinine, thyroid function tests (TFTs), urinalysis, and ECG should be obtained. Pregnancy tests should also be obtained in women of childbearing years given the risk of teratogenic effects (e.g., Ebstein's anomaly) that are associated with use in the first trimester. There is general consensus that therapeutic lithium levels range from 0.8 to 1.2 mEq/L, although certain patients may have idiosyncratic responses outside of this range. Elderly patients with slower rates of drug metabolism and lower volumes of distribution, for example, may experience side effects within this typical range and may require maintenance at lower serum levels with a narrower therapeutic window. Steady state levels can be checked after 4 to 5 days. Lithium levels can change dramatically during or immediately after pregnancy or if patients are taking thiazide diuretics, nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin receptor–blockers, or in those who have deteriorating renal function or are dehydrated. Patients on a stable maintenance dose of lithium should have levels checked no less than once every 6 months, along with routine renal and thyroid function testing.

Patients taking carbamazepine or valproic acid for bipolar disorder should have baseline and follow-up CBC, electrolytes, and LFTs, in addition to routine level monitoring, typically every 6 months. In the case of carbamazepine, which can cause agranulocytosis, the CBC should be checked every 2 weeks for the first 2 months of treatment, and then at least once every 3 months thereafter. Pregnancy tests should be considered for women of childbearing age.

Anxiety

The medical differential for new-onset anxiety is broad; it includes drug effects, thyroid or parathyroid dysfunction, hypoglycemia, cardiac disease (including myocardial infarction and mitral valve prolapse), respiratory compromise (including asthma, chronic obstructive pulmonary disease, and pulmonary embolism), and alcohol or benzodiazepine withdrawal. Rare causes, such as pheochromocytoma, porphyria, and seizure disorder, should be investigated if suggested by other associated clinical features. Based on this broad differential diagnosis, laboratory work-up may include TFTs, serum glucose or glucose tolerance testing, chest x-ray examination, pulmonary function tests, cardiac work-up, urine vanillylmandelic acid or porphyrins, and an EEG.

Care of the Geriatric Population

Given the increased likelihood of medical conditions that cause psychiatric symptoms in older adults, special attention should be given to organic causal agents. Especially common are mental status changes resulting from urinary tract infections, anemia, thyroid disease, dementia, and iatrogenic effects from medications. Kolman[37] described five particularly useful tests for older adults: clean-catch urinalysis and culture, a chest x-ray examination, a serum B_{12} level, an ECG, and a BUN. Although the National Institutes of Health Consensus Development Conference identified the history and physical examination as the most important diagnostic tests in older adult psychiatric patients, they also specifically recommended checking a CBC, serum chemistries, TFTs, RPR, B_{12}, and folate levels. If clinically indicated, additional testing should include neuroimaging, an EEG, and a lumbar puncture. With suspected early dementia, in addition to the DRS (see Diagnostic Rating Scales, discussed earlier), positron emission tomography (PET) may be useful diagnostically.[38]

Substance Abuse

Substance abuse and withdrawal should always be considered in patients with mental status changes. Substances available for testing in serum and urine are summarized in Table 8–7. Alcohol levels can be quickly assessed using breath analysis (breathalyzer). It is important to remember that serum levels of alcohol do not necessarily correlate with the timing of withdrawal symptoms, especially in patients with chronically high alcohol levels (e.g., withdrawal starts well before the serum alcohol level reaches zero). Patients who present with a history of alcohol abuse should have LFTs and a CBC

TABLE 8–7 Serum and Urine Toxicology Screens

SUBSTANCE	SERUM DETECTION	URINE DETECTION
Alcohol	1–2 days	1 day
Amphetamine	Variable	1–2 days
Barbiturates	Variable	3 days to 3 weeks
Benzodiazepines	Variable	2–3 days
Cocaine	Hours to 1 day	2–3 days
Codeine, morphine, heroin	Variable	1–2 days
Delta-9-THC	N/A	~30 days, longer if chronic use
Methadone	15–29 hours	2–3 days
Phencyclidine	N/A	8 days
Propoxyphene	8–34 hours	1–2 days

N/A, Not applicable.

count checked; if macrocytic anemia is present, B_{12} and folate levels should also be assessed. Chronic liver damage can lead to coagulopathy (as manifested by an elevated prothrombin time or international normalized ratio [INR]) and other manifestations of synthetic failure (e.g., low albumin level). In the case of cocaine abuse, there should be a low threshold for obtaining an ECG with any cardiac symptom.

Eating Disorders

As part of their medical evaluation, patients who present with severe eating disorders should have routine laboratory studies to evaluate electrolyte status and nutritional measures (e.g., albumin level). Patients who are actively purging can present with metabolic alkalosis (manifested by an elevated bicarbonate level), hypochloremia, and hypokalemia. Serum aldolase levels can be increased in those who abuse ipecac; chronic emesis can also lead to elevated levels of amylase. Cholecystokinin levels can be blunted in bulimic patients, relative to controls, following ingestion of a meal. Finally, patients who abuse laxatives chronically may present with hypocalcemia.

Pharmacogenomic Testing

In recent years, research has greatly expanded knowledge of individual genetic variability, particularly as it applies to the metabolism of and response to psychotropic medications. A major focus has been on the cytochrome P450 (CYP) system, responsible for metabolism of many psychotropic agents (summarized in Table 8–8). Commercially-available tests, including one FDA-approved test, permit examination of an individual's CYP polymorphisms through gene chip technology, suggesting patients who may be slow or rapid metabolizers of the substrate drugs.[39] In theory, such knowledge might help clinicians make dosing decisions for particular patients, potentially facilitating treatment with certain medications with narrow therapeutic windows. Recent guidelines, however, have not supported the clinical use of such tests in treating nonpsychotic major depression with selective serotonin reuptake inhibitors (SSRIs), for example, because of the relatively high cost and lack of available evidence for clinical benefit.[40] Other pharmacogenomic tests work to predict clinical response to clozapine, development of agranulocytosis from clozapine, and development of antipsychotic-induced metabolic syndrome, though none are in routine clinical use at this time. Genotype testing for serotonin receptor and transporter variations are available but not yet clinically proven. Current research focuses heavily on the pharmacogenetics of antidepressants, but no tests for clinical response are yet available. The concept of personalized prescriptions, or tailoring drugs to an individual's genetic makeup, remains a future goal and research interest for psychiatry, but pharmacogenomic tests have not yet reached routine clinical practice.

THE ELECTROENCEPHALOGRAM

The EEG employs surface (and sometimes nasopharyngeal) electrodes to measure the low-voltage electric activity of the brain. Used primarily in the evaluation of epilepsy and other neurologic disorders, the EEG is often useful in evaluating organic causes of psychiatric symptoms.

TABLE 8–8 Cytochrome P450 Isoenzymes Active in Metabolizing Commonly Prescribed Psychotropic Medications

CYP1A2	CYP2C9	CYP2C19	CYP2D6	CYP3A3/4/5
Amitriptyline	Fluoxetine	Amitriptyline	Amitriptyline	Alprazolam
Clomipramine	Moclobemide	Citalopram	Amphetamines	Amitriptyline
Clozapine	Ramelteon	Clomipramine	Aripiprazole	Aripiprazole
Duloxetine	THC	Clozapine	Atomoxetine	Buspirone
Fluvoxamine		Diazepam	Clozapine	Carbamazepine
Haloperidol		Imipramine	Codeine	Clozapine
Imipramine		Moclobemide	Desipramine	Haloperidol
Methadone		Ramelteon	Dextromethorphan	Imipramine
Mirtazapine		Sertraline	Duloxetine	Lamotrigine
Olanzapine			Fluoxetine	Methadone
Ramelteon			Mianserin	Midazolam
Tacrine			Haloperidol	Nefazodone
			Hydrocodone	Oxcarbazepine
			Methadone	Pimozide
			m-CPP	Quetiapine
			Nortriptyline	Risperidone
			Olanzapine	Trazodone
			Oxycodone	Triazolam
			Paliperidone	Zaleplon
			Paroxetine	Zolpidem
			Phenothiazines	Ziprasidone
			Risperidone	
			Sertraline	
			Thioridazine	
			Tricyclics (TCAs)	
			Venlafaxine	

Electroencephalogram signals are presumed to reflect primarily cortical activity, especially from neurons in the most superficial cortical cell layers. The frequencies of electric activity have been divided into four bands: delta (0 to 4 Hz), theta (4 to 8 Hz), alpha (8 to 12 Hz), and beta (greater than 12 Hz). The awake state is characterized by an alpha predominance. Beta waves emerge during stage 1 sleep (drowsiness); during stage 2, vertex sharp theta and delta waves are observed. Delta waves are seen in stages 3 and 4 sleep. During rapid eye movement sleep, the EEG will record low-voltage fast waves with ocular movement artifacts. Sleep deprivation, hyperventilation, and photic stimulation can sometimes activate seizure foci. For patients with nonepileptiform EEGs but a residual high suspicion for seizure activity, serial studies, sleep-deprived studies, or long-term monitoring can produce a higher yield. Video long-term monitoring can help link often infrequent clinical events with the associated electrical patterns.

Electroencephalogram patterns associated with neuropsychiatric conditions are summarized in Table 8–9. EEG findings in generalized, absence, and partial complex seizures disorders are well characterized and are diagnostic.

TABLE 8–9 EEG Findings Associated with Neuropsychiatric Conditions

Seizure	
• Generalized	• Bilateral, symmetric, synchronous, paroxysmal spike; sharp waves followed by slow waves
• Absence	• 3-Hz spike-wave complexes
• Complex partial	• Temporal lobe spikes, polyspikes, and waves
Pseudoseizure	Normal EEG
Delirium	Generalized theta and delta activity
• Hepatic or uremic encephalopathy	• Triphasic waves
Dementia	
• Alzheimer's and vascular	• Alpha slowing of the background
• Subacute sclerosing panencephalitis and Creutzfeldt–Jakob disease	• Periodic complexes accompanying myoclonic jerks
Locked-In Syndrome	Normal EEG
Persistent Vegetative State	Slow and disorganized EEG
Death	Electrocerebral silence
Medications	
• Benzodiazepines and barbiturates	• Beta activity
• Neuroleptics and antidepressants	• Nonspecific changes
Focal Lesion	Focal delta slowing
Increased Intracranial Pressure	FIRDA

EEG, Electroencephalogram; *FIRDA*, frontal, intermittent, rhythmic delta activity.

When interpreted within the context of the clinical presentation, abnormal EEG data can help support several other broad diagnostic categories, including delirium, dementia, medication-induced mental status changes, and focal lesions. Normal data can provide support for diagnoses of pseudoseizures and locked-in syndrome, but they are not able to rule out a variety of ictal states because of limitations on the placement of surface electrodes. Although an increased number of EEG abnormalities have been described in a variety of primary psychiatric disorders, at present the EEG is not clinically useful to definitively rule in any primary psychiatric diagnosis.

NEUROIMAGING

Neuroimaging has emerged as a powerful tool in both neuropsychiatric research and in the clinical investigation of organic causal agents for psychiatric presentations; however, rarely do neuroimaging studies establish a primary psychiatric diagnosis. Although less invasive than other diagnostic tests, imaging studies come with their own risks to the patient, and they remain costly.[41] Following a thorough initial evaluation, the decision to use neuroimaging needs to be made on a case-by-case basis; at present, the major objective of neuroimaging studies in patients with psychiatric symptoms is to prevent missing a treatable brain lesion. A suggested list of indications for brain imaging in psychiatric patients is given in Table 8–10. The following sections describe the major neuroimaging techniques currently available, as well as their clinical utility.

Computed Tomography

Computed tomography (CT) scans use multiple x-rays to provide cross-sectional images of the brain. On CT films, areas of increased beam attenuation (e.g., of the skull) appear white, whereas those of low attenuation (e.g., gas) appear black, and those of intermediate attenuation (e.g., soft tissues) appear in shades of gray. Contrast material may be used to visualize areas where the blood–brain barrier has been compromised, for example, by tumors, bleeding, inflammation, and abscesses; however, up to 5% of patients can develop idiosyncratic reactions to contrast media, manifested by hypotension, nausea, flushing, urticaria, and anaphylaxis. CT scans can be obtained rapidly and are the imaging modality of choice in identifying acute hemorrhage and trauma, as well as in situations in which magnetic

*When initial history, physical examination, and laboratory studies are not definitive.

ECT, Electroconvulsive therapy.

resonance imaging (MRI) is contraindicated. CT scans are generally better tolerated by patients with anxiety or claustrophobia. Although useful in examining gross pathological conditions, CT lacks the resolution to detect subtle white matter lesions or changes in smaller structures, such as the hippocampi and basal ganglia. Because CT scans use ionizing radiation, they are contraindicated in pregnancy.

Although CT scans have a well-established role in the identification of structural abnormalities responsible for psychiatric symptoms in patients with organic lesions, they cannot be used to diagnose primary psychiatric illness. However, there are nonspecific structural changes visible on CT that have been consistently identified in the brains of psychiatric patients. Since Weinberger and coworkers[42] first described increased ventricular-to-brain ratios in patients with schizophrenia, several investigators have observed enlarged ventricles in those with eating disorders, alcoholism, bipolar disorder, dementia, and depression.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI), which provides detailed images of the brain in axial, sagittal, and coronal planes, takes advantage of the interaction between protons and an external magnetic field. In the magnetic field of the MRI scanner, hydrogen protons in the water molecules of the brain become aligned as dipoles with, or against, the field. A radiofrequency pulse is applied, shifting the spin on the protons to a higher energy level; when the signal is turned off, spin returns to the ground state and the proton releases energy. The frequency of energy release (or relaxation) depends on the chemical environment surrounding the proton. A coil that detects the energy emission generates signals that are processed by the scanner to create images. Adjusting the relaxation time parameters (known as T1 and T2) can result in images that are "weighted" differently; whereas T1-weighted images provide anatomic detail and gray–white matter differentiation, T2-weighted images highlight areas of pathological conditions.

Magnetic resonance imaging is considered superior to CT for differentiation of white and gray matter, identification of white matter lesions (e.g., in multiple sclerosis, vasculitis, and leukoencephalitis), and visualization of the posterior fossa. As with CT, contrast medium may be used to identify lesions where the blood–brain barrier has been compromised. MRI is contraindicated in patients with metallic implants (including pacemakers) and is often less tolerable to patients because of the longer length of the study, the enclosed space, and the noise.

MRI may be used clinically to rule out structural brain lesions in patients with psychiatric symptoms, including acute psychosis or delirium, severe mood disorder, and abrupt personality changes. In addition to the structural changes that CT scans are capable of detecting, MRI appears to be more sensitive at detecting atrophic changes in dementia, inflammation-induced edema, and white matter lesions. Compared with CT, MRI is capable of detecting acute strokes earlier, using a method called diffusion-weighted imaging.

Functional MRI (fMRI), which is primarily a research tool at present, uses a process of acquisition sequences to approximate cerebral blood flow; accordingly, one can infer regions of brain activation and deactivation at rest, as well as during execution of sensory, motor, or cognitive tasks. Certain patterns of activation have emerged consistently in dementia, major depression, schizophrenia, and obsessive–compulsive disorder. Although fMRI is not currently considered a diagnostic or clinical tool, it is starting to provide enhanced knowledge about psychiatric illnesses and psychotropic medications, which will likely help guide research, drug development, and clinical practice in the future.

A related imaging modality, magnetic resonance spectroscopy (MRS), permits *in vivo* measurements of certain markers of brain tissue metabolism and biochemistry. For example, using proton-based MRS, one can measure local concentrations of *N*-acetylaspartate (a putative marker of neuronal integrity), choline (a marker of membrane turnover), creatine (a marker of intracellular energy metabolism), glutamine, glutamate, and gamma-aminobutyric acid. Localized reductions in *N*-acetylaspartate have been implicated in multiple neuropsychiatric disorders, including schizophrenia, temporal lobe epilepsy, Alzheimer's disease, acquired immune deficiency syndrome dementia, and Huntington's disease. In the near future, the combined use of fMRI and MRS holds great promise for delineating abnormal structure–function relationships underlying psychopathologic conditions.[43]

PET and SPECT

Positron emission tomography (PET) employs radioactive markers to visualize directly cortical and subcortical brain functioning. Some examples of these markers include F-18 fluorodeoxyglucose (which provides a picture of brain glucose metabolism), oxygen-15 (a surrogate for regional cerebral blood flow), and receptor-specific radioligands (which indicate activity at neurotransmitter receptors). Studies can be performed only where an on-site cyclotron is present to prepare the emitter tracers. Single photon emission computed tomography (SPECT) uses photon-emitting nucleotides measured by gamma detectors to localize brain activation or pharmacological activity; commonly used tracers include xenon-133 and technetium Tc-99m hexamethylpropyleneamine (which measure cerebral blood flow) and, as in PET, radioligands with specific receptor activity. Although PET scans provide greater spatial and temporal resolution, signal-to-noise ratio, and variety of ligands, SPECT is more readily available, better tolerated, and less expensive.

Although both PET and SPECT are primarily used as research tools in delineating pathophysiology and rational drug designs, clinical use of these techniques is becoming increasingly common. PET and SPECT may be used in concert with the EEG to determine seizure foci, especially in patients with partial complex seizures; during a seizure, scans can demonstrate areas of increased metabolism, whereas interictally the focus will be hypometabolic and hypoperfused. Moreover, in both Alzheimer's disease and multi-infarct dementia, abnormal patterns of cortical metabolism and receptor function as evidenced on PET and SPECT appear to predate structural changes visible on MRI.[44,45] With the continued development of receptor-specific ligands and other functional markers, these imaging modalities may continue to find a more prominent role in clinical diagnosis and management.

CONCLUSION

Although diagnosis in psychiatry continues to rely primarily on the interview and other clinical phenomenology, diagnostic rating scales and laboratory testing serve important roles in eliminating organic causal agents from the differential diagnoses, monitoring the effects of treatment, and guiding further management decisions. Neuroimaging has provided a noninvasive means to detect subtle neurophysiological dysfunction in psychiatric patients and has begun to find meaningful clinical as well as research applications. It is clear that these quantitative measures will assume increasing prominence and importance in twenty-first century psychiatry.

Maurizio Fava, M.D.
Theodore A. Stern, M.D.

A major depressive disorder (MDD) serious enough to warrant professional care affects approximately 16% of the general population during their lifetime.[1] Both the Epidemiological Catchment Area (ECA) study and the National Comorbidity Survey study have found that MDD is prevalent, with cross-sectional rates of up to 6.6%.[1] Although this condition ranks first among reasons for psychiatric hospitalization (23.3% of total hospitalizations), it has been estimated that 80% of all persons suffering from it are either treated by nonpsychiatric personnel or are not treated at all.[2]

Depression is second only to hypertension as the most common chronic condition encountered in general medical practice.[3] Depression is estimated to rival virtually every other known medical illness with regard to its burden of disease morbidity early in this millennium.[4] With respect to physical function, depressed patients score, on average, 77.6% of normal function, with advanced coronary artery disease (CAD) and angina being 65.8% and 71.6%, respectively, and back problems, arthritis, diabetes, and hypertension ranging from 79% to 88.1%.[5] MDD has also been characterized by increased mortality.[6–8] In the general population, suicide accounts for about 0.9% of all deaths, and depression is the most important risk factor for suicide, with about 21% and 18% of the patients with recurrent depressive disorders and dysthymic disorder, respectively, attempting suicide.

Depressed patients often have co-morbid medical illnesses (e.g., arthritis, hypertension, backache, diabetes mellitus [DM], and heart problems). Similarly, the presence of one or more chronic medical conditions raises the recent (6-month) and lifetime prevalences of mood disorder. Patients affected by chronic and disabling physical illnesses are at higher risk of depressive disorders, with rates being typically greater than 20%. Among patients hospitalized for CAD, 30% present with at least some degree of depression.[9] Patients with DM also have a twofold increased prevalence of depression, with 20% and 32% rates in uncontrolled and controlled studies, respectively, conducted with depression symptom scales.[10,11] Depression is also more common in obese persons than it is in the general population.[12] At the Massachusetts General Hospital (MGH), the psychiatric consultant called to see a medical patient makes a diagnosis of MDD in approximately 20% of cases, making MDD among the most common problems seen for diagnostic evaluation and treatment. The prevalence of chronic medical conditions in depressed patients is higher regardless of the medical context of recruitment, with an overall rate ranging from 65% to 71% of patients.[13] Several studies indicate that depression significantly influences the course of concomitant medical diseases. In general, the more severe the illness, the more likely depression is to complicate it.[14]

In acutely ill hospitalized older persons, the health status of patients with more symptoms of depression is more likely to deteriorate and less likely to improve during and after hospitalization.[15] Some degree of depression in patients hospitalized for CAD is associated with an increased risk of mortality, and also with continuing depression for at least the first year after hospitalization.[9] Proceeding to cardiac surgery while suffering from MDD, for example, is known to increase the chance of a fatal outcome.[16] Depression in the first 24 hours after myocardial infarction (MI) was associated with a significantly increased risk of early death, reinfarction, or cardiac arrest.[17] Even in depressed outpatients, the risk of mortality, chiefly as a result of cardiovascular disease, is more than doubled.[18] The increased risk of cardiac mortality has also been confirmed in a large community cohort of individuals with cardiac disease who presented with either MDD or minor depression.[19] Those subjects without cardiac disease but with depression also had a higher risk (from 1.5- to 3.9-fold) of cardiac mortality.[19]

In patients with type 1 or 2 diabetes, depression was associated with a significantly higher risk of DM-specific complications (e.g., retinopathy, nephropathy, neuropathy, macrovascular complications, and sexual dysfunction).[20] Data from the Hispanic Established Population for the Epidemiologic Study of the Elderly indicated that death rates in this population were substantially higher when a high level of depressive symptoms was co-morbid with DM (odds ratio, 3.84).[21]

Depression symptom severity is also associated with poor diet and with poor medication adherence, functional impairment, and higher health care costs in primary care patients with DM.[22] Underrecognition and undertreatment of depression in the elderly has been associated in primary care with increased medical utilization.[23] Among the elderly (age 65 years or older), a significant correlation exists between depression and the risk of recurrent falls, with an odds ratio of 3.9 when four or more depressive symptoms

are present. These data are of particular importance because falls in the elderly are a well-recognized public health problem.[24] Patients with cancer and co-morbid depression are at higher risk for mortality[25] and for longer hospital stays. Unfortunately, despite the impact of depression on overall morbidity, functional impairment, and mortality, a significant proportion of those with depression (43%) fail to seek treatment for their depressive symptoms.[26]

Failure to treat depression leaves the patient at risk for further complications and death. There is a clinical sense, moreover, that any seriously ill person who has neurovegetative symptoms, and who has given up and wishes that he or she were dead, is going to do worse than if he or she had hope and motivation. MDD, even if the patient is healthy in every other way, requires treatment. When a seriously ill person becomes depressed, the failure to recognize and to treat the disorder is even more unfortunate.

Prompt and effective treatment of medical co-morbidity is equally important for the outcome of depression. In a study of patients with DM, the severity of depression during follow-up was related to the presence of neuropathy at study entry, and to incomplete remission during the initial treatment trial.[27] By the 10th year of insulin-dependent DM, roughly 48% of a sample of young diabetics developed at least one psychiatric disorder, with MDD being the most prevalent (28%).[28] In addition to DM, other medical and neurologic conditions have been associated with an increased risk for MDD. For example, Fava and colleagues'[29] review showed that MDD is a life-threatening complication of Cushing's syndrome, Addison's disease, hyperthyroidism, hypothyroidism, and hyperprolactinemic amenorrhea, and that treatment that primarily addresses the physical condition may be more effective than antidepressant drugs for such organic affective syndromes. A study of computerized record systems of a large staff-model health maintenance organization showed that patients diagnosed as being depressed had significantly higher annual health care costs ($4246 versus $2371, $P < .001$) and higher costs for every category of care (e.g., primary care, medical specialty care, medical inpatient care, and pharmacy and laboratory costs) than patients without depression.[30] Depressive disorders are likely to cause more disability than are most other chronic diseases (e.g., osteoarthritis and DM), with a possible exception being MI.[31]

MAKING THE DIAGNOSIS OF DEPRESSION

The criteria for MDD according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)[32] should be applied to the patient with medical illness in the same way as to a patient without medical illness. The DSM-IV has a category for mood disorders "due to" a general medical condition. A stroke in the left hemisphere, for example, is commonly followed by a syndrome clinically indistinguishable from MDD. It can now be referred to as a "major depression-like" condition when full criteria are met. Our recommendation is to diagnose a mood disorder using the DSM-IV criteria. MDD can now be diagnosed as such, but there is still no term in the DSM-IV to represent what the Research Diagnostic Criteria referred to as minor depression—a distinction that is important in the medically ill.

The DSM-IV classification of MDD has traditionally had a greater focus on the psychological symptoms of depression (e.g., depressed mood, lack of interest, excessive guilt, thoughts of suicide, feelings of worthlessness, indecisiveness). Although some of the physical or somatic symptoms of MDD (primarily fatigue and disturbances of both sleep and appetite) are included in the DSM-IV classification of this disorder, it is apparent that physical symptoms are underrepresented in the current nosology, despite the fact that they represent the chief complaint for a substantial proportion of patients who suffer from MDD.

Diagnosis is crucial to treatment. Three questions face the consultant at the outset: (1) Does the patient manifest depression? (2) If so, is there an organic cause, such as use of a medication, that can be eliminated, treated, or reversed? (3) Does it arise from the medical condition (e.g., Cushing's disease), and treatment of that condition will alleviate it, or must it be treated itself (e.g., poststroke depression [PSD])?

Major Depression

Depression is a term used by most to describe even minor and transient mood fluctuations. It is seen everywhere and is often thought to be normal; therefore it is likely to be dismissed even when it is serious. This applies all the more to a patient with serious medical illness: If a man has terminal cancer and meets the full criteria for MDD, this mood state is regarded by some as "appropriate." Depression is used here to denote the disorder of MDD—a seriously disabling condition for the patient, capable of endangering the patient's life; it is not just an emotional reaction of sadness or despondency. If, while recovering from an acute stroke, a patient has a severe exacerbation of psoriasis, no one says that the cutaneous eruption is appropriate, even though the stress associated with the stroke has almost certainly caused it. Moreover, caregivers are swift to treat the exacerbation. When a patient with a history of MDD lapses into severe depression 1 month after beginning radiation therapy for an inoperable lung cancer, some may see a connection to the prior depressive illness and hasten to treat it. Far more common is the conclusion that anyone with that condition would be depressed. The majority of terminally ill cancer patients do not develop MDD no matter how despondent they feel. If a patient is hemorrhaging from a ruptured spleen, has lost a great deal of blood, becomes hypotensive, and goes into shock, no one calls this appropriate. Like shock, depression is a dread complication of medical illness that requires swift diagnosis and treatment.

Two assumptions are made here: (1) A depressive syndrome in a medically ill patient shares the pathophysiology of a (primary) major affective disorder, and (2) proper diagnosis is made by applying the same criteria. Patients who suffer from unipolar depressive disorders typically present with a constellation of psychological and cognitive (Table 9–1), behavioral (Table 9–2), and physical and somatic (Table 9–3) symptoms. Because far less epidemiologic information is available on depression in the medically ill, the requirement that the dysphoria be present for 2 weeks or longer should be regarded as only a rough approximation in the medically ill. According to the DSM-IV,[32] at least five of the following nine symptoms should be present most of the day, nearly every day, and should include either depressed mood or loss of interest or pleasure:

TABLE 9–1 Unipolar Depressive Disorders: Common Psychological and Cognitive Symptoms

Depressed mood
Lack of interest or motivation
Inability to enjoy things
Lack of pleasure (anhedonia)
Apathy
Irritability
Anxiety or nervousness
Excessive worrying
Reduced concentration or attention
Memory difficulties
Indecisiveness
Reduced libido
Hypersensitivity to rejection or criticism
Reward dependency
Perfectionism
Obsessiveness
Ruminations
Excessive guilt
Pessimism
Hopelessness
Feelings of helplessness
Cognitive distortions [e.g., "I am unlovable"]
Preoccupation with oneself
Hypochondriacal concerns
Low or reduced self-esteem
Feelings of worthlessness
Thoughts of death or suicide
Thoughts of hurting other people

TABLE 9–2 Unipolar Depressive Disorders: Common Behavioral Symptoms

Crying spells
Interpersonal friction or confrontation
Anger attacks or outbursts
Avoidance of anxiety-provoking situations
Social withdrawal
Avoidance of emotional and sexual intimacy
Reduced leisure-time activities
Development of rituals or compulsions
Compulsive eating
Compulsive use of the Internet or video games
Workaholic behaviors
Substance use or abuse
Intensification of personality traits or pathologic behaviors
Excessive reliance or dependence on others
Excessive self-sacrifice or victimization
Reduced productivity
Self-cutting or mutilation
Suicide attempts or gestures
Violent or assaultive behaviors

TABLE 9–3 Unipolar Depressive Disorders: Common Physical and Somatic Symptoms

Fatigue
Leaden feelings in arms or legs
Difficulty falling asleep (early insomnia)
Difficulty staying asleep (middle insomnia)
Waking up early in the morning (late insomnia)
Sleeping too much (hypersomnia)
Frequent naps
Decreased appetite
Weight loss
Increased appetite
Weight gain
Sexual arousal difficulties
Erectile dysfunction
Delayed orgasm or inability to achieve orgasm
Pains and aches
Back pain
Musculoskeletal complaints
Chest pain
Headaches
Muscle tension
Gastrointestinal upset
Heart palpitations
Burning or tingling sensations
Paresthesias

1. Depressed mood, subjective or observed, most of the day, nearly every day
2. Markedly diminished interest or pleasure in all, or almost all, activities, nearly every day
3. Significant (more than 5% of body weight per month) weight loss or gain
4. Insomnia or hypersomnia, nearly every day
5. Psychomotor agitation or retardation that is observable by others, nearly every day
6. Fatigue or loss of energy, nearly every day
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional), not merely about being sick, nearly every day
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day
9. Recurrent thoughts of death (not just a fear of dying), recurrent suicidal ideation without a plan, or a suicide attempt or a specific plan for committing suicide

Two questions (does the patient suffer from depressed mood? is there diminished interest or pleasure?) have a high sensitivity (about 95%), but unfortunately a low specificity (57%), for diagnosing MDD. Consequently, posing these two questions can be useful as a first approach to the patient who presents with risk factors for depression. However, further inquiry is typically required to establish the diagnosis. Although depressive disorders are frequently associated with medical illnesses, the DSM-IV considers that potential medical illnesses underlying depressive symptoms should be excluded before making the diagnosis of MDD. This hierarchical approach is typically ignored by clinicians, who tend to make the diagnosis of MDD even in the presence of co-morbid medical conditions that may be etiologically related to the condition itself. Nevertheless, the issue of differential diagnosis with medical diseases still exists, as patients may present with transient demoralization as a result of their physical illness or of fatigue or other cognitive and neurovegetative symptoms (but not fulfilling the criteria for MDD or even minor depression). For instance, weight loss and fatigue may also be associated with a variety of disorders

(e.g., DM, cancer, thyroid disease). The medical and psychiatric history, together with the physical examination, should guide any further diagnostic work-up.

The aforementioned DSM-IV symptoms may at first seem invalid in the medically ill. If the patient has advanced cancer, how can one attribute anorexia or fatigue to something other than the malignant disease itself? Four of the nine diagnostic symptoms could be viewed as impossible to ascribe exclusively to depression in a medically ill patient: sleep difficulty, anorexia, fatigue or energy loss, and difficulty concentrating. Endicott[33] developed a list of symptoms that the clinician can substitute for, and count in place of, these four: fearful or depressed appearance; social withdrawal or decreased talkativeness; brooding, self-pity, or pessimism; and mood that is not reactive (i.e., the patient cannot be cheered up, does not smile, or does not react positively to good news). Although this method is effective, Chochinov and colleagues[34] compared diagnostic outcomes using both the regular (Research Diagnostic Criteria) and the substituted criteria in a group of medically ill patients. If one held the first two symptoms to the strict levels—that is, depressed mood must be present most of the day, nearly every day, and loss of interest applies to almost everything—the outcome for both diagnostic methods yielded exactly the same number of patients with the diagnosis of MDD.

The first help comes from discovery of symptoms that are more clearly the result of MDD, such as the presence of self-reproach ("I feel worthless"), the wish to be dead, or psychomotor retardation (few medical illnesses in and of themselves produce psychomotor retardation; hypothyroidism and Parkinson's disease are two of them). Insomnia or hypersomnia can also be helpful in the diagnosis, although the patient may have so much pain, dyspnea, or frequent clinical crises that sleep is impaired by these events. Although libidinous interests may not be high in an intensive care unit patient, some form of interest can usually be assessed, as when talk gets around to children or grandchildren, hobbies, or people. Do they still find that their affect brightens, or is it blunted? The ability to think or concentrate, like the other symptoms, needs to be specifically asked about in every case.

Unfortunately, to some a request for psychiatric consultation is tantamount to saying that physical symptoms are only "in your head" or are the result of malingering. Instead, depression is as much a somatic as a psychic disorder. The somatic manifestations of depression (e.g., insomnia, restlessness, anhedonia) may even be construed as proof to a patient that they have no "psychic" illness. "No, doctor, no way am I depressed; if I could just get rid of this pain, everything would be fine." Persistence and aggressive questioning are required to elicit the presence or absence of the nine symptoms.

If the history establishes six of nine symptoms, the consultant may not be certain that three of them have anything to do with depression but may just as likely stem from a co-morbid medical illness. If the patient were found to be hypothyroid, the treatment of choice would not be antidepressants but judicious thyroid replacement. Usually, however, everything is being done for the patient to alleviate the symptoms of the primary illness. If this appears to be the case, our recommendation is to make the diagnosis of MDD and proceed with treatment.

States Commonly Mislabeled as Depression

Up to a third of patients referred for depression have, on clinical examination, neither MDD nor minor depression. By far the most common diagnosis found among these mislabeled referrals at the MGH has been an organic mental syndrome. A quietly confused patient may look depressed. The patient with dementia or with a frontal lobe syndrome caused by brain injury can lack spontaneity and appear depressed. Fortunately, the physical and mental status examinations frequently reveal the tell-tale abnormalities.

Although much less common, mental retardation may also be mistaken for depression, especially when failure to grasp or to comply with complex instructions makes no sense to those caring for the patient ("He seems not to care"). If suspected, mental retardation can be confirmed by history from family, by review of past records, or by formal testing of intelligence.

Another unrecognized state, sometimes called depression by the consultee and easier for the psychiatrist to recognize, is anger. The patient's physician, realizing that the patient has been through a long and difficult illness, may perceive reduction in speech, smiling, and small talk on the patient's part as depression. The patient may thoroughly resent the illness, be irritated by therapeutic routines, and be fed up with the hospital environment but, despite interior smoldering rage, may remain reluctant to discharge wrath in the direction of the physician or nurses.

Excluding Organic Causes of Depression

When clinical findings confirm that the patient's symptoms are fully consistent with MDD, the consultant must still create a differential diagnosis of this syndrome. Could the same constellation of symptoms be caused by a medical illness or its treatment? Should the patient's symptoms be caused by an as yet undiagnosed illness, the last physician with the chance of detecting it is the consultant. Differential diagnosis in this situation is qualitatively the same as that described for considering causes of delirium (see Chapter 10). With depression, although the same process should be completed, certain conditions more commonly produce depressive syndromes and are worthy of comment.

Review of the medications that the patient is taking generally tells the consultant whether the patient is receiving something that might alter mood. Ordinarily, one would like to establish a relationship between the onset of depressive symptoms and either the start of, or a change in, a medication. If such a connection can be established, the simplest course is to stop the agent and monitor the patient for improvement. When the patient requires continued treatment, as for hypertension, the presumed offending agent can be changed, with the hope that the change to another antihypertensive will be followed by resolution of depressive symptoms. When this fails or when clinical judgment warrants no change in medication, it may be necessary to start an antidepressant along with the antihypertensive drug. The literature linking drugs to depression is inconclusive at best. Clinicians have seen depression following use of reserpine and steroids[35] and from withdrawal from cocaine, amphetamine, and alcohol. Despite anecdotal reports, β-blockers do not appear to cause depression. It has been suggested that depression in some cases appears

as a reaction to subclinical cardiovascular symptoms,[36] so the differential diagnosis should also take into account medical conditions. The most common central nervous system (CNS) side effect of a drug is confusion or delirium, and this is commonly mislabeled as depression because a mental status examination has not been conducted.

Abnormal laboratory values should not be overlooked, because they may provide the clues to an undiagnosed abnormality responsible for the depressive symptoms. Laboratory values necessary for the routine differential diagnosis in psychiatric consultation should be reviewed. A work-up is not complete if the evaluation of thyroid and parathyroid function is not included.

Many medical illnesses have been associated with depressive symptoms. The list is extensive, and for all practical purposes it can be included with the list of medical illnesses that can cause delirium (see Chapter 10).

MDD is never "appropriate" (e.g., "This man has inoperable lung cancer metastatic to his brain and is depressed, which is appropriate"). MDD is a common and dread complication of many medical illnesses as they become more severe. To call it anything else is to endanger the patient and neglect one of the worst forms of human suffering.

The disability associated with depressive illness is seldom recognized, yet it and mental illness in general show a stronger association with disability than with severe physical diseases.[37] One line of evidence regarding the capacity of MDD to undermine physical health is its association with decreases in trabecular bone in women (14% in the femoral neck),[38] a magnitude consistent with a 40% increase in hip fracture rates over a period of 10 years.

MDD carries its own dangers and increases the risk of cardiovascular disease. Depressed patients with CAD show a significantly higher (24% versus 4%) prevalence of ventricular tachycardia[39] and a reduction in heart rate variability,[40] both of which increase the risk of sudden death. After acute MI, the presence of MDD is the strongest predictor of death at 6 months, and depressive symptoms (defined as a Beck Depression Inventory score greater than 10) the strongest predictor of death at 18 months. Both of these predict lethality when combined with premature ventricular beats at a rate greater than 10 per hour.[41,42]

In general, the more serious the illness, the more likely the patient is to succumb to a depressive episode. Careful studies have found a high incidence of MDD in hospitalized medical patients.[14] For more than 50 years, carcinoma of the pancreas has been associated with psychiatric symptoms, especially depression, which in some cases seems to be the first manifestation of the disease.[43] Two carefully controlled studies have shown these patients to have significantly more psychiatric symptoms and major depression than patients with other malignancies of gastrointestinal origin, leading some to suspect that depression in this case is a manifestation of a paraneoplastic syndrome.[44,45]

When medical illness is localized to the CNS, the incidence of depression is dramatically higher.[14] For example, patients with acquired immune deficiency syndrome (AIDS) and possibly infection by the human immunodeficiency virus (HIV) can be expected to show higher than expected rates of depressive illness.[46,47]

Stroke

Direct injury to the brain can produce changes of affect that progress to a full syndrome of MDD. Robinson and co-workers[48–50] have intensively studied mood disorders that result from strokes. Left-hemisphere lesions involving the prefrontal cortex or basal ganglia are the most likely to be associated with poststroke depression (PSD) and to meet criteria for MDD or dysthymia.[50] Depressive symptoms appear in the immediate poststroke period in about two thirds of patients, with the rest manifesting depression by the 6th month. MDD and minor depression have different courses: MDD, left untreated, had a natural course of about 1 year, but minor depression had a more chronic (about a 2-year) course. Moreover, some untreated patients with minor depression went on to develop MDD. In depressed patients whose left-hemisphere strokes had a posterior cerebral artery distribution, depression was not only less severe but also of shorter duration, with a natural history of about 6 months. Additional risk factors for developing MDD were a prior stroke, preexisting subcortical atrophy, and a family or personal history of an affective disorder. Aphasia did not appear to cause depression, but nonfluent aphasia was associated with depression; both seemed to result from lesions of the left frontal lobe. Although the severity of functional impairment at the time of acute injury did not correlate with the severity of depression, depression appeared to retard recovery. Among patients with left-hemispheric damage, those who were depressed showed significantly worse cognitive performance, which was seen in tasks that assessed temporal orientation, frontal lobe function, and executive motor function. Successful treatment of PSD has been demonstrated by double-blinded studies with nortriptyline[51] and trazodone [52] and been reported with electroconvulsive therapy (ECT)[53] and use of psychostimulants.[54] In fact, a recent study has shown that nortriptyline was more effective than fluoxetine in treating depressive symptoms in patients with PSD.[55] Early and aggressive treatment of PSD is required to minimize the cognitive and performance deficits that this mood disorder inflicts on patients during the recovery period.

Right-hemisphere lesions deserve special attention. When the lesion was in the right anterior location, the mood disorder tended to be an apathetic, indifferent state associated with "inappropriate cheerfulness." However, such patients seldom look cheerful and may have complaints of loss of interest or even worrying. This disorder was found in 6 of 20 patients with solitary right-hemisphere strokes (and in none of 28 patients with single left-hemisphere lesions).

Prosody is also a problem for those with a right hemisphere injury. Ross and Rush[55a] focused on the presentation of aprosodia (lack of prosody or inflection, rhythm, and intensity of expression) when the right hemisphere is damaged. A patient with such a lesion could appear quite depressed and be labeled as having depression by staff and family but simply lacks the neuronal capacity to express or recognize emotion. If one stations oneself out of the patient's view, selects a neutral sentence (e.g., "The book is red"), asks the patient to identify the mood as mad, sad, frightened, or elated, and then declaims the sentence with the emotion to be tested, one should be able to identify those patients with a receptive aprosodia. Next, the patient is asked to deliver the same sentence with a series of different

emotional tones to test for the presence of an expressive aprosodia. Stroke patients can suffer from both aprosodia and depression, but separate diagnostic criteria and clinical examinations exist for each one.

Dementia

Primary dementia, even of the Alzheimer's type, increases the vulnerability of the patients to suffering MDD, even though the incidence is not as high as it is in multiinfarct or vascular dementia. The careful postmortem studies of Zubenko and colleagues[56,57] supported the hypothesis that the pathophysiology of secondary depression is consistent with theories of those for primary depression. Compared with demented patients without depression, demented patients with MDD showed a 10- to 20-fold reduction in cortical norepinephrine levels.

Multi-infarct or vascular dementia so commonly includes depression as a symptom that Hachinski and associates[58] included it in the Ischemia Scale. Cummings and co-workers[59] compared 15 patients with multi-infarct dementia with 30 patients with Alzheimer's disease and found that depressive symptoms (60% versus 17%) and episodes of MDD (4/15 versus 0/30) were more frequent in patients with the former.

Subcortical Dementias

Patients with Parkinson's disease and Huntington's disease commonly manifest MDD. In fact, Huntington's disease may present as MDD before the onset of either chorea or dementia.[60] The diagnosis is made clinically. Some have noted that as depression in the Parkinson's patient is treated, parkinsonian symptoms also improve, even before the depressive symptoms have subsided. This is especially striking when ECT is used,[61,62] although the same improvement has been reported after use of tricyclic antidepressants (TCAs). Treatment of MDD in either disease may increase the comfort of the patient and is always worth a try. Because Huntington's patients may be sensitive to the anticholinergic side effects of TCAs, anticholinergic agents should be tried first.

Another subcortical dementia worth noting is Binswanger's encephalopathy, a state of white matter demyelination presumably secondary to arteriosclerosis; it is characterized by an insidious, slowly progressive state with abulia and a paucity of focal neurologic findings.[63] Whenever affective symptoms are discovered, a trial of an antidepressant may provide striking relief for the patient.

Because the HIV-1 is neurotropic, even asymptomatic HIV-seropositive individuals, when compared with seronegative controls, demonstrate a high incidence of electroencephalographic abnormalities (67% versus 10%) and more abnormalities on neuropsychological testing.[64] The unusually high lifetime and current rates of mood disorders in HIV-seronegative individuals at risk for AIDS[65] demands an exceedingly high vigilance for their appearance in HIV-positive persons. Depression, mania, or psychosis can appear with AIDS encephalopathy, but the early, subtler signs (e.g., impaired concentration, complaints of poor memory, blunting of interests, lethargy) may respond dramatically to antidepressants, such as psychostimulants.[66,67] The selective serotonin reuptake inhibitors (SSRIs) (such as sertraline, fluoxetine, and paroxetine) have also been effective in the treatment of depression in HIV-positive patients.[68–72] A small open trial also supports the use of bupropion in these patients.[73]

We recommend that pharmacologic treatment be considered seriously whenever a patient meets criteria for either minor depression or MDD.

CHOICE OF AN APPROPRIATE ANTIDEPRESSANT TREATMENT

In Chapter 34, the properties, side effects, dosages, and drug interactions of antidepressant medications are discussed in detail. Whenever MDD is diagnosed, the effort to alleviate symptoms almost always includes somatic treatments. The consultant who understands the interactions among antidepressants, illnesses, and nonpsychotropic drugs is best prepared to prescribe these agents effectively. ECT remains the single most effective somatic treatment of depression. A nation-wide review has only sustained its merit. Indications for its use are discussed in Chapter 33.

Prescribing Antidepressants for the Medically Ill

Ever since sudden death in cardiac patients was first associated with amitriptyline,[74,75] physicians have tended to fear the use of TCAs when cardiac disease is present. However, depression itself is a life-threatening disease, and it should be treated. Choice of an agent often begins with the knowledge that a patient is especially troubled by insomnia; however, in patients with certain medical illnesses, the decision must be made on a case-by-case basis, taking into consideration the side-effect profile (risk), the anticipated benefits, and potential drug–drug interactions. In obese diabetic patients, fluoxetine has ameliorated mean blood glucose levels, daily insulin requirements, and glycohemoglobin levels,[76–80] perhaps by improving insulin sensitivity.[81,82] In contrast, TCAs, such as nortriptyline, may actually worsen glycemic control.[83] However, TCAs have been found to be superior to fluoxetine in decreasing pain secondary to diabetic neuropathy.[84]

One could also make a similar argument for patients with hypercholesterolemia, because the SSRI fluvoxamine has decreased serum cholesterol levels,[85] whereas TCAs appear to increase cholesterol levels.[86]

With respect to making a decision based on insomnia, the sedative potency of the available antidepressants can generally be predicted by their in vitro affinity for the histamine H_1 receptor. Table 9–4 shows these values.[87,88] The antihistaminic property of these drugs gives a reasonably good estimate of their sedative properties. Trazodone, which has low affinity for the H_1 receptor, is, however, a sedating agent.

This same property can also be used to predict how much weight gain may be associated with use of the antidepressant. Patients troubled by obesity may be placed at additional risk if treated with those agents higher on the list. For the most part, the SSRIs, bupropion, nefazodone, trazodone, and venlafaxine have negligible antihistaminic potency. The monoamine oxidase inhibitors (MAOIs) generally have low sedative potency, although

phenelzine sulfate can produce complaints of drowsiness. Mirtazapine,[89] a powerful antagonist of the H_1 receptor, is quite sedating and can be associated with significant weight gain.

All antidepressants in the cyclic, SSRI, and MAOI categories usually correct sleep disturbances (insomnia or hypersomnia) when these are symptoms of depression, a therapeutic effect not thought to be related to their effects on brain histamine. Therefore, this discussion highlights a sedative effect of the drugs that occurs in addition to, and independent of, these agents' ability to correct the specific sleep disturbances of MDD (e.g., to lengthen rapid-eye-movement sleep latency).

Occasionally, the consultant may encounter a patient in whom antihistamines have been tried and have failed to achieve a therapeutic effect, such as in the treatment of an urticarial rash or the itching associated with uremia. Doxepin hydrochloride, possibly the most potent antihistamine in clinical medicine, has demonstrated superiority with a 10-mg dose when compared with 25 mg of diphenhydramine hydrochloride.[90]

Threatening the successful use of antidepressants is the presence of unwanted side effects. The three groups of side effects that are particularly relevant for the treatment of depression in the acute medical setting are orthostatic hypotension (OH), anticholinergic effects, and cardiac conduction effects. The clinical ratings for these three side-effect groups with current antidepressants are presented in Table 9–5. We will discuss side effects specific to each antidepressant class, and side effects associated with abrupt discontinuation of antidepressant treatment. When these side effects are understood, safe clinical prescription of antidepressant drugs is far more likely.

Orthostatic Hypotension

OH is not directly related to each drug's in vitro affinity for the α_1-noradrenergic receptor. Table 9–5 presents the drugs with a clinical rating of their likelihood of causing an orthostatic drop in blood pressure (BP). In general, among the TCAs, tertiary amine agents are more likely to cause an orthostatic fall in BP than are secondary amines. For reasons that are not clearly understood, imipramine, amitriptyline, and desipramine are the TCAs most commonly associated with clinical mishaps, such as falls and fractures. The orthostatic effect appears earlier than the therapeutic effect for imipramine and is objectively verifiable at less than half the therapeutic plasma level. Hence the drug may have to be discontinued long before a therapeutic plasma level is reached. Once postural symptoms develop, increasing the dosage of the antidepressant may not make the symptoms worse.

Paradoxically, a pretreatment fall of more than 10 mm Hg in orthostatic BP actually predicts a good response to antidepressant medication in older adult depressed patients.[91,92] Naturally, younger patients may tolerate a fall in BP more easily than older patients, so an orthostatic fall in BP may not produce symptoms serious enough to require discontinuation of the drug. The presence of cardiovascular disease increases the likelihood of OH. When patients with no cardiac disease take imipramine, the incidence of significant OH is 7%. With conduction disease, such as a bundle-branch block (BBB), the incidence rises to 33%, and with congestive heart failure (CHF), it reaches 50%.[93] Of the traditional TCAs, nortriptyline has been shown to be the least likely to cause OH, an extremely valuable factor when depression in cardiac or older adult patients requires treatment.[94] MAOIs cause significant OH with about the same frequency as imipramine (i.e., often). Moreover, the patient starting on an MAOI usually does not experience OH until the medication is having a significant therapeutic effect, roughly 2 to 4 weeks later.

Among other agents, trazodone is associated with OH moderately often, as is mirtazapine. Fluoxetine, sertraline, paroxetine, citalopram, fluvoxamine, bupropion, venlafaxine, and psychostimulants are essentially free of this side effect. Bupropion, psychostimulants, and venlafaxine may raise systolic BP slightly in some patients. Some have noted that even though the objective fall in standing BP continues for several months, some patients with initial symptoms accommodate subjectively and no longer complain of the side effect.

Anticholinergic Effects

The anticholinergic effects of TCAs are a nuisance for many patients. Urinary retention, constipation, dry mouth, confusional states, and tachycardia are the most common. The increase in heart rate is usually manifested as a sinus tachycardia that results from muscarinic blockade of vagal tone on the heart. As many as 30% of normal individuals respond to amitriptyline with tachycardia.[95] This side effect correlates nicely with the in vitro affinity of each drug for the acetylcholine muscarinic receptor (see Table 9–4). As seen in the table, amitriptyline is the most anticholinergic of the antidepressants, with protriptyline a close second. These two agents regularly cause tachycardia in the medically ill, and one should monitor the heart rate as the dosage is increased. If significant tachycardia results, another agent may have to be used. Many hospitalized patients, particularly those with ischemic heart disease, are already being treated with β-blockers, such as propranolol. When this is the case, the β-blocker usually protects the patient from developing a significant tachycardia.

All of the cyclic agents except trazodone are anticholinergic. If one switches from, for example, imipramine to desipramine because the patient developed urinary retention, the patient is quite likely to develop urinary retention again on desipramine. Amoxapine and maprotiline are not significantly less anticholinergic than desipramine. Trazodone is almost devoid of activity at the muscarinic receptor, and it is a reasonable choice when another agent has caused unwanted anticholinergic side effects.

Fluoxetine, bupropion, venlafaxine, and the MAOIs exert minimal activity at the acetylcholine muscarinic receptor; hence, they can also be useful alternatives when these side effects impair a patient's access to an antidepressant. There is laboratory evidence (see Table 9–4) with anecdotal clinical support that paroxetine is more anticholinergic, close in in vitro potency to imipramine. Likewise, in Richelson's[88] laboratory, sertraline and maprotiline appear to have quite similar anticholinergic effects. For maprotiline, this effect is clinically noticeable (e.g., dry mouth) but usually mild. Similar mild effects seem to accompany the use of mirtazapine. Effects of fluvoxamine and nefazodone are generally mild.

TABLE 9–5 Characteristics of Antidepressant Drugs

	ELIMINATION HALF-LIFE (hr)	SEDATIVE POTENCY	ANTICHOLINERGIC POTENCY	ORTHOSTATIC HYPOTENSION	CARDIAC ARRHYTHMIA POTENTIAL	TARGET DOSAGE (mg/day)	DOSAGE RANGE (mg/day)
Tricyclics

Cardiac Conduction Effects

All TCAs appear to prolong ventricular depolarization. This tends to produce a lengthening of the P-R and QRS intervals as well as of the Q-T interval corrected for heart rate (QTc) on the electrocardiogram (ECG). When the main effect of these agents is measured by His-bundle electrocardiography, the His-ventricular portion of the recording is preferentially prolonged. That is, these drugs, which are sodium-channel blockers, tend to slow the electric impulse as it passes through the specialized conduction tissue known as the His-Purkinje system. This makes them resemble in action the class IA arrhythmic drugs, such as quinidine and procainamide hydrochloride. In practical terms, this means that depressed cardiac patients with ventricular premature contractions, when started on an antidepressant, such as imipramine, are likely to experience improvement or resolution of their ventricular irritability, even if the abnormality is as serious as inducible ventricular tachycardia. Both imipramine and nortriptyline have proved efficacy as antiarrhythmics and share the advantage of a half-life long enough to permit twice-daily doses.[96–98]

Ordinarily, this property does not pose a problem for the cardiac patient who does not already have disease in the conduction system. The patient who already has conduction system disease is the focus of concern. First-degree heart block is the mildest pathologic form and probably should not pose a problem for antidepressant treatment. When the patient's abnormality exceeds this (e.g., right BBB, left BBB, bifascicular block, BBB with a prolonged P-R interval, alternating BBB, or second- or third-degree atrioventricular [AV] block), extreme caution is necessary in treating the depression. Cardiology consultation is almost always already present for the patient. Electrolyte abnormalities, particularly hypokalemia or hypomagnesemia, increase the danger to these patients, and they require careful monitoring.

Occasionally, the question arises clinically whether one of the cyclic agents is less likely than another to cause a quinidine-like prolongation in conduction, particularly when the patient already shows some intraventricular conduction delay. Maprotiline should be regarded as similar to the TCAs in its effects on cardiac conduction. Amoxapine has been touted to have fewer cardiac side effects, based on patients who had taken overdoses. Although these patients were noted to have suffered seizures, coma, and acute renal failure, the authors thought it worth noting that less cardiac toxicity resulted,[99,100] but atrial flutter and fibrillation have been reported in patients taking amoxapine.[101,102] Trazodone does not prolong conduction in the His-Purkinje system, but aggravation of the preexisting ventricular irritability has been reported.[103] Hence clinical caution cannot be abandoned.

MAOIs are remarkably free of arrhythmogenic effects, although there are several case reports of atrial flutter or fibrillation, or both, with tranylcypromine. Consultees tend to dread them, fearing drug and food interactions.

How, then, should the consultant approach the depressed patient with conduction disease? Depression can itself be life-threatening and more damaging to cardiac function than a drug. Therefore, it must be treated. In the case of a depressed patient with cardiac conduction problems, one can begin with an SSRI, bupropion, venlafaxine, nefazodone, or mirtazapine. Should the depression not remit completely, reasonable options include augmentation with a psychostimulant or switching to a psychostimulant. Should the patient improve, the stimulant can be continued as long as it is helpful. By starting with a low dosage (2.5 mg of either dextroamphetamine or methylphenidate), one is reasonably assured that toxicity will not result. The fragile patient can have heart rate and BP monitored hourly for 4 hours after receiving the drug. If no beneficial response is noted, the next day the dosage should be raised to 5 mg (our usual starting dosage), then to 10, 15, and 20 mg on successive days, if necessary. Some response to the stimulant should be seen, even a negative one (e.g., feeling more tense, "wired," or agitated). It makes little sense to stop a stimulant trial if no response is seen, or unless the patient can report some subjective verification of a drug effect. Of course, an elevation of heart rate or BP may be a reason to stop the trial. The degree of clinical vigilance must match the clinical precariousness of the patient. Discussion of the type and intensity of monitoring takes place with the consultee.

The role of the psychiatric consultant is to recommend aggressive treatment for depression, with the consultee helping to decide what means is appropriate and to detect possible side effects. If the patient's depression fails to remit despite a number of adequate antidepressant trials, an MAOI is reasonable even with an unstable cardiac condition, provided that the patient can tolerate the OH that may result. The adage, "start low, go slow," which is so appropriate in the treatment of older adult patients, is also a good rule for medically unstable patients.

If the depression has left the patient dangerously ill, suicidal, or catatonic, ECT is the treatment of choice. When an antidepressant can be used, monitoring must take into account both the development of a steady state (which typically takes about five half-lives of the drug) and the rate at which the dosage is being increased. When the patient requires a daily dosage increase, a daily rhythm strip may be necessary as well as another one, five half-lives after reaching the level thought to represent the therapeutic dosage. Plasma levels are especially useful when a 4- to 8-week drug trial is judged worthwhile. Reliable levels have been established only for nortriptyline hydrochloride (50 to 150 ng/mL), desipramine hydrochloride (>125 ng/mL), and imipramine hydrochloride (>200 ng/mL).

Myocardial Depression

Antidepressants have not been shown to impair left ventricular function significantly in depressed or nondepressed patients with either normal or impaired myocardial contractility.[104–107] Even with TCA overdose, impairment of left ventricular function is generally mild.[108] Hence, CHF is not an absolute contraindication to antidepressant therapy.[106–108] The patient with heart failure is far more vulnerable to OH; hence the SSRIs, bupropion, venlafaxine, and nortriptyline, are the preferred agents.

A severely depressed patient could suffer an acute MI. Both conditions are a threat to survival, and the MI is no contraindication to antidepressant treatment. ECT or drugs may be mandatory. Using the previously mentioned principles, psychiatrists and cardiologists must combine their efforts to restore the patient's health.

Other Side Effects (Specific to Each Antidepressant Class)

Other common side effects of bupropion include anxiety and nervousness, agitation, insomnia, headache, nausea, constipation, and tremor. Bupropion is contraindicated in the treatment of patients with a seizure disorder or bulimia, because the incidence of seizures is approximately 0.4% at dosages up to 450 mg/day, and increases almost 10-fold at higher dosages.

Common side effects of venlafaxine include nausea, lack of appetite, weight loss, excessive sweating, nervousness, insomnia, sexual dysfunction, sedation, fatigue, headache, and dizziness.

Mirtazapine's side effects include dry mouth, constipation, weight gain, and dizziness. The relative lack of significant drug–drug interactions with other antidepressants makes mirtazapine a good candidate for combination strategies (i.e., combining two antidepressants together at full dosages).

Trazodone's most common side effects are drowsiness, dizziness, headache, and nausea, with priapism being an extremely rare but potentially serious side effect in men.

Antidepressant Discontinuation Syndrome

Several reports have described discontinuation-emergent adverse events with abrupt cessation of SSRIs and venlafaxine,[109,110] including dizziness, insomnia, nervousness, nausea, and agitation. The likelihood of developing these symptoms may be inversely related to the half-life of the SSRI used, because these symptoms are more likely to develop after abrupt discontinuation of paroxetine and to a lesser degree with sertraline, with few symptoms seen with fluoxetine discontinuation.

Psychostimulant Use

Earlier MGH experience with the use of dextroamphetamine and methylphenidate, which showed them to be safe and effective in depressed mentally ill patients,[111] has been reconfirmed.[54] Their use as therapeutic agents was gradually discontinued a number of years ago,[112] but when patients with symptoms of MDD and minor depression continued to respond to stimulants, often achieving remission of their symptoms, these agents once again became used as independent antidepressants in our consultation practice. Their effects on heart rate and BP have been trivial, even though any patient with hypertension or unstable cardiac rhythm requires monitoring of vital signs when started on these agents. The most common fear expressed about their use was that they would reduce appetite in patients who were already anorectic from their illness or their depression or both. However, this was not the case. Instead, increased appetite has been reported by the patients—another striking and important benefit associated with their use.

Finally, in those patients who suffered both depressive symptoms and either dementia or an organic brain syndrome (e.g., from head injury), there was a fear that use of a stimulant would result in agitation, confusion, or psychosis. In 17 patients with an associated diagnosis of dementia, only two showed a worsening of confusion, which disappeared within 24 hours of discontinuation of the drug.[111] Hence, our practice is now to begin with a stimulant. If it helps (as it did to a moderate or marked degree in 48% of the patients), it does so within a short time: Approximately 93% of the patients who responded positively reached their maximum benefit by the second day. As long as it helps, the stimulant is maintained. Tolerance was not found in our patient sample. The same dosage of the stimulant was maintained until the depressive symptoms cleared or the patient was discharged. A small group of patients were discharged with instructions to continue taking the agent at home. The majority stopped the medication within 2 or 3 weeks. A few continued for 1 year or longer.

There is a strong bias against stimulants (dextroamphetamine more so than methylphenidate), because of associated street abuse. In the MGH review cited, neither tolerance nor abuse was found in the patients for whom these agents were prescribed.[112]

Hepatic Metabolism

Essentially all antidepressants are metabolized by the hepatic P450 microsomal enzyme system. The interactions produced by the competition of multiple drugs for these metabolic pathways are complex (see Chapter 34). For example, mirtazapine is a substrate for, but not an inhibitor of, the 2D6, 1A2, and 3A4 isoenzymes.

How long antidepressants need to be maintained in patients with MDD associated with medical illness is not known. Even though patients with primary affective disorder should be maintained on their antidepressant for more than 6 months, the same requirement is not clear for patients with MDD in the medical setting. In patients with PSD, and possibly in other instances in which primary brain disease or injury appears to cause depression, antidepressants should be continued for 6 months or longer.

Secondary Mania

Occasionally, a clinician is asked to see a patient with mania or hypomania of 1 week's duration (or longer), in whom no history of affective disorder can be obtained. Described by Krauthammer and Klerman,[113] this phenomenon results from an organic dysfunction. Table 9–6 lists some causes of secondary mania. The emergence of mania or hypomania usually signifies the presence of bipolar disorder, but cases such as those in Table 9–6 continue to accumulate in the literature, indicating that alteration of brain states can lead to a clinical picture indistinguishable from primary mania.[114–123] Of clinical note was the report that in HIV-positive patients with mania, an abnormal magnetic resonance imaging (MRI) scan predicted poor response to lithium and neuroleptics but a beneficial response to anticonvulsants.[122]

Use of Lithium Carbonate in the Medically Ill

The treatment of secondary mania is the same as that for primary mania. Neuroleptics, lithium carbonate, or anticonvulsants are required in most cases, although lorazepam and clonazepam may prove to be helpful in the acute phase.

A word of caution is appropriate when lithium is used in older adults or in patients with cardiac disease. On the ECG of a patient taking lithium, a benign and reversible T-wave flattening is seen in approximately 50% of cases. Lithium

TABLE 9–6 Reported Causes of Secondary Mania

Drugs	Alcohol intoxication, alprazolam, captopril, cimetidine, corticosteroids, cyclobenzaprine, cyproheptadine, disulfiram, felbamate, isoniazid, levodopa, L-glutamine, L-tryptophan, lysergic acid diethylamide, methylphenidate, metrizamide, metoclopramide, procainamide, procarbazine, propafenone, sympathomimetics, thyroxine, tolmetin, triazolam, yohimbine, zidovudine
Drug withdrawal	Clonidine, diltiazem, atenolol, isocarboxazid, propranolol
Metabolic	Hemodialysis, postoperative state, hyperthyroidism, vitamin B_{12} deficiency, Cushing's syndrome, cerebral hypoxia
Infection	Influenza, Q fever, post–St. Louis type A encephalitis, cryptococcosis, human immunodeficiency virus, neurosyphilis
Neoplasm	Meningiomas, gliomas, thalamic metastases, brainstem tumor
Epilepsy	Complex partial seizures with right temporal focus
Surgery	Right hemispherectomy
Cerebrovascular accident	Thalamic stroke
Other	Cerebellar atrophy, head trauma, multiple sclerosis, Wilson's disease

appears to have some inhibitory effects on impulse generation and transmission in the atrium. Hence, the reports of adverse cardiac effects of lithium have been those of sinus node dysfunction and first-degree AV block.[124–126] Because older adults seem particularly prone to these effects, caution is essentially reserved for them and for patients who have preexisting disturbances of atrial conduction.[127]

Ordinarily, lithium's effects on the heart can be assumed to be benign, but as any serious illness becomes more complicated and as treatments increase, patients are at greater risk. Mania, like depression, can seldom be tolerated by the patient or by caregivers. Whether the alternative treatments (such as use of calcium channel blockers, or use of adjunctive measures, such as lorazepam) are useful in secondary mania remains to be established.

Thioridazine

A final caution about cardiovascular toxicity should include discussion of thioridazine. Notorious among neuroleptics for its potential cardiac side effects, this drug should not be used in combination with TCAs unless there is a special need. It, too, possesses quinidine-like properties, has been associated with reports of sudden death that antedate similar reports with TCAs,[128] and was more recently implicated in the causation of ventricular tachycardia alone[129] and in combination with desipramine.[130] Thioridazine's anticholinergic potency is high (roughly equivalent in vitro to that of desipramine), which can be troublesome. This property, however, might make it particularly useful to treat the delirium of a patient with Parkinson's disease. As little as 5 to 10 mg can be helpful in such a patient. Again, it is important to avoid hypokalemia and hypomagnesemia, which predispose patients to cardiac rhythm disturbances.

OTHER DSM-IV DIAGNOSES OF DEPRESSION

Dysthymic Disorder

For the diagnosis of dysthymia (300.40), DSM-IV specifies a chronic state of depression that does not meet the full criteria for MDD. To qualify, the patient must have depressed (or, for children and adolescents, irritable) mood for most of the day, and on more days than not, for more than 2 years, and have two or more of the following six symptoms: (1) poor appetite or overeating, (2) insomnia or hypersomnia, (3) low energy or fatigue, (4) low self-esteem, (5) poor concentration or difficulty making decisions, and (6) feelings of hopelessness. For medically ill patients, this diagnosis could be used, dropping the duration requirement, to specify minor depression. Use of antidepressants is necessary in minor depression after stroke, but there are few if any other studies to guide treatment.

In DSM-IV the diagnostic criteria for MDD can be applied even when the depression follows the medical condition (and is therefore secondary). The terminology states that the mood disturbance is "due to," for example, stroke, MI, or HIV infection. The mood can be described as "with depressive features," "with major depressive-like episode," "with manic features," or "with mixed features."

Adjustment Disorder with Depressed Mood

Adjustment disorder with depressed mood (309.00) is probably the most overused diagnosis by consultation psychiatrists. It should not be given to a medical patient unless the depressive reaction is maladaptive, either in intensity of feeling (an overreaction) or in function (e.g., when a despondent patient interacts minimally with caregivers and family).

Bereavement

Bereavement (V62.82) refers to the death of a loved one. In the case of the medical patient, of course, it is the self that is mourned after a narcissistic injury (e.g., an MI). DSM-IV unnecessarily restricts bereavement to loss of a loved one. In acute grief, MDD can be a difficult diagnosis, but, when it is present, it requires treatment (perhaps even more than when it is present without acute grief). Clues helpful to determine the presence of MDD include (1) guilt beyond that about actions taken around the time of the death of the loved one, (2) thoughts of death (other than wanting to be with the lost person) or feeling one would be better off dead—suicidal ideation should count in favor of MDD, (3) morbid preoccupation with worthlessness, (4) marked psychomotor retardation, (5) prolonged and marked functional impairment, (6) hallucinations other than seeing, hearing, or being touched by the deceased person.

Prigerson and associates[131] developed two useful empirical constructs: bereavement depression (depressive symptoms in wake of a loss) and complicated grief. The first predicts future medical burden of the person, and the latter predicts functional impairment at 18-month follow-up. The symptoms related to the bereavement-depression factor are hypochondriasis, apathy, insomnia, anxiety, suicidal ideation, guilt, loneliness, depressed mood, psychomotor retardation, hostility, and low self-esteem. The symptoms that are the principal components of the complicated grief factor are yearning for, and preoccupation with, thoughts of the deceased, crying, searching for the deceased, disbelief about the death, being stunned by the death, and inability to accept the death. When patients with a Hamilton depression scale score higher than 17 were treated with nortriptyline, at dosages that averaged a low but therapeutic level of 68.1 ng/mL, those treated lowered their bereavement-depression scores substantially. This supports our clinical recommendation that any person who meets criteria for MDD should be treated. There is no evidence that antidepressants retard the grieving process.

DESPONDENCY CONSEQUENT TO SERIOUS ILLNESS

Despondency in serious illness appears to be a natural response and is here regarded as the psychic damage done by the disease to the patient's self-esteem. Bibring's[132] definition of depression is "response to narcissistic injury." The response is here called *despondency* and not *depression* because depression is reserved for those conditions that meet the research criteria for primary or secondary affective disorder. In any serious illness, the mind sustains an injury of its own, as though the illness, for example, MI, produces an ego infarction. Even when recovery of the diseased organ is complete, recovery of self-esteem appears to take somewhat longer. In patients who had an MI, for example, although the myocardial scar has fully formed in 5 to 6 weeks, recovery of the sense of psychological well-being seems to require 2 to 3 months.

Management of the Acute Phase of Despondency

A mixture of dread, bitterness, and despair, despondency presents the self as broken, scarred, and ruined. Work and relationships seem jeopardized. Now it seems to the patient too late to realize career or personal aspirations. Disappointment with both what has and what has not been accomplished haunts the individual, who may now feel old and a failure. Concerns of this kind become conscious early in acute illness, and their expression may prompt consultation requests as early as the second or third day of hospitalization.[133]

Management of these illness-induced despondencies is divided into acute and long-term phases. In the acute phase, the patient is encouraged but never forced to express such concerns. The extent and detail are determined by the individual's need to recount them. Many patients are upset to find such depressive concerns in consciousness and even worry that this signals a "nervous breakdown." It is therefore essential to let patients know that such concerns are the normal emotional counterpart of being sick and that even though there will be ups and downs in their intensity, these concerns will probably disappear gradually as health returns. It is also helpful for the consultant to be familiar with the rehabilitation plans common to various illnesses, so that patients can also be reminded, while still in the acute phase of recovery, that plans for restoring function are being activated.

Paradoxically, many of the issues discussed in the care of the dying patient (see Chapter 41) are relevant here. Heavy emphasis is placed on maintaining the person's sense of self-esteem. Self-esteem often falters in seriously ill persons even though they have good recovery potential. Hence, efforts to learn what the sick person is like can help the consultant alleviate the acute distress of a damaged self-image. The consultant should learn any "defining" traits, interests, and accomplishments of the patient so that the nurses and physicians can be informed of them. For example, after learning that a woman patient had been a star sprinter on the national Polish track team preparing for the 1940 Olympics, the consultant relayed this both in the consultation note and by word of mouth to her caregivers. "What's this I hear about your having been a champion sprinter?" became a common question that made her feel not only unique but appreciated. The objective is to restore to life the real person within the patient who has serious organic injuries or impairment.

Few things are more discouraging for the patient, staff, or consultant than no noticeable sign of improvement. When there is no real progress, all the interventions discussed in Chapter 41 are necessary. At other times, progress is being made, but so slowly that the patient cannot feel it in any tangible way. By using ingenuity, the consultant may find a way to alter this. Many of the following suggestions apply, and knowledge of the physiology of the illness is essential. Psychological interventions, however, can also be helpful. For example, getting a patient with severe CHF out of bed and into a reclining chair (known for 25 years to produce even less cardiovascular strain than the supine position)[134] can provide reassurance and boost confidence. For some patients with severe ventilatory impairments and difficulty weaning from the respirator, a wall chart depicting graphically the time spent off the ventilator each day (one gold star for each 5-minute period) is encouraging. Even if the patient's progress is slow, the chart documents and dramatizes each progressive step. Of course, personal investment in very ill persons may be far more therapeutic in itself than any gimmick, but such simple interventions have a way of focusing new effort and enthusiasm on each improvement.

Management of Post-Acute Despondencies: Planning for Discharge and After

Even when the patients are confident their illness is not fatal, they usually become concerned that it will cripple them. Such psychological "crippling" is a normal hazard of organic injury. Whether the patient had an uncomplicated MI and is still employable, or has chronic emphysema with a carbon dioxide tension of 60 mm Hg, only restoration of self-esteem can protect him or her from emotional incapacitation. Even when the body has no room for improvement,

the mind can usually be rehabilitated. Arrival home from the hospital often proves to be a vast disappointment. The damage caused by illness has been done, acute treatment is completed, and health professionals are far away. Weak, anxious, and demoralized, the patient experiences a "homecoming depression."[135] Weakness is a universal problem for any individual whose hospitalization required extensive bed rest; in fact, it was the symptom most complained of by one group of post-MI patients visited in their homes.[135] Invariably the individuals attribute this weakness to the damage caused by the disease (e.g., to the heart, lungs, and liver). A large part of this weakness, however, is the result of muscle atrophy and the systemic effects of immobilization. Bed rest includes among its ill effects venous stasis with threat of phlebitis, embolism, OH, a progressive increase in resting heart rate, loss of approximately 10% to 15% of muscle strength per week (resulting from atrophy), and reduction of approximately 20% to 25% in maximal oxygen uptake capacity in a 3-week period. This was dramatically illustrated by the study of Saltin and associates[136] of five healthy college students who, after being tested in the laboratory, were placed on 3 weeks' bed rest. Three of the men were sedentary, and two were trained athletes. As shown in Figure 9–1, after the period of bed rest, it took the three sedentary men 8, 10, and 13 days to regain their pre–bed-rest maximal oxygen uptake levels, whereas it took the two athletes 28 and 43 days to reach their initial values. The better the patient's condition, the longer it takes for the recovery of strength. Entirely unaware of the physiology of muscle atrophy, patients mistakenly believe that exercise, the only treatment for atrophy, is dangerous or impossible.

Fear can be omnipresent after discharge from the hospital. The least bodily sensation, particularly in the location of the affected organ, looms as an ominous sign of the worst recurrence (e.g., MI, malignancy, gastrointestinal bleeding, or perforation), metastatic spread, (another) infection, or some new disaster that will cripple the individual even further. Most of the alarming symptoms felt in the early post-hospital days are so trivial that they would never have been noticed before, but the threshold is far lower now, and patients may find any unusual sensation a threat. When the alarm has passed, they may feel foolish or even disgusted with themselves for being hypochondriacal. It helps to know in advance that such hypersensitivity to bodily sensations commonly occurs, that it is normal, and that it will be limited in time. Although there are wide ranges in the time it takes for this problem to disappear, a well-adjusted patient who had an uncomplicated MI requires from 2 to 6 months for these fears to resolve (far more time than the recovery of the myocardium). With specific measures, this time may be shortened.

Whether the person can improve a physical function such as oxygen consumption (e.g., as after an MI or gastrointestinal bleeding) or cannot do so at all (e.g., after chronic obstructive pulmonary disease), the mental state is basically the same—a sense of imprisonment in a damaged body that is unable to sustain the everyday activities of a reasonable life. The illness has mentally crippled the individual. Horizons have shrunk drastically, so that the person may feel literally unable or afraid to leave the house, to walk across a room, or to stray far from the phone. Moreover, such people are likely to regard routine activities like walking, riding a bike, or raking leaves as too exhausting or dangerous. For some individuals, life comes to a near standstill.

The best therapy for such psychological constriction is a program that emphasizes early and progressive mobilization in the hospital and exercise after discharge. A physician might naturally be wary of prescribing this for a person with severe chronic obstructive pulmonary disease who is dyspneic while walking at an ordinary pace. For some significantly impaired chronic pulmonary patients,[137] however, objective exercise tolerance can be increased as much

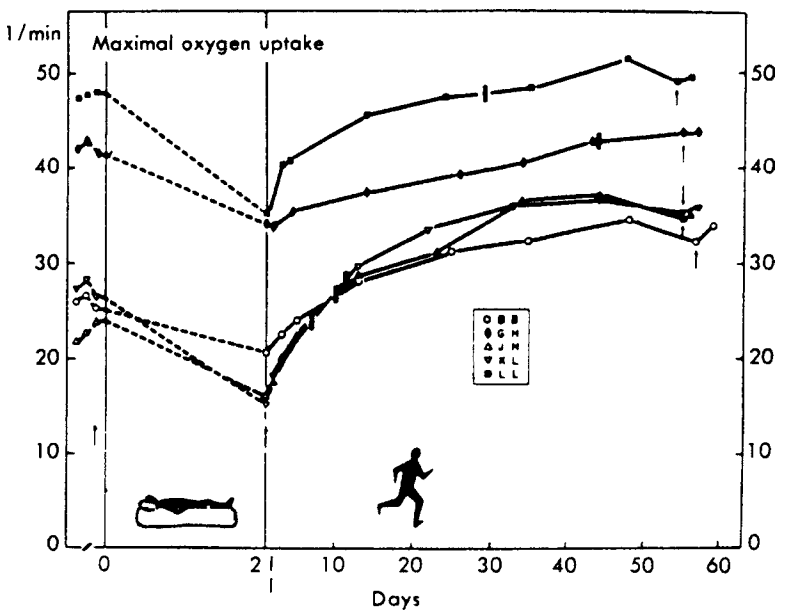

Figure 9–1. Maximal oxygen uptake in sedentary and athletic men after 3 weeks' bed rest.

as 1000-fold. The improvement is the result of better limb muscle conditioning. The patient does not have to change pulmonary function at all to experience significantly greater endurance.[138] Several self-imposed restrictions (e.g., never being far from an oxygen tank) are dramatically relieved. The psychiatric consultant should be aware that patients with chronic pulmonary disease that is considered to be irreversible can be significantly helped by a specific rehabilitation program.[139–142]

The writing of exercise regimens for the recuperation period has been greatly helped by the definition and use of the metabolic equivalent (MET). One MET is defined as the energy expenditure per kilogram per minute of the average 70-kg person sitting quietly in a chair. This amounts to approximately 1.4 cal/min or 3.5 to 4.0 mL of oxygen consumed per kilogram per minute. Table 9–7 lists activities for which measurements in METs have been determined.[143] For example, after recovery from uncomplicated MI, the average middle-aged person is capable of performing at a level of 8 to 9 METs. This includes running at 5.5 miles per hour (jogging slightly faster than 11-minute miles), cycling at 13 miles per hour, skiing at 4 miles per hour, noncompetitive squash and handball, fencing, and vigorous basketball. If, however, less-than-ordinary activity produces symptoms, the capacity of the postcoronary patient is nearer 4 METs. Despite obvious impairment, this level of capacity includes swimming the breaststroke at 20 yards per minute; cycling at 5.5 miles per hour; walking up a 5% incline at 3 miles per hour; playing table tennis, golf (carrying clubs), badminton and lawn tennis doubles, and raking leaves. For the patient, these are carefully computed, quantitated capacities. A list of activities quantified in METs is far more concrete and specific than statements such as "Use your own judgment" or "Do it in moderation." Instead, the patient can be given a list and told to select activities up to a specific level of METs. The physician who wishes to determine a tolerable level can use such devices as the step test, treadmill, and bicycle ergometer for which energy demand in METs at different levels has already been determined. Handy charts can be obtained from the American Heart Association manual.[144]

Activity levels can be gradually increased whenever appropriate. Patients should take responsibility for the extra costs that emotional involvement may require. For example, they could be told, "I am now moving you to a level of activity of 5 METs. You will find at this level all the activities that your heart (or lungs or body) is physically capable of performing. Activities you enjoy are the best. Remember that getting emotionally upset or very competitive during activity increases the energy cost to your heart. If you cannot do some of these things without getting all worked up, you will have to ease off; only you can judge that. But you now know that you are physically capable of performing at 5 METs." In this statement, vagueness remains, but only in the area of subjective emotions. Patients should be aware that they experience emotions physically and mentally even though they cannot be asked to detect changes in their left-ventricular end-diastolic pressure or arterial oxygen saturation. Moreover, emotional self-control is a fair request to make of patients who, although not responsible for detecting a rising wedge pressure on the tennis court, must try to control rising killer instincts.

Patients with chronic CAD almost always have reduced exercise capacity. Lower maximal stroke volume and heart rate decrease cardiac output and limit maximum oxygen consumption ($\dot{V}o_2max$).[145] Yet exercise training increases $\dot{V}o_2max$ for these patients, even when stroke volume cannot be enlarged (as it is in healthy persons who train). As with the chronic lung patients, the increase in exercise capacity results from changes in the muscles, especially the leg muscles. (β-Blockers, which blunt $\dot{V}o_2max$ improvement in healthy exercisers, do not prevent it in CAD patients.) Thompson[146] suggested that CAD patients as well as patients recovering from uncomplicated MI and bypass surgery walk at least 10 minutes per day and add 5 minutes per week to the walk until they are walking 45 or more minutes, four to five times a week. The patients should be instructed to walk briskly but not at a rate that causes dyspnea (which occurs at approximately 50% to 70% $\dot{V}o_2max$).

Even CHF does not necessarily proscribe exercise. In a group of patients with severely limited left-ventricular function and ejection fractions of 25% or less, Squires and associates[147] were able to produce, without morbidity or mortality, in an 8-week training program, substantial improvement in exercise capacity. Of those fully employed before CHF occurred, more than half returned to full-time work.

In any serious illness in which there are likely to be so many "don'ts" constricting the patient's world, an exercise regimen provides something to do that widens the space of existence. If a patient were limited by a maximum tidal volume of 13 L/min, an exercise program could not increase it, but it would help the patient to see that even within those limits he or she can increase exercise tolerance, venture further (e.g., away from oxygen), and perhaps experience increased freedom. Some patients suffer illnesses in which reserves wax and wane (e.g., the cancer patient with remissions and exacerbations, aplastic anemia patients between transfusions). They may view life energy as a fixed quantity that is used up by activity little by little; thus they fear activity. The psychological benefits of exercise are such that activities should bring some sense of renewed vitality (improved sleep and appetite are common effects) rather than a sense of depletion or exhaustion. As the hematocrit level decreases (or the blood urea nitrogen level increases), the capacity for exercise decreases. To continue exercising, such a person could set as a target a heart rate that was commonly experienced while exercising at his or her prescribed level of MET, or time and distance could be decreased accordingly. When his chronic CHF worsened, one man simply returned to the scene of his exercising, changed into his exercise gear, and sat talking with the regulars before returning home.

Geriatric Implications

Age further compounds the bias against encouraging physical exercise. Contrary to popular myth, vigorous exercise training in youth confers no later cardiovascular health benefits. Moderate exercise (defined as 70% to 80% of maximal heart rate) in later age does so. The trainability of older men has been shown not to depend on whether they trained in their youth. Moreover, as a person ages and functional reserve decreases, the size of the training effect becomes greater.[148]

TABLE 9–7 Energy Expenditure per Kilogram per Minute in the Average 70-kg Person

ACTIVITY	MET
Self-Care	
Rest, supine	1
Sitting	1
Standing, relaxed	1
Eating	1
Conversation	1
Dressing, undressing	2
Washing hands, face	2

MET, Metabolic equivalent.

The best measure of the effects of aging on functional activity is the $\dot{V}o_2max$. As one ages, there is a clearly demonstrated decline in $\dot{V}o_2max$, but it is much steeper for sedentary than for active men. A concrete expression of the difference between the two lifestyles is that by the time the two groups reach the decade of 50 to 59 years of age, there is already a 10-year difference between them. It is thus true, at least in terms of aerobic capacity, that exercise keeps a person younger.

All-cause mortality and physical fitness have been studied in both men and women. When fitness was divided into quintiles, the age-adjusted all-cause mortality rates declined from 64.0 and 39.5 per 10,000 person-years in the least fit men and women, to 18.6 and 8.5 per 10,000 person-years in the most fit men and women. Higher levels of fitness appeared to delay mortality, primarily as a result of lowered rates of cardiovascular disease and cancer.[149]

Even though there is no evidence that exercise in moderation is more hazardous for older adults, how often is it regularly urged for a person of 95? Fiatarone and co-workers[150] demonstrated that frail, institutionalized volunteer nonagenarians, after only 8 weeks in a supervised weightlifting program for legs only, showed a 174% increase in muscle strength and highly significant gains in muscle mass and walking speed. They concluded, "The potential for reversal of 'age-related' muscle weakness has been unexploited."[150] The most important target of conditioning in the geriatric population is the leg muscles. There are no data to prove that better conditioning would prevent falls, one of the most serious causes of morbidity in older persons, but it seems likely that improved muscle strength, tone, balance, and mobility would almost certainly help. Likewise, there may be subtle brain damage that limits an older adult's capacity to perform activities. One measure of this is the number and severity of subcortical hyperintensities seen on MRI scans.[151] Even if these are present, one should never avoid a reconditioning program for an older adult. There are no studies on the effects of such a program on these changes.

Just as the original illness or injury can be demoralizing, so can the seeming snail's pace of recovery. This normal despondency can further retard rehabilitation. Few things heal self-esteem as effectively as regaining the sense of a sound body. The consultant who helps the patient grieve for those losses beyond restoration, while correcting misconceptions about inactivity and encouraging the patient to shoulder the work of recovery, shortens the convalescence of both body and mind.

10 Delirious Patients

Jason P. Caplan, M.D.
Ned H. Cassem, M.A., Ph.L., M.D., S.J., B.D.
George B. Murray, B.S., Ph.L., M.S., M.Sc., M.D., S.J.
Jennifer M. Park, M.D.
Theodore A. Stern, M.D.

Delirium has likely replaced syphilis as "the great imitator" because its varied presentations have led to misdiagnoses among almost every major category of mental illness. Delirium is a syndrome caused by an underlying physiologic disturbance and marked by a fluctuating course, with impairments in consciousness, attention, and perception. Delirium thus is often mistaken for depression when the patient has a withdrawn or flat affect, for mania when the patient has agitation and confusion, for psychosis when the patient has hallucinations and paranoia, for anxiety when the patient has restlessness and hypervigilance, for dementia when the patient has cognitive impairments, and for substance abuse when the patient has impairment in consciousness. With so diverse an array of symptoms, delirium assumes a position of diagnostic privilege in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[1] in that almost no other diagnosis can be made in its presence.

Perhaps even more noteworthy, delirium is a signifier of often serious somatic illness.[2] Delirium has been associated with increased length of stay in hospitals[3] and with an increased cost of care.[4,5] Among intensive care unit (ICU) patients, prospective studies have noted that delirium occurs in 31% of admissions[6]; when intubation and mechanical ventilation are required, the incidence soars to 81.7%.[7]

Sometimes, delirium is refered to as an acute confusional state, a toxic-metabolic encephalopathy, or acute brain failure; unquestionably, it is the most common cause of agitation in the general hospital. Delirium ranks second only to depression on the list of all psychiatric consultation requests. Given its prevalence and its importance (morbidity and mortality), the American Psychiatric Association issued practice guidelines for the treatment of delirium in 1999.[8]

Placed in this context, the consequences of misdiagnosis of delirium can be severe; prompt and accurate recognition of this syndrome is paramount for all clinicians.

DIAGNOSIS

The essential feature of delirium, according to the DSM-IV, is a disturbance of consciousness that is accompanied by cognitive deficits that cannot be accounted for by past or evolving dementia (Table 10–1).[1] Disturbance of the sleep–wake cycle is also common, sometimes with nocturnal worsening (sundowning) or even by a complete reversal of the night–day cycle, though, despite previous postulation, sleep disturbance alone does not cause delirium.[9] Similarly, the term *ICU psychosis* has entered the medical lexicon; this is an unfortunate misnomer because it is predicated on the belief that the environment of the ICU is capable of inducing delirium and that the symptomatology of delirium is limited to psychosis.[9] Despite wide variation in the presentation of the delirious patient, the hallmarks of delirium, although perhaps less immediately apparent, remain quite consistent from case to case.

Both Chedru and Geschwind[10] and Mesulam and coworkers[11] regard impaired attention as the main deficit of delirium. This inattention (along with an acute onset, waxing and waning course, and overall disturbance of consciousness) forms the core features of delirium, whereas other related symptoms, such as withdrawn affect, agitation, hallucinations, and paranoia, serve as a frame that can sometimes be so prominent as to detract from the picture itself.

Psychotic symptoms (such as visual or auditory hallucinations and delusions) are common among patients with delirium.[12] Sometimes the psychiatric symptoms are so bizarre or so offensive (e.g., an enraged and paranoid patient shouts that pornographic movies are being made in the ICU) that diagnostic efforts are distracted. The hypoglycemia of a man with diabetes can be missed in the emergency department (ED) if the accompanying behavior is threatening, uncooperative, and resembling that of an intoxicated person.

Although agitation can distract practitioners from making an accurate diagnosis of delirium, disruptive behavior alone will almost certainly garner some attention. The hypoactive presentation of delirium is more insidious, because the patient is often thought to be depressed or anxious because of the medical illness. Studies of quietly delirious patients show the experience to be as disturbing as the agitated variant[13]; quiet delirium is still a harbinger of serious medical pathology.[14,15]

The core similarities found in cases of delirium have led to postulation of a final common neurologic pathway for its symptoms. Current understanding of the neurophysiologic basis of delirium is one of hyperdopaminergia and hypocholinergia.[16] The ascending reticular activating system (RAS) and its bilateral thalamic projections regulate alertness, with neocortical and limbic inputs to this system

TABLE 10–1 DSM-IV Diagnostic Criteria for Delirium

A disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention
A change in cognition (e.g., memory deficit, disorientation, or a language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia
A disturbance that develops over a short period (usually hours to days) and tends to fluctuate during the course of the day
Evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of a general medical condition

DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition.

controlling attention. Because acetylcholine is the primary neurotransmitter of the RAS, medications with anticholinergic activity can interfere with its function, resulting in the deficits in alertness and attention that are the heralds of delirium. Similarly, it is thought that loss of cholinergic neuronal activity in the elderly (e.g., resulting from microvascular disease or atrophy) is the basis for their heightened risk of delirium. Release of endogenous dopamine due to oxidative stress is thought to be responsible for the perceptual disturbances and paranoia that so often lead to mislabeling the delirious patient "psychotic." As we discuss later, cholinergic agents (e.g., physostigmine) and dopamine blockers (e.g., haloperidol) have proved efficacious in managing delirium.

Early detection of changes in cognition can be key to timely identification and treatment of delirium (and perhaps of a heretofore undiagnosed somatic illness responsible for the delirium). Unfortunately, several studies have revealed that physicians who are not psychiatrists are quite unreliable in their ability to accurately identify delirium in their patients, and most patients referred to psychiatric consultation services with purported depression are ultimately found to have delirium. Because consultation psychiatrists cannot perform repeated examinations on all patients admitted to the general hospital (even on those at high risk for delirium), a number of screening protocols designed to be serially administered by nursing staff have been developed and validated for use. Some of the most commonly used of these scales are summarized in Table 10–2.[17–23]

DIFFERENTIAL DIAGNOSIS

As useful as screening protocols may be, treatment relies on a careful diagnostic evaluation; there is no substitute for a systematic search for the specific cause of delirium. The temporal relationship to clinical events often gives the best clues to potential causes. For example, a patient who extubated himself was almost certainly in trouble before self-extubation. When did his mental state actually change? Nursing notes should be studied to help discern the first indication of an abnormality (e.g., restlessness, mild confusion, or anxiety). If a time of onset can be established as a marker, other events can be examined for a possible causal relationship to the change in mental state. Initiation or discontinuation of a drug, the onset of fever or hypotension, or the acute worsening of renal function, if in proximity to the time of mental status changes, become likely culprits.

TABLE 10–2 Delirium Assessment Tools

TOOL	STRUCTURE	NOTES
Confusion Assessment Method (CAM)[17]	Full scale of 11 items Abbreviated algorithm targeting four cardinal symptoms	Intended for use by nonpsychiatric clinicians
Confusion Assessment Method for the Intensive Care Unit (CAM-ICU)[18]	Algorithm targeting four cardinal symptoms	Designed for use by nursing staff in the ICU
Intensive Care Delirium Screening Checklist (ICDSC)[19]	Eight-item screening checklist	Bedside screening tool for use by nonpsychiatric physicians or nurses in the ICU
Delirium Rating Scale (DRS)[20]	Full scale of 10 items Abbreviated seven- or eight-item subscales for repeated administration	Provides data for confirmation of diagnosis and measurement of severity
Delirium Rating Scale—Revised–98 (DRS-R-98)[21]	Sixteen-item scale that can be divided into a three-item diagnostic subscale and a thirteen-item severity subscale	Revision of DRS is better suited to repeat administration
Memorial Delirium Assessment Scale (MDAS)[22]	Ten-item severity rating scale	Grades severity of delirium once diagnosis has been made
Neecham Confusion Scale[23]	Ten-item rating scale	Designed for use by nursing staff Primarily validated for use in elderly populations in acute medical or nursing home setting

ICU, Intensive care unit.

Without a convincing temporal connection, the cause of delirium may be discovered by its likelihood in the unique clinical situation of the patient. In critical care settings, as in EDs, there are several (life-threatening) states that the clinician can consider routinely. These are states in which intervention needs to be especially prompt because failure to make the diagnosis may result in permanent central nervous system (CNS) damage. These conditions are Wernicke's disease, hypoxia, hypoglycemia, hypertensive encephalopathy, hyper- or hypothermia, intracerebral hemorrhage, meningitis or encephalitis, poisoning (exogenous or iatrogenic), and status epilepticus. These conditions are usefully recalled by the mnemonic device "WHHHHHIMPS" (Table 10–3). Other less urgent but still acute conditions that require intervention include subdural hematoma, septicemia, subacute bacterial endocarditis, hepatic or renal failure, thyrotoxicosis or myxedema, delirium tremens, anticholinergic psychosis, and complex partial seizures. If these conditions are not already ruled out, they are easy to verify. A broad review of conditions commonly associated with delirium is provided by the mnemonic "I WATCH DEATH" (Table 10–4).

Bacteremia commonly clouds a patient's mental state. In prospectively studied seriously ill hospitalized patients, delirium was commonly correlated with bacteremia.[24] In that study, the mortality of septic patients with delirium was higher than that in septic patients with a normal mental status. In the elderly, regardless of the setting, the onset of confusion should trigger concern about infection. Urinary tract infections (UTIs) and pneumonias are among the most common infections in older patients, and when bacteremia is associated with a UTI, confusion is the presenting feature nearly one third (30%) of the time.[25] Once a consultant has eliminated these common conditions as possible causes of a patient's disturbed brain function, there is time enough for a more systematic approach to the differential diagnosis. A comprehensive differential diagnosis, similar to the one compiled by Ludwig[26] (slightly expanded in Table 10–5) is recommended. A quick review of this list is warranted even when the consultant is relatively sure of the diagnosis.

To understand the acute reaction of the individual patient, one should begin by completely reviewing the medical record. Vital signs can reveal periods of hypotension or fever. The highest temperature recorded will also be key. Operative procedures and the use of anesthetics can also induce a sustained period of hypotension or reveal unusually large blood loss that requires replacement. Laboratory values should be scanned for abnormalities that could be related to an encephalopathic state.

TABLE 10–3 Life-Threatening Causes of Delirium: WHHHHIMPS

Wernicke's disease
Hypoxia
Hypoglycemia
Hypertensive encephalopathy
Hyperthermia or hypothermia
Intracerebral hemorrhage
Meningitis or encephalitis
Poisoning (exogenous or iatrogenic)
Status epilepticus

TABLE 10–4 Conditions Commonly Associated with Delirium: "I WATCH DEATH."

CATEGORY	CONDITIONS
Infectious	Encephalitis, meningitis, syphilis, pneumonia, urinary tract infection
Withdrawal	From alcohol or sedative–hypnotics
Acute metabolic	Acidosis, alkalosis, electrolyte disturbances, liver or kidney failure
Trauma	Heat stroke, burns, following surgery
CNS pathology	Abscesses, hemorrhage, seizure, stroke, tumor, vasculitis, or normal-pressure hydrocephalus
Hypoxia	Anemia, carbon monoxide poisoning, hypotension, pulmonary embolus, lung or heart failure
Deficiencies	Of vitamin B_{12}, niacin, or thiamine
Endocrinopathies	Hyper- or hypoglycemia, hyper- or hypoadrenocorticism, hyper- or hypothyroidism, hyper- or hypoparathyroidism
Acute vascular	Hypertensive encephalopathy or shock
Toxins or drugs	Medications, pesticides, or solvents
Heavy metals	Lead, manganese, or mercury

The old chart, no matter how thick, cannot be overlooked without risk. Some patients have had psychiatric consultations for similar difficulties on prior admissions. Others, in the absence of psychiatric consultations, have caused considerable trouble for their caregivers. Similar to a patient's psychiatric history, the family psychiatric history can help make a diagnosis, especially if a major mood or anxiety disorder, alcoholism, schizophrenia, or epilepsy is present.

Examination of current and past medications is essential because pharmacologic agents (in therapeutic doses, in overdose, or with withdrawal) can produce psychiatric symptoms. These medications must be routinely reviewed, especially in patients whose drugs have been stopped because of surgery or hospitalization or whose drug orders have not been transmitted during transfer between services. Of all causes of an altered mental status, use of and withdrawal from drugs are probably the most common. Some, such as lidocaine, are quite predictable in their ability to cause encephalopathy; the frequency and severity of symptoms are dose-related. Other agents, such as antibiotics, usually cause delirium only in someone whose brain is already vulnerable, as in a patient with a low seizure threshold.[27] Table 10–6 lists some drugs used in clinical practice that have been associated with delirium.

The number of drugs that can be involved either directly or indirectly (e.g., because of drug interactions) is numerous. Fortunately, certain sources provide regular review of published summaries and drug updates.[28] Although physicians are usually aware of these hazards,

TABLE 10–5 Differential Diagnosis of Delirium

GENERAL CAUSE	SPECIFIC CAUSE
Vascular	Hypertensive encephalopathy Cerebral arteriosclerosis Intracranial hemorrhage or thrombosis Emboli from atrial fibrillation, patent foramen ovale, or endocarditic valve Circulatory collapse (shock) Systemic lupus erythematosus Polyarteritis nodosa Thrombotic thrombocytopenic purpura Hyperviscosity syndrome Sarcoid
Infectious	Encephalitis Bacterial or viral meningitis, fungal meningitis (*cryptococcal, coccidioidal, Histoplasma*) Sepsis General paresis Brain, epidural, or subdural abscess Malaria Human immunodeficiency virus Lyme disease Typhoid fever Parasitic (*toxoplasma, trichinosis, cysticercosis, echinococcosis*) Behçet's syndrome Mumps
Neoplastic	Space-occupying lesions, such as gliomas, meningiomas, abscesses Paraneoplastic syndromes Carcinomatous meningitis
Degenerative	Senile and presenile dementias, such as Alzheimer's or Pick's dementia Huntington's chorea Creutzfeldt-Jakob disease Wilson's disease
Intoxication	Chronic intoxication or withdrawal effect of sedative–hypnotic drugs, such as bromides, opiates, tranquilizers, anticholinergics, dissociative anesthetics, anticonvulsants, carbon monoxide from burn inhalation
Congenital	Epilepsy Postictal states Complex partial status epilepticus Aneurysm
Traumatic	Subdural and epidural hematomas Contusion Laceration Postoperative trauma Heat stroke Fat emboli syndrome
Intraventricular	Normal pressure hydrocephalus
Vitamin deficiency	Thiamine (Wernicke–Korsakoff syndrome) Niacin (pellagra) B_{12} (pernicious anemia)
Endocrine-metabolic	Diabetic coma and shock Uremia Myxedema Hyperthyroidism, Parathyroid dysfunction Hypoglycemia Hepatic or renal failure Porphyria Severe electrolyte or acid and base disturbances Paraneoplastic syndrome Cushing's or Addison's syndrome Sleep apnea Carcinoid Whipple's disease
Metals	Heavy metals (lead, manganese, mercury) Other toxins
Anoxia	Hypoxia and anoxia secondary to pulmonary or cardiac failure, anesthesia, anemia
Depression—other	Depressive pseudodementia, hysteria, catatonia

Modified from Ludwig AM: *Principles of clinical psychiatry*, New York, 1980, The Free Press.

a common drug, such as meperidine, when used in doses greater than 300 mg/day for several days, causes CNS symptoms because of the accumulation of its excitatory metabolite, normeperidine, which has a half-life of 30 hours and causes myoclonus (the best clue of normeperidine toxicity), anxiety, and ultimately seizures.[29] The usual treatment is to stop the offending drug or to reduce the dosage; however, at times this is not possible. Elderly patients and those with mental retardation or a history of significant head injury are more susceptible to the toxic actions of many of these drugs.

Psychiatric symptoms in medical illness can have other causes. Besides the abnormalities that can arise from the effect of the patient's medical illness (or its treatment) on the CNS (e.g., the abnormalities produced by systemic lupus erythematosus or high-dose steroids), the disturbance may be the effect of the medical illness on the patient's mind (the subjective CNS), as in the patient who thinks he or she is "washed up" after a myocardial infarction, quits, and withdraws into hopelessness. The disturbance can also arise from the mind, as a conversion symptom or as malingering about pain to get more narcotics. Finally, the abnormality may be the result of interactions between the sick patient and his or her environment or family (e.g., the patient who is without complaints until the family arrives, at which time the patient promptly looks acutely distressed and begins to whimper continuously). Nurses are commonly aware of these sorts of abnormalities, although the abnormalities might go undocumented in the medical record.

TABLE 10–6 Drugs used in Clinical Practice that Have Been Associated with Delirium

Antiarrhythmics
Disopyramide
Lidocaine
Mexiletine
Procainamide
Propafenone
Quinidine
Tocainide

Antibiotics
Aminoglycosides
Amodiaquine
Amphotericin
Cephalosporins
Chloramphenicol
Gentamicin
Isoniazid
Metronidazole
Rifampin
Sulfonamides
Tetracyclines
Ticarcillin
Vancomycin

Anticholinergics
Atropine
Benztropine
Diphenhydramine
Eye and nose drops
Scopolamine
Thioridazine
Trihexyphenidyl

Tricyclic Antidepressants
Amitriptyline
Clomipramine
Desipramine
Imipramine
Nortriptyline
Protriptyline
Trimipramine

Anticonvulsants
Phenytoin

Antihypertensives
Captopril
Clonidine
Methyldopa
Reserpine

Antiviral Agents
Acyclovir
Interferon
Ganciclovir
Nevirapine

Barbiturates

β-blockers
Propranolol
Timolol

Cimetidine, ranitidine

Digitalis preparations

Disulfiram

Diuretics
Acetazolamide

Dopamine agonists (central)
Amantadine
Bromocriptine
Levodopa
Selegiline

Ergotamine

GABA agonists
Baclofen
Benzodiazepines
Zaleplon
Zolpidem

Immunosuppressives
Aminoglutethimide
Azacytidine
Chlorambucil
Cytosine arabinoside (high dose)
Dacarbazine
FK-506
5-Fluorouracil
Hexamethylmelamine
Ifosfamide
Interleukin-2 (high dose)
L-Asparaginase
Methotrexate (high dose)
Procarbazine
Tamoxifen
Vinblastine
Vincristine

Monoamine oxidase inhibitors
Tranylcypromine
Phenelzine
Procarbazine

Narcotic analgesics
Meperidine (normeperidine)
Pentazocine
Podophyllin (topical)

Nonsteroidal antiinflammatory drugs
Ibuprofen
Indomethacin
Naproxen
Sulindac

Other medications
Clozaril
Cyclobenzaprine
Lithium
Ketamine
Sildenafil
Trazodone
Mefloquine

Sympathomimetics
Aminophylline
Amphetamine
Cocaine
Ephedrine
Phenylephrine
Phenylpropanolamine
Theophylline

Steroids, ACTH

ACTH, Adrenocorticotropic hormone; *GABA*, gamma aminobutyric acid.

THE EXAMINATION OF THE PATIENT

Appearance, level of consciousness, thought, speech, orientation, memory, mood, judgment, and behavior should all be assessed. In the formal mental status examination (MSE), one begins with the examination of consciousness. If the patient does not speak, a handy common-sense test is to ask oneself, "Do the eyes look back at me?" One could formally rate consciousness by using the Glasgow Coma Scale (Table 10–7), a measure that is readily understood by consultees in other specialties.[30]

If the patient can cooperate with an examination, attention should be examined first because if this is disturbed, other parts of the examination may be invalid. One can ask the patient to repeat the letters of the alphabet that rhyme with "tree." (If the patient is intubated, ask that a hand or finger be raised whenever the letter of the recited alphabet rhymes with "tree.") Then the rest of the MSE can be performed. The Folstein Mini-Mental State Examination (MMSE),[31] which is presented in Table 4–8, is usually included. Specific defects are more important than is the total score. Other functions (such as writing, which Chedru and Geschwind[10] considered to be one of the most sensitive indicators of impairment of consciousness) are often abnormal in delirium. Perhaps the most dramatic (though difficult to score objectively) test of cognition is the clock drawing test, which can provide a broad survey of the patient's cognitive state (Figure 10–1).[32] A more-recently developed and validated bedside test, the Montreal Cognitive Assessment (MoCA),[33] usefully incorporates some aspects of the MMSE (i.e., tests of memory, attention, and orientation) with tests of more complex visuospatial and executive function (including clock drawing and an adaptation of the trail making B task). Although not specifically validated for detecting delirium, the MoCA (available at www.mocatest.org) has been consistently shown to have greater sensitivity than the MMSE for mild cognitive impairment in a variety of conditions and typically requires less than 10 minutes to administer.

The patient's problem can involve serious neurologic syndromes as well; however, the clinical presentation of the patient should direct the examination. In general, the less responsive and more impaired the patient is, the more one should look for *hard signs*. A directed search for an abnormality of the eyes and pupils, nuchal rigidity, hyperreflexia (withdrawal), hung-up reflexes (myxedema), one-sided weakness or asymmetry, gait (normal pressure hydrocephalus), Babinski's reflexes, tetany, absent vibratory and position senses, hyperventilation (acidosis, hypoxia, or pontine disease), or other specific clues can help verify or reject hypotheses about causality that are stimulated by the abnormalities in the examination.

TABLE 10–7 Glasgow Coma Scale

CRITERION	SCORE
Eye opening (E)	
Spontaneous	4
To verbal command	3
To pain	2
No response	1
Motor (M)	
Obeys verbal command	6
Localizes pain	5
Flexion withdrawal	4

Extension (decerebration)	2
No response	1
Verbal (V)	
Oriented and converses	5
Disoriented and converses	4
Inappropriate words	3
Incomprehensible sound	2
No response	1
Coma Score = (E + M + V)	**Range 3 to 15**

From Bastos PG, Sun X, Wagner DP et al: Glasgow Coma Scale score in the evaluation of outcome in the intensive care unit: findings from the Acute Physiology and Chronic Health Evaluation III study, *Crit Care Med* 21:1459–1465, 1993.

Frontal lobe function deserves specific attention. Grasp, snout, palmomental, suck, and glabellar responses are helpful when present. Hand movements thought to be related to the premotor area (Brodmann's area 8) can identify subtle deficiencies. The patient is asked to imitate, with each hand separately, specific movements. The hand is held upright, a circle formed by thumb and first finger ("okay" sign), then the fist is closed and lowered to the surface on which the elbow rests. In the Luria sequence, one hand is brought down on a surface (a table or one's own leg) in three successive positions: extended with all five digits parallel ("cut"), then as a fist, and then flat on the surface ("slap"). Finally, both hands are placed on a flat surface in front of the patient, one flat on the surface, the other resting as a fist. Then the positions are alternated between right and left hands, and the patient is instructed to do likewise.

For verbally responsive patients, their response to the "Frank Jones story" can be gauged (I have a friend, Frank Jones, whose feet are so big he has to put his pants on over his head. How does that strike you?). Three general responses are given. Type 1 is normal: The patient sees the incongruity and smiles (a limbic response) and can explain (a neocortical function) why it cannot be done. Type 2 is abnormal: The patient smiles at the incongruity (a limbic connection), but cannot explain why it cannot be done. Type 3 is abnormal: The patient neither gets the incongruity nor can explain its impossibility.

Laboratory studies should be carefully reviewed, with special attention paid to indicators of infection or metabolic disturbance. Toxicology screens are also usually helpful in allowing the inclusion or exclusion of substance intoxication or withdrawal from the differential diagnosis. Neuroimaging can prove useful in detecting intracranial processes that can result in altered mental status. Of all the diagnostic studies available, the electroencephalogram (EEG) may be the most useful tool in the diagnosis of delirium. Engel and Romano[34] reported in 1959 their (now classic) findings on the EEG in delirium, namely, generalized slowing to the theta-delta range in the delirious patient, the consistency of this finding despite wide-ranging underlying conditions, and resolution of this slowing with effective treatment of the delirium. EEG findings might even clarify the etiology of a delirium, because delirium tremens is associated with low-voltage fast activity superimposed on slow waves, sedative–hypnotic toxicity produces fast beta activity (>12 Hz), and hepatic encephalopathy is classically associated with triphasic waves.[35]

SPECIFIC MANAGEMENT STRATEGIES FOR DELIRIUM

Thoughts about (and treatment of) delirium have changed dramatically in the past several decades. In the 1970s, atropine was routinely administered to newly admitted

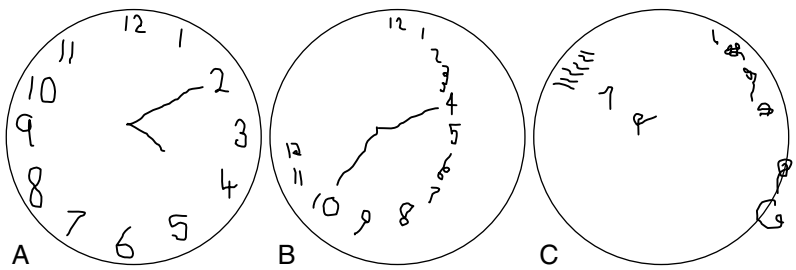

Figure 10–1. The clock drawing test. The patient is provided with a circular outline and asked to draw the numbers as they appear on the face of a clock. Once the numbering is complete, the patient is asked to set the hands to a particular time (often "ten past" the hour to test if the patient can suppress the impulse to include the number ten). **A,** This drawing demonstrates good planning and use of space. **B,** This drawing features some impulsiveness because the numbers are drawn out without regard for actual location, and the time "ten past four" is represented by hands pointing to the digits ten and four. Note the perseveration indicated by the extra loops on the digits *3* and *6*. Impulsiveness and perseveration indicate frontal lobe dysfunction. **C,** This drawing demonstrates gross disorganization, although the patient took several minutes to draw the clock and believed it to be a good representation.

coronary care unit (CCU) patients with bradycardia. Some patients, particularly older ones with preexisting organic brain disease, developed delirium. For such patients, parenteral propantheline bromide (Pro-Banthine), a quaternary ammonium compound that does not cross the blood–brain barrier and is equally effective in treating bradycardia, was substituted. This approach may still be taken, but problems are seldom so simple. Often the drugs that cause delirium (such as lidocaine or prednisone), cannot be changed without causing harm to the patient. Alternatively, pain can cause agitation in a delirious patient. Morphine sulfate can relieve pain but can unfortunately lead to decreases in blood pressure and respiratory rate.

Psychosocial or environmental measures are rarely effective in the treatment of a *bona fide* delirium of uncertain or unknown cause. Nevertheless, it is commendable to have hospital rooms with windows, calendars, clocks, and a few mementos from home on the walls[36]; soft and low lighting at night helps sundowners; and, most of all, a loving family in attendance reassures and reorients the patient. The psychiatric consultant is often summoned because psychosocial measures have failed to prevent or to treat the patient's delirium. Restraints (e.g., Posey vests; geriatric chairs; helmets; locked leather restraints for application to one or more extremities, chest, and even head) are also available and quite useful to protect patients from inflicting harm on themselves or staff. One or several of these is often in place when the consultant arrives. One hoped-for outcome of the consultation is that the use of these devices can be reduced or eliminated. The unfortunate misnomer *chemical restraint* is often applied to the most helpful class of drugs for delirium, neuroleptics. However, physicians do not use chemical restraints (i.e., tear gas, pepper spray, mace, or nerve gas) in the treatment of agitated patients.

When the cause of the delirium seems straightforward, the treatment revolves around resolution or reversal of the underlying cause. A discovered deficiency can be replaced (e.g., of blood, oxygen, thiamine, vitamin B_{12}, levothyroxine, or glucose). Pathologic conditions can be treated (e.g., volume replacement for hypotension, diuretics for pulmonary edema, antibiotics for infection, calcium for hypocalcemia, or dialysis for acute lithium toxicity). Implicated drugs, such as meperidine and cimetidine, can be stopped or reduced.

Specific antidotes can reverse the delirium caused by some drugs. Flumazenil and naloxone reverse the effects of benzodiazepines and opioid analgesics, respectively. However, caution is required because flumazenil can precipitate seizures in a benzodiazepine-dependent patient, and naloxone can also precipitate narcotic withdrawal in a narcotic-dependent patient.

Anticholinergic delirium can be reversed by intravenous (IV) physostigmine in doses starting at 0.5 to 2 mg. Caution is essential with use of this agent because the autonomic nervous system of the medically ill is generally less stable than it is in a healthy patient who has developed an anticholinergic delirium as a result of a voluntary or accidental overdose. Moreover, if there is a reasonably high amount of an anticholinergic drug on board that is clearing from the system slowly, the therapeutic effect of physostigmine, although sometimes quite dramatic, is usually short lived. The cholinergic reaction to intravenously administered physostigmine can cause profound bradycardia and hypotension, thereby multiplying the complications.[37,38] A continuous IV infusion of physostigmine has been successfully used to manage a case of anticholinergic poisoning.[39] Because of the diagnostic value of physostigmine, one might wish to use it even though its effects will be short-lived. If one uses an IV injection of 1 mg of physostigmine, protection against excessive cholinergic reaction can be provided by preceding this injection with an IV injection of 0.2 mg of glycopyrrolate. This anticholinergic agent does not cross the blood–brain barrier and should protect the patient from the peripheral cholinergic actions of physostigmine.

DRUG MANAGEMENT

Definitive treatment of delirium requires identification of the underlying somatic etiology, but all too often the cause of delirium is not readily identified or treated. These situations call for management of the symptoms of delirium until a more specific and effective treatment can be initiated. Opioids, benzodiazepines, neuroleptics, barbiturates, neuromuscular-blocking agents, inhalant anesthetics, and assorted other agents (such as propofol, ketamine, isoflurane, chloral hydrate, and clonidine), are available (alone or in creative combinations).

Benzodiazepines (e.g., diazepam 2.5 mg IV or midazolam 0.5 to 1 mg) are often effective in mild agitation in the setting of withdrawal from drugs that work at the alcohol, benzodiazepine, and barbiturate receptor. Morphine is also often used because it calms agitation and is easily reversed if hypotension or respiratory depression ensues. Especially in higher doses, these agents can cause or exacerbate confusion in older patients. This occurs much less often with neuroleptics, unless thioridazine (which has potent anticholinergic properties) is used.

Neuroleptics are the agent of choice for delirium. Haloperidol is probably the antipsychotic most commonly used to treat agitated delirium in the critical care setting; its effects on blood pressure, pulmonary artery pressure, heart rate, and respiration are milder than those of the benzodiazepines, making it an excellent agent for delirious patients with impaired cardiorespiratory status.[40]

Although haloperidol can be administered orally or parenterally, acute delirium with extreme agitation typically requires use of parenteral medication. IV administration is preferable to intramuscular (IM) administration because drug absorption may be poor in distal muscles if delirium is associated with circulatory compromise or with borderline shock. The deltoid is probably a better IM injection site than the gluteus muscle, but neither is as reliable as the IV route. Second, because the agitated patient is commonly paranoid, repeated painful IM injections can increase the patient's sense of being attacked by enemies. Third, IM injections can complicate interpretations of muscle enzyme studies if enzyme fractionation is not readily available. Fourth, and most important, haloperidol is less likely to produce extrapyramidal side effects (EPS) when given IV than when given IM or by mouth (PO), at least for patients without a prior serious psychiatric disorder.[41]

In contrast to the immediately observable sedation produced by IV benzodiazepines, IV haloperidol has a mean

distribution time of 11 minutes in normal volunteers[42]; this may be even longer in critically ill patients. The mean half-life of IV haloperidol's subsequent, slower phase is 14 hours. This is still a more rapid metabolic rate than the overall mean half-lives of 21 and 24 hours for IM and PO doses. The PO dose has about half the potency of the parenteral dose, so 10 mg of PO haloperidol corresponds to 5 mg given IV or IM.

Haloperidol has not been approved by the Food and Drug Administration (FDA) for IV administration. However, any approved drug can be used for a nonapproved indication or route if justified as "innovative therapy." For critical care units desirous of using IV haloperidol, one approach is to present this to the hospital's institutional review board (IRB) or human studies committee with a request to use the drug with careful monitoring of results based on the fact that it is the drug of choice for the patient's welfare, it is the safest drug available for this purpose, and it is justifiable as innovative therapy. After a period of monitoring, the committee can choose to make the use of the drug routine in that particular hospital.

Over decades of clinical use, IV haloperidol has been associated with few side effects on blood pressure, heart rate, respiratory rate, or urinary output and has been linked with few EPS. The reason for the latter is not known. Studies of the use of IV haloperidol in psychiatric patients have not shown that these side effects were fewer. They rarely appear after IV administration in medically ill patients probably because many of the medically ill patients have other medications in their system, especially benzodiazepines (which protect against EPS), or because patients with psychiatric disorders are more susceptible to EPS.[41]

Before administering IV haloperidol, the IV line should be flushed with 2 mL of normal saline. Phenytoin precipitates with haloperidol, and mixing the two in the same line must be avoided. Occasionally, haloperidol also precipitates with heparin, and because many lines in critical care units are heparinized, the 2-mL flush is advised. The initial bolus dose of haloperidol usually varies from 0.5 to 20 mg; usually 0.5 mg (for an elderly person) to 2 mg is used for mild agitation, 5 mg is used for moderate agitation, and 10 mg for severe agitation. A higher initial dose should be used only when the patient has already been unsuccessfully treated with reasonable doses of haloperidol. To adjust for haloperidol's lag time, doses are usually staggered by at least a 30-minute interval. If one dose (e.g., a 5-mg dose) fails to calm an agitated patient after 30 minutes, the next higher dose, 10 mg, should be administered. Calm is the desired outcome. Partial control of agitation is usually inadequate, and settling for this only prolongs the delirium or guarantees that excessively high doses of haloperidol will be used after the delirium is controlled.

Haloperidol can be combined every 30 minutes with simultaneous parenteral lorazepam doses (starting with 1 to 2 mg). Because the effects of lorazepam are noticeable within 5 to 10 minutes, each dose can precede the haloperidol dose, be observed for its impact on agitation, and be increased if it is more effective. Some believe that the combination leads to a lower overall dose of each drug.[43]

After calm is achieved, agitation should be the sign for a repeat dose. Ideally the total dose of haloperidol on the second day should be a fraction of that used on day 1. After complete lucidity has been achieved, the patient needs to be protected from delirium only at night, by small doses of haloperidol (1 to 3 mg), which can be given orally. As in the treatment of delirium tremens, the consultant is advised to stop the agitation quickly and completely at the outset rather than barely keep up with it over several days. The maximum total dose of IV haloperidol to be used as an upper limit has not been established, although IV administration of single bolus doses of 200 mg have been used,[44] and more than 2000 mg has been used in a 24-hour period. The highest requirements have been seen with delirious patients on the intra-aortic balloon pump.[45] A continuous infusion of haloperidol has also been used to treat severe, refractory delirium.[46] It has previously been argued that (despite strong empirical clinical evidence) high-dose haloperidol made little pharmacologic sense, given the high rates of dopamine receptor blockade at relatively low doses. In vitro research has revealed that the butyrophenone class of neurolpetics (haloperidol and droperidol) might protect neurons from oxidative stress resulting from interactions at the sigma receptor.[47,48] These interactions might provide the physiologic basis for the clinical benefits of high-dose haloperidol.[49]

When delirium does not respond and agitation is unabated, one might wonder if the neuroleptic (e.g., haloperidol) is producing akathisia. The best indication as to whether the treatment is causing agitation is the patient's description of an irresistible urge to move—usually the limbs, lower more often than upper. If dialogue is possible, even nodding yes or no (provided that the patient understands the question) can confirm or exclude this symptom. If the patient cannot communicate, limited options remain: to decrease the dose or to increase it and judge by the response. In our experience, it is far more common for the patient to receive more haloperidol and to improve.

Hypotensive episodes following the administration of IV haloperidol are rare and almost invariably result from hypovolemia. Ordinarily, this is easily checked in ICU patients who have in-dwelling pulmonary artery catheters, but because agitation is likely to return, volume replacement is necessary before one administers further doses. Local caustic effects on veins do not arise. IV haloperidol is generally safe for epileptic patients and for patients with head trauma, unless psychotropic drugs are contraindicated because the patient needs careful neurologic monitoring. Although IV haloperidol may be used without mishap in patients receiving epinephrine drips, after large doses of haloperidol a pressor other than epinephrine (e.g., norepinephrine) should be used to avoid unopposed β-adrenergic activity. IV haloperidol does not block a dopamine-mediated increase in renal blood flow. It also appears to be the safest agent for patients with chronic obstructive pulmonary disease.

As with all neuroleptic agents, IV haloperidol has been associated with the development of torsades de pointes (TDP).[50–54] The reasons for this are unclear, although particular caution is urged when levels of potassium and magnesium are low (because these deficiencies independently predict TDP), when a baseline prolonged QT interval is noted, when hepatic compromise is present, or when a specific cardiac abnormality (e.g., mitral valve prolapse or a dilated ventricle) exists. Progressive QT widening after administration of haloperidol should alert one to

the danger, however infrequent it may be in practice (4 of 1100 cases in one unit).[51] Delirious patients who are candidates for IV haloperidol require careful screening. Serum potassium and magnesium should be within normal range, and a baseline electrocardiogram (ECG) should be checked for the pretreatment QT interval corrected for heart rate (QTc). If necessary, potassium and magnesium shoud be repleted and the QTc and levels of potassium and magnesium should be monitored regularly for the duration of neuroleptic treatment. QT interval prolongation occurs in some patients with alcoholic liver disease; this finding is associated with adverse outcomes (e.g., sudden cardiac death).[55] Several other commonly used medications also carry the potential for QTc prolongation (Table 10–8). Medication lists should be reviewed closely for other agents that could be discontinued or therapeutically exchanged if QTc prolongation becomes a concern.

Other available parenteral first-generation neuroleptics for treatment of agitation are perphenazine, thiothixene, trifluoperazine, fluphenazine, and chlorpromazine. Perphenazine is approved for IV use as an antiemetic. Chlorpromazine is extremely effective, but its potent α-blocking properties can be dangerous for critically ill patients. When administered IV or IM, it can abruptly decrease total peripheral resistance and cause a precipitous fall in cardiac output. Nevertheless, used IV in small doses (10 mg) it can be safe and effective in the treatment of delirium.

The availability of injectable formulations of olanzapine and ziprasidone has prompted a growing interest in using the second-generation antipsychotics in managing delirium.[56] Risperidone has the most available data supporting its use, and multiple studies show it to be efficacious and safe for treating delirium[57–59]; one small randomized double-blind comparative study found no significant difference in efficacy compared with haloperidol.[60] The other members of this class (olanzapine, ziprasidone, quetiapine, clozapine, and aripiprazole) have far less supporting evidence, though some small studies seem to indicate some promise for management of delirium.[61–65] Agranulocytosis associated with clozapine and the resultant regulation of its use effectively eliminates any routine application of it in managing delirium. All drugs in this class feature an FDA black box warning indicating an increased risk of death when used to treat behavioral problems in elderly patients with dementia. Similar warnings regarding a potential increased risk of cerebrovascular events are reported for risperidone, olanzapine, and aripiprazole. One study examining the mean prolongation of the QTc for various neuroleptic agents on a per-dose-equivalent basis revealed that haloperidol was associated with the lowest increase of all the drugs tested.[66] With decades of clinical experience in the use of haloperidol, and a dearth of available data on these newer agents, haloperidol remains the agent of choice for treating delirium.

To date, there are few published data to support pharmacologic prophylaxis of delirium for the critically ill, although one randomized, double-blind, placebo-controlled study examining the preoperative use of haloperidol in elderly patients undergoing hip surgery indicated decreases in the severity and duration of delirium and length of hospital stay but no statistically significant decrease in the actual incidence of delirium.[67] A double-blind, randomized, placebo-controlled study involving the prophylactic administration of olanzapine to patients undergoing joint replacement surgery demonstrated a decreased incidence of delirium and more frequent discharge to home (as opposed to a rehabilitation hospital) when they received olanzapine before surgery.[68] There is also some limited evidence suggesting that the pro-cholinergic action of cholinesterase inhibitors provides some protection against the development of delirium.[69,70]

TABLE 10–8 Non-Neuroleptic Medications Associated with Prolongation of the QT Interval

ANTIARRYTHMICS	ANTIINFECTIOUS	OTHER
Amiodarone	Atazanavir	Alfuzosin
Disopyramide	Azithromycin	Amantadine
Dofetilide	Chloroquine	Arsenic trioxide
Flecainide	Clarithromycon	Bepridil
Ibutilide	Erythromycin	Chloral hydrate
Procainamide	Foscarnet	Cisapride
Quinidine	Gatifloxacin	Dolasetron
Sotalol	Gemifloxacin	Felbamate
	Halofantrine	Granisetron
	Levofloxacin	Indapamide
	Moxifloxacin	Isradipine
	Ofloxacin	Lapatinib
	Pentamidine	Levomethadyl
	Sparfloxacin	Lithium carbonate
	Telithromycin	Methadone
	Voriconazole	Nicardipine
		Octreotide
		Ondansetron
		Oxytocin
		Probucol
		Ranolazine
		Sunitinib
		Tacrolimus
		Tizanidine
		Vardenafil
		Venlafaxine

DELIRIUM IN SPECIFIC DISEASES

Critically ill patients with human immunodeficiency virus (HIV) infection may be more susceptible to the EPS of haloperidol and to neuroleptic malignant syndrome (NMS),[71–74] leading an experienced group to recommend use of molindone.[74] Molindone is associated with fewer of such effects; it is available only as an oral agent, and it can be prescribed from 5 to 25 mg at appropriate intervals or, in a more acute situation, 25 mg every hour until calm is achieved. Risperidone (0.5 to 1 mg per dose) is another recommended oral agent. If parenteral medication is required, 10 mg of chlorpromazine has been effective. Perphenazine is readily available for parenteral use as well, and 2-mg doses can be used effectively.

Patients with Parkinson's disease pose a special problem because dopamine blockade aggravates their condition. If oral treatment of delirium or psychosis is possible, clozapine, starting with a small dose of 6.25 or 12.5 mg,

is probably the most effective agent available that does not exacerbate the disease. With the risk of agranulocytosis attendant to the use of clozapine, quetiapine can play a valuable role in this population because its very low affinity for dopamine receptors is less likely to exacerbate this disorder.[75]

IV benzodiazepines (particularly diazepam, chlordiazepoxide, and lorazepam) are routinely used to treat agitated states, particularly delirium tremens, and alcohol withdrawal.[76] Neuroleptics have also been used successfully, and both have been combined with clonidine. IV alcohol is also extremely effective in treating alcohol withdrawal states, particularly if the patient does not seem to respond as rapidly as expected to higher doses of benzodiazepines. The inherent disadvantage is that alcohol is toxic to liver and brain, although its use can be quite safe if these organs do not show already extensive damage, and it is sometimes quite safe even when they do. Nonetheless, use of IV alcohol should be reserved for extreme cases of alcohol withdrawal when other, less-toxic measures have failed. A 5% solution of alcohol mixed with 5% dextrose in water run at 1 mL per minute often achieves calm quickly. Treatment pathways have been developed to provide nonpsychiatric clinicians with guidance on the management of alcohol withdrawal,[77] though care must always be taken to ensure that benzodiazepines are not inappropriately administered because they almost certainly exacerbate a delirium that results from any other cause.[78]

Propofol is now commonly used to sedate critically ill patients and can also be extremely effective in managing agitation.[79–81] It has moderate respiratory depressant and vasodilator effects, although hypotension can be minimized by avoiding boluses of the drug. Impaired hepatic function does not slow metabolic clearance, but clearance does decline with age, and its half-life is significantly longer in the elderly. This drug's rapid onset and short duration make it especially useful for treating short periods of stress. When rapid return to alertness from sedation for an uncompromised neurologic examination is indicated, propofol is a nearly ideal agent[82]; however, its use in treating a prolonged delirious state has specific disadvantages.[83] Delivered as a fat emulsion containing 0.1 g of fat per milliliter, propofol requires a dedicated IV line, and drug accumulation can lead to a fat-overload syndrome that has been associated with overfeeding and with significant CO_2 production, hypertriglyceridemia, ketoacidosis, seizure activity 6 days after discontinuation, and even fatal respiratory failure.[83–85] Obese patients provide a high volume of distribution, and their doses should be calculated using estimated lean, rather than actual, body mass. If the patient is receiving fat by parenteral feeding, this must be accounted for or eliminated and adequate glucose infusion must be provided to prevent ketoacidosis. Although no clear association has been demonstrated with addiction, tolerance, or withdrawal, doses seem to require escalation after 4 to 7 days' infusion. Seizures seen after withdrawal or muscular rigidity during administration are poorly understood. The drug is costly, especially when used for prolonged infusions.

Dexmedetomidine is a selective α_2-adrenergic agonist used for sedation and analgesia in the ICU setting. Its action on receptors in the locus ceruleus results in anxiolysis and sedation, and agonism of spinal cord receptors provides analgesia. This unique mechanism of action allows effective management in agitation without the risks of respiratory depression, dependence, and deliriogenesis associated with the benzodiazepines traditionally employed in the ICU.[86] Its relative lack of amnestic effect might further limit its use as monotherapy in the treatment of the delirious patient owing to an increased likelihood of distressing recollections persisting from the period of sedation.[87] In current practice, dexmedetomidine can serve as a useful (but costly) adjunct agent to quell agitation when more traditional approaches have met with limited success.

Drug infusions may be more effective and efficient than intermittent bolus dosing because the latter can intensify side effects (such as hypotension), waste time of critical care personnel, and permit more individual error. The contents of the infusion can address simultaneously multiple aspects of a patient's difficulties in uniquely appropriate ways. The report of the sufentanil, midazolam, and atracurium admixture for a patient who required a temporary biventricular assist device is an excellent example of multiple-drug infusion and creative problem-solving.[88,89]

CONCLUSION

Of all psychiatric diagnoses, delirium demands the most immediate attention because delay in identifying and treating delirium might allow the progression of serious and irreversible pathophysiologic changes. Unfortunately, delirium is all too often underemphasized, misdiagnosed, or altogether missed in the general hospital setting.[90–92] Indeed, it was not until their most recent editions that major medical and surgical texts corrected chapters indicating that delirium was the result of anxiety or depression, rather than an underlying somatic cause that required prompt investigation. In the face of this tradition of misinformation, it often falls to the psychiatric consultant to identify and manage delirium while alerting and educating others to its significance.

11 Demented Patients

William E. Falk, M.D.
Ilse R. Wiechers, M.D., M.P.P.

As life expectancy extends, we are likely to confront an epidemic of dementia in general hospitals, with the number of cases of Alzheimer's disease (AD), the most common cause of dementia, increasing fourfold in the coming decades.[1] Unfortunately, most dementing disorders, including AD, are incurable, but progression can be slowed if the condition is identified and managed appropriately; only a few dementing illnesses are reversible. Given that a major task for consultation psychiatrists is to assist in the diagnosis and treatment of dementing disorders, this chapter provides an overview of dementing disorders and an approach to their identification and management.

Often, the request to see an inpatient on a medical or surgical floor is for a behavioral disturbance associated with a delirium (see Chapter 10), not for cognitive difficulties alone. Nonetheless, a patient who develops delirium in the hospital may have a previously undiagnosed dementing disorder. A patient with such a disorder is more likely to develop an acute confusional state than is someone without dementia. For example, a demented patient may become delirious as a result of a urinary tract infection (UTI), whereas a cognitively intact elderly patient probably would not. As a useful rule of thumb, the presence of a delirium in an elderly patient should suggest the co-existence of an underlying dementia until proved otherwise.

Another common request is for evaluation of depressive symptoms associated with dementia. It is a diagnostic challenge to determine whether the mood symptoms are causing, co-existing with, or resulting from cognitive difficulties.[2] Determining the sometimes subtle differences in the history and presentation of delirium, depression, and AD can be helpful in the diagnosis of these disorders (Table 11–1).

Other presenting problems should alert the physician to an underlying dementia. These include poor medication compliance and injuries that could be accounted for by memory impairment. For example, many elderly patients experience burns as a result of dangerous cooking methods. Another reason for referral may be the patient's difficulty in coping with the inpatient setting itself. Despite a gradual cognitive decline, the patient may have functioned adequately in his or her familiar home setting. In the alien environment of the hospital, however, unfamiliar people provide care on an unusual schedule. As a result, trusted coping mechanisms may not work; anxiety, dysphoria, agitation, or paranoia can develop.

EPIDEMIOLOGY

Improvements in public health, nutrition, and medical care for the elderly have led to dramatic increases in the United States' population over the age of 65. Furthermore, those who live beyond the age of 85, the so-called oldest old, are the fastest-growing segment of the United States' population.[3] The significance of the aging population lies in the fact that age is a risk factor for dementia. Although the results of epidemiologic studies vary depending on the subjects sampled and the method employed, dementia occurs in approximately 15% of all individuals over the age of 65 and in up to 45% of those over the age of 80.[4] On this basis, nearly 5.7 million people over age 65 in the United States are affected. The global prevalence of dementia has been estimated at over 24 million people; the number of people affected will double every 20 years and reach 81 million by the year 2040.[5]

The most common type of dementia (accounting for 50% to 70% of cases) is AD. Among the neurodegenerative dementias, dementia with Lewy bodies (DLB) is the next most common, followed by frontotemporal dementia (FTD). Vascular dementia (which can have a number of different etiologies) can exist in the absence of AD, but the two frequently co-occur. Dementias associated with Parkinson's disease and Creutzfeldt–Jakob disease (CJD) are much less common.[6]

DIAGNOSIS

The definition of dementia in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[7] emphasizes that memory impairment is a necessary, but not sufficient, sign of the syndrome. At least one of the following additional findings must also be present: aphasia (a difficulty with any aspect of language), apraxia (the impaired ability to perform motor tasks despite intact motor function), agnosia (an impairment in object recognition despite intact sensory function), or a disturbance of executive function (including the ability to think abstractly, as well as to plan, initiate, sequence, monitor, and stop complex behavior). Associated features include impaired judgment, poor insight, personality change, and psychiatric symptoms (e.g., persecutory delusions and hallucinations, particularly visual). Motor disturbances (falls, ataxia, and extrapyramidal signs) and dysarthria (slurred speech) may be associated with certain dementing disorders.

TABLE 11–1 Clinical Features of Delirium, Depression, and Alzheimer's Disease

	DELIRIUM	DEPRESSION	AD
Onset	Abrupt	Relatively discrete	Insidious
Initial Symptoms	Difficulty with attention and disturbed consciousness	Dysphoric mood or lack of pleasure	Memory deficits—verbal and/or spatial
Course	Fluctuating—over days to weeks	Persistent—usually lasting months if untreated	Gradually progressive, over years
Family history	Not contributory	May be positive for depression	May be positive for AD
Memory	Poor registration	Patchy/inconsistent	Recent > remote
Memory complaints	Absent	Present	Variable—usually absent
Language deficits	Dysgraphia	Increased speech latency	Confrontation naming difficulties
Affect	Labile	Depressed/irritable	Variable—may be neutral

AD, Alzheimer's disease.

Additional essential elements for a diagnosis of dementia include a significant impact on social or occupational function and a significant decline from a previous level of function. Finally, the impairment occurs at times when delirium is absent. These final criteria are necessary to rule out age-associated memory impairment, congenital mental retardation, and life-threatening acute confusional disorders.

Scores of specific disorders can cause dementia (Table 11–2). The consultant cannot have in-depth knowledge of all of them but can identify common or typical and rare

TABLE 11–2 Dementia: Diagnosis by Categories with Representative Examples

Degenerative
Alzheimer's disease
Frontal lobe dementia with/without motor neuron disease
Pick's disease
Diffuse cortical Lewy body disease
Corticobasal degeneration
Huntington's disease
Wilson's disease
Parkinson's disease
Multiple system atrophy
Progressive supranuclear palsy

Psychiatric
Depression
Schizophrenia

Vascular
Vascular dementia
Binswanger's encephalopathy
Amyloid dementia
Diffuse hypoxic/ischemic injury

Obstructive
Normal pressure hydrocephalus
Obstructive hydrocephalus

Traumatic
Chronic subdural hematoma
Dementia pugilistica
Postconcussion syndrome

Neoplastic
Tumor—Malignant—primary and secondary
Tumor—Benign (e.g., frontal meningioma)
Paraneoplastic limbic encephalitis

Infections
Chronic meningitis
Postherpes encephalitis
Focal cerebritis/abscesses
HIV dementia
HIV-associated infection
Syphilis
Lyme encephalopathy
Subacute sclerosing panencephalitis
Creutzfeldt-Jakob disease
Progressive multifocal leukoencephalopathy
Parenchymal sarcoidosis
Chronic systemic infection

Demyelinating
Multiple sclerosis
Adrenoleukodystrophy
Metachromatic leukodystrophy

Autoimmune
Systemic lupus erythematosus
Polyarteritis nodosa

Drugs/Toxins

Medications
Anticholinergics
Antihistamines
Anticonvulsants
β-blockers

or unusual presentations. In addition, certain associated physical findings can direct the consultant to particular diagnoses (Figure 11–1).

Many elderly individuals complain of memory difficulties, often involving learning new information or names or finding the right words. In most circumstances, such lapses are normal. The term *mild cognitive impairment (MCI)* was coined to label an intermediate category between the normal cognitive losses that are associated with aging and those linked with dementia. MCI is characterized by a notable decline in memory or other cognitive functions compared with age-matched controls. MCI is common among the elderly, although estimates vary widely depending on the diagnostic criteria and assessment methods employed; some, but not all, individuals with MCI progress to dementia. The identification of those at risk for progression of cognitive impairment is an active area of research.[8,9]

Alzheimer's Disease

Alzheimer's disease (AD) is a progressive, irreversible, and fatal brain disease that affects memory, thinking, and behavior. The classic brain lesions of AD are known as neurofibrillary tangles (NFTs) and neuritic plaques (NPs). Although a definitive diagnosis of AD relies upon postmortem findings of these lesions,[10] detailed clinical assessments (by psychiatrists, neurologists, and neuropsychologists) in combination with use of structural and functional neuroimaging have a high concordance rate with autopsy-proven disease.

Progressive memory loss is the hallmark of AD. Other common cognitive clinical features include impairment of language, visual–spatial ability, and executive function. Patients may be unaware of their cognitive deficits, but this is not uniformly the case. There may be evidence of forgetting conversations, having difficulty with household finances, being disoriented to time and place, and misplacing items regularly. At least two domains of cognitive impairment, including progressive memory decline (that affects functional ability), are required to make a clinical diagnosis of AD.[11] In addition to its cognitive features, AD is associated with a number of neuropsychiatric symptoms, even in its mildest phases.[12] In particular, irritability, apathy, and depression are common early in the course of the disease, whereas psychosis (including delusions and hallucinations) tends to occur later.

Vascular Dementia

Vascular dementia refers to a variety of vascular-related causes of dementia, including multi-infarct dementia (MID) and small vessel disease. The pathophysiology of vascular dementia can be related to recurrent or localized embolic strokes, smaller subcortical strokes (e.g., lacunar infarcts), or cerebral hemorrhages. It is important to keep in mind that cerebral hemorrhages (resulting from hypertension or amyloid angiopathy) require a different type of clinical management than does typical vascular occlusive disease.

The clinical features of vascular dementia depend on the localization of the lesions; both the type of cognitive deficits and the time course of the cognitive changes vary. Embolic or large-vessel stroke-related dementia often progresses in a stepwise pattern, with intervening periods of stability punctuated by abrupt declines in cognitive function. Although this might be considered the classic presentation, it may not be its most common form.[13] Presentations that involve relatively isolated psychotic symptoms in the setting of preserved memory should also raise the possibility of vascular dementia. Likewise, apathy, executive dysfunction, and a relatively intact memory are suggestive of a small-vessel ischemic process.

The main difficulty that arises in the diagnosis of vascular dementia is distinguishing it from AD. Classically, vascular dementia is distinguished from AD on the basis of an abrupt onset and a stepwise course. In addition, prominent executive dysfunction and preserved recognition memory are also suggestive of vascular dementia. However, the symptoms of vascular dementia often overlap with those of AD; in fact, evidence of both conditions is often found at autopsy.

Dementia with Lewy Bodies

Dementia with Lewy bodies (DLB) shares clinical features of both AD and Parkinson's disease; this makes accurate diagnosis a challenge.[14] The main pathologic features of DLB are proteinaceous deposits called Lewy bodies, composed of α-synuclein in the cortex and brainstem.[15,16] Features that suggest DLB include visual hallucinations (which often occur early in the course, in contrast to the pattern seen in AD), a fluctuating course, an extreme sensitivity to neuroleptic medications, autonomic dysfunction (with falls), disorientation, and executive and visual–spatial dysfunction (with relatively spared language and memory function). Sleep disorders are also common; in particular, rapid eye movement–behavior disorder is problematic. Other neuropsychiatric manifestations (e.g., apathy, irritability, depression, agitation) are also common. Parkinsonian symptoms are also necessary for the diagnosis of DLB; in most cases, motor symptoms occur within 1 year of the onset of cognitive problems. By contrast, in Parkinson's disease with dementia, the motor symptoms typically precede cognitive problems by several years. Although specific clinical features of the disease (e.g., hallucinations, fluctuations, visual–spatial deficits, and rapid eye movement–behavior disorder) are helpful in the identification of this disease, clinical–pathologic concordance has not been great, and postmortem pathologic findings of Lewy bodies in the cerebral cortex, amygdala, and brainstem are necessary to confirm the diagnosis.[17,18]

Frontotemporal Dementias

Frontotemporal dementias (FTDs) are a heterogeneous group of neurodegenerative disorders that involve degeneration of different regions of the frontal and temporal lobes, resulting in a variety of clinical presentations. Currently included under the category of FTDs are Pick's disease, frontotemporal lobar degeneration, primary progressive aphasia, and semantic dementia.[19] FTDs tend to manifest at younger ages than typical AD, with the majority of cases occurring in people younger than 65 years of age.

The classic hallmarks of FTDs are behavioral features, usually out of proportion to, or even preceding, memory impairment. In general, there is a subtle onset and a progression of symptoms (with loss of judgment, disinhibition, impulsivity, social misconduct, loss of awareness, and interpersonal withdrawal). Other typical symptoms are stereotypies, excessive oral–manual exploration, hyperphagia, wanderlust, excessive joviality, displays of sexually provocative behaviors, and use of inappropriate words or actions. Clinical presentations of FTD vary depending on the relative involvement of the hemisphere (right or left) or lobe (frontal or temporal) affected.[20] Patients may initially have more involvement of the right temporal lobe than the left and exhibit primarily a behavioral syndrome with emotional distance, irritability, and disruption of sleep, appetite, and libido. With greater initial left than right temporal lobe involvement, patients tend to exhibit more language-related problems, including anomia, word-finding difficulties, repetitive speech, and loss of semantic information (e.g., semantic dementia).[21] In some cases of FTD, the frontal lobes may be involved more than the temporal lobes. In these instances, patients exhibit symptoms of elation, disinhibition, apathy, or aberrant motor behavior.

Dementia Caused by Other Medical Conditions

Dementias caused by other medical conditions include a broad range of disorders that are causally associated with a dementia: structural lesions; trauma; infections; endocrine, nutritional, and metabolic disorders; and autoimmune diseases. Two notable examples include dementias caused by normal pressure hydrocephalus (NPH) and CJD.

NPH is recognized by the classic clinical features of gait disturbance, frontal systems dysfunction, and urinary incontinence.[22] Intermittent pressure increases are thought to cause ventricular expansion over time, with damage to the adjacent white matter tracts that connect the frontal lobes. Evaluation usually includes structural brain imaging (magnetic resonance imaging [MRI] or computed tomography [CT]) that demonstrates ventricular enlargement that is out of proportion to the atrophy present.

CJD is a rare disorder that causes a characteristic triad of dementia, myoclonus, and distinctive periodic electroencephalographic (EEG) complexes. CJD is caused by prions, novel proteinaceous infective agents, that induce changes in the cerebral cortex and lead to the distinctive microscopic, vacuolar appearance of spongiform encephalopathy. The cerebrospinal fluid in almost 90% of CJD cases contains traces of prion proteins detected by a routine lumbar puncture. Treatment of afflicted individuals is supportive, insofar as the condition follows a characteristic course, with death arriving after an average of 6 months.[23]

Substance-Induced Persisting Dementia

To establish the diagnosis of substance-induced persisting dementia, there must be evidence from the history, physical examination, or laboratory data that cognitive deficits consistent with dementia are probably caused by exposure to a substance. The term *persisting* is important because the diagnosis cannot be made during a period of acute intoxication or during drug withdrawal. The most common cause of this type of disorder is chronic alcohol usage, but toxins, poisons, inhalants, sedative–hypnotics, and other medications are also causes.

Dementia Resulting from Multiple Causes

In the diagnostic section of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), the phrase "dementia due to multiple etiologies" serves to emphasize that a patient can have more than one cause for cognitive decline. Although many combinations can occur, perhaps the most common is the co-existence of AD and vascular disease. Some authorities refute this assertion, suggesting that diffuse DLB is the second most common primary dementing disorder and that its combination with AD is not sufficiently recognized.[24] AD can also co-exist with reversible causes of dementia (e.g., vitamin B_{12} deficiency, hypothyroidism), further emphasizing the importance of a thorough medical and neurologic work-up.

EVALUATION OF DEMENTIA

Brain failure deserves at least as careful an assessment as the failure of any other organ. Only through thoughtful evaluation can remediation of the cognitive decline be possible. Although in most cases the goal of treatment is not a cure, there is still much that can be done to help afflicted patients and their families. The evaluation requires a reliable history (cognitive, psychiatric, medical, and family), complete medical and neurologic examinations, appropriate laboratory testing, and assessments of the mental status and cognitive function.

History

A meticulous cognitive history is an extremely sensitive diagnostic tool. Onset, course, and associated symptoms must be elicited carefully because these details of history often provide critical diagnostic clues. Because of time constraints, consultants may be inclined to limit their history-taking to the patient alone. Although some mildly impaired patients may have sufficient capacity to provide an accurate account of their deficits, many (owing to their amnesia, agnosia, or failure of insight) do not. To rely solely on the patient's report is unwise; it may be inaccurate, and it will be incomplete. Additional history is best obtained from family members or close friends. It is important to interview informants away from the patient because informants are often uncomfortable discussing evidence of cognitive decline in the presence of the patient. Even a phone call to a family member or a friend can be helpful, as can a review of old medical records, when available.

A good cognitive history must establish the time at which cognitive changes first became apparent. This information provides important clues regarding the nature of the disorder because some diseases (e.g., CJD) are well known for causing a rapid rate of decline. If the time of onset of the disorder is known, the rate of decline can be estimated by seeing how long it has taken the patient to reach the current level of dysfunction. The rate of progression can only be approximated; however, it is helpful for family members to have such estimations so that plans for the future can be facilitated.

Next, it is important to determine the nature of the behavioral changes that were evident when the disease began. This information can also be helpful in the diagnostic process. For example, an early symptom of FTD is personality change, as manifested by inappropriate behavior, whereas the early symptoms of AD may involve increased passivity or apathy and a gradual, progressive decline in the ability to learn new information. Several years after the onset of the disease, when most patients are actually diagnosed, the cognitive symptoms of the two disorders may be quite similar, so information about the initial symptoms may be critical.

It is also important to determine whether the initial symptoms developed gradually or suddenly. If the onset of illness was insidious, as in AD, the family may realize only in retrospect that a decline has occurred. In contrast, a series of small strokes may produce symptoms of sudden onset, even if lesions were not evident on a CT scan or MRI of the head. Delirium generally has an acute onset as well. However, if it results from a condition such as a gradually developing drug toxicity, its onset may be subacute or insidious.

The manner in which symptoms have progressed also provides important diagnostic information. Stepwise deterioration characterized by sudden exacerbation of symptoms is typical of vascular dementia. A physical illness (e.g., pneumonia, a hip fracture) in a patient with AD, however, can also cause a sudden decline in cognitive function. Thus careful questioning is necessary to determine the underlying cause of a stepwise decline in function.

Accurate histories of cognitive function are difficult to obtain because most patients and family members are not attuned to subtle behavioral changes. Important aspects of the medical history may not be recognized. For example, the family may state that the first symptoms of the disease were the patient's anxiety and depression about work. Only after further inquiry will family members remember several episodes that preceded the onset of work-related anxiety in which the patient could not remember how to deal with a complex situation or learn how to use new equipment.

Family members may also have difficulty understanding why certain subtle distinctions are important for diagnosis. For example, they may report that the patient's first symptom was forgetfulness, but when asked to provide instances of this forgetfulness, they may explain that the patient had difficulty installing a new knob in the kitchen or had trouble finding a familiar location. Both features would suggest spatial difficulty more than memory difficulty. In addition, an unwillingness to admit that certain impairments exist may prevent family members from providing accurate information.

Finally, family members may misinterpret even direct questions. Although a history of a gradual, progressive decline is essential to the diagnosis of AD, informants

frequently state that the disorder came on suddenly because they suddenly became aware that something was wrong. This realization on the part of the family often coincides with external events (e.g., a trip to an unfamiliar place prevented the patient from employing overlearned habits and routines and thus exposed the cognitive decline). The hospital is obviously one such setting; it is not uncommon for family members to state, "He was fine until he got here!" When this misconception appears, it is necessary to determine when subtle symptoms of cognitive change first occurred. Usually, family members can recall episodes that they had previously ignored that suggest an earlier change in cognitive function. Annual family gatherings or holiday events are useful occasions about which to inquire.

It is also important to determine the patient's current functional status. This information is best obtained in an informal manner by asking about the patient's typical day. Alternatively, scales, such as the activities of daily living (ADL) and the instrumental activities of daily living (IADL) scales (Table 11–3), have been developed for this purpose. The ADL scale surveys six basic areas of function and determines whether the individual can perform these tasks independently or with assistance.[25] The IADL scale provides a sense of a patient's executive functions.[26] A substantial discrepancy between the functional and cognitive status of the patient generally suggests the presence of a psychiatric illness. For purposes of comfort, safety, rehabilitation, and determination of appropriate level of care, ADL and IADL results should be evaluated carefully.

The psychiatric history, with particular attention paid to reports of past mood or psychotic disorders, may assist in the differentiation of cognitive changes observed in depression from those of a primary dementing disorder. Although cognitive changes can be seen in depression, the history and mental status examination usually allow the physician to separate depression and dementia or suggest that both are present. Neurovegetative symptoms of depression may be difficult to link specifically to mood or cognitive disorders because anergia, sleep disturbance, and appetite changes can be seen in both depression and dementia. Thus it is important to modify the questions asked to encompass the possibility of cognitive impairment. For example, if the tasks are simplified and within the capabilities of a nondepressed, demented patient, the patient is typically able to carry them out. Similarly, if food is presented in a manner that the patient can manage, such as meat cut into bite-size pieces, the patient may show a newfound gusto in his or her appetite (see Table 11–1).

In reviewing the medical history, the physician should consider whether surgical procedures (e.g., gastrectomy predisposing to vitamin B_{12} deficiency) or medical illnesses (e.g., hypertension, systemic lupus erythematosus) contribute to the symptoms of cognitive dysfunction. It is crucial to determine whether the patient underwent blood transfusions (particularly during the early to mid-1980s, when human immunodeficiency virus testing was not readily available), was exposed to toxins (e.g., lead or other heavy metals, carbon monoxide), or has a history of head trauma. Careful questioning should cover alcohol and drug usage (not just current patterns), including a past history of abuse or overuse. Many nonpsychotropic agents, including those sold over the counter, can have negative effects on cognition. For example, antihistamines and antispasmodic drugs can cause cognitive difficulties. Valuable historical data includes information regarding impairments in hearing or vision, incontinence, falls, and gait disturbances.

The family history portion of the evaluation is also helpful. Certain dementing disorders (e.g., Huntington's disease) have definite genetic modes of transmission (e.g., autosomal dominant), whereas for others (e.g., certain vascular dementias) the specific mode of transmission may be unclear, but their prevalence is much higher in affected families than in the population at large. Several familial subtypes of AD with genetic loci have been identified. An estimated 7% of cases with an onset before the age of 60 are familial, with an autosomal dominant inheritance. Several genes, including beta-amyloid precursor protein and presenilin 1 and 2, have been associated with early-onset AD.[27] For the majority of patients with AD, there appears to be a complex interaction among genetic and other factors.[28] Variations in the gene for apolipoprotein E (APOE) may increase the risk of developing AD or predispose to earlier onset.[29] APOE remains the only documented late-onset AD gene.[30]

TABLE 11–3 Assessment of Functional Status

Medical and Neurologic Examination

The consultant should review recent examinations in the medical record to assess their adequacy and accuracy. The cognitive portion of prior examinations may note only that the patient was alert and oriented. Additionally, if notes report "disorientation," it is often unclear from the chart whether the patient could not remember the day of the week or whether he or she was confused or psychotic. Consequently, the psychiatric consultant should look for medical and neurologic findings that are associated with dementing disorders. For example, focal areas of muscle weakness and pyramidal signs may suggest vascular dementia. The presence of extrapyramidal movements may point to one of the dementias that principally affects subcortical motor areas. Mild to moderate AD, however, may also be associated with extrapyramidal symptoms (EPS) and other neurologic signs.[31] A comprehensive neurologic examination should include careful assessment of ocular function, gait, and praxis, as well as the presence of any frontal release signs.

Laboratory Examination

Table 11–4 lists hematologic and other tests that are typically ordered as part of a dementia evaluation. Whenever possible and appropriate, results of prior testing in other settings should be obtained. For example, a chest x-ray examination or CT scan should not be reordered if one was recently done unless an acute change has occurred. Additional tests (e.g., serum copper and ceruloplasmin for Wilson's disease or serum and urine porphyrins for acute intermittent porphyria) should be requested when the history and examination suggest a particular disorder.

Psychiatric Mental Status Examination

The bedside psychiatric examination covers considerable territory, but it focuses on assessments of affective and psychotic signs and symptoms. The physician should probe for mood symptoms, irritability or tearfulness, and nihilistic or suicidal thinking. Depressed elderly patients may, among their somatic complaints, describe decrements in memory. Depressed patients, as opposed to patients with AD, however, may perform better on more difficult memory tasks than on simple ones.

Psychotic symptoms can be present in primary psychiatric disorders, such as psychotic depression or schizophrenia, but they can also be associated signs of delirium or dementia. The prevalence of psychosis in moderate to severe AD is estimated to be in the range of 40% to 80%.[32] Usually, delusions in patients with AD are of a paranoid nature, often involving the mistaken belief that misplaced items have been stolen. With progression of the disease, the patient may come to believe that spouses are parents or that they are actually imposters (i.e., Capgras syndrome). Illusions and hallucinations, usually of a visual nature, also occur with advanced AD. For example, some patients describe seeing "little people" entering their homes. Despite their unusual nature, not all hallucinations or delusions are troublesome to the patient. Mood and psychotic symptoms can occur as part of the clinical picture of many dementing disorders. Generally, they are nonspecific. However, taken together with other elements of the assessment, such symptoms can provide clues as to whether a psychiatric disorder or a dementing disorder is present.

Bedside Cognitive Assessment

Domains of cognitive function that require rapid and accurate bedside assessment can be remembered with the mnemonic A CALM VISAGE (the face the consultant would put forward when confronted with a patient who is difficult to diagnose). These domains include the following: Attention, Conceptualization, Appearance/behavior, Language, Memory, VISual–spatial, Agnosia and apraxia, and GEneral intelligence.

Attention is important to consider because simple attentional abilities must be preserved if any other cognitive task is to be performed adequately. If the patient has difficulty concentrating on a task for even a few minutes at a time, assessment of other domains will likely be inaccurate. For this reason, attention is often evaluated first. Auditory and visual attention can be assessed easily by means of digit span and letter cancellation tests. For the digit span test, the patient is asked to repeat a series of numbers spaced 1 second apart. The examiner provides gradually increasing spans; unimpaired individuals are able to repeat five to seven numbers. For the letter cancellation test, the patient is asked to cross off a particular letter each time he or she observes it in any series of letters. A gross assessment can be inferred from how well the patient responds to questions during an interview. The physician should note whether the level of arousal appears to fluctuate or the patient seems easily distracted during the interview.

Tasks that examine conceptualization include tests of concept formation, abstraction, set-shifting, and set-maintenance. Similarities and proverbs are useful in this regard.

Observation of appearance and behavior is helpful in determining whether patients are able to care adequately for themselves. Detecting that a patient's buttons are misaligned, for example, may suggest that he or she has spatial difficulties or an apraxia.

Language testing for aphasia should include evaluation of comprehension, repetition, reading, writing, and naming. If aphasia has been ruled out or is not suspected, confrontation naming (e.g., of objects and their parts, such as jacket and lapel or watch and stem) should be included in

an assessment of the older individual because declines in naming ability occur with age but are prominent in a number of disorders, including AD. In addition, alterations in verbal fluency (tested by having the patient name as many animals or words beginning with a certain letter as possible in a minute) are seen in many dementing diseases.[33]

The presence of memory dysfunction is essential for a diagnosis of dementia. The nature and severity of the memory impairment can serve as a guide to diagnosis, but the assessment of memory is complicated by the fact that changes in memory capacity normally occur with aging. Normal elders may require more time to retain new information. Therefore careful testing is important to differentiate normal from pathologic memory performance. Testing should include not only short-term memory but also memory of personal events (e.g., details of marriage, names of children) and significant historical dates (e.g., John F. Kennedy's assassination, September 11).

Assessment of visual–spatial abilities may be more difficult in older than in younger individuals because of the frequency of visual–sensory deficits in the elderly. It is difficult to enlarge certain test stimuli to evaluate this domain; therefore figure copying (e.g., of intersecting pentagons or a cube) is the most useful method of assessment.

When agnosia or apraxia is evident, the patient's disease is usually quite advanced. Agnosia is diagnosed when a patient fails to recognize a familiar object despite intact sensory function. With apraxia, the patient's ability to carry out motor tasks is impaired despite intact motor systems and an understanding of the tasks. For example, the patient is unable to mimic the use of common objects (e.g., use of a toothbrush) or to carry out well-learned motor behaviors (e.g., pretending to blow out a candle). A subtle finding is "organification of praxis" in which the subject, for example, uses a finger as the toothbrush.

In addition to the areas of assessment previously mentioned, the examiners should estimate general intelligence to determine whether the patient has access to previously acquired knowledge. A rough approximation can be inferred from the patient's highest level of education. Alternatively, the vocabulary subtest of *The Wechsler Adult Intelligence Scale–Revised* can be used to estimate level of intelligence.[34]

Standardized Cognitive Testing

Nonstandard testing developed by the clinician can be used to evaluate the cognitive domains noted previously, but a variety of standardized, brief mental status tests can be useful as well. However, although screening tests may identify cognitive difficulties, they are not sufficient to establish a diagnosis of dementia.

Commonly used screening tests are the Mini-Mental State Examination (MMSE),[35] the Blessed Dementia Scale,[36] and the Short Portable Mental Status Questionnaire.[37] All have high test–retest reliability, and all are relatively brief, taking 5 to 15 minutes to administer. Of these, the MMSE is most often used in clinical settings (see Table 4–8 for details) because it assesses a broad range of cognitive abilities (i.e., attention, concentration, memory, language, spatial ability, and set-shifting) in a simple, straightforward manner. Scores on the MMSE range from 0 to 30, with scores greater than 26 generally indicating normal cognitive function. Mildly impaired patients typically obtain MMSE scores of 20 to 26, moderate impairment is reflected in scores of 11 to 20, and severe impairment is indicated by scores of 10 or lower. A cutoff score of 23 is generally recommended as suggestive of cognitive dysfunction; however, the application of this cutoff score must be modified in light of the patient's education level. For example, an extremely bright, well-educated patient may score 29 or 30 despite having significant impairment.

The MMSE is a useful screening tool in the assessment of demented patients with mild to moderate cognitive impairments, but it is less helpful in the evaluation of severely impaired patients. The quantification of cognitive abilities in severely impaired patients can serve a variety of needs, including the ability to follow patients throughout an intervention trial, the assessment of spared abilities (which health care professionals can use in the development of management strategies), and the examination of the relationship among postmortem neurochemical and neuropathologic findings and cognitive status shortly before death. The Test for Severe Impairment (TSI) is a useful scale for severely impaired patients that can contribute to improved patient management.[38] It minimizes the need for the patient to use language skills because severely impaired patients often have minimal intact verbal skills. Nonetheless, the TSI can evaluate motor performance, language comprehension, language production, immediate and delayed memory, general knowledge, and conceptualization.

On the other end of the spectrum, patients with MCI often score within the normal range on the dementia screening tools discussed previously. The Montreal Cognitive Assessment (MoCA) was created as a 10-minute screening tool to assist in the detection of MCI.[39] It assesses many cognitive domains, and although somewhat more challenging than the MMSE, it assesses executive and abstract functions in a superior manner. Components of the visual–spatial and executive function testing include a brief "Trails B," copying a cube, and drawing a clock. The MoCA is available free of charge for noncommercial clinical use and available online (www.mocatest.org) in a multitude of languages (Figure 11–2).

With all structured tests, the examiner must not simply look at the total score but rather assess the qualitative areas of low and high function. The pattern of deficits may confirm a diagnostic opinion. Conversely, determining that areas of function have been preserved assists the clinician in making recommendations to the patient and the family for adaptive coping with the dementia.

TREATMENT CONSIDERATIONS

The approach to treatment of a dementing disorder depends on the specific diagnosis established as well as on the troublesome symptoms and signs that must be managed. Treatment is divided into three broad categories: medical and surgical interventions, behavioral interventions, and pharmacotherapy. Pharmacotherapy can be divided further into treatments for cognitive symptoms and neuropsychiatric symptoms of dementia.

Medical and Surgical Interventions

Some dementing disorders can be helped dramatically by surgical interventions. For example, the treatment for NPH is removal of cerebrospinal fluid by way of a lumbar puncture or ventriculoperitoneal shunting. It is important to perform cognitive and motor testing before and after the removal of a large volume of cerebrospinal fluid.[40] Similarly, draining of frontal subdural hematomas can improve patients' cognition and behavior.

Other reversible medical disorders that cause dementia should be corrected. For example, thyroid repletion in the myxedematous patient improves cognitive function. In many conditions, however, damage has already been done, and repletion may provide only marginal improvement. For example, a patient who had deteriorated over several years was found to have an extremely low vitamin B_{12} level. Her dementia was profound, and it did not respond to intramuscular injections of vitamin B_{12}. Further deterioration of her cognition and other nervous system functions, however, may have been prevented by the treatment.

Sometimes the reduction or elimination of drugs can be helpful. For example, patients with Parkinson's disease and psychotic symptoms secondary to use of dopamine agonists may require dosage adjustment to reduce the psychotic symptoms. Other examples are barbiturate-induced cognitive decline and benzodiazepine-induced memory impairment. Elimination of the sedative is essential because cognitive symptoms caused by the drug are most likely to remit with cessation. Care must be taken, however, to avoid a withdrawal syndrome caused by too abrupt a discontinuation.

Searching for treatable contributors to cognitive decline is important, even when the principal diagnosis is AD. Identification of co-existing medical conditions that have a deleterious effect on the patient's cognition is critical. For example, the aggressive treatment of a urinary tract infection improves not only physical comfort but also intellectual function (because infection in the setting of AD usually causes delirium). Pain, too, may have a negative effect on cognition. A patient whose AD was manageable at home became severely aggressive and more confused owing to the discomfort of an impacted bowel. Another patient with presumed vascular dementia showed some improvement in cognition after treatment for congestive heart failure.

Behavioral Interventions

Once drug effects and contributing medical conditions are identified and managed, acute behavioral symptoms associated with dementia may subside. The environmental strangeness of the hospital, however, may be enough to trigger new psychiatric and behavioral problems, such as paranoid thinking and agitation.

Often, behavioral management alone reduces certain symptoms; such nonpharmacologic interventions should be used in every case. The basic approaches are well known but bear repeating (Table 11–5). When considering behavioral interventions, always remember the ABCs of behavioral analysis: antecedent, behavior, and consequences. For example, a patient is easily upset and confused when she cannot remember her nurse; as a result, she yells and sometimes throws things at the nurse when she comes into the room, putting both the patient and nurse in danger (e.g., from inadvertent removal of intravenous lines or being struck by thrown objects). When tailoring behavioral interventions, the physician should consider each aspect of the behavioral analysis. Possible solutions to the aforementioned case include posting the names of providers in the patient's room, removing potentially dangerous objects from within reach of the patient's bed, and reassuring the patient.

TABLE 11–5 Behavioral Management for Dementia Patients

Reorient to the environment (e.g., clock, calendar); post names of care providers
Simplify communication (e.g., yes/no questions)
Reassure, distract, and redirect (e.g., familiar pictures from home)
Use eyeglasses and hearing aids appropriately
Encourage activity and exercise
Offer soothing therapies (e.g., music therapy or aromatherapy)
Provide one-on-one supervision
Apply physical restraint (when necessary for the safety of the patient and others)

The manner in which staff members communicate with the patient is also important. Speaking loudly enough (but not too loudly) is a critical first step. Decreased hearing acuity affects all elders, but this does not mean that shouting is necessary. The content of what is said should be simple and to the point. If the patient has considerable expressive language difficulties, questions should be framed so that a yes-or-no response is adequate. Reassurance and distraction are preferred responses to patients who are paranoid or easily distressed.[41]

Pharmacotherapy for Cognitive Symptoms

Pharmacotherapies in dementia generally target both cognitive decline and the behavioral and other psychiatric consequences of disease. Because AD is associated with cholinergic dysfunction, cholinesterase inhibitors (ChE-Is) have been developed and are now widely used in treatment (Table 11–6). The commonly used ChE-Is in the United States include donepezil, rivastigmine, and galantamine. A fourth agent, tacrine, is no longer widely used because of its association with hepatotoxicity. The ChE-Is differ in their pharmacologic properties, administration regimens, drug interactions, and effect on hepatic enzymes. The most common side effects include nausea, vomiting and diarrhea; other bothersome adverse effects include insomnia or vivid dreams, fatigue, muscle cramps, incontinence, bradycardia, and syncope. As a result, these drugs may be contraindicated in the setting of bradycardia or sick sinus syndrome; severe asthma and peptic ulcer disease may also be relative contraindications.

In patients with AD, all the ChE-Is have been shown to produce improvements in cognition, functional outcomes (e.g., in ADL and IADL), and neuropsychiatric and behavioral symptoms.[42,43] Treatment with these agents should begin as early as possible in patients with AD.[44] The usefulness of these agents in other forms of dementia is not as well studied. One randomized, double-blind, placebo-controlled study comparing rivastigmine against placebo found that rivastigmine appeared to moderately improve cognition and to a

TABLE 11–6 Characteristics of Cholinesterase Inhibitors

DRUG	CHEMICAL CLASS	TOTAL DAILY DOSE	REGIMEN	ADVERSE EVENTS
Donepezil	Piperidine	5-10 mg	Daily	GI, headaches, weakness
Rivastigmine	Carbamate	6-12 mg (oral), 4.6-9.5 mg (transdermal)	Twice daily (oral) or daily (transdermal)	GI, headaches, dizziness
Galantamine	Tertiary alkaloid	16-24 mg	Once daily (extended release) or twice daily (immediate release)	GI, insomnia
Tacrine	Aminoacridine	80-160 mg	Four times daily	Elevated liver enzymes, GI

GI, Gastrointestinal.

lesser extent ADL in patients with dementia associated with Parkinson's disease.[45] Review of the literature on the use of ChE-Is in DLB found no convincing evidence for their use.[46]

Goals of therapy with ChE-Is include a delay in cognitive decline, a delay of functional decline, and treatment or prevention (or both) of the development of behavioral symptoms. It is important to note that the downhill slope of the illness will continue. ChE-Is also have a small beneficial effect on burden and active time use among caregivers of persons with AD.[47]

Memantine, an *N*-methyl-D-aspartate antagonist, has been approved by the Food and Drug Administration for treatment of moderate to severe AD. Memantine normalizes levels of glutamate, a neurotransmitter involved in learning and memory, and which in excessive quantities is thought to contribute to neurodegeneration. Common side effects include dizziness, agitation, headache, and confusion. Evidence indicates that adding memantine to the regimen of patients with moderate to severe AD (who were already receiving stable doses of donepezil) results in better outcomes on measures of cognition, ADL, and behavior.[48,49]

Initiating pharmacotherapy for cognitive symptoms is not usually in the domain of the psychiatric consultant in the general hospital; this is typically the work of outpatient treaters. However, one reason to consider starting these medications in an inpatient medical setting might be to monitor for side effects and tolerability in patients with significant co-morbid medical illnesses. Initiation of ChE-Is may also be considered in this setting for treatment of neuropsychiatric symptoms, as described later. The consultant may be asked to consider reasons to stop ChE-Is, such as side effects, new medical contraindications, poor compliance, or rapid decline in the patient's illness. Any benefits of treatment are rapidly lost upon discontinuation.

Pharmacotherapy for Neuropsychiatric Symptoms

Pharmacotherapy may also be useful for managing disruptive or distressing psychiatric or behavioral symptoms unresponsive to the medical corrections and behavioral interventions noted. However, certain symptoms are poorly responsive to drug therapies. For example, the motor restlessness and wandering behavior seen in patients with AD are typically nonresponsive to medications; in addition, some treatments (e.g., neuroleptics that cause akathisia) may actually aggravate the problem.[50] When other symptoms, such as visual hallucinations or delusions, cause no distress to the patient and are not dangerous, medication is not required. When treatment is necessary, the golden rule of geriatric pharmacotherapy is, "Start low, go slowly, but go all the way." This maxim applies whether target symptoms relate to apathy, depression, psychosis, agitation, or some combination of these domains.

Apathy is the most common behavioral change in AD.[51] It is defined as a lack of motivation relative to the prior level of function, with a decrease in goal-directed behaviors, goal-directed cognition, and emotional responsiveness.[52] The lack of motivation must not be attributable to intellectual impairment, emotional distress, or a diminished level of consciousness. It is important to distinguish apathy from depression in patients with dementia because the treatments are different (Table 11–7). Treatments for apathy include use of psychostimulants,[53] dopamine agonists (e.g., bupropion and amantadine),[54] and ChE-Is.[55]

The depressive component of any dementia should be assessed and treated aggressively. If the degree to which affective symptoms are contributing to cognitive dysfunction is unclear, a therapeutic trial of an antidepressant should be employed. Choice of an agent is based principally on the side effects it produces; other considerations include drug–drug interactions and cost. The selective serotonin reuptake inhibitors (e.g., citalopram and sertraline), bupropion, and mirtazapine have favorable side effect profiles and should be considered, despite a paucity of literature on their use in depression associated with dementia. Care should be taken to avoid those drugs with greater anticholinergic side effects (e.g., paroxetine). Nortriptyline has been used effectively in depression following strokes and is generally well tolerated.[56] Tertiary amine tricyclic antidepressants (TCAs) that are highly anticholinergic (e.g., amitriptyline,

TABLE 11–7 Apathy Versus Depression in Alzheimer's Disease

	APATHY	DEPRESSION
Mood	Blunted	Dysphoric
Attitude	Indifferent	Pessimistic, hopeless
Self-concept	Bland	Self-critical
Thoughts/ actions	Decreased initiative and persistence	Guilty, suicidal

imipramine) should be avoided. Finally, as long as they are administered in a safe manner, monoamine oxidase inhibitors (MAOIs) may be useful in the treatment of depression associated with AD.[57]

Hallucinations (particularly visual), delusions (e.g., paranoid, persecutory, somatic), and agitation (which can take the form of motor restlessness, verbal outbursts, or physical aggression) are common in patients with dementia and MCI.[58] Before any medication is instituted, reversible causes (e.g., infection, drug effects) should be investigated. If the symptoms are causing significant distress and placing the patient or caregiver at risk, and if nonpharmacological interventions have failed, the first-line treatment is an antipsychotic medication.

First-generation or typical antipsychotics (e.g., haloperidol, trifluoperazine, perphenazine, thiothixene) have been well studied and show modest improvement in target symptoms.[59,60] However, elderly patients may be particularly sensitive to the side effects of these agents (e.g., sedation, postural hypotension, EPS). Second-generation or atypical antipsychotics (e.g., risperidone) have also been well studied in patients with dementia.[61,62] Direct comparison of atypical antipsychotics in the CATIE-AD trial (which randomized patients to olanzapine, quetiapine, risperidone, or placebo) found no differences among treatments in the main outcome, time to all-cause discontinuation.[63] A meta-analysis of randomized controlled trials of atypical antipsychotics found that drop-outs and adverse events further limit effectiveness; approximately one third of patients dropped out of the studies (with no difference between drug and placebo), and cognitive scores worsened on medications.[64]

Further complicating the picture is the evidence showing an increased risk of cerebrovascular adverse events in patients with dementia taking atypical antipsychotics.[65] The risk of death in patients taking typical antipsychotics is comparable to or higher than the rates in patients taking atypical antipsychotics.[66-68] More recent data have found that the use of both typical and atypical antipsychotic drugs carries a similar, dose-related increased risk of sudden cardiac death.[69]

Thus the clinician facing the challenge of treating a dementia patient with psychosis or agitation must carefully weigh the risk of not treating neuropsychiatric symptoms against the risks of the treatment previously discussed. This requires consideration of the evidence supporting efficacy of a given agent, the morbidity and risk associated with the target symptoms, the patient's medical conditions, and the risks and benefits of the proposed antipsychotic being considered. It is essential that the clinician obtain informed consent from the patient's health care decision-maker before starting any antipsychotic medications. In general, dosing of atypical antipsychotics is lower in elderly patients than other populations (see Table 44–3). In addition to oral forms, some agents may be administered intramuscularly when required.[70,71] Usage should be reassessed periodically, particularly because target symptoms may subside with disease progression, and tardive movement disorders occur frequently in this population and typically do not resolve spontaneously.[50]

Treatment of psychosis and agitation associated with Parkinson's disease requires special mention. High-potency neuroleptics may aggravate tremor and bradykinesia. Clozapine has been found to be useful in controlling psychotic symptoms in patients with Parkinson's disease and DLB.[72,73]

Several additional medications can be used in addition to antipsychotics in patients with agitation. Benzodiazepines have also been used to treat the agitation associated with dementia; however, the risk of worsening cognition and inducing behavioral disinhibition should be weighed, particularly before prescribing a long-acting agent (e.g., diazepam, clonazepam) or prescribing them for protracted periods.[74] The short-acting lorazepam (in an oral dosage of 0.25 to 1 mg) is often quite helpful when administered before an uncomfortable or potentially frightening procedure, such as a lumbar puncture or MRI scan. The use of buspirone for treatment of agitation has been reported, but at least a few weeks are necessary to achieve a modest benefit with this agent.[75]

Among the antidepressants, trazodone has been the subject of most case reports demonstrating behavioral improvement in agitated, demented patients.[76] A small, randomized controlled trial of trazodone use in patients with FTD found a significant decrease in behavioral symptoms.[77] Similarly, a naturalistic follow-up study of patients with AD found that after 6 months, patients treated with trazodone exhibited no increase in behavioral or psychological symptom frequency or severity, nor was an increase noted in caregiver burden.[78] In our experience, it has been modestly effective for agitation but quite useful for nocturnal insomnia.[79] Starting at a dosage of 25 to 50 mg per day, trazodone can be increased to as much as 400 mg daily, as tolerated. Sedative effects are usually quite rapidly achieved. Although generally well tolerated, trazodone may induce postural hypotension and priapism.

β-blockers (e.g., propranolol, pindolol) have been beneficial in treatment of agitation associated with dementias of various causes.[80] The risk of side effects, however, may outweigh potential benefits; a gradual dosage escalation is necessary, particularly with geriatric patients.

Finally, lithium carbonate, carbamazepine, and valproic acid have reportedly been used to treat agitation associated with dementia.[81-83] Of the three, valproic acid may hold the most promise because doses found effective were low and side effects were minimal and well tolerated. In an open-label study of 10 elderly patients with AD or vascular dementia, Lott and colleagues[83] observed moderate or better improvement in eight, with doses ranging from 250 to 750 mg (yielding levels of 13 to 52 g/mL). However, a recent review of four placebo-controlled trials found conflicting and inconclusive results.[84] Hence, further research is needed to determine the optimal use of valproic acid for treatment of neuropsychiatric symptoms in this population.

There is also growing evidence that ChE-Is and memantine have modest benefit in the neuropsychiatric symptoms and behavioral disturbances in AD and possibly other related dementias with cholinergic deficits.[42,48,85] Mood symptoms and apathy have most commonly responded to ChE-Is, whereas memantine has been associated with a reduction in irritability and agitation.[55] Using ChE-Is or memantine for neuropsychiatric symptoms offers another alternative to antipsychotic medications in patients with dementia. Unfortunately, the effects of these drugs are modest and often provide only temporary improvement.

CONCLUSION

As the population ages, the number of people with dementing disorders is increasing dramatically; most have AD or vascular dementia. The role of the psychiatric consultant in the diagnosis and treatment of dementing disorders is important, particularly in the identification of treatable psychiatric and behavioral symptoms.

Family members are the hidden victims of progressive dementia. They typically appreciate the consultant's communication about the diagnosis and the expected course of the disorder. They can benefit from advice about how best to relate to the patient, how to restructure the home environment, and how to seek out legal and financial guidance if appropriate. Family members also should be made aware of the assistance available to them through such organizations as the Alzheimer's Association.

12 Psychotic Patients

Oliver Freudenreich, M.D.
Donald C. Goff, M.D.

Psychosis, broadly defined, is a gross impairment of reality testing. Psychosis can result from a wide range of psychiatric and medical disturbances and may take several forms. The elderly woman lying quietly in bed listening to Satan whisper bears little resemblance to the wildly agitated young man who accuses the nursing staff of trying to poison him. Hallucinations and delusions are the two classic psychiatric symptoms whose presence would indicate that the patient has lost touch with reality (i.e., suffers from psychosis). Hallucinations, which are sensory perceptions in the absence of an external source, can occur in any sensory modality and may take the form of voices, visions, odors, or even complex tactile perceptions (such as electric shocks or the sensation that one is being fondled). Delusions are firmly held false beliefs. Delusional individuals cling to their beliefs with unfaltering conviction even in the face of overwhelming evidence to the contrary. Delusions range from beliefs that are plausible, albeit unlikely (such as being monitored by the Central Intelligence Agency), to bizarre convictions (e.g., that one's internal organs have been replaced with empty beer cans). Another category of psychotic symptoms comes under the rubric of a formal thought disorder, which refers to a disruption in the form, or organization, of thinking. Patients with a formal thought disorder may be incoherent; they may not be able to make sense of reality or to communicate their thoughts to others.

When called to see a patient with psychosis, the psychiatric consultant can be of immediate help by ensuring that patient and staff are safe; moreover, he or she can demystify this often-frightening condition. Psychosis can best be approached by proceeding with a well-ordered differential diagnosis, which transforms the patient's condition in the eyes of medical staff from insanity, with all its disturbing connotations, to a more comprehensible disorder of brain function.

DIAGNOSTIC EVALUATION

It cannot be stressed enough that the presence of psychotic symptoms does not always mean that a primary psychiatric disorder like schizophrenia is present. Therefore, the diagnostic assessment of a psychotic patient begins with a thorough consideration of toxic or medical conditions that can present with psychosis (Table 12–1).[1,2] A medical history, review of systems, family history, and physical examination are crucial elements of this process because most organic causes can be identified on this basis. A bedside examination of cognitive function should be performed. The Mini-Mental State Examination supplemented by the clock drawing test will usually suffice as an initial cognitive screen. Serious deficits in attention, orientation, and memory suggest delirium or dementia rather than a primary psychotic illness. Careful delineation of the temporal course of psychotic symptoms is of particular importance. One should consider whether the disorder is chronic, episodic, or of recent onset. The pattern of psychotic symptoms should be examined to determine whether a mood disorder, substance abuse, medication use, or medical or neurological illness is present. Substance abuse, such as intoxication with stimulants, is a frequent and reversible cause of psychosis. Many medications have the potential to cause psychosis; unfortunately, causality is often difficult to prove (Table 12–2). Such drug-induced psychoses should be considered if the psychosis is of new onset, if there is no personal history of psychosis, or if the psychosis starts in the hospital, particularly if a delirium is present. A urine toxicologic screening test might identify unsuspected drug use, but it would not rule out drug-induced psychosis if it were negative, nor would a positive toxicologic screening test necessarily establish a cause for the psychosis, because co-morbid substance use and abuse is common in psychotic disorders. Routine testing includes determination of a sedimentation rate, a complete blood cell count, serum electrolytes, urinalysis, and levels of calcium, glucose, creatinine, and blood urea nitrogen. In addition, liver function tests, thyroid function tests, and syphilis serology (specific, such as the fluorescent treponemal antibody absorption test), are appropriate. Human immunodeficiency virus (HIV) testing should be recommended.[3] Extended work-ups may include karyotyping for chromosomal abnormalities or urine testing for metabolic disorders.[4] The diagnostic yield from neuroimaging of the brain (magnetic resonance imaging or computed tomography) is low in the absence of localizing neurological findings.[5] Neuroimaging should be obtained, however, in cases with atypical or unresponsive psychotic symptoms when psychotic symptoms first appear and should be considered even in cases with typical psychotic features, because the long-term costs and morbidity of this disorder are potentially quite high in relation to the expense of diagnostic procedures. The electroencephalogram (EEG) can be useful when evaluating a confused patient where a delirium is suspected or when a history of serious head trauma or symptoms suggestive of a seizure disorder are present.[6–8] An EEG is rarely helpful if it is employed as a routine screening procedure. Similarly, a

TABLE 12–1 Selected Medical Conditions Associated with Psychosis

CNS, Central nervous system; *HIV*, human immunodeficiency virus; *SSPE*, subacute sclerosing panencephalitis; *VCFS*, velo-cardio-facial syndrome.

lumbar puncture is not necessary for a routine work-up, but it can be lifesaving if a treatable central nervous system (CNS) infection is suspected.

Several neuropsychiatric disorders in particular should be considered during the diagnostic work-up of a patient with psychosis.[9] Huntington's disease is suggested by family history of Huntington's disease, dementia, and choreiform movements; psychotic symptoms may occur before motor and cognitive symptoms become prominent.[10] Neuroimaging may be necessary to establish the diagnosis in some cases. Parkinson's disease also may present with psychosis, along with bradykinesia, tremor, rigidity, and a festinating gait. The diagnosis of Parkinson's disease can be complicated by exposure to neuroleptics—review of the time course of neurologic symptoms in relation to the use of antipsychotics should clarify this diagnostic possibility.[11] Wilson's disease may also present with psychotic symptoms, tremor, dysarthria, rigidity, and a gait disturbance.[12,13] Kayser–Fleischer rings, which are golden brown deposits that encircle the cornea, are pathognomonic for this disease. The diagnosis can be confirmed by measuring concentrations of ceruloplasmin in the urine and serum. Finally, acute intermittent porphyria is characterized by acute episodes of abdominal pain, weakness, and peripheral neuropathy; this condition may be associated with psychosis.[14,15] Because this is a hereditary (autosomal dominant) illness, a family history often points to this diagnosis. During acute attacks, levels of δ-aminolevulinic acid and porphobilinogen are elevated in the urine.

It is of course impossible to rule out all possible diseases that could potentially cause psychosis. Thankfully, a thoughtful approach that combines clinical history and a physical examination (including a neurologic examination) with selected laboratory tests will usually suffice to exclude treatable medical illnesses and provide a medical baseline for future reference.[16] Table 12–3 suggests one screening battery that accomplishes these important initial diagnostic goals.

After an organic cause has been ruled out, the psychiatric differential diagnosis of psychosis flows from the diagnostic criteria contained in the Psychotic Disorders section of the *Diagnostic and Statistical Manual of Mental Disorders*,

TABLE 12–2 Substances Associated with Psychosis

DRUGS OF ABUSE

Associated with Intoxication
Alcohol
Amphetamine
Anabolic steroids
Cannabis
Cocaine
Hallucinogens: LSD, MDMA
Inhalants: glues and solvents
Opioids (meperidine)
Phencyclidine (PCP), ketamine
Sedative-hypnotics (including withdrawal): barbiturates and benzodiazepines

Associated with Withdrawal
Alcohol
Sedative-hypnotics

Medications (Broad Classes with Selected Medications)
Anesthetics and analgesics (including NSAIDs)
Anticholinergic agents and antihistamines
Antiepileptics (with high doses)
Antihypertensive and cardiovascular medications (e.g., digoxin)
Antiinfectious medications (antibiotics [e.g., fluoroquinolones, TMP/SMX], antivirals [e.g., nevirapine], tuberculostatics [e.g., INH], antiparasitics [e.g., metronidazole, mefloquine])
Antiparkinsonian medications (e.g., amantadine, levodopa)
Chemotherapeutic agents (e.g., vincristine)
Corticosteroids (e.g., prednisone, ACTH)
Interferon
Muscle relaxants (e.g., cyclobenzaprine)
Over-the-counter medications (e.g., pseudoephedrine, caffeine in excessive doses)

Toxins
Carbon monoxide
Heavy metals: arsenic, manganese, mercury, thallium
Organophosphates

Key Diagnostic Questions to Determine Causality between a Substance and Psychosis
Does the patient have a history of psychosis?
Does the patient have a history of illicit drug use?
Did the psychosis start after a medication was started? After the patient came to the hospital?
Is there evidence of delirium?

ACTH, Adrenocorticotropic hormone; *INH*, isoniazid; *LSD*, d-lysergic acid diethylamide; *MDMA*, methylenedioxymethamphetamine; *NSAID*, nonsteroidal antiinflammatory drug; *TMP/SMX*, trimethoprim/sulfamethoxazole.

TABLE 12–3 Medical Work-up for First-Episode Psychosis

Physical exam with emphasis on neurologic exam
Vital signs
Weight and height (BMI), waist circumference
Electrocardiogram (ECG)

Laboratory Tests

Broad screening and medical baseline:
Complete blood count (CBC)
Electrolytes including calcium
Renal function tests (BUN/creatinine)
Liver function tests
Erythrocyte sedimentation rate (ESR)
Antinuclear antibody (ANA)
Fasting glucose
Fasting lipid profile
Consider prolactin level
Hepatitis C (if risk factors are present)
Pregnancy test (in women of childbearing age)
Urine drug screen

Exclude specific treatable disorders:
Thyroid stimulating hormone (TSH)
Fluorescent treponemal antibody absorbed (FTA-ABS)
HIV test
Ceruloplasmin
Vitamin B_{12}

Neuroimaging
MRI (preferred over CT)

Ancillary Tests
Expand etiological search if indicated, taking into account epidemiology: e.g., chest x-ray, electroencephalogram (EEG), lumbar puncture, karyotype, heavy metal testing, Lyme antibodies
Expand medical monitoring if indicated: e.g., eye exam (if risk factors for cataracts are present)

Modified from Freudenreich O, Schulz SC, Goff DC: Initial medical work-up of first-episode psychosis: a conceptual review, *Early Interv Psychiatry* 3:10–18, 2009.

Fourth Edition, Text Revision (DSM-IV-TR).[17] It should be emphasized, however, that these criteria are guidelines for diagnosis; they are to be used only in conjunction with a full understanding of the descriptions of disorders contained in the text (Table 12–4). A clear, longitudinal view of the illness is necessary to identify affective episodes and to determine whether the patient's level of function has declined. In addition, the range and severity of psychotic and negative symptoms must be determined and a judgment made as to whether delusional beliefs are bizarre or plausible.

Psychotic patients are often unable to provide an accurate history; therefore information must be collected from as many sources as possible. In one study, information necessary for diagnosis, such as the presence of persecutory delusions, was missed more than 30% of the time when the assessment was based on the interview only.[18] Concurrent substance abuse is also frequently missed in patients with schizophrenia if toxicologic screening is not performed.[19]

If major depression and mania are not present and have not played a prominent role in the past, the diagnosis is likely to be schizophrenia, delusional disorder, or schizotypal personality disorder (depending on the severity of the illness). To meet criteria for schizophrenia, the patient must have demonstrated a decline in function and displayed, for at least 4 weeks, symptoms of the active phase, which can consist of either bizarre delusions or typical auditory hallucinations (voices conversing or keeping up a running commentary). If neither of these psychotic symptoms is present, the active phase criteria can also be met by the presence of any two of the following: nonbizarre delusions, less typical hallucinations, disorganized speech,

TABLE 12–4 Psychiatric Disorders That May Present with Psychosis

Continuous Psychosis
Schizophrenia
Schizoaffective disorder, bipolar type (with prominent episodes of mania)
Schizoaffective disorder, depressed type (with prominent depressive episodes)
Delusional disorder (plausible, circumscribed delusions)
Shared psychotic disorder (in which delusions are induced by another person)
Episodic Psychosis
Depression with psychotic features
Bipolar disorder (manic or depressed)
Schizophreniform disorder (<6 mo duration)
Brief psychotic disorder (<1 mo duration)
Key Diagnostic Questions
Has a reversible, organic cause been ruled out?
Are cognitive deficits prominent? (delirium or dementia)
Is the psychotic illness continuous or episodic?
Have psychotic symptoms (active phase) been present for at least 4 weeks?
Has evidence of the illness been present for at least 6 months?
Is there evidence of a decline in level of functioning?
Are negative symptoms present?
Are mood episodes prominent?
Have there been episodes of major depression or mania?
Do psychotic features occur only during affective episodes?

disorganized behavior, or negative symptoms. Negative symptoms of schizophrenia fall into two main clusters: a cluster of reduced affective experience or expression (i.e., affective blunting and alogia) and an amotivation cluster (i.e., avolition, anhedonia, and asociality).[20] The diagnosis of schizophrenia is made only after evidence of the illness has been present for at least 6 months—if symptoms have been present for less than 6 months, the provisional diagnosis of schizophreniform disorder is used. Patients whose psychotic symptoms remit within 4 weeks of their onset are diagnosed as having a brief psychotic disorder if no organic cause is identified.

If the patient's condition does not meet the criteria for schizophrenia or schizophreniform disorder, but a nonbizarre (plausible) delusion is present, the diagnosis of delusional disorder is made, provided that the patient does not exhibit severe deterioration in function outside of the circumscribed delusional system. Typical delusions include the belief that one has a physical defect or medical condition or that one is being followed, poisoned, infected, loved by a famous person, or cheated on by a spouse. Patients who do not meet the active phase criteria for schizophrenia but who present with chronic, bizarre, or idiosyncratic thoughts or behaviors are classified as having schizotypal personality, which probably is a less severe form of schizophrenia.

If the patient meets criteria for major depression and has exhibited psychotic symptoms only during episodes of depression, the diagnosis is major depression with psychotic features. If psychotic features characteristic of schizophrenia have also occurred during periods when the patient was euthymic, the illness is classified as schizoaffective disorder, depressed type if depressions have been prominent throughout the course of the illness, or schizophrenia with superimposed depression if depressions have been infrequent. Patients who have experienced manic episodes and who have been psychotic only during affective episodes are diagnosed as having bipolar disorder. If psychosis has been present between manic and depressive states, the diagnosis is schizoaffective disorder, bipolar type, or schizophrenia with superimposed mood disorder; again, the diagnosis depends on how prominent a role affective episodes have played in the overall course of the illness. The proper psychiatric diagnosis of a patient who is psychotic on a cross-sectional examination requires an intimate knowledge of the patient's longitudinal course, something that is often unavailable during an inpatient admission.

CLINICAL PICTURES AND CORRESPONDING PROBLEMS ON THE MEDICAL WARD

It is often surprising to see that psychotic patients do perfectly well when admitted to a medical or surgical service; they tend to require little in the way of special treatment. One survey found that only half of patients with schizophrenia admitted to a general hospital required psychiatric consultation.[21] Interestingly, the most common reason for a psychiatric consultation in patients with schizophrenia admitted to the medical service of the Massachusetts General Hospital was "schizophrenia" (30%); there was no specific question. This may reflect a concern that is evoked by managing a patient with schizophrenia.[22] Other referrals revolve around depression (16%), capacity assessment (14%), and help with prescription of psychotropic medications (10%). For patients with psychotic disorders, the role of the consultation psychiatrist in the general hospital can be seen as threefold: conducting conventional consultations with an emphasis on making a correct diagnosis and instituting proper treatment, educating staff about the nature of schizophrenia, and serving as an advocate for the chronically mentally ill so that they can receive standard and comprehensive medical care.[23,24] In one chart review study, patients with schizophrenia who needed a medical or surgical admission had higher rates of complications in the form of infections and postoperative complications compared to patients who did not carry a schizophrenia diagnosis.[25] Effective consultation and advocacy could thus have real-life implications for some patients with schizophrenia.

The specific form of illness that a patient with schizophrenia manifests determines the nature of the staff's concerns as well as the staff's level of comfort. Studies have demonstrated that the symptoms of schizophrenia tend to cluster into at least three groups: reality distortion (e.g., delusions and hallucinations), disorganization (e.g., formal thought disorder and inappropriate affect), and negative symptoms (e.g., apathy, anhedonia, social withdrawal, alogia, and flat affect).[26,27] A fourth symptom domain, cognitive deficits, has been rediscovered.[28] Schizophrenia was once known as dementia praecox because of its prominent cognitive problems. The majority of patients with schizophrenia display symptoms from all four categories and are

classified as having an undifferentiated type. Some patients, however, exhibit prominent symptoms from only one category, and the difficulties they encounter in the general hospital are determined by which cluster of symptoms predominates.

In all cases, a question can arise as to whether the patient is competent to make treatment decisions. Some patients may already have a guardian who must be involved in treatment decisions; if not, assessment for competency and initiation of appropriate legal steps may be necessary to ensure proper medical treatment. It is crucial to assess to what degree, if at all, delusions affect the patient's decision-making. The consultant should make it clear that patients with psychosis may have the capacity to make certain decisions, such as weighing risks and benefits of proceeding with or refusing medical treatment, even when their judgment is impaired in other realms. The idiosyncratic speech manifest by some patients may give an exaggerated impression of cognitive impairment, whereas their capacity to understand aspects of their medical condition may be adequate.

The Paranoid or Delusional Patient

Patients with schizophrenia whose symptoms are restricted to complex delusional systems and hallucinations are classified as having the paranoid type, even when their delusions are not persecutory in nature. In the absence of overt disorganization and negative symptoms, individuals with paranoid schizophrenia may go unnoticed by hospital staff. These patients often conceal all psychiatric symptoms and fail to exhibit the bizarre appearance and speech that attract attention in others with schizophrenia. Patients with paranoid schizophrenia may antagonize nursing staff because of their anger, argumentativeness, or patronizing manner. Nursing staff often appreciate learning that these annoying characteristics are actually common features of the illness. Despite complex and bizarre delusional beliefs, these individuals may elude detection and complete a medical or surgical hospitalization without incident. Difficulties arise when circumstances in the hospital collide with an individual's delusions. The patient who believes that the Mafia is attempting to kill him may refuse all hospital food for fear of being poisoned. Others become convinced that their physicians are members of the conspiracy that is plotting against them or that the surgeons have implanted a microchip intended to control or monitor their thoughts. To assess safety and to anticipate potential problems with compliance, the psychiatric consultant must understand the full scope of the person's delusional system and the nature of any hallucinatory experiences.

Because paranoid patients usually are reluctant to reveal their delusional beliefs, the consultant must proceed carefully and deliberately. A direct, interrogatory approach often convinces the patient that conspirators sent the interviewer. Because delusional individuals are preoccupied and distressed by their delusional beliefs, it is usually sufficient to engage them in a neutral, nonthreatening discussion about their current interests and activities. Comments that seem out of place or inappropriate to the content may provide clues as to the subject of the delusional system, and these should be explored. Questions should never imply a judgment about psychopathology, but rather they should demonstrate the interviewer's interest and concern. Examples of such questions include, "Are you safe? Have you noticed any strange coincidences? Are you aware of anyone trying to play with your mind? How do you understand what is happening to you? What is it that you overhear from others about this?" The interviewer should neither agree with the delusion nor attempt to reality-test—impartial interest and concern are usually a welcome relief to a delusional patient. This technique is sometimes called *partial joining of perspectives*.[29] Ideally, the consultant can serve as an intermediary, listening to the concerns of both the patient and the hospital staff; as a consequence he or she can mediate misunderstandings.

In addition to persecutory delusions, somatic delusions may also pose unique problems for the patient with schizophrenia admitted to a medical service. In a retrospective chart survey, McGilchrist and Cutting found that more than half of patients with schizophrenia described somatic delusions.[30] These delusions were typically bizarre (such as the belief that a third arm is growing out of one's chest) and could usually be immediately recognized as delusional. Having heard a patient's somatic delusions, however, medical staff tend to discount other somatic complaints. The consultant may be needed to help sort out which physical complaints merit further investigation by hospital staff and which delusional concerns are best ignored.

The Disorganized Patient

The disorganized patient can be problematic on a medical service. Disordered speech may make communication about medical symptoms difficult and may interfere with discussions about treatment options. If disorganization is subtle, the patient may merely appear stubborn or oppositional, and make routine nursing tasks difficult. One major area of concern for disorganized patients is their lack of judgment and behavioral control. These patients may engage in inappropriate behaviors (such as masturbating or disrobing in public, stealing food, and smoking in restricted areas). Of even greater concern is the occasional violent or self-injurious behavior of an agitated, disorganized patient. These patients typically require aggressive pharmacotherapy and may require physical restraints or round-the-clock attendants. A review of past behavioral problems, which can be provided by outpatient caregivers or family, can help the consultant anticipate behavioral problems that are likely to arise during a medical or surgical hospitalization.

The Patient with Negative Symptoms or Neurocognitive Deficits

Individuals with schizophrenia who display prominent negative symptoms may encounter unique difficulties when admitted to medical or surgical services. Moreover, negative symptoms are often compounded by cognitive deficits, particularly in the realms of sustained attention, memory, and executive function. Patients may seem indifferent to their medical problems and unappreciative of their care. Nursing staff can easily be put off by the poor hygiene and soiled clothing. Sustaining empathy and enthusiasm for the care of a withdrawn, unmotivated patient can require unusual

efforts by nursing staff. This process may be facilitated by the psychiatric consultant, who can explain that poor hygiene, apathy, and deficits in interpersonal skills are symptoms of illness that require management and that should not be interpreted as willful or as a weakness of character. Often if the consultant can provide a description of the patient as a vibrant, healthy young adult before onset of the illness, nursing staff can find it easier to empathize. When ongoing treatment or rehabilitation is required after discharge, a comprehensive plan should be developed to provide supervision for avolitional patients, who otherwise would be unlikely to follow through with treatment. If little history about the patient's baseline level of function is available, it is important to rule out other causes of negative symptoms, such as a hypoactive delirium or a seizure disorder.[31]

The Manic Patient

Although psychotic features in patients with schizophrenia are typically bizarre and idiosyncratic, patients who are manic are much more likely to present with grandiose delusions that typically impair judgment and self-esteem. These patients may be difficult to manage because of their boundless energy and their grandiose misinterpretation of their situation. Staff may at first mistake mania for unusually high energy, talkativeness, and positive self-esteem; eventually they turn to the psychiatric consultant when the patient refuses to stop pacing or to stop talking to other patients late at night, or when he or she is belligerent or insists that he or she is free of any medical problems. Patients with irritable or dysphoric mania may present with persecutory delusions and can be superficially indistinguishable from a patient with paranoid schizophrenia. Management of the manic patient should begin with containment and isolation from distracting stimuli and behavioral temptations. Short-term behavioral control can be achieved with use of antipsychotics in combination with benzodiazepines, whereas the ultimate goal of sustained remission with the prevention of relapse requires a therapeutic blood level of lithium carbonate, valproic acid, or another mood stabilizer.[32]

The Psychotic Depressed Patient

The delusions of the psychotically depressed patient usually reflect ruminative concerns about guilt, worthlessness, or physical decrepitude. These patients may puzzle their medical or surgical caregivers with somatic delusions involving fanciful disease or dysfunction. Their overwhelming sense of hopelessness and sense of being responsible for their plight may also interfere with attempts to involve them in treatment decisions—they may seem more interested in euthanasia. Some psychotically depressed patients withdraw and may become mute. Persecutory delusions also occur in psychotic depression, but these beliefs tend to be less bizarre than those encountered in patients with schizophrenia. In fact, it may be quite difficult to discern whether strangers are actually attempting to break into the patient's house or whether family members are stealing the elderly aunt's savings. Treatment of psychotic depression typically requires either a course of electroconvulsive therapy or the use of an antipsychotic agent, plus an adequate dose of an antidepressant.[33]

The Elderly Psychotic Patient

Psychotic symptoms are relatively common among the medically ill or disabled elderly. One survey found that 21% of newly admitted nursing home patients were delusional, and approximately 4% of elderly individuals in the community suffer from persecutory delusions.[34] Isolation and sensory impairment probably contribute to the higher incidence of paranoia and agitation in the elderly. *Late paraphrenia* is an older term still used to describe such patients.[35] In addition, such individuals are at particular risk for a host of organic causes of psychosis, including dementia, medication toxicity, and depression. Late-onset schizophrenia, which occurs after the age of 45 and may first present in old age, usually occurs in women and appears as a paranoid psychosis.[36] Psychotic symptoms are quite common in patients with Alzheimer's disease; approximately one third of patients with Alzheimer's disease develop paranoid delusions, and 7% develop auditory hallucinations.[37] Management of psychosis in the elderly involves first and foremost a comprehensive screening for organic causes, plus supportive measures and the judicious use of antipsychotics. Supportive measures should be individualized but include reassurance, visits from family to alleviate isolation, strategies to maintain the sleep–wake cycle, and measures to compensate for sensory or cognitive deficits, such as providing clear and repeated instructions, to counteract misinterpretation of reality. If antipsychotics are used to treat the psychosis of Alzheimer's disease, clinicians face two problems. For one, antipsychotics must be used with great care, because they increase the risk of death in this population.[38,39] Moreover, antipsychotics might have limited efficacy for the neuropsychiatric complications of Alzheimer's disease (e.g., agitation and psychosis).[40,41]. Unfortunately, safer or more effective options may not always be available.

MANAGEMENT OF PSYCHOTIC PATIENTS

General Considerations

As has been emphasized, the first step in approaching the treatment of a psychotic patient is to clarify the diagnosis, along with any prior psychotropic medication use. Delirium, which is characterized by fluctuations in mental status and by confusion, must be recognized and the underlying cause addressed. The pharmacological management of delirium is described in Chapter 10. Specific information about individual antipsychotic agents and drug–drug interactions is provided in Chapter 34.

Target symptoms for antipsychotics fall into three categories: (1) psychotic symptoms (e.g., hallucinations, delusions, and disorganization), (2) agitation (e.g., distractibility, affective lability, tension, and increased motor activity), and (3) negative symptoms (e.g., apathy, flat affect, social isolation, and poverty of speech). The pharmacologic treatment of psychotic symptoms is similar in many ways to the treatment of infection with antibiotics—the clinician needs to choose the proper medication at a sufficient dose and then await therapeutic results while monitoring side effects. Contrary to common wisdom, a response to antipsychotics can often be seen after a few days or even after a single dose, particularly for agitation.[42]

Psychotic symptoms and agitation usually improve with antipsychotics, regardless of cause. Most causes of organic psychosis, such as stimulant intoxication (e.g., amphetamines and cocaine), respond readily to antipsychotics. The decision whether to use an antipsychotic in cases of organic psychosis should be informed by a weighing of the anticipated duration and severity of the psychosis and the potential side effects of the drug. When time-limited psychoses, such as those produced by psychoactive substances, are treated with an antipsychotic, care should be taken that this medication not be continued indefinitely after the patient is discharged from the hospital, particularly if a conventional neuroleptic is used; the risk of irreversible tardive dyskinesia (TD) must be considered.

Drug Selection

Selection of an antipsychotic agent is usually guided by efficacy considerations, side-effect profiles, and available formulations (i.e., tablet, rapidly-dissolving wafer, liquid, IM, IV, or depot preparations). First-generation antipsychotics, which act by blocking dopamine D_2 receptors, are of similar efficacy and differ primarily in their potency (i.e., the dose required for their clinical effect) and in their side effects.[43] Second-generation antipsychotics were developed based on the observation that clozapine, though an effective antipsychotic, did not cause extrapyramidal symptoms (EPS).[44] However, four large randomized treatment trials known by their acronyms, CATIE, CUtLASS, TEOSS, and EUFEST have been unable to clearly establish superior efficacy of second-generation antipsychotics as a class.[45–49] It has, however, become clear that not all second-generation antipsychotics are alike; each drug needs to be considered individually.[50] Clozapine remains the gold standard with regard to efficacy; of the other second-generation agents, evidence suggestive of enhanced efficacy is strongest for olanzapine.[51]

Although now controversial, use of the first-generation antipsychotics rapidly declined during the past decade as second-generation antipsychotics were introduced. High-potency, first-generation agents continue to have their strongest support in the short-term treatment of medically compromised agitated patients; they have been relatively free of serious medical side effects. An additional role for first-generation antipsychotics is in the treatment of patients for whom compliance is a problem. Currently, haloperidol and fluphenazine are available in depot (long-acting) IM formulations, in addition to long-acting risperidone. As many as 70% of patients with schizophrenia do not take their medications as prescribed, in part because of ongoing substance use, medication side effects, and a lack of insight, but also because of a poor response to treatment.[52,53] We could be seeing a reassessment of selected first-generation antipsychotics, like perphenazine and molindone, that served as comparators in recent trials and demonstrated good efficacy and tolerability, comparable to second-generation antipsychotics. Molindone is particularly attractive because it does not cause weight gain in most patients.[47] The issue of TD remains a concern, however.

If a patient has been taking an antipsychotic with good results, it is best not to make changes in the regimen unless medical problems or potential drug interactions necessitate a switch. Exacerbations in otherwise stable patients, particularly if related to stress and accompanied by depressive symptoms, usually improve without altering the medication or raising the dosage.[54]

First-Generation Antipsychotics

Low-potency first-generation antipsychotic agents like chlorpromazine (CPZ) are often prescribed in dosages of 300 to 600 CPZ mg-equivalents/day; they are associated with orthostatic hypotension, anticholinergic side effects, sedation, and weight gain, and they are less readily or safely administered in a parenteral fashion.[43] Thioridazine, which can produce substantial QT interval prolongation, has been discontinued by the manufacturer of the brand name product. High-potency agents, such as haloperidol, are more likely to produce EPS, such as acute dystonias, parkinsonism, and akathisia (see later discussion), except when administered intravenously. Haloperidol is available for parenteral (including IV) administration. In the setting of serious medical illness, particularly if other medications with anticholinergic or hypotensive side effects are being administered, haloperidol is typically the antipsychotic of choice. It is important to minimize the small risk of torsades de pointes from parenteral haloperidol by reducing risk factors for it (e.g., hypokalemia) and by tracking the QTc. Although considerable inter-individual variability exists, daily oral doses of haloperidol between 5 and 15 mg are adequate for the vast majority of patients; increasing the dose beyond the dose range may only aggravate side effects without improving antipsychotic efficacy. IM and IV administration tends to require roughly half the dose. In the elderly, 0.5 mg to 2 mg of haloperidol at bedtime may be sufficient. If a patient has not previously received an antipsychotic, it is best to start with a low dose (e.g., haloperidol 2 to 5 mg orally) before increasing it to a standard therapeutic dose.

Extrapyramidal Side Effects and Tardive Dyskinesia

Younger patients (i.e., those younger than 40 years of age) started on high-potency first-generation antipsychotics are especially vulnerable to developing an acute dystonic reaction during the first week of treatment.[55] Dystonia, the sudden constriction of muscles, is a frightening and uncomfortable experience; when manifest as a laryngeal spasm, it can be life-threatening. The occurrence of dystonia early in treatment jeopardizes future compliance with antipsychotics; therefore it is important to anticipate and treat this side effect aggressively. Prophylaxis with an anticholinergic agent, such as benztropine 1 to 2 mg twice daily, substantially reduces the likelihood of a dystonic reaction even in a high-risk patient.[56] Dystonia is less common with the use of second-generation agents than with first-generation high-potency agents; moreover, it probably does not occur with either quetiapine or clozapine.

Akathisia is an extremely unpleasant sensation of motor restlessness that is primarily experienced in the lower extremities in patients who receive an antipsychotic medication. For the psychotic patient hospitalized on a medical service, akathisia can make bedrest unbearable. Akathisia

substantially increases the risk that a patient will leave the hospital against medical advice, and it has been associated with self-injurious behaviors as well as with a worsening of psychosis. Untrained staff frequently mistake akathisia for psychotic agitation, which leads to unfortunate escalations of antipsychotic doses. For patients in acute distress, diazepam 10 mg can provide immediate relief. For the long-term management, dose reduction may improve akathisia; if relief is not obtained, propranolol (10 to 20 mg two to four times daily) is often helpful. Even more effective is a switch to a second-generation antipsychotic, which usually resolves the problem.

Antipsychotic-induced parkinsonism can easily be mistaken for depression or for the negative symptoms of schizophrenia.[57] The presence of tremor and rigidity distinguishes this side effect in more severe cases; subtle cases can easily be missed. Parkinsonian side effects commonly improve with a reduction of the neuroleptic dosage or with addition of an antiparkinsonian agent (e.g., benztropine 1 to 2 mg twice daily or amantadine 100 mg two or three times daily). Because anticholinergic agents impair attention and memory and can produce a vast array of troublesome side effects in the elderly, long-term use of these agents should be avoided.[58] Second-generation antipsychotics as a class produce substantially fewer parkinsonian side effects; both clozapine and quetiapine are essentially free of EPS, which makes them the drugs of choice for patients with idiopathic Parkinson's disease complicated by psychosis.[59]

Tardive dyskinesia rarely appears after less than 6 months of treatment with an antipsychotic; once present, TD may be irreversible.[60] TD usually takes the form of involuntary, choreiform movements of the mouth, tongue, or upper extremities, although a dystonic form has also been described.[61] Studies suggest that the risk for developing TD with first-generation agents is approximately 5% per year of exposure, with a lifetime risk possibly as high as 50% to 60%.[62] The incidence of TD is much higher in the elderly, although a substantial proportion of these cases may represent spontaneously occurring dyskinesias.[63] As part of informed consent, patients requiring prolonged antipsychotic treatment with first-generation agents should be educated about the risk of developing TD after their acute psychosis has been treated and before 6 months has elapsed. Preliminary evidence that indicated α-tocopherol (vitamin E), at dosages of 400 to 1200 IU daily, improved symptoms of TD was not supported by a much larger controlled trial, and the best treatment for TD is prevention.[64] Clozapine has not been linked to TD; switching a patient from a conventional agent to clozapine increases the likelihood of improvement in TD.[65] Lowering the dose of a conventional antipsychotic or switching to an atypical agent can occasionally produce a "withdrawal dyskinesia," which typically resolves within 6 weeks, or may unmask an underlying dyskinesia that was previously suppressed by the antipsychotic.[66]

Second-Generation Antipsychotics

Second-generation antipsychotics as a class produce fewer neurologic side effects (e.g., dystonia, akathisia, and parkinsonism) than first-generation agents; they are also associated with less TD (about 0.8% per year).[67] In this class, risperidone is most likely to induce EPS, particularly at dosages higher than 6 mg/day. It is important to appreciate that second-generation antipsychotics differ substantially with regard to other side effects. Risperidone and its active and marketed metabolite, 9-hydroxyrisperidone (paliperidone) are unique among the second-generation agents because of their propensity to produce hyperprolactinemia.[43] Aripiprazole by contrast can lower prolactin levels.[68] Clozapine and olanzapine have been associated with substantial weight gain that can be a major obstacle to adherence. Risperidone and quetiapine are associated with intermediate weight gain, and ziprasidone and aripiprazole appear to produce little or no weight gain.[69] Considerable research over the past decade has focused on the effects of second-generation antipsychotics on glucose metabolism and lipids. The observed insulin-resistance and dyslipidemia are only in part explained by weight gain, and some antipsychotics seem to directly affect metabolism.[70] Despite differences in the propensity to cause metabolic side effects, it is recommended that all patients who receive second-generation antipsychotics be carefully monitored, with particularly close monitoring of patients at higher risk (e.g., family history of diabetes; clozapine or olanzapine treatment).[71]

Olanzapine and aripiprazole have few or no cardiac effects, and they can safely be initiated at a full therapeutic dose. Clozapine, risperidone, quetiapine, and ziprasidone have alpha-adrenergic effects that necessitate dose titration to avoid orthostatic hypotension; paliperidone can be given without titration. Clozapine produces the most hypotension and tachycardia. Ziprasidone appears to prolong the QT interval more than other atypical agents, but less than thioridazine.[72] Serious cardiac events have been rare in patients treated with ziprasidone (not differing from placebo in registration trials), and reported cases of overdose have been benign. However, ziprasidone's effect on cardiac repolarization may be problematic in the presence of underlying heart disease or when it is added to other agents with similar effects. Potential cardiac toxicity remains a clinical concern with all antipsychotics, however. A large retrospective cohort study did not find a difference between first- and second-generation antipsychotics in associated risk for sudden death.[73] Instead, both classes produced a dose-related increase in risk for sudden death.

Clozapine, although clearly possessing unique antipsychotic efficacy, can produce many bothersome and even potentially lethal side effects, including agranulocytosis (in approximately 1% of patients), sialorrhea, weight gain, hypotension, tachycardia, seizures, impairment of esophageal and bowel motility, and urinary incontinence.[43] Clozapine has also been linked to cardiomyopathy, pericarditis, and pulmonary embolism. Despite the list of potentially serious medical complications, clozapine was found in one study to decrease mortality; this net positive effect on mortality rates probably reflects the magnitude of its protective effect against suicide in contrast to its relatively low frequency of serious adverse effects.[74] However, any potential protection from death due to suicide has to be weighed against the possibility of a premature death from cardiovascular disease for the individual patient.[75,76]

If a patient is to be started or restarted on clozapine, a colleague with experience in the use of this agent should be

consulted to clarify the system for monitoring white blood cell counts and to outline strategies for the initiation and optimization of the dosage of this unique agent. Clozapine treatment should not be interrupted when patients are admitted to a medical or surgical service because abrupt discontinuation has been associated with acute worsening of psychosis and with cholinergic rebound. If clozapine has been discontinued for more than 4 days, clozapine should be reintroduced at a low dose and titrated upward toward the patient's previous optimal dose.

Treating Agitation

Usual therapeutic doses of antipsychotics do not always treat agitation associated with psychosis successfully. Benzodiazepines can effectively enhance the tranquilizing effect of antipsychotics or be used alone for the treatment of agitation.[77–79] Lorazepam can be combined (in the same syringe) with haloperidol for acute behavioral control—usually 1 mg of lorazepam is given with 5 mg of haloperidol intramuscularly. Once agitation is controlled, the patient can be started on a usually therapeutic dose of an antipsychotic, with a benzodiazepine (e.g., lorazepam 1 to 2 mg) given as needed or as a standing order two to three times daily for as long as is needed. Typically, as the psychotic symptoms improve with use of an antipsychotic, use of a benzodiazepine often becomes unnecessary. Alternatively, several second-generation antipsychotics (i.e., aripiprazole, olanzapine, and ziprasidone) are available for IM use for the control of agitation.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a rare, potentially lethal complication of neuroleptic treatment characterized by hyperthermia, rigidity, confusion, diaphoresis, autonomic instability, elevated creatine phosphokinase (CPK), and leukocytosis. Although the first symptoms of NMS may involve mental status changes, the syndrome may evolve gradually and culminate in fever and an elevated CPK. NMS probably occurs in fewer than 1% of patients who receive conventional antipsychotics, although subsyndromal cases may be much more common.[80,81] Parallels have been drawn between NMS and malignant hyperthermia (which results from general anesthesia), largely on the basis of common clinical characteristics. Patients with a history of either NMS or malignant hyperthermia, however, do not appear to be at increased risk for developing the other syndrome, and analysis of muscle biopsy specimens has not consistently demonstrated a physiological link between the two conditions. Lethal catatonia is a spontaneously occurring syndrome that may be indistinguishable from NMS and that has been described in the absence of neuroleptic treatment.[82] In addition, antipsychotic agents may impair temperature regulation and so may produce low-grade fever in the absence of other symptoms of NMS.[83] The clinician's immediate response to NMS should be to discontinue antipsychotic medications and hospitalize the patient to allow for IV fluids and cooling. Whether bromocriptine or dantrolene facilitates recovery remains the subject of debate. It is important that reinstitution of antipsychotics be delayed until at least 2 weeks after the episode of NMS has resolved.[84] NMS has been associated with use of clozapine and other second-generation antipsychotics.[85] It has been suggested that a variant of NMS without rigidity may result from use of second-generation antipsychotics; although if such a syndrome occurs, it is probably quite rare, and typical presentations (i.e., with muscular rigidity) are to be expected.

Drug Interactions with Antipsychotic Agents

Antipsychotic drugs interact with other medications as a result of alterations of hepatic metabolism and combined use of drugs with additive side effects (such as anticholinergic effects or impairments of cardiac conduction). Most conventional antipsychotics are extensively metabolized by the 2D6 isoenzyme of the hepatic P450 enzyme system, whereas atypical agents generally have more variable hepatic metabolism, typically involving isoenzymes 3A4, 1A2, and 2D6.[86] Fortunately, the therapeutic index (safety/risk ratio) of antipsychotic drugs is quite large, and interactions with agents that inhibit hepatic metabolism are unlikely to be life-threatening, but may increase side effects. Among the atypical antipsychotics, clozapine produces the most serious adverse effects when blood levels are dramatically elevated; obtundation and cardiovascular effects have been associated with inhibition of clozapine metabolism by fluvoxamine or erythromycin. Fluvoxamine, a selective serotonin reuptake inhibitor (SSRI), has been shown to quadruple clozapine plasma concentrations.[87] Some patients experience a doubling of clozapine blood levels when they quit smoking, along with sedation and worsening of other side effects. Addition of 2D6 inhibitors (e.g., SSRIs) to conventional antipsychotics would be expected to increase EPS, but in one placebo-controlled trial this was not clinically significant despite substantial increases in blood levels of haloperidol and fluphenazine.[88] Drugs that induce hepatic metabolism, such as certain anticonvulsants (e.g., carbamazepine, phenobarbital, and phenytoin), may lower blood concentrations of antipsychotics substantially and cause loss of therapeutic efficacy.[89]

Considerable inter-individual variability exists for the metabolism of antipsychotic drugs, even without the complication of drug interactions. Therapeutic plasma concentrations have been best established for haloperidol because it is the antipsychotic least complicated by active metabolites. Plasma concentrations between 5 and 15 ng/ml have been associated with an optimal therapeutic response.[90] Clozapine has been found to be effective at serum concentrations of between 200 and 300 ng/ml, although some patients might benefit from levels above 350 ng/ml.[91] The risk of toxicity, particularly seizures, is generally believed to be significant at levels above 1000 ng/ml.

Great care must be taken if low-potency agents (such as chlorpromazine or clozapine) are combined with other highly anticholinergic drugs because the additive anticholinergic activity may produce confusion, urinary retention, and constipation. In addition, low-potency antipsychotics can depress cardiac function and can significantly impair cardiac conduction when added to class I antiarrhythmic agents (such as quinidine and procainamide). Ziprasidone also significantly affects cardiac conduction and should not be combined with low-potency phenothiazines or with antiarrhythmic agents.

WORKING WITH THE PATIENT AND THE FAMILY

Patients with schizophrenia may be unable to directly express their fears or concerns; instead, they may exhibit anxiety or insomnia and may become increasingly delusional in the face of stress. Efforts to anticipate and answer a patient's unspoken fears about his or her medical status can greatly alleviate other symptoms, although this process may need to be repeated daily. Patients with schizophrenia may also lack the capacity to "filter out" extraneous stimuli in their environment and so may become easily overwhelmed or overly stimulated in a busy, chaotic environment.[92] Placing a patient with schizophrenia in as quiet and orderly a room as possible can help the patient retain a sense of control and foster reality testing. The patient's need for privacy should be respected, and nursing staff should be advised that some patients with schizophrenia do not respond to overly nurturing or seemingly intrusive attention.

Families of patients with schizophrenia can be an invaluable source of information in any setting; they can help establish the diagnosis and identify potential behavioral problems. Family members might have a clear idea if poor adherence or illicit drug use contribute to psychiatric problems. Patients are poor judges of cognitive problems and functional limitation, whereas family members can often provide an accurate picture of these domains.[93] Working with families is always important; it is arguably most important when the patient experiences or is recovering from his or her first psychotic episode. Education about the illness, a discussion about the use of medication, and identification of the early signs of relapse after remission can start in the hospital and help with the transition to outpatient care. Families need to know about the risk for suicide in schizophrenia because they could be the first ones to recognize that a patient is becoming hopeless or disillusioned after discharge. It has been well demonstrated that educating families about the illness and helping them develop reasonable expectations for their loved one with schizophrenia significantly improves the course of the illness and is time well spent.[94]

MORE PROBLEMS IN THE CARE OF PSYCHOTIC PATIENTS

Assessment of Dangerousness

The public has long associated mental illness with violence. However, any such link is complex, and having a mental illness per se does not predict violence.[95] Instead, clinicians need to assess well-established predictors of violence, particularly substance use and past violence, preferably not only by self-report which is unreliable.[96] Obviously, unmitigated psychosis can potentially result in acts of violence. Although assaultive behavior is probably more likely in disorganized patients as a result of impaired control of aggression, violent acts such as homicide, which involve planning or complex behaviors, are much more likely in patients with persecutory or religious delusions (when they are convinced that they have no alternative but to act violently—either to defend themselves or family or to obey God's command). Negative symptoms reduce the risk for violence because afflicted patients are less likely to initiate activity. Command hallucinations appear to increase the risk of violence only when the individual interprets the voices within a delusional system in such a way that the voices cannot be disobeyed.[97] For example, a patient may believe that it is God's voice giving orders to attack someone believed to be possessed by Satan. Although the potential for violence from disorganized or delusional patients is a cause for concern, homicide is actually committed by fewer than 1% of patients with schizophrenia.

Suicide is the main cause of premature death in patients with schizophrenia; 5% of patients with schizophrenia commit suicide and as many as 50% make an attempt.[98] In addition to delusions and hallucinations, depression and substance abuse are important risk factors for suicide. The consultant must explore carefully these risk factors as well as any history of violent or self-injurious behaviors. In patients at high risk for violence or suicide, the antipsychotic clozapine should be considered. Studies have shown a specific protective effect of clozapine on violence and suicide that may not be shared by other antipsychotics.[99,100]

Even in patients with schizophrenia and a history of violence, unusual diagnoses of concurrent illness like encephalitis need to be ruled out.[101] Regardless of its cause, in cases in which risk of violence or self-harm is ongoing in the hospital, patients must be monitored continuously. If safe, a sitter is preferred over use of restraints, but some situations require restraints for the safety of the patient, other hospital patients, and staff. However, the indication for restraint must be clear, and restraint has to be part of an overall treatment plan. Inappropriate restraint is not only unjust, but any restraint carries risks, such as deep vein thrombosis and death from pulmonary embolism.[102]

Pain Threshold in Schizophrenia

A large literature suggests that patients with schizophrenia may have dramatically elevated pain thresholds, which can obscure serious medical problems.[103] In one study, 21% of schizophrenic patients did not describe pain associated with a perforated peptic ulcer, and 37% felt no pain during acute appendicitis.[104] It has been estimated that more than 95% of the general public would experience excruciating pain with either condition. The mechanism underlying this often-dramatic analgesic effect remains unclear, but it does not appear to be the result of medication. It is important for the psychiatric consultant to make medical colleagues aware of this characteristic of patients with schizophrenia so that the existence of serious pathological processes is not dismissed because of an absence of typical manifestations of pain.

Polydipsia (Water Intoxication)

Polydipsia is defined as chronic or intermittent ingestion of large volumes of water; it is reported in 6% to 17% of chronically ill psychiatric patients. Polydipsia is most frequently diagnosed in patients with schizophrenia, in whom it generally appears 5 to 15 years after the onset of illness.[105] Polydipsia may lead to several complications, including bladder dilatation, enuresis, incontinence, hydronephrosis,

renal failure, and congestive heart failure. Approximately 25% to 50% of patients with polydipsia develop hyponatremia within the first 10 years of this condition. Often referred to as *water intoxication*, symptoms of polydipsia with hyponatremia include nausea, vomiting, blurred vision, tremors, cramps, ataxia, confusion, lethargy, seizures, coma, and death. Polydipsia with hyponatremia should be considered a serious complication of psychotic illness that requires careful evaluation and management. Acute care includes supportive treatment, fluid restriction, normal saline, and, in severe cases, use of hypertonic saline. Rapid correction of an abnormal serum sodium level is unwise, however, because it can lead to congestive heart failure and central pontine myelinolysis. A medical admission is often necessary until the serum sodium normalizes. Long-term management includes frequent monitoring of serum sodium concentrations and restriction of fluid intake when possible. Switching from conventional neuroleptics to clozapine may significantly improve polydipsia and hyponatremia in some patients.[106]

Medical Co-Morbidities

As a group, patients with schizophrenia carry a high burden of medical illnesses, including, among others, obesity, diabetes, cardiovascular disease, HIV infection, and hepatitis,[107] Cardiovascular disease has surpassed death from suicide as the primary contributor to an average reduction in life expectancy of two decades or more, a gap that seems to be worsening.[108] Unfortunately, part of the excess mortality is iatrogenic, because antipsychotics, regardless of class, can potentially contribute to cardiac deaths directly (i.e., from sudden death) and more indirectly via the development of cardiac disease (due to weight gain, diabetes, and dyslipidemia).[73,109] Appropriate attention to the medical care of patients with psychotic illnesses has emerged as an important mandate for psychiatrists.[110–112] A medical hospital admission provides an excellent opportunity to review the adequacy of medical treatment with emphasis on the highly prevalent metabolic syndrome (about 40% in one large sample), cardiovascular risk factors, and antipsychotic-related problems.[113–115] Patients who do not have a primary care doctor can be identified and linked with community providers.

Cigarette Smoking

Twenty years ago, approximately 85% of patients with schizophrenia smoked cigarettes, usually quite heavily.[116] However, more recent surveys show that patients with schizophrenia can successfully quit. In one cohort study, the rate of everyday smokers had dropped to below 50%.[117] For those patients who still smoke, quitting should be one of the most important health goals, particularly in the light of the aforementioned importance of cardiovascular disease. A hospital admission might provide a window of opportunity to motivate the patient for a quit attempt, particularly if the admission was predicated by smoking. During admission, nicotine dermal patches can provide some protection against nicotine withdrawal. Smoking reduces the drug levels of most antipsychotic drugs, particularly drugs that are metabolized by the 1A2 P450 enzyme system (e.g., olanzapine and clozapine). During lengthier hospital stays, the possible effects (e.g., an increase in EPS) of forced abstinence on drug metabolism should be considered[118]; this effect is not mediated by nicotine, but by tar products, and hence not reversed by nicotine patches.

Medication Adherence and Insight into Illness

One hallmark of schizophrenia is an often striking lack of insight into their mental illness: its symptoms, consequences, and need for treatment.[119] A psychotic patient who has just been involuntarily committed to a psychiatric hospital after fighting with police might report that the reason for the admission was that he came for coffee. Thankfully, this is an extreme example, and many patients have at least some understanding of the role of psychiatric treatment and can participate meaningfully in decisions regarding use of antipsychotics. Clinicians need to determine the specific reason for poor antipsychotic adherence so specific remedies can be sought.[120] In some patients, supervision is all that is required, whereas in others, one of the assisted treatment options (such as assertive community treatment [ACT]) will be required. There is little doubt that for the great majority of patients, maintenance antipsychotics must play a pivotal role in preventing psychotic relapse. This is true for patients who have been ill for many years, and for patients who are recovering from their first psychotic episode. In one study of first-episode psychosis patients who discontinued maintenance antipsychotics, 78% and 96% of patients experienced another psychotic episode within 1 and 2 years, respectively.[121] The prevention of further psychotic episodes is paramount because psychotic episodes come at a high cost to the patient: professional lives are interrupted; there is stigma and embarrassment associated with a psychiatric hospitalization; and there is always the danger of violence, accidental injury, and death.[122] On the other hand, medical hospital staff can be reassured that antipsychotics can usually be held for a brief medical hospital stay or procedure *if necessary* because relapse is measured in weeks or months, not days for remitted patients. For most patients with schizophrenia who require a medical admission these long-term adherence issues are not usually relevant, and house staff will merely need to continue the psychiatric outpatient regimen. However, an admission is a good decision point to review the adequacy of oversight of all medications.

Anxious Patients

Mark H. Pollack, M.D.
Michael W. Otto, Ph.D.
Curtis W. Wittmann, M.D.
Jerrold F. Rosenbaum, M.D.

Clinical challenges in the diagnosis and treatment of anxiety are abundant in the general hospital setting: discerning normal from pathologic anxiety, differentiating medical from psychiatric causes, and choosing effective therapeutic approaches. In addition to a knowledge of medical and psychiatric differential diagnosis, the clinician may rely on a variety of strategies and interventions that involve pharmacologic, cognitive–behavioral, interpersonal, and psychodynamic skills. The ubiquity of anxiety and the nonspecific nature of anxiety symptoms can confound the care of the patient. Pathologic anxiety symptoms and behavior may be attributed to other physical causes or, when viewed as "only anxiety," may be prematurely dismissed as insignificant.

Anxiety is indistinguishable from fear except as to cause. The former is the same distressing experience of dread and foreboding as the latter, except that it derives from an unknown internal stimulus or is inappropriate to the reality of the current situation. Anxiety is manifested in the physical, affective, cognitive, and behavioral domains. The possible physical symptoms of anxiety reflect autonomic arousal and include an array of bodily perturbations (Table 13–1). The anxious state ranges from edginess and unease to terror and panic. Cognitively, the experience is one of worry, apprehension, and thoughts concerned with emotional or bodily danger. Behaviorally, anxiety triggers a multitude of responses concerned with diminishing or avoiding the distress.

The importance of recognizing and attending to the suffering of the anxious patient is not always readily apparent, given the universality of the experience of anxiety. Anxiety is expected and normal as a transient response to stress and may be a necessary cue for adaptation and coping. Excessive or pathologic anxiety, however, is no more a normal state than is the production of excess thyroid hormone.

Pathologic anxiety is distinguished from a normal emotional response by four criteria: autonomy, intensity, duration, and behavior. *Autonomy* refers to suffering that, to some extent, has a life of its own, with a minimal basis in recognizable environmental stimuli. *Intensity* refers to the level of distress; the severity of symptoms is such that the patient's level of anguish moves the physician to offer relief. The patient's capacity to bear discomfort has been exceeded. The *duration* of suffering also can define anxiety as pathologic. Symptoms that are persistent rather than transient, possibly adaptive, responses indicate disorder and are a call to evaluation and treatment. Finally, *behavior* is a critical criterion; if anxiety impairs coping, if normal function is disrupted, or if behavior such as avoidance or withdrawal results, the anxiety is of a pathologic nature.

Stereotyped syndromes of pathologic anxiety are described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, under anxiety disorders (Table 13–2).[1] In epidemiologic studies, anxiety disorders were found to be among the most common psychiatric disorders in the general population.[2] This observation predicts that a significant percentage of the general hospital population would also suffer from anxiety symptoms. Some patients suffer from an anxiety disorder before admission to the hospital for medical care, but medical and surgical settings are also associated with the onset of anxiety symptoms as a consequence of hospitalization, medical illness, or treatment (e.g., adjustment disorder with anxious mood and organic anxiety disorder).[3]

THE NATURE AND ORIGIN OF ANXIETY

Despite the protean physiologic manifestations of anxiety, the experience of anxiety can be divided into two broad categories: (1) an acute, severe, and brief wave of intense anxiety with impressive cognitive, physiologic, and behavioral components, and (2) a lower-grade persistent distress, quantitatively distinct and with some qualitative differences as well. Pharmacologic and epidemiologic observations suggest a clinically relevant distinction between these two states.

In light of phenomenological similarities, fear and anxiety most likely reflect a common underlying neurophysiology. The first category of anxiety resembles acute fear or alarm in response to life-threatening danger: a cognitive state of terror, helplessness, or sense of impending disaster or doom, with autonomic but primarily sympathetic activation, and an urgency to flee or seek safety. The second type of anxiety corresponds to a state of alertness with a heightened sense of vigilance to possible threats and less intense levels of inhibition, physical distress, and behavioral impairment.

The two fear states resemble the clinical syndromes of panic attacks and generalized or anticipatory anxiety. As innate responses for protecting the organism and enhancing survival, panic and vigilance are normal when faced with threatening stimuli. As anxiety or psychopathologic symptoms, other factors besides actual physical threat must

TABLE 13–1 Physical Signs and Symptoms of Anxiety

Anorexia	Muscle tension
"Butterflies" in stomach	Nausea
Chest pain or tightness	Pallor
Diaphoresis	Palpitations
Diarrhea	Paresthesias
Dizziness	Sexual dysfunction
Dry mouth	Shortness of breath
Dyspnea	Stomach pain
Faintness	Tachycardia
Flushing	Tremulousness
Headache	Urinary frequency
Hyperventilation	Vomiting
Light-headedness	

TABLE 13–2 Anxiety Disorders

Panic disorder: Recurrent panic attacks ranging in severity from severe (experienced as terror, "going to die," or "losing control") to mild (only limited-symptom attacks or a rare panic attack); if complicated by fear of places with restricted or embarrassing escape or where help is unavailable, by travel restriction (or need for a companion), or by endurance of such situations despite intense anxiety, the diagnosis is panic disorder with (mild, moderate, or severe) agoraphobia.

Phobic disorders:

Simple phobia: Intense fear of and attempt to avoid specific objects or situations (e.g., heights)

Social phobia: Intense anxiety or discomfort in situations of scrutiny by others, with typical fear of embarrassment or humiliation (e.g., stage fright)

Agoraphobia: Fear of wide open spaces, crowds (without history of panic disorder)

Generalized anxiety disorder: A 6-month history of anxious symptoms but no panic attacks, with cognitive (worry) and autonomic symptoms

Posttraumatic stress disorder: A syndrome with onset following a traumatic, usually life-threatening, event. The course may resemble panic disorder with the herald attack a real-life threat rather than spontaneous panic. Recurrent images of the original event frequently occur.

Obsessive–compulsive disorder: Recurrent intrusive unwanted thoughts and images as well as compulsive behaviors, such as rituals, characterize this disorder; panic attacks and generalized anxiety also occur

Adapted from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders*, ed 4, Washington, DC, 1994, American Psychiatric Association.

Note: The most common form of anxious suffering in a hospital population is most likely a transient situational reaction or an adjustment disorder with anxiety.

be implicated as triggers or cause. Of several explanatory models proposed, the biological model places emphasis on the nervous system, the psychodynamic on meanings and memories, and the behavioral on learning.

Animal and neuronal receptor studies suggest that a number of central systems are involved in fear and pathologic anxiety.[4,5] The alarm or panic mechanism is likely to have a critical component involving central noradrenergic mechanisms, with particular importance placed on a small retropontine nucleus, the primary source of the brain's norepinephrine, the locus ceruleus (LC). When this key to sympathetic activation is stimulated in monkeys, for example, an acute fear response can be elicited with distress vocalizations, fear behaviors, and flight. Furthermore, destruction of the LC leads to abnormal complacency in the face of threat.[6] Biochemical perturbations that increase LC firing similarly elicit anxious responses in animals and humans that are blocked by agents that decrease LC firing, some of which are in clinical practice as anti-panic agents (e.g., antidepressants, alprazolam).[7]

Another critical system involves limbic system structures, including the amygdala and septohippocampal areas. An important role of the limbic system is to scan the environment for life-supporting and life-threatening cues, as well as to monitor internal or bodily sensations, and to integrate these with memory and cognitive inputs in assessing the degree of threat and need for action to maintain safety.[8]

Vigilance, or its psychopathologic equivalent, generalized anxiety, most probably involves limbic system activity: limbic alert. Benzodiazepine receptors in high concentration in relevant limbic system structures may play a role in modulating limbic alert, arousal, and behavioral inhibition[9] by increased binding of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA).[10] As one might expect, there are neuronal connections between the LC and the limbic system. An increased firing rate of LC neurons may serve as a rheostat to generate levels of arousal from vigilance to alarm.

A number of neurotransmitters are implicated as modulators of both the limbic alert and the central alarm systems. For example, LC firing is regulated by the α_2-noradrenergic autoreceptors as well as by 5-hydroxytryptamine (5-HT), serotonin receptors, GABA-benzodiazepine receptors, and opioid and other receptors. The limbic system also has important GABA-benzodiazepine receptor and serotonergic modulations. Peptides, such as cholecystokinin,[11] have also been implicated as potential activators of the alarm system, and an accruing body of work points to abnormalities in corticotropin-releasing factor and hypothalamic pituitary axis function as critical in the genesis and maintenance of pathologic affective states.[12] As a critical function, the central security system is endowed with redundancy of regulation.

When inappropriately activated, vigilance and alarm (the stereotyped functions of the security system) are manifested as psychopathology: anxiety states. The more sustained, variably intense, but distressing arousal state of vigilance (i.e., preparation for threat) becomes generalized anxiety. The sudden, stereotyped, and intense (but false) alarm response is a panic attack.

Cognitive–behavioral formulations of anxiety disorders, although attending to possible differences in biological reactivity, focus primary attention on the information processing and behavioral reactions that characterize an individual's anxiety experience. Although anxiety patterns may stem from a variety of experiences, including (mis)information, observational learning, and direct conditioning events with real or perceived trauma, the enduring consequences of such learning can be found in current patterns of behavior. In cognitive–behavioral formulations, emphasis

is placed on the role of thoughts and beliefs (cognitions) in activating anxiety, as well as on the role of avoidance or other escape responses in maintaining both fear and faulty thinking patterns. Faulty cognitions are frequently marked by the overprediction of the likelihood or degree of catastrophe of negative events and may focus on external experiences (e.g., "my colleagues will laugh at me if I ask this question") or internal experiences (e.g., "I am going to lose control if this anxiety gets worse"). Intolerance and catastrophic misinterpretations of the anxiety experience itself play a role in a variety of anxiety conditions and can help propel mild anxiety into a full, intense panic attack. Attempts to neutralize anxious feelings, with avoidance or compulsive behavior, can serve to lock in anxiety reactions and help develop the chronic arousal and anticipatory anxiety that marks many anxiety disorders.

Recent evidence has offered a bridge between neurobiological and cognitive–behavioral understandings of anxiety. Increased attention has been paid to the consolidation of memories after traumatic experiences and potential therapeutic interventions (e.g., blocking of the noradrenergic or glucocorticoid systems to decrease the potential for developing posttraumatic stress disorder [PTSD] after trauma). Knowledge of the *N*-methyl-D-aspartate (NMDA) system's involvement in the extinction of learned behaviors has offered the possibility of pharmacologic enhancement of cognitive behavior therapy (CBT) techniques. D-Cycloserine, a partial NMDA agonist, has facilitated treatment of specific phobias, obsessive–compulsive disorder (OCD), panic disorder, and social anxiety disorders when combined with CBT.[13]

Developmental experiences receive particular emphasis in psychodynamic approaches to anxiety. Although Freud's early writing implied a more physiologic basis for anxiety attacks in terms of undischarged libido, later emphasis was on anxiety as a signal of threat to the ego, signals elicited because of events and situations with similarities (symbolic or actual) to early developmental experiences that were threatening to the vulnerable child (traumatic anxiety), such as separations, losses, certain constellations of relationships, and symbolic objects or events (e.g., snakes, successes). More recently, psychodynamic thinking has emphasized object relations and the use of internalized objects to maintain affective stability under stress.

Phobic disorders, associated with the experience of panic, anticipatory anxiety, or no anxiety symptoms at all (depending on the success of avoidance behavior), serve to illustrate the different models of understanding anxiety. The biological view recognizes the stereotyped nature of phobias. Most of the objects and situations in everyday life that truly threaten us are rarely selected as phobic stimuli; children, who proceed normally through a variety of developmental phobias (e.g., strangers, separation, darkness), rarely become phobic of objects and situations that parents attempt to associate with danger (e.g., electric outlets and roads), and most phobic stimuli have meaning in the context of biological preparedness and were presumably selected through evolution.[14] Most human phobias are of objects and situations that make sense in the context of enhancing survival before the dawn of civilization: places of restricted escape, groups of strangers, heights, and snakes, for example. Social phobias—for example, fear of scrutiny by others—resemble the intense discomfort elicited in primates introduced into a new colony or in any animal simply being stared at. A glare is a threat. When panic attacks and anticipatory anxiety heighten the general sense of danger and insecurity, a variety of phobias may be manifested as part of the patient's increased concern with security and safety.

The principal explanatory models in psychiatry of how a normal protective system might become the source of distress and dysfunction include the biological (with its emphasis on constitutional vulnerability), the cognitive–behavioral (with its emphasis on self-perpetuating patterns of cognitions and behaviors), and the psychodynamic (with its emphasis on meanings, memories, and internal representations derived from developmental experience). The pragmatic and pluralistic modern clinician should not regard these models as mutually exclusive. Potential biological vulnerabilities, for example, may never become manifest without specific developmental experiences, sustained adversity, or trauma. Accumulating evidence indicates that for anxiety disorders, as with affective and psychotic disorders, biological systems are responsive to, and perturbable by, environmental influences. Potentially dysregulated (i.e., anxiety-prone) neurobiologic systems may remain homeostatic until developmental experience, life events, or other stressors disturb them. An integrated model predicts risk for manifested anxiety disorders as a consequence of constitutional vulnerability shaped by developmental experience (whether harmful or protective) and, in later (adult) life, either activated or influenced by environmental factors and maintained by ongoing chains of maladaptive cognitions and avoidance responses.

ANXIETY IN THE MEDICAL SETTING

Although some distress from anxiety is expected as a routine consequence of hospitalization, anxiety may also be a significant clinical issue in the treatment of patients in a medical setting. The hospitalized patient encounters a world of both internal and external dangers: assaults on bodily integrity in the form of uncomfortable procedures and forced intimacy with strangers; the atmosphere of illness, pain, and death; and separation from loved ones and familiar surroundings. The patient typically experiences uncertainty about his or her illness and its implications for the patient's capacity to work and maintain social and family relationships. Just as depression has been described as a "psychobiologic final common pathway" of a number of interacting determinants,[15] it is likely that anxiety too represents a multiply determined expression of the variety of psychological, biological, and social factors having impact on the patient.

The anxious patient can be a diagnostic challenge. The presence of anxiety may represent the patient's reaction to the meaning and implications of medical illness or to the medical setting, a manifestation of the physical disorder itself, or the expression of an underlying psychiatric disorder. The distinction between anxiety as a symptom and anxiety as a syndrome may be difficult to make in the medical setting, where there may be an overlap between normal situational anxiety or fear, anxiety-like symptoms resulting from a variety of organic disease states and their treatments, and the characteristic presentation of anxiety disorders.

Methodological obstacles surface in attempts to identify the nature and prevalence of anxiety in medical patients.[16]

Studies of anxiety in the medical setting are often difficult to interpret because of a lack of clarity of case definition and assessment measures, heterogeneity of the study populations, absence of appropriate control groups, and the nonspecific and often transitory nature of the anxiety symptoms themselves.

Approximately 60% of patients with psychiatric conditions are treated by primary practitioners; the most common disorders are depression and anxiety.[17,18] In a study of patients who presented to a group of primary care physicians, anxiety was the fifth most common diagnosis overall; others suggest this may be an underestimate.[19,20] Anxiety is the chief complaint of 11% of patients presenting in primary care settings.[21] This prevalence is mirrored by the high rate of prescribing benzodiazepines by primary care physicians.[22] Panic disorder has a reported prevalence of 1% to 2% in the general population,[23] as compared with 6% to 10% of patients in a primary care setting[24] and 10% to 14% of patients in a cardiology practice.[25] Patients with anxiety disorders, furthermore, are but a subgroup of those for whom anxiety is a complicating factor in their diagnosis and treatment in the hospital.

In view of the likely frequency of normal anxiety in this setting, there must be special circumstances surrounding those patients identified by primary caregivers as deserving psychiatric attention. Although some overly anxious patients go unrecognized, those who generate concern have impressed their caregivers in some way by the autonomy, intensity, duration, or behavior associated with their distress. Several typical scenarios of anxiety in the general hospital can be recognized.

Anxiety from the Failure to Cope

For most patients, potentially overwhelming stressors of hospitalization are mitigated by a variety of coping mechanisms. The sources of threat and the flood of perceptions signaling potential danger are managed by common strategies: rationalization and self-reassurance ("I've come this far," "the doctors know what they're doing," "safest place in the world"), denial and minimization ("the chest pain is just heartburn," "these machines will protect me"), religious faith, support from family and friends, and other strategies determined by the patient's personality style.

Even for those without a pre-illness anxiety disorder, coping strategies may fail and yield to a sense of fear and vulnerability. A host of factors may be implicated in this failure: personality features with brittleness or a tendency to regress in the face of threat (or paradoxically in a setting that evokes passivity and offers access to nurturance), the suddenness of the onset of threat (acute, life-threatening medical or surgical disease), unavailability of familial or other social support, feelings of aloneness or abandonment, or the unconscious meaning of the particular illness or injury. The patient becomes frightened, trembles, cannot sleep, repeatedly seeks attention and reassurance, registers excessive pain complaints and other physical symptoms, and becomes disruptive and unable to manage the fear. For many, especially the young or those with organic brain syndromes (e.g., mental retardation or dementia), catastrophic emotional responses are more readily triggered.

CASE 1

A psychiatric consultation request was received for a 17-year-old high school junior following above-the-knee amputation for osteogenic sarcoma without evidence of metastasis at the time of surgery. He had returned to school with a prosthesis and had done well. Some months later, a pulmonary metastasis was discovered, and he was rehospitalized for surgery and chemotherapy. Although anticipating a favorable outcome at this point, his behavior was unlike that of his prior hospitalization. He raged at caregivers, acted panicky, and withdrew from contact. Consultation was sought for treatment of his anxiety.

He was a tall, handsome, athletic young man admired by his peers, a leader who managed his life with braggadocio and pseudo-independence. For the first time in his illness, he was overwhelmed and frightened. Two critical issues emerged from the interview. In the past, he had had a great deal of support from his peers, but lately he had refused their visits. He was embarrassed by hair loss from chemotherapy. Second, during this hospitalization, his father, feeling overwhelmed by this turn of events, had decreased the frequency of visits to his son, claiming increased work demands.

Two interventions calmed the acute anxiety. First, an effort was made to find a well-suited wig; second, a psychotherapeutic contact with the father helped him to manage his grief adequately to increase the frequency of visits and thereby relieve his son's separation anxiety.

Although the oncologist's request was for an anxiolytic prescription, recognition of the failure of coping ability yielded the appropriate therapy for the acute anxiety.

This case serves to underscore two points: (1) Previously well-adapted individuals can become anxious in the face of serious or life-threatening illness, and (2) despite the appropriateness of anxiety in the face of serious illness, other factors, potentially remediable, may be involved in triggering anxious symptoms or behavior. In this case, troublesome behavior was evident; for others, only more subtle physical symptoms may have occurred.

Anxiety That Results from Traumatic Procedures

In recent years, increasing attention has been paid to the role of serious medical illness and invasive procedures in producing marked anxiety reactions that approach or meet criteria for PTSD. For example, symptoms of PTSD have been documented in patients after myocardial infarction (MI), coronary artery bypass graft surgery,[26] and treatment for breast cancer,[27] and in those who require intensive care (a setting associated with increased morbidity and mortality).[28] Estimates of rates of PTSD in these samples of patients range from 5% to 10%,[27] with rates of PTSD in patients hospitalized after traumatic physical injuries as high as 30% to 40%.[29] The emergence of PTSD is considered most likely when a traumatic event is perceived as both uncontrollable and life-threatening[30]; as such, any attempts to help patients regain or maintain a sense of control over their experiences may prevent or reduce emergent distress.

CASE 2

A 52-year-old woman with a prior history of depression, anxiety, chronic back pain, and severe peripheral vascular disease was admitted to the hospital as preparation for a femoral artery–popliteal artery bypass. Consultation was requested for management of anxiety because surgery had previously been attempted but was aborted when the patient became acutely anxious after propofol had been administered and the staff was beginning to disrobe her.

During the course of the consultation, the patient revealed that she had been the victim of a sexual assault at age 24. In the past, she had not needed treatment for symptoms related to this event. However, during the initiation of the prior surgery, she began to suffer from reexperiencing phenomenon while she was being disrobed.

Education was provided to the patient regarding the sequence of events that would take place leading up to and during the operation. The surgical staff was educated about the effects of past trauma and the need for special consideration regarding this patient. An agreement was made to allow the patient to disrobe herself prior to the initiation of the surgery. This increased her sense of control and she was able to tolerate the surgery, which went very well.

This case demonstrates the importance not only of the events that take place during a hospitalization, but also a patient's previous experiences with trauma. By talking with the patient and identifying the historical factors as well as the present conditions that made this experience difficult for her, a plan was devised to alleviate as much of her anxiety as possible. Under these conditions, she was able to take a more active role and complete the necessary medical procedure.

Attention is also being paid to the PTSD that may follow surgery performed under inadequate anesthesia.[31] Memory for events during anesthesia has been documented in controlled trials,[32,33] leading to recommendations that the surgical staff provide reassurance to patients during surgery and monitor their own verbalizations in the presence of anesthetized patients. In a series of 30 patients who underwent coronary artery bypass graft surgery, postoperative anxiety was a significant predictor of those who reported recall, with the proportion of patients recalling intraoperative events ranging between 10% and 23%,[32] although other reports suggested that rates of recall may be far less.[34] Sources of this variability may be that some patients do not readily discuss their memories and that memories may emerge some time after discharge.[35] Routine postoperative inquiry about possible awareness has been recommended to ensure that patients have an opportunity to discuss their memories, if present, and to allow assessment of the need for treatment if traumatic reactions are evident.[36]

Reactions to awareness during surgery include generalized anxiety and irritability, repetitive nightmares, and preoccupation with death, as well as reluctance to discuss the memory or associated symptoms.[35] More severe reactions have also been documented, including the full emergence of PTSD after experiences of awareness during surgery. Patients who are aware during surgery may face the terrifying experience of pain occurring in conjunction with anesthesia-induced paralysis (ensuring that no overt coping or escape responses are available) and the fear of death. As memories of the trauma emerge, patients may face the full spectrum of PTSD symptoms, including reexperiencing symptoms (intrusive memories, nightmares, and overresponsivity to cues of the surgery), avoidance of reminders of the experience (e.g., avoidance of strong emotions, prone bodily positions or sleep, medical television shows, colors similar to those of surgical scrub suits), and symptoms of pervasive autonomic arousal (e.g., exaggerated startle, sleep difficulties, hypervigilance, and irritability). Timely identification of this syndrome can aid in rapid referral for full psychiatric evaluation and treatment, which may include both cognitive–behavioral and pharmacologic interventions.

Anxiety That Interferes with Evaluation or Treatment

A request for consultation may be a consequence of anxiety that interferes with a patient's evaluation or treatment: refusal of work-up or treatment because of fear of pain or discomfort, catastrophic interpretation of physical symptoms or of the planned work-up ("they're looking for cancer") with an excessively fearful response, or the need to minimize or deny a potentially serious condition and its implications, limiting cooperation with evaluation.

CASE 3

Examination of a 38-year-old woman revealed a large breast lump. Although initially reluctant, she eventually agreed to a mammogram. In the waiting room, she became increasingly anxious and, when her name was called, refused to come in for the test. A psychiatric consultation was called to provide management of the patient's anxiety to permit the mammogram.

An attractive woman, she had stopped working as a teacher 12 years earlier after marrying a successful business executive and having the first of her two children. On interview she spoke of a favorite aunt who had died of breast cancer after disfiguring surgeries, and of her own fear of a similar lesion. She was plagued by the thought that the loss of a breast would cause her husband to lose interest and abandon her. She had not informed her husband of her current medical situation.

Meeting subsequently with both husband and wife, the psychiatrist gave explicit information about the possibility of malignancy and treatment options. The husband's manifest interest, support, and affection were reassuring; after the mammogram, a benign lump was removed.

Discovery of the meaning to the patient of the illness and the procedure permitted an intervention that sufficiently reduced her anxiety to allow evaluation and treatment. As with any situational anxiety, the fear of serious or fatal illness can be managed with education, support, cognitive and behavioral strategies, and at times the short-term use of benzodiazepines.

Review of a patient's conceptualization of his or her medical condition, the procedures the patient faces, and the patient's interpretation of symptoms offers the physician the opportunity to correct quickly cognitive distortions

that may needlessly engender anxiety. Care should be taken in discussing symptoms and procedures, with sensitivity to an individual's coping style. The clinician should elicit the patient's conceptualization of his or her condition (or upcoming procedure) and provide corrective information when distortions are encountered.

Additional strategies may be helpful when phobias about select medical procedures are encountered. For example, the enclosed chamber of the magnetic resonance imaging (MRI) scanner presents a phobic challenge to some individuals, engendering fears of overwhelming anxiety because of the inability to "escape" the MRI scanner quickly. For individuals with a history of claustrophobia, panic disorder, or PTSD, pretreatment with medications (e.g., benzodiazepines) or CBT may be required. In less severe cases, anxiety may be managed with simple procedures designed to maximize the patient's sense of safety and control. For example, compliance and comfort during the MRI scan may be aided by explaining to the patient the periods when he or she can shift positions or rub his or her hands together, the patient's ability to communicate with the nurse or technician, the patient's understanding of sounds and sensations to be experienced during the procedure, and the patient's ability to terminate the procedure, if need be. Initial practice of being moved into and out of the scanning chamber before the actual experience, as well as discussion of normal sensations of heat and anxiety experienced by patients while being scanned, can help normalize the experience and prevent catastrophic interpretations. There is evidence from analogue studies that information about the somatic sensations to be experienced during a procedure can help reduce anxiety and panic reactions.[37] Instruction in comforting imagining may also aid the patient in tolerating the procedure.

Anxiety that occurs in patients with a known and potentially fatal illness is more accurately termed *fear* because there is a known danger. Such fear, however, can adversely affect the course of illness and treatment. A study of survivors of MI, for example, indicated that 95% had increased tension and anxiety, and of one group of post-MI patients discharged from the hospital, 40% did not return to work; in 80%, psychological impairment, including anxiety, was the cause.[38] Worry that activity will cause further heart damage or death interferes with rehabilitation and the return to autonomous function. Most effective therapeutic approaches for these patients center on education, group discussion, and support and stress management techniques.[39] Anxious patients with a diagnosed serious or fatal illness require treatment that includes education in addition to the possible use of supportive, cognitive–behavioral, or insight-oriented psychotherapy and anxiolytic or antidepressant medications.

Among patients with medical disorders, such as gastrointestinal (GI) disorders or allergies, the course and symptoms of the illness may be exacerbated by anxiety.[39,40] Anxiety, like other emotional responses, may adversely affect normal physiologic function; asthma symptoms are exacerbated by emotional arousal or stress, and the increased symptoms generate further anxiety.[41] Psychological and emotional responses and behavior possibly affect the survival of patients with cancer through effects on the immune system.[42]

Medical Illness That Mimics Anxiety Disorder

Anxiety symptoms may be the principal manifestation of an underlying medical illness.[43] Of patients referred for psychiatric treatment, 5% to 42% have been reported as having an underlying medical illness responsible for their distress, with depression and anxiety as frequent complaints.[44,45] Of reported cases of medical illnesses causing anxiety symptoms, 25% have been secondary to neurologic problems; 25% to endocrinologic causes; 12% to circulatory, rheumatoid, or collagen vascular disorders and chronic infection; and 14% to miscellaneous other illnesses.[43] A most common organic cause of anxiety may be alcohol and drug use; the anxiety results from either intoxication or, more typically, withdrawal states.[46]

The clinical presentation of anxiety in the medical setting takes many forms. The bewildering array and variable nature of the physical and psychic symptoms reported by anxious patients may lead the physician to overlook symptoms related to another disorder.[47] The relative contribution of situational, psychiatric, and physiologic factors to the presentation of anxiety-like symptoms in a medical patient is often murky. The number of medical illnesses, furthermore, that may generate or exacerbate anxiety symptoms (Table 13–3) clearly renders an exhaustive evaluation for each of them impractical. A thorough yet efficient evaluation of the differential diagnostic possibilities, however, includes the following considerations[43,48]:

1. In a patient with a known medical illness, the condition and its associated complications and treatment may be the cause of anxiety. For example, in the asthmatic patient, hypoxia, respiratory distress, and sympathomimetic bronchodilators may all contribute to the experience of anxiety. In some patients, risk factors or predisposition, such as a family history of medical illness capable of causing anxiety-like symptoms (e.g., thyroid disease), may be clues to diagnosis.
2. In medical illnesses considered mimics of anxiety, the quality of anxiety symptoms when closely examined may be different from that seen in primary anxiety disorders. For example, Starkman and associates[49] studied 17 patients with pheochromocytoma and compared their anxiety symptoms with those of a group of 52 patients with anxiety disorders. Most patients with pheochromocytoma did not meet the criteria for panic disorder or generalized anxiety disorder (GAD); none developed agoraphobic symptoms, and their overall severity of symptoms was lower. There was a significant lack of psychological as opposed to physical symptoms of anxiety in most of these patients.
3. Similarly, patients with primary anxiety disorders are more likely to have emotional trauma related to the onset of anxiety, daily symptoms, neurotic features, and gradual resolution of symptoms after an attack and are less likely to have a loss of speech or consciousness during an episode of anxiety than are patients with anxiety associated with temporal lobe epilepsy.[50] Thus, the lack of a significant emotional experience of anxiety or the occurrence of anxiety only coincidental with particular physical events (e.g., a run of ventricular tachycardia on a cardiac monitor or spike activity on an electroencephalogram) may suggest the presence of an organic anxiety syndrome. Evaluation directed toward the somatic

system (e.g., GI or cardiac) most prominently affected by anxiety symptoms may provide the greatest yield from further diagnostic investigations.

4. In patients with an onset of anxiety symptoms after the age of 35 years, a lack of personal or family history of anxiety disorders, a negative childhood history of anxiety symptoms, an absence of significant life events heralding or exacerbating anxiety symptoms, a lack of avoidance behavior, and a poor response to standard antianxiety agents, the presence of an organically based anxiety syndrome should be considered.[40]
5. Even for the apparently healthy patient, particular scrutiny should be directed at more common conditions associated with anxiety: arrhythmias, thyroid abnormalities, excessive caffeine intake, and other drug use. Anxiety-like symptoms may be the first clue to a withdrawal syndrome in a patient with unreported regular sedative–hypnotic (e.g., ethchlorvynol, glutethimide, or a benzodiazepine) or alcohol use before admission to the hospital. Intoxication or withdrawal from prescription or over-the-counter medication or substances of abuse should also be suspected. Up to 3% of individuals have been reported to develop psychiatric symptoms after using prescribed or over-the-counter medication.[51]

CASE 4

A psychiatric consultation was requested from the medical service for a 31-year-old female clerk who developed anxiety attacks shortly after learning that she had contracted syphilis from her boyfriend. She had previously experienced spontaneous anxiety attacks in her mid 20s that had remitted early in a 6-month course of imipramine hydrochloride, and she had been symptom free since. During the interview with the psychiatrist, she manifested anger and sadness about her boyfriend's infidelity and her own victimization, as well as anxiety about the future of their relationship. Her anxiety attacks, however, were different from those she had previously experienced. They consisted of blurred vision; dull biparietal headaches, primarily left-sided; numbness in her extremities; and feelings of dizziness. She reported feeling anxious after the onset of these symptoms. On further questioning, the patient described a history of menstrual irregularities over the past 2 to 3 years, and galactorrhea. Her prolactin level was found to be elevated, and a computed tomography scan revealed a pituitary adenoma. Surgical resection of the adenoma resulted in resolution of her anxiety attacks, although she elected to pursue psychotherapy to consider issues raised by the difficulties in her relationship.

This case serves to illustrate the following points. The presence of a history of an anxiety disorder or a recent stressor does not eliminate the need to consider medical illness in the differential diagnosis of a new or different presentation of anxiety. The patient's experience of anxiety attacks was primarily somatic, and it was fortuitous that she had a history of more typical anxiety attacks for comparison; the nature of her symptoms led to a careful exploration for neurologic disease and allowed an appropriate and timely intervention.

Anxiety That Mimics Medical Illness

The autonomic arousal associated with anxiety states allows anxiety to present as a great imitator of medical illness. Patients with anxiety disorders repeatedly visit their primary care physicians or make the rounds of a variety of medical practitioners to seek a medical diagnosis to explain their symptoms. Along the way, they may be considered hypochondriacs, crocks, or just nervous, and they may receive benzodiazepines or reassurance but fail to be offered adequate or definitive treatment. Patients with untreated panic disorder, for example, have increased rates of alcoholism and sedative–hypnotic abuse, presumably in an attempt to self-medicate.[20,52] Sheehan and associates[53] noted that 70% of patients with panic disorder in their series had been to at least 10 medical practitioners without receiving a diagnosis or adequate treatment. They had high somatization scores on the Symptom Checklist-90, which decreased with the treatment of the panic disorder. The majority of these patients met the criteria for somatization disorder and tended to focus on the somatic symptoms of the untreated panic disorder. The nature of a patient's complaints may contribute to missed diagnosis and misdiagnosis. Greater than 90% of patients with panic present primarily with somatic complaints.[54] Although 95% of patients with mood or anxiety disorders are correctly diagnosed if the affective symptoms are their presenting complaint, only 48% are accurately assessed if they present with somatic complaints.[55] Individuals with somatization disorder are nearly 100 times more likely than those in the general population to suffer from a co-morbid panic disorder.[56] Of 55 patients with panic disorder referred by primary care physicians in one study, 49 (89%) initially presented with one or two somatic complaints and were misdiagnosed for from months to years.[20] The three most common somatic loci of symptoms were cardiac, GI, and neurologic, with 45 (81%) of the 55 patients presenting with a pain complaint. These patients may focus on specific physical symptoms, such as chest pain or diarrhea, thereby obscuring other anxiety symptoms, or they may deny affective or cognitive responses to avoid the stigmatization of psychiatric illness. As noted, anxiety may also exacerbate preexisting physical conditions, such as asthma, which then become the focus of the attention of both the patient and the physician.

The cost of unrecognized and untreated anxiety disorders in patients is high in terms of continued suffering, inefficient use of medical personnel, and costly repetitive diagnostic procedures. In one study of "high utilizers" of medical services, 58% had a mood or anxiety disorder, including 22% with panic disorder.[57] Clancy and Noyes[58] have documented the high rate of medical specialty consultations and procedures (most commonly cardiologic, neurologic, and GI) requested by patients with panic disorder. In one series of patients with chest pain who were undergoing coronary arteriography, Bass and co-workers[59] noted that 61% of the patients with insignificant coronary disease had psychiatric morbidity on a standardized interview, as opposed to only 23% of those with significant coronary disease. In those with normal coronary arteries, the most common psychiatric diagnosis was anxiety neurosis. Recognition and treatment of the anxiety disorder, in some cases, may have eliminated the necessity for arteriograms.

In another study, 30% of patients admitted to a cardiac care unit were determined to have no coronary disease but were subsequently diagnosed with panic disorder.[60] Wulsin and colleagues[61] noted that 43% of patients who presented to the emergency department (ED) with chest pain had panic attacks, and 16% had panic disorder; patients with panic disorder who presented to the ED with chest pain made more subsequent medical and ED visits than those without panic disorder.[62] Richter and associates[63] estimated that the average patient with noncardiac chest pain spends $3500 per year on ED, physician, and hospital visits and medications. In one series,[21] panic disorder exacerbated the symptoms of patients with preexisting medical disease and led to multiple hospitalizations—a trend that was reversed with treatment of the panic disorder. Dirks and associates[64] reported that patients with chronic asthma and high levels of anxiety had more hospitalizations than asthmatic patients with physiologic illness of comparable severity but normal degrees of anxiety.

Anxiety may play an especially important role in the intensification of hypochondriacal concerns. Once a fear of disease is activated, that fear provides a context for organizing subsequent experiences, including the experience of anxiety symptoms. The fear of disease helps direct attention to somatic symptoms, including anxiety-related symptoms, and can help engender a self-perpetuating cycle of vigilance, worry, and disease concern.[65,66]

Although consideration of the medical differential diagnosis for anxiety is crucial, recognition and treatment of anxiety disorders is essential in preventing inefficient use of medical resources and patient exposure to costly and occasionally dangerous diagnostic and therapeutic procedures. Failure to make the pertinent psychiatric diagnosis may result in a patient continuing to "doctor shop" in the search to discover "what's really wrong with me," with repeated diagnostic procedures resonating with the patient's hypochondriacal concerns. Untreated anxiety can exacerbate symptoms of existing medical pathologic conditions and drive a cycle of escalating help-seeking behavior and hospitalization.

CASE 5

An ED psychiatric consultation was requested for a 35-year-old man seen acutely by cardiology staff six times in the past month for chest pain and tachycardia. He had been admitted to the cardiac care unit twice, where MIs were ruled out. An extensive negative work-up at another hospital had included a cardiac angiogram. After being told "there's nothing wrong with your heart, you're just nervous" and being given a prescription for diazepam, he sought emergency treatment at our institution in the hope that "they'll find out what's wrong." He had refused previous consultations with psychiatry in the fear that he would be dismissed as "a head case," but he finally agreed to evaluation at the insistence of the medical team.

He was an athletic-looking salesman in his 30s, a self-described "take-charge kind of guy" without any previous psychiatric or medical history. He had a family history of hypertension and was concerned about potential "inherited heart problems." His electrocardiogram recorded a sinus tachycardia of 120 beats per minute and ST-T wave changes deemed secondary to the elevated rate. The episodic periods of anxiety, chest pain, tachycardia, diaphoresis, and hyperventilation had begun approximately a year earlier without clear precipitants during highway driving and had caused him to pull off the road and to seek emergency medical treatment. He reported anticipating long trips with trepidation lest the episodes of chest pain be repeated.

His diagnosis was panic disorder with mild agoraphobia, and treatment was initiated with alprazolam. He felt reassured that he was not crazy and had a definable condition for which treatment was available. The panic attacks remitted shortly thereafter, as did the patient's use of emergency medical services.

Treatment with a number of agents can dramatically relieve the spells and secondary complications of panic disorders, thus underscoring the importance of early diagnosis. Further, because of the physical nature of the symptoms, general medical and ED evaluators need to be alert to the clinical phenomena of a panic attack. Patients who describe their symptoms as anxiety or who evolve a major depression may be more likely to be identified as having a psychiatric disorder. Given the dramatic physical complaints in a variety of bodily systems, however, as with depression, in which somatic symptoms may dominate the presentation and mask diagnosis, an analogy may be made with missed or masked panic disorder.

The absent report of the affective, behavioral, or cognitive components of a panic attack can obscure the diagnosis in the face of paroxysmal physical symptoms. One case report[67] described a patient with a symptom picture that suggested a panic attack but the patient failed to describe the emotional experience of anxiety or panic; alexithymia, or the inability to describe one's emotions, was offered as a possible mechanism for the clinical picture. The predominance of physical symptoms or the absence of cognitive or behavioral responses, however, may not reflect alexithymia or a cognitive impairment, but rather variability in symptom expression. Some patients suffer panic attacks without experiencing a need to flee; others experience panic attacks without a sense of terror or dread, but do not necessarily lack the ability to describe their own emotions.

Most patients with clinically significant panic attacks also suffer limited-symptom attacks that feature only one or two physical symptoms. These may be interspersed with major attacks and may be either situational or unexpected, consisting, for example, of runs of tachycardia or bouts of flushing, hyperventilation, or dizziness. Panic disorder, in its early stages, may be manifested exclusively by such minor attacks. Similarly, as anti-panic therapy is effective, both unexpected and situational limited-symptom attacks may be the last vestige of the disorder or continue to represent a residual disorder.

As stated, patients vary in the primary somatic locus of anxiety distress.[48] For example, predominant panic attack symptoms may appear as cardiovascular symptoms (tachycardia or palpitations), neurologic symptoms (dizziness or paresthesias), respiratory symptoms (dyspnea), GI symptoms (diarrhea), and so forth. Recurrent limited-symptom attacks may therefore be initially indistinguishable from

symptoms of a number of disorders in these systems (see Table 13–3). Limited-symptom attacks also may be a harbinger of progression to the full syndrome, but in some cases they may also be disabling themselves and progress to such panic disorder complications as persistent anxiety, phobic avoidance, and depression.

CASE 6

A 32-year-old married factory supervisor had been out of work for 2 years because of stomach pain, nausea, and vomiting. He described his discomfort as "gnawing pains" that would occur paroxysmally, followed by vomiting with little warning. In the previous 5 years, he had had extensive GI work-ups and medical management, vagotomy and pyloroplasty, and ultimately hemigastrectomy without relief of symptoms. He was totally disabled and was referred for psychiatric evaluation. The following features were noted: (1) His severe pain was paroxysmal with lower-grade persistent symptoms; (2) diazepam helped diminish, but did not eradicate, his symptoms; (3) he was homebound and described attacks of stomach pain and vomiting only when he left his apartment—for example, to go shopping; (4) the onset had followed the break-up of a relationship; (5) a major depression had evolved.

On treatment with sertraline (co-administered with diazepam), he experienced complete symptomatic relief in 6 weeks and with maintenance treatment remained symptom free for 5 years. He sought and found a new job after treatment and has been continuously employed for the past 5 years. He recalled frequently needing to leave school as a child because of a nervous stomach.

This case reflects a missed or masked diagnosis of panic disorder because of the predominance of a limited-symptom attack resembling a GI syndrome. Clues to a diagnosis of panic disorder were evident, and appropriate treatment led to dramatic improvement in this disabled patient. Features reminiscent of more typical patients with panic disorder were identified before definitive treatment, including severe paroxysmal and lower-grade persistent symptoms, onset with a major life event, agoraphobic features, a childhood history suggesting separation anxiety, partial relief with benzodiazepines, and secondary depression. No family history of panic attacks or agoraphobia was reported in this case.

Panic Disorder Associated with Medical Illness

An association between panic disorder and other medical illnesses has been described. More than a third of patients with chronic obstructive pulmonary disease have an anxiety disorder, including 8% to 25% with panic disorder.[68–70] Pollack and associates[71] found an elevated prevalence of panic disorder (11%) among patients referred to a general hospital for pulmonary function testing, including two thirds of those with chronic obstructive pulmonary disease. Almost half of all patients evaluated reported substantial symptoms of anxiety.

Katon[20] and Noyes and co-workers[72] reported an increased incidence of peptic ulcers and hypertension in patients with panic disorder. Close to a third of patients with irritable bowel syndrome have panic disorder, and 44% of panic patients have irritable bowel syndrome; symptoms of both conditions improve with treatment of the panic disorder.[73]

Retrospective studies by Coryell and colleagues[74] suggest an increased risk of premature mortality from cardiac disease in men with panic disorder. A relationship also exists between mitral valve prolapse (MVP) and panic disorder. MVP, usually asymptomatic, may predispose to arrhythmias and occurs in roughly 5% to 10% of the population. Although diagnosed much more frequently in patients with panic disorder (30% to 50%) than in normal subjects or in those with generalized anxiety,[75,76] the nature of the association between the disorders remains unclear. A proposed genetic linkage remains controversial.[77] Patients with panic attacks and MVP do not differ from those with panic alone in their family history of panic disorder or their response to treatment.[78]

PRIMARY ANXIETY DISORDERS

Patients with a number of primary psychiatric disorders may present with anxiety in the medical setting. A history of psychiatric illness may precede the patient's entry into the medical setting and then be exacerbated by the medical condition. For some, however, the onset of symptoms associated with a psychiatric disorder is provoked by the stress of medical illness. Anxiety disorders include panic disorder with and without agoraphobia, GAD, simple phobia, social phobia, PTSD, and OCD.[1]

Panic Disorder

A panic attack usually lasts minutes with fairly stereotypical physical, cognitive, and behavioral components. Patients with panic disorder may experience these attacks intermittently over time or in clusters and, as stated, may develop a number of complications, including persistent anxiety, phobic avoidance, depression, alcoholism, or other drug overuse.

Physical symptoms (e.g., cardiac, respiratory, neurologic, and GI symptoms) are experienced as if there is a sudden surge of autonomic, primarily sympathetic, arousal. Cognitively, the patient feels a sense of terror or fear of losing control, dying, or going crazy and behaviorally often feels driven to flee from the setting in which the attack is experienced to a safe, secure, or familiar place or person.

The initial attack that appears to "turn on" the disorder, the herald attack, is particularly well remembered by the patient. Subsequent attacks may be a mixture of spontaneous, unexpected attacks and those preceded by a buildup of anticipatory anxiety; the latter, called situational attacks, occur in settings in which the patient might sense being at risk for panic, such as crowded places. Attacks may be major, with four or more symptoms, or limited-symptom attacks with fewer symptoms.

Panic disorder has its typical onset in early adult life and afflicts women two to three times as commonly as men. More than half of patients with panic disorder have a history of anxiety disorders beginning in childhood.[79] The disorder is clearly familial and very likely has a genetic basis,

given a higher concordance in monozygotic as compared with dizygotic twins,[80] but it is not clear whether a genetic influence is specific to panic disorder or whether it represents a general anxiety-proneness that may be expressed variably as any of a number of anxiety disorders.

The onset of the disorder in a clinical population typically follows either a major life event, such as a loss, threat of loss, other upheavals in work or home situations, or some physiologic event, such as medical illness (e.g., hyperthyroidism, vertigo) or drug use (marijuana, cocaine). For example, some patients whose first or herald attack appears to be triggered by a physiologic perturbation, such as follows marijuana use, may continue thereafter with persistent or recurrent symptoms without further drug use.

A panic attack, like an endogenous false alarm, appears to turn on a state of vigilance or postpanic anxiety that resembles GAD. Between attacks, patients may remain symptomatic with low-level constant anxiousness and anticipatory anxiety that may crescendo into panic in certain situations or be punctuated by panic unexpectedly.

In this state of vigilance, phobic avoidance may occur as a complication. The patient may develop mild or extensive phobic avoidance, usually of travel or places of restricted escape, immediately after the onset of attacks, after a number of attacks, or never at all. In some cases, the phobic avoidance evolves as a progressive constriction with the cumulative avoidances of settings where attacks have occurred.

Major depressive episodes may also complicate the course of the patient with panic disorder and occur in up to two thirds of cases.[81] For some, the demoralization attending the sustained distress and progressive disability of panic disorder extends to a typical depression with characteristic signs and symptoms. As noted, the relationship between panic and depression is a complicated one, however. Some patients manifest no depressive symptoms; for others, it is unclear which disorder is primary because symptoms arise concurrently. Alcohol use can temporarily tame the distress of panic disorder but soon yields to rebound symptoms, thereby setting the stage for alcohol overuse.

Generalized Anxiety Disorder

Patients with GAD suffer from chronic worry about a number of life circumstances (e.g., finances or danger to loved ones) that is difficult to control and is present on more days than not for longer than 6 months.[1] These patients are often called "nervous" or "worriers" by family or friends. Their anxiety is accompanied by a number of somatic and cognitive symptoms associated with motor tension and autonomic hyperactivity (e.g., muscle tension, restlessness, difficulties concentrating, and sleep disturbances). Although the disorder may be differentiated from panic disorder by the persistent rather than episodic nature of the symptoms, careful questioning often reveals that patients with GAD may experience panic attacks as well.[82,83] Many patients with GAD in the medical setting manifest anxiety in addition to the symptoms of other psychiatric disorders (e.g., panic disorder, depression, or alcohol abuse).[84]

Specific Phobias

Patients with specific phobias are afraid of circumscribed situations or objects (e.g., heights, closed spaces, animals, or the sight of blood).[1] Exposure to the feared stimulus results in intense anxiety and avoidance that interferes with the patient's life. Some patients are so afraid of needles or blood that compliance with procedures in the medical setting is nearly impossible. Acute treatment with benzodiazepines may decrease the patient's anxiety to the point where he or she agrees to treatment. The only consistently effective treatment for specific phobias, however, is behavioral therapy, a technique that involves exposure and desensitization to the feared object or situation.[85]

Social Phobia (Social Anxiety Disorder)

Social phobia, also referred to as social anxiety disorder, is diagnosed when the patient perceives that he or she will be the object of public scrutiny and fears that he or she will behave in a way that will be humiliating or embarrassing.[1] This perception leads to persistent fear and avoidance, or to endurance with intense distress. Circumscribed situations may be feared (e.g., speaking before a group, performance anxiety, writing or eating in the presence of others, or urinating in public lavatories); many patients experience more global difficulties in which most social interactions are difficult. Again, depression and alcoholism can frequently occur with social phobia.[86,87] Patients with a social phobia may have intense anxiety in the hospital because they are under intense scrutiny by others. Long-term treatments include antidepressants with selective serotonin reuptake inhibitors (SSRIs) (fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, escitalopram), serotonin–norepinephrine reuptake inhibitors (SNRIs) (venlafaxine), and monoamine oxidase inhibitors (MAOIs) (phenelzine, tranylcypromine) generally being more effective than tricyclic antidepressants (TCAs) (e.g., imipramine, desipramine, nortriptyline), β-blockers (for performance anxiety rather than generalized social phobia), or CBT. Some reports support the clinical efficacy of high-potency benzodiazepines (HPBs) (e.g., clonazepam,[88] alprazolam[89]) for the treatment of social phobia; when immediate intervention is necessary, the use of these agents is appropriate.

Posttraumatic Stress Disorder

Patients with PTSD have experienced or witnessed a traumatic event involving death or serious injury to themselves or others and responded with feelings of intense fear, horror, or helplessness.[1] Afflicted patients frequently reexperience the traumatic event. They have recurrent dreams or suddenly act or feel as though the event is recurring (i.e., a flashback). Individuals with PTSD frequently avoid situations that remind them of the event and may become numb, irritable, or hypervigilant and experience difficulty with sleep or concentration. Although much attention has been directed toward PTSD in combat veterans, PTSD can occur in civilians who suffer life-threatening accidents or assaults or who have survived natural disasters. PTSD is unfortunately common and often unrecognized in the medical setting, with reported rates of PTSD in over

a third of patients hospitalized after traumatic injury, such as occurring in motor vehicle accidents, assaults, or fires.[90,91] Injured patients who develop PTSD have increased functional impairment and problem-drinking when followed up a year after surgery.[92]

Acute stress disorder involves the development of dissociation and reexperiencing symptoms along with avoidance, anxiety, increased arousal, and significant distress or impairment lasting up to 4 weeks after a trauma.[1] The presence of acute stress disorder is associated with the development of PTSD.[93]

There is growing interest in whether early intervention for trauma victims can prevent the development of PTSD. Emerging data suggest that whereas single-session debriefing after a traumatic event is likely to have no benefit and may in fact interfere with the natural recovery process,[94,95] more extensive, multiple–session cognitive–behavioral interventions incorporating information, cognitive restructuring, and exposure elements appear effective.[96,97] Pharmacologic interventions have also demonstrated potential benefit in reducing the morbid sequelae of trauma. One small double-blind randomized trial in a cohort of burned children demonstrated significant reduction in symptoms of acute stress disorder with imipramine as compared with chloral hydrate treatment.[98] A small placebo-controlled trial demonstrated that a 10-day course of propranolol (40 mg four times daily) initiated within 6 hours of a traumatic event resulted in reduction of PTSD symptoms and physiologic arousal at 3-month follow-up.[99] In addition to agents that inhibit the adrenergic system, there has been increasing investigation of glucocorticoids as a means of preventing PTSD, as well as of decreasing symptoms related to recall of traumatic memories.[100] Although further research in this area is warranted and ongoing, the work to date suggests a potential benefit of pharmacologic intervention strategies that address memory systems in reducing the morbid consequences of trauma exposure.

Both CBT[101] and SSRI pharmacotherapy have become first-line interventions for the treatment of PTSD.[102] They are frequently co-administered to improve outcome. Although far from definitive, there is evidence suggesting that benzodiazepine administration may impede the recovery process in traumatized individuals,[103,104] and that other agents, including atypical neuroleptics (e.g., risperidone, olanzapine) and anticonvulsants (e.g., lamotrigine, topiramate, gabapentin) may be useful alternatives as well as having a role in management of the refractory patient.

Obsessive–Compulsive Disorder

Patients with OCD suffer from recurrent, intrusive, unwanted thoughts (i.e., obsessions, such as the fear of hurting a loved one or the fear of contamination) or compulsive behaviors or rituals (such as repetitive handwashing or checking a door multiple times to make sure it is locked).[1] The obsessions and compulsions are distressing and time consuming (i.e., they may take more than 1 hour per day) and interfere with the patient's normal function. In the medical setting, the patient with OCD may suffer a marked increase in anxiety if physical disability or hospital routine makes it impossible for him or her to perform compulsive rituals. CBT aimed at reducing the patient's obsessive thoughts and compulsive behavior has demonstrated clear efficacy for OCD. Benzodiazepine therapy may be necessary to control overwhelming anxiety, particularly in acute treatment. Effective long-term treatments include use of serotonergic antidepressants (e.g., SSRIs, clomipramine) as well as behavioral therapy.

Other Psychiatric Disorders

Anxiety symptoms may be associated with a number of psychiatric disorders (such as schizophrenia, depression, and bipolar disorder) other than primary anxiety disorders. Vague uneasiness extending to severe anxiety may either precede or accompany the symptoms of schizophrenia. Patients with significant degrees of anxiety may have a reduced level of function and manifest withdrawal that superficially resembles schizophrenia. The presence of hallucinations, delusions, and bizarre and disordered thinking, a marked degree of social withdrawal, and a characteristic premorbid personal and family history usually allows an uncomplicated differentiation of schizophrenia from anxiety disorders.

The relationship between anxiety and depression is complex. Weissman and co-workers[105] reported an increased prevalence of both panic disorder and depression in the families of probands with both disorders. One estimate holds that one third of patients with panic disorder, with or without agoraphobia, develop a secondary major depression, and 22% have had a major depressive disorder before developing panic disorder.[106] The incidence of a major depressive episode in patients with panic disorder has been reported as ranging between 28% and 90%, depending on the diagnostic criteria used.[107] Leckman and associates[108] found that 58% of a group of depressed patients had anxiety symptoms meeting *Diagnostic and Statistical Manual for Mental Disorders*, 3rd edition, criteria for agoraphobia, panic disorder, or GAD.

Although this overlap between syndromes can make the distinction between anxiety and depression difficult, a number of clinical considerations may be useful. Psychomotor retardation, persistent dysphoria, early morning awakening, diurnal variation, a sense of hopelessness, and suicidal thoughts are more indicative of depression. Patients with an anxiety disorder have often not lost interest in their usual activities but rather have lost the ability to negotiate them comfortably. They are more likely to report autonomic hyperactivity, derealization, perceptual distortions, and anxious impatience than hopelessness.[46] Advances in neurobiology at this time offer few diagnostic markers for differentiating anxiety and depressive disorders. The sleep of patients with panic disorders differs from the sleep of depressives during all-night polysomnograms.[109] There are also differences in physiologic parameters and platelet receptor–binding patterns between anxious and depressed patients.[110,111]

The principal concern in differentiating depression from anxiety is to not overlook treatment with an antidepressant and, in particular, to avoid the common scenario of prescribing only a benzodiazepine for the anxiety component of a depression, thereby leaving the depression untreated. Fortunately, the frequent overlap in clinical presentations

between primary depressive and primary anxiety disorders is mirrored by an overlap in therapeutic considerations. One important consideration, however, is the possibility that depressed symptoms may reflect an underlying bipolar (manic–depressive) disorder. Anxiety disorders are a common co-morbidity among bipolar individuals.[112] However, the use of antidepressants in bipolar patients may precipitate mania and provoke greater mood cycling. Bipolar disorder should be considered in the differential diagnosis of depression, particularly in those patients with a history of marked mood instability or a family history of manic–depressive illness, as well as in individuals who become more agitated or dysphoric after antidepressant administration. For bipolar patients, use of an anticonvulsant may treat both the mood and the anxiety disorder, with use of benzodiazepines, in preference to antidepressants, considered for persistent anxiety in individuals without a substance abuse diathesis. Although cognitive–behavioral interventions for anxiety and depression differ in both their focus and procedures, it is not unusual for treatment of one condition to extend benefit to the associated disorder. For example, the CBT of panic disorder is associated with improvement in co-morbid depression. Nonetheless, co-morbidity generally serves as a predictor of worse overall treatment response to CBT, just as it does for pharmacologic approaches.[113]

TREATMENT

The nature of the medical setting favors expedient interventions, such as drug treatment to ease acute distress, because of the time-limited nature of medical and surgical stays (Table 13–4). Nonetheless, as illustrated by the case examples, comprehensive assessments, including systematic scrutiny of cognitive and psychosocial factors, may lead to practical interventions short of formal psychotherapy, including CBT. In addition, disrupted relations with family members may be provocative, and family interventions may prove therapeutically expedient.

Pharmacologic Treatment of Panic Disorder

The drug treatment of anxiety essentially involves selecting agents for panic, GAD, or both. As with recognizing the primacy of depression in some anxious patients, if the presence of panic attacks is overlooked, treatment for generalized anxiety alone is likely to be inadequate, and patient suffering will continue. Familiarity with panic disorder, its complications, and its treatments is a necessary resource in evaluating and caring for anxious patients.

Although early intervention offers the likelihood of preventing complications, many patients come for treatment

TABLE 13–4 Selected Pharmacologic Treatments for Anxiety Disorders

AGENT	USUAL INITIAL DOSAGE (mg)	DOSAGE RANGE (mg)	CHIEF DOSAGE LIMITATIONS	DISORDERS
Tricyclic Antidepressants (TCAs)				
Imipramine	10-25	150-300	Jitteriness, TCA side effects	PD, AG, GAD, PTSD, OCD
Clomipramine	25	25-250	Sedation, weight gain, TCA side effects	PD, AG, GAD, PTSD
Monoamine Oxidase Inhibitors (MAOIs)				
Phenelzine	15-30	45-90	Diet, MAOI side effects	PD, AG, SP, ?GAD, OCD, PTSD
Selective Serotonin Reuptake Inhibitors (SSRIs)				
Fluoxetine	10	10-80	SSRI side effects	PD, AG, SP, OCD, PTSD
Sertraline	25	25-200	SSRI side effects	PD, AG, SP, OCD, PTSD
Paroxetine	10	10-50	SSRI side effects	PD, AG, SP, OCD, PTSD
Paroxetine-CR	12.5	12.5-62.5	SSRI side effects	PD, AG, SP, OCD, PTSD
Fluvoxamine	50	50-300	SSRI side effects	PD, AG, SP OCD, PTSD
Citalopram	10	20-60	SSRI side effects	PD, AG, SP, OCD, PTSD
Escitalopram	5	10-20	SSRI side effects	PD, AG, SP, OCD, PTSD
Serotonin–Norepinephrine Reuptake Inhibitor (SNRI)				
Venlafaxine	37.5	75-225	SSRI side effects, hypertension	PD, AG, SP, OCD, PTSD
Benzodiazepines				
Alprazolam	0.25 qid	2-10/day	Sedation, discontinuation syndrome	PD, AG, GAD, SP, ?SpP
Clonazepam	0.25 hs	1-5/day	Abuse, psychomotor and memory impairment	PD, AG, GAD, SP, ?SpP
Diazepam	2.5	5-30/day	—	GAD, SpP, PD, SP
Other anxiolytics				
Buspirone	5 tid	15-60/day	Dysphoria	GAD
Propranolol	10-20	10-160/day (maintenance use)	Depression	SP, ?PD, ?GAD

AG, Agoraphobia; *d*, day; *GAD*, generalized anxiety disorder; *OCD*, obsessive-compulsive disorder; *PD*, panic disorder; *PTSD*, posttraumatic stress disorder; *SP*, social phobia; *SpP*, specific phobia.

after years of symptoms and disability. Even in the face of chronicity, however, most patients achieve substantial if not dramatic benefit with available treatments, which include anti-panic pharmacotherapy and CBT. Given the apparent primacy of the panic attack in the distress and evolution of complications of the disorder, our usual approach is to initiate anti-panic medications for patients who continue to experience panic attacks, with the expectation of regression and remission of complications once the attacks have ceased. For patients with residual phobic avoidance despite the prevention of panic attacks, behavioral and cognitive strategies are employed. For some patients, behavioral and cognitive strategies are employed initially, especially when the frequency and intensity of unexpected panic are minimal, with pharmacotherapy subsequently applied if emergence or exacerbation of panic attends the behavioral program.

Antidepressants

The SSRIs (including fluoxetine, sertraline, paroxetine, citalopram, escitalopram, and fluvoxamine) have become first-line agents for the treatment of panic disorder as well as other anxiety disorders[114,115] because of their broad spectrum of efficacy, favorable side-effect profile, and lack of cardiotoxicity. Although effective, these agents may worsen anxiety for some patients at the initiation of treatment. Thus, treatment of panic patients or the anxious depressed should be initiated at half or less of the usual starting dosage (e.g., fluoxetine 5 to 10 mg/day, sertraline 25 mg/day, paroxetine 10 mg/day [or 12.5 mg/day of the controlled-release formulation], citalopram 10 mg/day, escitalopram 5 mg/day, and fluvoxamine 50 mg/day) to minimize the early anxiogenic effect. Dosages can usually be raised, after about a week of acclimation, to typical therapeutic levels. Typical target dosages for this indication are fluoxetine 20 to 40 mg/day, paroxetine 20 to 60 mg/day (25 to 72.5 mg/day of the controlled-release formulation), sertraline 100 to 150 mg/day, citalopram 20 to 60 mg/day, escitalopram 10 to 20 mg/day, and fluvoxamine 150 to 250 mg/day, although some patients may respond at lower levels. Patients with OCD and PTSD may require higher dosages (e.g., fluoxetine 60 to 80 mg/day) to receive maximal benefit.

Onset of benefit with the SSRIs and other antidepressants usually occurs after 2 to 3 weeks of treatment. Although generally better tolerated for acute and long-term treatment than older available classes of antidepressants, SSRIs may be associated with transient or persistent adverse effects, including nausea and other GI symptoms, headaches, sexual dysfunction, and apathy. Despite their reputation as stimulating agents, sleep disturbance is generally not a persistent or significant problem during SSRI therapy. The SSRIs are usually administered in the morning; emergent sleep disruption can usually be managed by the addition of hypnotic agents.

The extended release SNRI venlafaxine has also demonstrated efficacy for the treatment of panic disorder and the other anxiety disorders. Like other antidepressants, it may cause uncomfortable stimulation early in the treatment of anxious patients, so dosing should be initiated with low dosages (i.e., venlafaxine 37.5 mg/day). Other antidepressants, such as mirtazapine, are also probably effective for the treatment of anxiety disorders, but the systematic data supporting their use for these indications are limited. Trazodone appears to be less effective for panic disorder than other agents; studies assessing the effectiveness of bupropion for panic disorder are small and have shown mixed results.

The TCA imipramine hydrochloride has well-established efficacy in panic disorder.[116] Although other TCAs are probably also effective (e.g., desipramine is frequently employed because of its lower anticholinergic burden), this class of agents has several drawbacks, including a delayed onset of benefit and treatment-emergent adverse effects. In addition to the usual TCA side effects (such as dry mouth, constipation, and orthostatic hypotension), panic patients are particularly prone to a sudden worsening of their disorder with the first doses. To minimize the effect of this adverse response, treatment can be initiated with small test doses (e.g., 10 mg of imipramine hydrochloride). If this is well tolerated, standard antidepressant dosing can be pursued; for others, the adverse response typically fades over a few days, thus allowing an upward titration of dosage. For a small percentage of patients, this apparent worsening of the disorder does not subside. Mavissakalian and Perel[117] reported that a reasonable target dosage of imipramine for treatment of panic disorder and agoraphobia in most patients is approximately 2.25 mg/kg per day (usually between 100 and 200 mg/day for most patients), with a total plasma level of 75 to 150 ng/mL for imipramine and its metabolite, desipramine.

The MAOI phenelzine has stood up well in clinical use and controlled trials,[116] and many clinicians believe that MAOIs may be the most comprehensively effective agents for treating panic disorder, blocking panic attacks, relieving depression, and offering a confidence-enhancing effect of considerable value to the patient needing to recover from vigilance and phobic avoidance. Except for postural hypotension, MAOIs are free of most of the early TCA and SSRI side effects, including the anxiogenic response. Unfortunately, as treatment proceeds, a variety of challenging problems emerge, including insomnia, weight gain, edema, sexual dysfunction, nocturnal myoclonus, and other unusual symptoms. Further, many anxious patients are most circumspect about the dietary precautions and instructions about hypertensive crises. Because the SSRIs and the MAOIs offer similar spectra of efficacy in terms of treating panic disorder, social phobia, and atypical depressive symptoms, along with a superior safety and side-effect profile, they are generally used first in most patients. MAOIs, however, may be effective in patients failing to respond to other interventions; thus, although this has not been systematically studied, many clinicians believe that no patient should be considered truly treatment refractory to pharmacotherapy until the patient has had an MAOI trial.

Benzodiazepines

When treatment refusal, treatment discomfort from side effects, and treatment failure are considered, the need for a better-tolerated and effective anti-panic treatment is apparent. In some respects, benzodiazepines, such as alprazolam and clonazepam, fit this need. They have demonstrated anti-panic efficacy as well as patient acceptability and a reasonable record of safety. In addition, they provide the speed of action that is desirable in a medical setting.

Although it was once believed that higher-potency agents, such as alprazolam and clonazepam, were more effective than lower-potency agents, such as diazepam, for the treatment of panic, it appears that all benzodiazepines may be effective at equivalent dosages (i.e., 4 mg/day of alprazolam and 40 mg/day of diazepam).[118]

The usual dosage range for most panic disorder patients receiving alprazolam is 2 to 8 mg/day, with most achieving a benefit from around 4 to 6 mg/day. Clinical response is evident early, but lower dosages are necessary to initiate treatment so that the patient can accommodate to sedation. Most patients adapt within a few days to the sedating effects, and this allows a stepwise increase in panic-blocking doses. Adaptation to sedation usually occurs without a loss of therapeutic benefit, but some upward adjustment may be required after the first 2 weeks. A small percentage of patients appear particularly sensitive to the drug and experience persisting sedation despite time and careful titration. Alprazolam must be given in divided doses, usually three to four times a day, because of its relatively short duration of action; a recently introduced extended-release formulation permits once-a-day dosing. It does not change the elimination half-life or need for a gradual taper with discontinuation.

Despite the ease of administration of alprazolam and frequently dramatic results even in the first days of treatment, clinical drawbacks include concerns about abuse and dependency, rebound symptoms between doses, withdrawal, and early relapse. The abuse potential of alprazolam, like that of other benzodiazepines, varies widely among clinical populations; patients with a history of alcohol or other substance abuse are most at risk for abusing benzodiazepines. Numerous studies are reassuring that panic patients treated with benzodiazepines do not experience therapeutic tolerance or dosage escalation; in fact, dosages of benzodiazepines generally decrease over the maintenance period, often despite the presence or persistence of untreated anxiety symptoms.[119] Most well-informed panic and phobic patients who have endured severe distress over time treat their medication with respect and understand the wisdom of maintaining the lowest effective dose; thus, unless there is evidence that a particular patient is at risk, the use of this agent appears generally safe for the disorder under consideration. As with any benzodiazepine, without controlled prescribing for targeted symptoms, inappropriate use may occur. As seen with a benzodiazepine with a relatively short half-life, the discontinuation of alprazolam therapy, especially after long-term treatment, without a gradual taper tailored to the individual patient's sensitivity to decreasing dosages, may be followed by rebound symptoms (worsened anxiety) or a withdrawal syndrome.

With the pharmacokinetic drawbacks associated with a short half-life agent in mind, the longer-acting high potency benzodiazepine (HPB) clonazepam, has been effective for those patients who require an HPB. Because of its long half-life (15 to 50 hours), clonazepam is generally administered on a twice-a-day dosage schedule, with patients less likely to experience interdose rebound and withdrawal symptoms than on shorter-acting agents.

With a milligram-for-milligram potency approximately twice that of alprazolam, clonazepam's effective dosage range for panic patients is between 1 and 5 mg/day when given in morning and bedtime doses. Sedation is the limiting factor in dosage titration and is managed by initiating treatment with a low bedtime dosage and titrating upward if symptoms persist and sedation resolves. An initial dosage as low as 0.25 mg may be used in drug-naive patients or those particularly sensitive to benzodiazepines. Greater dosages may be given at bedtime than in the morning if the patient is not readily accommodating to sedation, but many patients function without sedation on equal morning and bedtime dosages, as with alprazolam.

The effect of a daily dose on panic attacks and generalized anxiety is apparent within a few days. Some patients, for unclear reasons, develop depressive symptoms as a treatment-emergent adverse effect when taking alprazolam or clonazepam. Resolution of depressive symptoms typically occurs with the introduction of an antidepressant; benzodiazepine treatment can then be withheld with the expectation of a comprehensive response to the antidepressant. Combined treatment can again be used if anxiety symptoms break through the antidepressant treatment.

Some clinicians initiate combined treatment with an antidepressant and an HPB to obtain the rapid anxiolysis associated with HPB treatment, decrease the activation associated with initiation of antidepressant therapy, and provide antidepressant coverage of co-morbid or benzodiazepine-induced depression. For many patients, the HPB can be tapered after a few weeks when the antidepressant begins to exert therapeutic effects; however, some patients remain on combined treatment with benefit and without adverse consequences.

Pharmacologic Treatment of Generalized Anxiety

As noted previously, the SSRIs and the SNRIs have become first-line pharmacologic agents for the treatment of anxiety disorders, including GAD. They are better tolerated than the older classes of antidepressants and have a broad spectrum of efficacy, which is a critical clinical concern given the high rates of co-morbidity, particularly depression affecting the generally anxious individual. In addition, SSRIs and SNRIs do not have significant abuse potential, which is an important consideration for generally anxious individuals with a predisposition to substance abuse. However, use of these agents may be associated with side effects, including sexual dysfunction and GI distress, that may adversely affect compliance. The delay in the onset of therapeutic benefit is a relative disadvantage for antidepressants as well as for buspirone; the call to intervene with medication for the anxious patient in the hospital typically requires a response with a more immediate-acting agent. Thus, benzodiazepines are usually used for acute management of anxiety, with antidepressant addition or substitution considered in patients requiring maintenance pharmacotherapy, particularly those with a depressive or substance abuse diathesis.

Benzodiazepines, by dint of their efficacy, tolerability, and rapid onset of effect, have long been the mainstay of anxiolytic pharmacotherapy, although the clinical decision to prescribe these agents for symptom relief is a difficult one. The attitudes of individual physicians toward prescribing may be characterized as falling along a spectrum between pharmacologic Calvinism and psychotropic hedonism,

reflecting a personal and moral stance toward prescribing medication for the relief of psychic distress. The abundant literature on antianxiety agents falls short of providing reliable measures for diagnosis and prescribing. Given the ubiquity of anxiety in hospital settings, the physician must frequently confront the question of whether to prescribe. The use of a benzodiazepine for the distressed, anxious patient is often a therapeutic act analogous to the provision of pain relief.

When compared with barbiturates and nonbarbiturate sedative and hypnotic agents (meprobamate, ethchlorvynol, glutethimide, methaqualone, and others), the benzodiazepines are more selectively anxiolytic, with less sedation and less morbidity and mortality in overdose and acute withdrawal. Because using a benzodiazepine represents a clinical decision to offer symptomatic relief, the critical clinical assessment is to evaluate the patient's response. The patient's coping should be enhanced in addition to, and as a consequence, of relief from suffering.

Choice of Benzodiazepine

All available benzodiazepines are effective in treating generalized anxiety. Drug selection is based on pharmacokinetic properties, which determine the rapidity of onset of effect, the degree of accumulation with multidosing, the rapidity of offset of clinical effect, and the risk of drug discontinuation syndrome.

For single or acute dosing, the onset of effect is determined by the rate of absorption from the stomach, and the offset by distribution from plasma into lipid stores. The half-life of a drug predicts the amount of accumulation of drug in plasma with multidosing and the speed of washout on drug discontinuation (and thus the quickness of return of symptoms or the risk of rebound and withdrawal). For example, a rapidly absorbed, lipophilic agent, such as diazepam, given acutely, has a rapid but relatively short-lived effect; with repeated dosing, however, plasma levels are higher than for a short half-life drug at steady state. The long half-life offers some tapering effect to help protect against rebound or withdrawal on discontinuation.

The clinician can choose a drug to have a fast onset for greater clinical effect, a slow onset to minimize sedation or confusion, short action to allow rapid clearing, or long action to minimize interdose or posttreatment rebound symptoms (Table 13–5). Treatment begins with low doses (e.g., diazepam 5 to 10 mg/day or its equivalent) and upward titration. Dosages vary, but for usual situational anxiety, 30 to 40 mg of diazepam a day or its equivalent are not usually exceeded.

Patients in whom benzodiazepine therapy is being prescribed to manage acute situational reactions should expect that treatment will be of limited duration. For specific phobic anxiety (e.g., fear of flying), occasional use is indicated. For generalized anxiety, using anxiolytics for periods of exacerbation may be effective, although increasing recognition of the distress and chronicity associated with persistent anxiety has underscored the observation that many patients often report sustained improvement and improved quality of life with maintenance treatment.

Precautions in Prescribing

A withdrawal syndrome, usually mild but potentially severe depending on the dose and the duration of treatment, may follow abrupt cessation of therapy. For patients receiving usual doses for less than 3 to 4 weeks—during hospitalization, for example—without prior use of sedatives, the risk of an abstinence syndrome is less. In general, however, treatment is discontinued by tapering doses, gradually adjusting decrements according to patient response.

Overuse of medication and drug-seeking from multiple sources is a concern for outpatient prescribing, but with the controlled use of drugs in the hospital, particular vigilance is appropriate primarily for the patient with a history of drug or alcohol abuse.

The sedative effects of benzodiazepines are additive with those of other CNS depressants, and plasma levels are higher with the use of certain drugs, such as cimetidine. A few patients, particularly with use of HPBs, are prone to increased hostility, aggressivity, and rage eruptions.

Pharmacologic Alternatives to Benzodiazepines

Anticonvulsants (including valproate, gabapentin, topiramate, and lamotrigine) are increasingly being studied

TABLE 13–5 Characteristics of Commonly Used Benzodiazepines

DRUG	HALF-LIFE (hr)	DOSAGE EQUIVALENT (mg)	ONSET	SIGNIFICANT METABOLITES	TYPICAL ROUTE OF ADMINISTRATION
Midazolam (Versed)	1-12	2.0	Fast	No	IV, IM
Oxazepam (Serax)	5-15	15	Slow	No	PO
Lorazepam (Ativan)	10-20	1.0	Intermediate	No	IV, IM, PO
Alprazolam (Xanax)*	12-15	0.5	Intermediate-fast	No	PO
Chlordiazepoxide (Librium)	5-30	10	Intermediate	Yes	PO, IV
Clonazepam (Klonopin)*	15-50	0.25	Intermediate	No	PO
Diazepam (Valium)	20-100	5.0	Fast	Yes	PO, IV
Flurazepam (Dalmane)	40	15.0	Fast	Yes	PO
Clorazepate (Tranxene)	30-200	7.5	Fast	Yes	PO

*Commonly used to treat panic disorder.

and used for a range of anxiety disorders, with some (e.g., gabapentin) administered as an alternative to benzodiazepines because of their sedating properties and tolerability.[120] Although typical neuroleptics (e.g., trifluoperazine) have long been used in clinical practice for the treatment of anxiety, concerns about extrapyramidal effects and tardive dyskinesia have limited this practice. Based on accruing open-label reports and controlled studies, the atypical neuroleptics also appear to have anxiolytic effects across a variety of conditions.[121]

However, although less likely to be associated with neurologic side effects (e.g., extrapyramidal symptoms, tardive dyskinesia) than older-generation agents,[122] the severity of potential metabolic consequences (e.g., weight gain, diabetes, increased triglycerides) associated with these agents suggests that caution must be taken when prescribing them.

β-blocking drugs, such as propranolol hydrochloride, have proved useful in alleviating some of the peripheral autonomic symptoms of anxiety (such as tremor and tachycardia). Although of second-line or third-line importance in treating panic attacks or more cognitively experienced symptoms (e.g., worry), β-blockers are often impressively useful in the performance-anxiety subtype of social phobia and when persistent peripheral symptoms (somatic anxiety) predominate. Agents, such as atenolol, that are less able to cross the blood–brain barrier than propranolol may have advantages for patients who experience fatigue or dysphoria when taking propranolol. Effective doses vary, and treatment requires upward titration from low initial doses.

Buspirone is a nonbenzodiazepine anxiolytic without sedative and anticonvulsant properties or abuse potential. It interacts with postsynaptic 5-HT (serotonin) receptors as a partial agonist and with dopamine receptors but apparently not with the benzodiazepine-GABA receptor.[123] Buspirone is ineffective in panic disorder, and although clinical trials suggest that it is effective for the treatment of GAD, many clinicians and patients have found it disappointing for this indication as well. For some patients, this may in part result from a latency of therapeutic response of weeks, similar to the antidepressants, and the presence of a critical beneficial dose threshold. The dosage range is 5 to 20 mg three times a day.

Cognitive-Behavioral Therapy

For patients with persisting anxiety symptoms, cognitive–behavioral strategies similar to those used for ambulatory patients with anxiety disorders may be adapted to the hospitalized medical patient. CBT for anxiety disorders brings to bear an array of cognitive restructuring, exposure, and symptom management techniques that target the core fears and behavioral pattern characterizing each anxiety disorder. Cognitive interventions include a variety of procedures to challenge and restructure the inaccurate and maladaptive cognitions that increase anxiety and help maintain anxiety disorders. Procedures range from informational discussions, self-monitoring, and socratic questioning to the construction of behavioral experiments in which patients can directly examine the veracity of anxiogenic expectations. A reliance on corrective experiences also lies at the heart of exposure interventions that provide patients with opportunities to extinguish learned fears, by directly confronting (in a hierarchical fashion) feared events and sensations. Symptom management techniques typically include relaxation and breathing retraining procedures to help eliminate anxiogenic bodily reactions. In addition, training in problem-solving or social skills may be necessary to eliminate behavioral deficits that help maintain anxiety disorders. Likewise, couple's sessions may be required to change family patterns that help maintain avoidant or other anxiety-related behaviors.

Cognitive–behavioral treatment centers on the elimination of core features of each disorder, with treatment for panic disorder targeting fears of arousal, anxiety, and panic symptoms; treatment for social phobia targeting fears of negative evaluations by others; and treatment for PTSD targeting fears of cues of the traumatic event, including fears of the memory and anxiety symptoms accompanying the memory of the trauma. Treatment for GAD focuses on the aberrant worry process itself but also includes symptom management procedures, and treatment for OCD focuses on breaking the link between intrusive thoughts, anxiety, and compulsive behaviors using exposure techniques combined with compulsion-response prevention.

The success of these strategies has made them among the most promising in the treatment literature, with the efficacy of CBT equaling or surpassing that of alternative treatments.[101,124–128] Nonetheless, referral for CBT may be limited by the availability of clinicians specializing in these methods. In addition, the hospital setting may not allow timely initiation of treatment or the completion of basic treatment packages. Basic treatment interventions are commonly delivered in a series of 12 to 16 sessions, although patients may respond much earlier. For patients unresponsive, uninterested, or unwilling to make the initial time investment required for CBT, pharmacotherapy offers the most efficacious alternative.

14 Alcoholic Patients: Acute and Chronic

Julie D. Ross, M.D., Ph.D.
David R. Gastfriend, M.D.
John A. Renner, Jr., M.D.

From cases of simple intoxication, when the diagnosis can be made on the basis of breath odor and slurred speech, to the more complicated mental status of withdrawal states, alcohol is responsible for more psychiatric and neuropsychiatric problems in general hospitals than are all other substances combined. One study found that nearly 25% of patients who were hospitalized for injuries were intoxicated at the time of their trauma,[1] and estimates of the prevalence of alcohol-related problems in general hospitals range from 12.5% to 30%.[2] Even when problem drinking is not in the immediate picture, a history of alcoholism or of heavy social drinking predisposes a patient to delirium in conjunction with surgery, fever, head trauma, or massive burns. This vulnerability may be related to the neuropathologic changes that have been found in the brains of heavy drinkers and alcoholics. Yet, the Centers for Disease Control and Prevention (CDC) reports that millions of Americans with drinking problems are still not given advice about how to restrict and control their use of alcohol.[3]

Failure to diagnose alcoholism and other substance abuse in hospitalized patients is exceedingly costly in terms of morbidity and expense. At a major East Coast teaching hospital, when investigators reviewed more than 1000 consecutive admissions during a 23-day period, the actual number of substance abusers admitted was 160, as assessed by an independent evaluator; however, in no cases did physicians document that substance abuse was addressed. Hospital costs for these 160 substance abusers totaled $4.3 million over the 23-day period.[4] When substance abusers were identified by hospital-based physicians and offered referrals, nearly two thirds accepted.[5] Months after referral, these patients reported improved outcomes with respect to alcohol problems (e.g., abstinence, duration since last drink, job performance, and personal happiness).[5–7]

Controlled studies have confirmed that even a single, brief, detailed discussion by the physician yields measurable reductions in the consequences of alcoholism.[8,9] Therefore, the Institute of Medicine[10] called for the screening of hospitalized patients for alcohol problems. A simple, inexpensive screening interview, the CAGE questionnaire (Table 14–1)[11] offers brevity, as well as low cost, and better sensitivity and specificity for alcohol problems than currently available blood markers (such as serum γ-glutamyl transpeptidase, serum transaminases, and mean corpuscular volume).[12] Laboratory markers, particularly the serum level of carbohydrate-deficient transferrin, can be helpful, however, in tracking decrements in patients' drinking following intervention.[11]

DRUNKENNESS

Inebriation is a potentially disruptive and dangerous state. Few sights are more frightening than that of a young and powerful patient, mindlessly angry, anesthetized to pain, yet in full possession of coordination and muscular power.

Management

The actions of ethanol on neuronal systems are complex; initially, use of ethanol at low doses produces electrical excitability, whereas at higher doses it depresses it. Behavioral disinhibition is mediated by alcohol's action as a gamma-aminobutyric acid (GABA) agonist, and its interactions with the serotonin system might account for its association with violent behavior.[13] Blood alcohol concentrations (BACs) as low as 40 mg/dL can impair memory, leading to an alcoholic blackout; argumentativeness or assaultiveness can arise at 150 to 250 mg/dL, and coma or death can occur at 400 to 500 mg/dL. Yet, chronic alcoholics, owing to tolerance, may be fully alert with blood alcohol concentrations of more than 800 mg/dL.[14] Because these interactions are unpredictable, the first principle of management is to *alert the hospital police or security force* before starting an interview with a boisterous drunk. Although such support is seldom required, it is reassuring to have police assistance at the ready, especially if the patient is armed or has a history of violence.

The second principle is for staff to *be tolerant and nonthreatening*. People who possess a skill for disarming an abusive intoxicated individual seem to have little or no need to express their authority or toughness, even though they may possess both qualities in abundance. They tolerate insults, threats, and oaths because they do not take them personally. Conversely, we have observed that persons who galvanize the alcoholic's anger and mobilize his or her aggression are often autocratic and rigid; their flimsy sense of security is easily punctured by an inebriate's invective. The successful interviewer temporarily accepts the intoxicated person as he or she is; the unsuccessful interviewer rapidly attempts to make the drunk act civil. This latter effort usually backfires.

When approaching an alcohol abuser, a handshake of introduction should be extended. Unless the patient

C	Have you felt the need to **C**ut down on your drinking?
A	Have people **A**nnoyed you by criticizing your drinking?
G	Have you ever felt bad or **G**uilty about your drinking?
E	Have you had a drink first thing in the morning to steady your nerves or to get rid of a hangover (i.e., an "**E**ye opener")?

*A score of two positive items indicates the need for detailed assessment.[11]

CASE 1

A psychiatrist was called to the emergency department (ED) to see a patient who had leapt from the examining table while a scalp laceration was being repaired. The patient accused the intern of deliberately trying to hurt him. The patient was a large man with a deep and penetrating voice and a menacing manner. The psychiatrist, a small woman, asked the others to leave, which they did reluctantly. They heard the patient thunder accusations for 3 to 4 minutes. Then quiet reigned. The psychiatrist emerged 5 minutes later, and the patient was lying peaceably on the examining table after having consented to an intramuscular (IM) injection of a sedative. The psychiatric technique was simple. During a pause for breath in his ranting, she told him that she was frightened. He stared at her for a moment. Then he muttered, "Don't want to scare you," and accepted the sedative.

is well known, the patient should be addressed by his or her proper name, for example, "Mr. Smith" or "Ms. Smith." For the time being, no attempt should be made to change the patient's behavior; instead, it is better to listen to their tirade and to make sense of it, rather than to demand that the patient lower his or her voice and to talk temperately. This approach has occasionally uncovered a legitimate grievance or misunderstanding that, once corrected, quickly alleviated the patient's bellicosity.

It is advisable to avoid direct eye contact that lasts for more than a few seconds at a time. More than momentary eye contact is often taken as a challenge; it becomes the prelude to combat (as it can be for animals). The interviewer should listen intently to what the patient has to say and appear puzzled or perplexed rather than angry or amused if the accusation or complaint is absurd. Above all, it is important to avoid a belligerent posture. A colleague once observed that he patterned his behavior with hostile drunks after the humble-submissive posture assumed by a wolf when bested in battle. Transposed to the human habitus, this physician keeps his eyes downcast, fists unclenched, and shoulders stooped. Once the patient sees that the interviewer is not going to attack, his outburst may quiet and his anger slacken.

The third principle is to *offer food*. Some of the most antagonistic alcoholics have been soothed by an offer of coffee. If the person is willing to leave the scene with the inducement of coffee, food, and quiet, he or she should be escorted to a lobby or foyer where people are within easy calling distance. Many alcoholic persons are claustrophobic and feel trapped in small rooms. Furthermore, it is discomforting for most physicians to be in an enclosed area with a potentially violent person. The value of offering food, cigarettes, or drink in this case can be justified by empirical evidence only. With food, the patient often loses his or her belligerence. The next step is to persuade the patient to take a sedative (if alert and agitated) or an antipsychotic (if still ataxic and dysarthric) and to go to bed.

As in handling other conditions of psychotic excitement, it often helps to let the patient know that his or her behavior is frightening. Resolution of intoxication follows steady-state kinetics, so that a 70-kg man metabolizes approximately 10 mL of absolute ethanol or 1.5 to 2 drink equivalents (1½ oz whiskey = 5 oz wine = 12 oz beer) per hour.[15]

To sedate an intoxicated patient, one must begin with a smaller dose than usual to avoid confusion secondary to the cumulative effects of alcohol and the agent used. Once the patient's tolerance has been established, a specific dose can be safely determined. In the patient who is excessively agitated without ataxia or dysarthria, lorazepam (Ativan) 1 to 2 mg offers effective absorption via all routes—orally, intramuscularly, or intravenously; diazepam (Valium) and chlordiazepoxide (Librium) are erratically and slowly absorbed after IM administration unless they are given in large, well-perfused sites. When incoordination suggests that the additive effect of a benzodiazepine has produced excessive sedation, it may be advantageous to use haloperidol (5 to 10 mg). The initial dose should be followed by a wait of 30 minutes to 1 hour before augmenting it.

Just being acutely intoxicated does not require hospitalization. If there is no risk of withdrawal, the patient can safely be referred to an alcohol detoxification program. Inpatient detoxification is preferable to outpatient care if the patient is not well known to the team; is psychosocially unstable; has serious medical, neurologic, or psychiatric co-morbidity; has previously suffered withdrawal complications; or is undergoing his or her first episode of treatment.[16] Repeatedly undertreated withdrawal can put the patient at subsequent risk for withdrawal seizures and for other neurologic sequelae. This increasing risk is believed to occur through "kindling," a type of electrophysiologic effect,[17] and it may be mediated, similar to other neurodegenerative effects of ethanol, via the glutamate excitatory neurotransmitter system.[18]

ALCOHOLIC COMA

Alcoholic coma, although rare, is a medical emergency. It occurs when extraordinary amounts of alcohol are consumed, often in conjunction with another drug. The main goals of treatment are to prevent aspiration by taking appropriate precautions, to monitor closely for respiratory depression (because of the potential need for admission to the intensive care unit), and to be prepared for respiratory arrest with a need for mechanical ventilation (realizing that the GABA antagonist flumazenil might not reverse ethanol's respiratory depression).[19]

PATHOLOGIC INTOXICATION AND ALCOHOLIC PARANOIA

In pathologic intoxication, the patient becomes intoxicated on small amounts (as little as 4 oz) of alcohol. There may be subsequent automatic behavior that is violent and for which the patient is totally amnestic. The alcoholic person with a known history of pathologic intoxication should be sedated heavily and confined until sobriety is ensured to avoid possible danger to others.

Pathologic intoxication might last for an hour or for days, and it usually ends after prolonged sleep. During the episode, the patient is agitated, impulsive, and often aggressive. Delusions and visual hallucinations can occur. Generally the disorder is marked by hyperactivity, anxiety, or depression. Suicide risk is increased during these episodes. It may be more likely in patients with borderline personality disorder or epilepsy or in persons who tend toward emotional instability and whose pattern of defense is easily disorganized. Haloperidol 5 to 10 mg PO or IM decreases agitated or violent behavior with a minimum of sedation and with little likelihood of potentiating seizures. Doses may be repeated in 30 minutes, if necessary.[20]

Alcoholic paranoia is somewhat similar to pathologic intoxication. It is a state of cognitive disorganization brought about by use of alcohol that may manifest as strong feelings of jealousy, antagonism, or suspicion.

The prognosis is poor for patients with pathologic intoxication or alcoholic paranoia. Such patients often have a history of violence and aggression with repeated incarcerations. The consultation psychiatrist should be on the watch for emergence of amnesia or for the return of the premorbid behavior after the intoxication has been slept off. Although the premorbid personality of the paranoid alcoholic patient is apt to be somewhat suspicious, it is not nearly as intense or threatening as when the patient is under the influence of alcohol.

ALCOHOL WITHDRAWAL SYNDROME

The syndrome of alcohol withdrawal can range from mild discomfort that requires no medication to multiorgan failure that requires intensive care. Uncomplicated withdrawal is surprisingly common and often missed. Although more than 90% of alcoholics in withdrawal need nothing more than supportive treatment, those with co-morbid illness in the general hospital undoubtedly have a higher rate of complications.[21] The most common features of uncomplicated alcohol withdrawal emerge within hours and resolve after 3 to 5 days as the blood alcohol concentration decreases. Symptoms of uncomplicated withdrawal are predictable: Loss of appetite, irritability, and tremulousness are early features. A hallmark of the abstinence syndrome is generalized tremor (fast in frequency and more pronounced when the patient is under stress). This tremor can involve the tongue to such an extent that the patient cannot talk. The lower extremities can tremble so that the patient cannot walk. The hands and arms can shake so violently that a drinking glass cannot be held without spilling the contents. The patient is hypervigilant, has a pronounced startle response, and complains of insomnia.

Less commonly, a patient experiences hallucinations (without delirium) or seizures associated with alcohol withdrawal. Illusions and hallucinations of a mild variety can appear and produce vague uneasiness. These symptoms can persist for as long as 2 weeks and then clear without the patient developing delirium. Grand mal seizures ("rum fits") can occur, usually within the first 2 days. More than one out of every three patients who suffer seizures develop subsequent delirium tremens (DTs).[22]

Treatment

Rigid adherence to only one protocol for all alcohol withdrawal is unrealistic. Moreover, the failure to individualize treatment can increase costs—an undesirable result in the era of managed and capitated care. Symptom-triggered dosing, in which dosages are individualized and only administered upon the appearance of early symptoms, can reduce medication doses and shorten symptom duration,[23,24] although benefits may be less dramatic in the medically ill.[25]

Chlordiazepoxide (50 to 100 mg orally) may be given initially, and may be followed by 50 to 100 mg every 1 to 2 hours until the patient is sedated and the vital signs are within normal limits. Alternatively, diazepam 10 to 20 mg may be given initially, and then repeated every 1 to 2 hours until sedation is achieved.

Often a first day's dose of a long-acting benzodiazepine is sufficient for the entire detoxification process because of the self-tapering effect and slow elimination.[26] Patients with impaired liver function are better managed with drugs that avoid oxidative metabolism and rely on glucouronidation (such as oxazepam or lorazepam); after control is achieved, doses may be tapered by 25% per day over the subsequent 3 to 6 days. Other protocols involve use of standing doses for prophylaxis and treatment of withdrawal; these can also reduce length of stay and hospital costs.[27]

ALCOHOLIC HALLUCINOSIS

Diagnosis

Much less common than delirium from alcohol withdrawal, but more bizarre, is alcoholic hallucinosis. The onset is usually within 48 hours after alcohol cessation, but it can occur during active drinking or weeks later. The patient experiences vivid auditory illusions and hallucinations that occur in an otherwise clear sensorium. These hallucinations can become accusatory and threatening. The patient reacts with fear but is fully oriented and realizes that the voices are hallucinations. As the accusations persist, however, the patient develops ideas of persecution. Although hallucinosis is more apt to occur in the setting of alcohol withdrawal, it is by no means uncommon in persons who continue to drink. Some authors believe that hallucinosis is programmed by a disturbance of the auditory pathways. Olfactory hallucinations can occur with alcoholic hallucinosis, but visual hallucinations seldom occur.

The clinical picture is one in which auditory hallucinations occur in the absence of tremor, disorientation, and agitation. Soon after the voices begin, a frightening systematized delusional system develops that can incite the patient to call the police or to arm himself or herself. Then

the patient is particularly dangerous. The patient is capable of acting with an otherwise clear mind. Suicide is a distinct danger in this condition and it can occur, as in delirium, without appreciable warning.

CASE 2

A 27-year-old merchant seaman had begun listening to a local disc jockey while at a bar the previous evening. His attention was suddenly caught when he heard his name announced as a third-prize winner. He had won 14 sheep, 5 head of cattle, and a strawberry farm in Kansas. A taxi driver who had listened to him for 3 hours and had driven him to multiple radio stations finally insisted on taking him to a hospital. Because this was the early 1950s, the era of the colossal giveaways, the story sounded plausible, especially because the patient told it in a straightforward and reasonable manner. The cab driver was asked by hospital personnel whether he had heard the announcement on the car radio. The driver exclaimed, "Oh, no! Not you too! " The seaman clearly believed these voices to be real. He readily agreed, however, to enter the hospital and seemed certain that the truth of his statement would be quickly discovered if he were hospitalized. A week later, he no longer heard voices and had substantially minimized the experience, just as he forgot that alcohol had caused it.

Other psychotic conditions, such as paranoid schizophrenia, may be confused with alcoholic hallucinosis. Creation of a differential diagnosis is apt to be difficult. The predominance of the auditory component of the disorder and a history of alcoholism can aid in the diagnosis of this condition.

Treatment

There is no specific treatment for alcoholic hallucinosis. Generally the condition clears within 30 days, but it can last another month. There are reported instances in which the hallucinosis continued for years. If the person continues to drink, recurrences are the rule.

The most important aspect of treatment is to determine whether the patient should be in a protected environment. Behavior destructive to the self or to others is common, and it can require commitment to a psychiatric hospital. Sedation with benzodiazepines can be given as needed. Because patients in general feel quite normal after the disappearance of auditory hallucinations, they often insist on being discharged as soon as the voices desist. As in DTs, the course can be intermittent, and the patient should be kept in a hospital until 1 to 2 days have passed without hallucinations. The patient should also be vigorously warned against drinking because the hallucinations are apt to return with a relapse.

ALCOHOL WITHDRAWAL SEIZURES

Withdrawal seizures are estimated to occur in only 1% of unmedicated alcoholics undergoing withdrawal, although the prevalence is increased in persons with prior alcohol withdrawal seizures, seizure disorders, and previous brain injury.[22] Although brain imaging may not be necessary in first-episode patients,[28] seizures during alcohol withdrawal require careful examination for other causes. Indications for imaging studies include neurologic and other physical findings suggesting focal lesions, meningitis, and subarachnoid hemorrhage—all of which can occur in patients with prior alcohol withdrawal seizures. Multiple prior detoxifications predispose to withdrawal seizures more than the quantity or duration of a drinking history; this implies kindling.[29] Seizures can occur during relative withdrawal or during the 6 to 24 hours after the cessation of drinking. Generalized seizures typically occur (i.e., in 75% of cases) in the absence of focal findings and in persons with otherwise unremarkable electroencephalogram (EEG) findings. Repeated seizures can occur over a 24-hour period; however, status epilepticus occurs in less than 10% of those who seize.[30]

Treatment

In patients without a prior seizure disorder, diphenylhydantoin offers no benefit over placebo, and given the potential for side effects, diphenylhydantoin is therefore not indicated.[29] Also, given that loading with carbamazepine or valproate might not address the rapid time course of withdrawal seizures, the most parsimonious approach remains effective treatment with benzodiazepines. In cases where there is a known seizure disorder, however, conventional management with anticonvulsants is in order.

DELIRIUM ASSOCIATED WITH ALCOHOL WITHDRAWAL

The major acute complication of alcohol withdrawal, DTs, has been renamed *alcohol withdrawal delirium* in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV).[31] Until open heart procedures spawned new postoperative deliria, DTs were by far the most commonly encountered delirium in a general hospital, reportedly occurring in 5% of hospitalized alcoholics.[32] Because deaths have occurred in 10% of patients with untreated alcohol withdrawal delirium and in 25% of those patients with medical or concomitant surgical complications,[33] it is imperative to be on the alert for this life-threatening condition.

Prediction

It is difficult to predict who will develop DTs. Until a decade ago, DTs rarely developed in patients younger than 30 years. This is no longer true. Today the condition is often observed in young patients who may have had a decade or more of chronic heavy alcohol consumption. The mechanisms might involve *N*-methyl-D-aspartate (NMDA)-glutamate receptor supersensitivity.[17] Although DTs are regarded as a withdrawal syndrome, some heavy drinkers fail to develop delirium after sudden withdrawal of ethanol. Infection, head trauma, and poor nutrition probably contribute to delirium. A history of DTs is an obvious predictor of future DTs.

CASE 3

A 64-year-old longshoreman entered the hospital with recurrent gout (16 episodes during a 3-year period). During each hospital admission he became tremulous and disoriented on the second night and went on to develop mild visual and vestibular hallucinations that cleared over 3 days. Large ships would issue though the walls or windows, and the whole room would rock and sway like a wharf in a storm. The pattern was identical, including his insistence that the only alcohol he ever swallowed was a drop or two from his mouthwash.

Diagnosis

The incidence of DTs is approximately 5% among hospitalized alcoholics and about 33% in patients with alcohol withdrawal seizures.[34] If DTs are to occur, they generally do so within 72 hours after abstinence begins. There have been reports, however, of cases in which the clinical picture of DTs did not emerge until 7 days after the last drink.[34] The principal features are disorientation (to time, place, or person), tremor, hyperactivity, marked wakefulness, fever, increased autonomic tone, and hallucinations. Hallucinations are generally visual but they may be tactile, olfactory, or auditory. Vestibular disturbances are common and often hallucinatory. The patient might complain of the floor moving beneath his or her feet or believe that he or she is on an elevator. The hallucinatory experience is always frightening. Animals, typically snakes, are seen in threatening poses. Mice or lice are felt and seen crawling on the skin.

Once the condition manifests itself, DTs usually last 2 to 3 days,[34] often resolving suddenly after a night of sound sleep. Should it persist for a longer time, one must suspect an underlying disorder, such as an infection or subdural hematoma. There are a few patients whose course is characterized by relapses with intervals of complete lucidity. These patients offer the consultant the most challenging diagnostic opportunities. As a rule of thumb, it is always wise to include DTs in the list of diagnoses considered whenever delirium appears.

A psychiatric consultant is apt to miss the diagnosis of DTs when the patient's manner, social position, or reputation belies the possibility of alcoholism. For example, the following problem arose after emergency surgery.

CASE 4

A 54-year-old woman was admitted to the hospital for a cholecystectomy. On her third postoperative day (her fifth day without alcohol), the nurses reported that they could not keep her in bed. She got up and walked about her room in a restless, agitated fashion, constantly gazing back over her shoulders as though she feared she was being followed. She wandered into other patients' rooms as well as down the hospital's corridor. She vigorously resisted every attempt to keep her confined to her quarters. The surgeon, when called, described her as "fearful, overactive, stubborn, but polite." Although she would not give any reason for her distress, she readily swallowed a 25-mg capsule of chlordiazepoxide hydrochloride. This produced no change in her behavior after 2 hours. She talked to herself while she paced, but she was able to maintain a shaky semblance of poise when approached by others. Although her physician opposed psychiatric consultation, the nurses prevailed because they feared she might inadvertently hurt herself. When a house officer suggested the possibility of a small stroke because of the patient's long history of hypertension, the physician agreed to request psychiatric advice.

After reviewing the history and noting a bilateral hand tremor while observing the patient, the psychiatrist diagnosed DTs. Although the patient refused to speak with him after he identified himself, the psychiatrist maintained his diagnosis because it was the most likely possibility in the absence of other signs. Her personal physician refused to accept the diagnosis but did follow the recommended regimen of medication (100 mg of chlordiazepoxide each hour) until the patient was able to stay in bed. The medication was then reduced to a maintenance level and supplemented by 50 mg of thiamine daily. Round-the-clock special nurses were also employed. In the morning, following a night's sleep, the patient was her normal self.

The patient subsequently admitted to drinking four to seven very dry martinis (each about 4 oz) daily. She had been doing so for the last 30 years and had delivered all her children without having developed DTs. She was so frightened by her experience, however, that she agreed to enter treatment for alcohol dependence.

The consultant can be easily misled when the delirium is intermittent and the patient is examined during a lucid period.

CASE 5

A 52-year-old architect was admitted to the hospital because of hematemesis. He readily admitted to heavy alcohol intake but had no difficulty until the fourth hospital day when he began to gaze fixedly at a point on the ceiling and to talk in low, menacing tones to an imaginary companion. He sweated, trembled, and thrashed about so wildly that he had to be restrained. He readily described auditory hallucinations of a persecutory nature; these became alarmingly vivid in the evening. The following morning when a psychiatrist was called to see him he was fully oriented, lucid, perfectly capable of discussing his hallucinations of the previous evening, and willing to accept the diagnosis of DTs. Restraints were removed. However, a few hours later the patient leapt out of bed, ran through the corridors, upset tables, and screamed that someone was chasing him. Once again he was placed in bed, forcibly restrained,, and given 8 mL of paraldehyde orally and 50 mg of chlorpromazine intramuscularly. When the psychiatrist returned a few hours later, the patient's mental status was entirely normal, and he could recall the violent episode. He was, in fact, so clear-thinking that the psychiatrist again suggested that the restraints be removed. Within 20 minutes, the patient sprang out of bed, left the unit, and almost left the hospital. After this second unexpected episode, the consultant sent him to a psychiatric hospital where he remained for the next 2 weeks with intermittent episodes of delirium.

Although a course marked by intermittent episodes is highly atypical for DTs, it does occur. Consultants should be wary of relinquishing restraints or discontinuing intensive observation until the patient has been lucid for 24 hours.

Differential Diagnosis

The differential diagnosis must include the many causes of delirium in a general hospital. Hypoglycemia and alcoholic and diabetic ketoacidosis can co-occur with alcohol withdrawal; these are readily distinguished by their attendant electrolyte and blood glucose abnormalities and by their differential response to emergency treatment. Delirium occurs after surgery and after concussion, as well as with other metabolic disorders. Two examples of the latter are impending hepatic coma and acute pancreatitis. A patient with impending hepatic coma may well be disoriented and confused but tends to manifest decreased activity rather than agitation.[35] Speech is slow and monotonous, and the face is masklike. Physical signs, such as jaundice, hepatomegaly, and *fetor hepaticus* from elevation of blood ammonia levels, help determine this diagnosis. A delirium sometimes occurs in acute pancreatitis. In this condition, however, there is generally severe abdominal pain and an elevated serum amylase concentration.[35]

Prognosis

The prognosis for DTs is reasonably good if the patient is aggressively medicated; however, death can occur as the syndrome progresses through convulsions to coma and death. Death can also result from heart failure, an infection (chiefly pneumonia), or injuries sustained during an agitated period. In a small percentage of patients the delirium can co-exist with Korsakoff's psychosis, in which case the patient might not regain full mentation.

Treatment

Prevention is the key. Symptom-triggered dosing for alcohol withdrawal has been shown to reduce DTs compared to standing orders for benzodiazepines in medically ill inpatients, and fixed-dose, round-the-clock protocols have also been beneficial.[25,27] As in the treatment of any delirium, the prime concern must be round-the-clock surveillance so that the patient cannot harm himself or herself or others. This monitoring is essential. Although not necessarily suicidal, delirious patients take terrible unpremeditated risks. Falling from windows, slipping down stairs, and walking through glass doors are examples of such unintended lethal behavior. Restraints should be used for as short a period as is needed. As required by law, when four-point restraints are used, the patient must be closely observed, and relief must be provided hourly. Usually, physical restraint can be avoided with aggressive pharmacotherapy.

The patient can require careful rehydration (up to several liters of saline per day), correction of electrolyte imbalance (particularly magnesium), prevention of hypoglycemia, or correction of hyperthermia (with a cooling blanket), as well as nutritional supplementation. Concurrent aggravating conditions (e.g., sepsis, meningitis, subdural hematoma, hepatic failure, and pancreatitis) must be considered.

The delayed onset of this state of hyperarousal might reflect alcohol's broad effects across multiple neurotransmitter systems, chief among which may be the NMDA-glutamate system.[18] Adrenergic hyperarousal alone appears to be an insufficient explanation; therefore, α-adrenergic agonists (e.g., clonidine and lofexidine) alone are not sufficient. Benzodiazepines might not suffice either; in rare cases, we have seen doses in excess of diazepam 2000 mg/day prove insufficient. Haloperidol (5 to 10 mg PO or IV) may be added and repeated after 1 to 2 hours when psychosis or agitation is present.

Because the B vitamins are known to help prevent peripheral neuropathy and the Wernicke–Korsakoff syndrome, their use is vital. Thiamine 100 mg should be given intravenously immediately, and 100 mg should be given intravenously for at least 3 days until a normal diet is resumed. Folic acid (1 to 5 mg per day PO or IM) should be included for megaloblastic anemia and peripheral neuropathy. A high-carbohydrate soft diet containing 3000 to 4000 calories a day should be given with multivitamins.

WERNICKE–KORSAKOFF SYNDROME

Victor and associates,[32] in their classic monograph *The Wernicke–Korsakoff Syndrome*, stated that "Wernicke's encephalopathy and Korsakoff's syndrome in the alcoholic, nutritionally deprived patient may be regarded as two facets of the same disease." Although perhaps 5% of alcoholics have this disorder, in 80% of these, the diagnosis is missed. In all of the cases reported by Victor and associates, alcoholism was a serious problem and was almost invariably accompanied by malnutrition. Malnutrition, particularly in the absence of thiamine, has been shown to be the essential factor.

Korsakoff's Psychosis

Korsakoff's psychosis, also referred to as *confabulatory psychosis* and *alcohol-induced persisting amnestic disorder* in DSM-IV,[31] is characterized by impaired memory in an otherwise alert and responsive person. This condition is slow to start and may be the end stage of a lengthy alcohol-dependence process. Hallucinations and delusions are rarely encountered. Curiously, confabulation, long regarded as the hallmark of Korsakoff's psychosis, was exhibited in only a limited number of cases in the large series collected and studied by Victor and associates.[32] Most of these patients had diminished spontaneous verbal output, no insight into the nature of their illness, and a limited understanding of the extent of their memory loss.

The memory loss is bipartite. The retrograde component involves the inability to recall the past, and the anterograde component is the lack of capacity for retention of new information. In the acute stage of Korsakoff's psychosis, the memory gap is so blatant that the patient cannot recall simple items (such as the examiner's first name, the day, or the time) after a few minutes, even though the patient is given this information several times. As memory improves, usually within weeks to months, simple problems can be solved, limited always by the patient's span of recall.

Patients with Korsakoff's psychosis tend to improve with time. In the series of Victor and associates,[32] 21% of the patients recovered more or less completely, 26% showed no recovery, and the rest recovered partially.[31] During the acute stage, there is, however, no way of predicting who will improve and who will not. The EEG may be unremarkable or might show diffuse slowing, and magnetic resonance imaging (MRI) might show changes in the periaqueductal area and medial thalamus.[14] The specific memory structures that are affected in Korsakoff's psychosis are the medial dorsal nucleus of the thalamus and the hippocampal formations.

Wernicke's Encephalopathy

Wernicke's encephalopathy appears suddenly and is characterized by ophthalmoplegia and ataxia followed by mental disturbance.[32] The ocular disturbance, which is necessary for the diagnosis, consists of paresis or paralysis of the lateral rectus muscles, nystagmus, and a disturbance in conjugate gaze. A global confusional state consists of disorientation, unresponsiveness, and derangement of perception and memory. Exhaustion, apathy, dehydration, and profound lethargy are also part of the picture. The patient is apt to be somnolent, confused, and slow to reply and can fall asleep in midsentence.

Once treatment with thiamine is started for Wernicke's encephalopathy, improvement in the ocular palsies is often evident within hours. Recovery from ocular muscle paralysis is complete within days or weeks. In cases reported by Victor and asssociates,[32] approximately one third recovered from the state of global confusion within 6 days of treatment, another third within 1 month, and the remainder within 2 months. The global confusional state is almost always reversible, in marked contrast to the memory impairment of Korsakoff's psychosis.

Treatment

Administration of the B vitamin thiamine (IM or IV) should be routine for all suspected intoxicated and dependence patients, directly in the ED or immediately on admission, whichever comes earlier.[36] The treatment for Wernicke's encephalopathy and Korsakoff's psychosis is identical, and both are medical emergencies. Because subclinical cognitive impairments can occur even in apparently well-nourished patients, routine orders should include thiamine, folic acid, and multivitamins with minerals, particularly zinc. Prompt use of vitamins, particularly thiamine, prevents advancement of the disease and reverses at least a portion of the lesions where permanent damage has not yet been done.[32] The response to treatment is therefore an important diagnostic aid. In patients who show only ocular and ataxic signs, the prompt administration of thiamine is crucial in preventing the development of an irreversible and incapacitating amnestic disorder.

Treatment consists of 100 mg of thiamine and 1 mg of folic acid given intravenously immediately and 100 mg of intravenous thiamine each day until a normal diet is resumed, followed by oral doses for 30 days. Parenteral feedings and the administration of B-complex vitamins become necessary if the patient cannot eat. Because these patients have impaired mental function, nursing personnel should be alerted to the patient's possible tendency to wander, to be forgetful, and to become psychotic. If the last should occur, benzodiazepines can be given.

MEMORY AND ALCOHOL

Cranial computed tomography (CT) and MRI scans, and neuropsychological tests have demonstrated a loss of brain tissue and cognitive impairments in persons who are alcoholics or heavy drinkers, findings that largely escaped notice until the advent of these modern techniques. Abnormalities on the CT scan have been reported in 50% or more of chronic alcoholic subjects.[37] These abnormalities can occur in subjects in whom there is neither clinical nor neuropsychological test evidence of cognitive defects. In chronic alcoholics, MRI has demonstrated accelerating gray matter loss with age, which is to some extent reversible with abstinence, suggesting that some of these changes are secondary to changes in brain tissue hydration.[38]

Short-term memory, performance on complex memory tasks, visual motor coordination, visual spatial performance, abstract reasoning, and psychomotor dexterity are the areas most seriously damaged. Intelligence scores often do not change, and there is a sparing of verbal skills and long-term memory. As a consequence of this sparing, it is possible for patients to appear quite intact unless they are administered neuropsychological tests. According to Rinn and coworkers,[39] subtle impairment of executive function might underlie fixed denial, which inhibits self-awareness of alcohol's damaging effects, impairs learning from counseling, simulates resistance, frustrates caregivers, and generates anger toward the patient. These defects, particularly memory disturbances, can be reversed at least in part with abstinence.

For both the cognitive reasons described and emotional reasons, the principal problem encountered in all therapeutic modalities is denial. Many alcoholic patients in the general hospital who have problems secondary to drinking have difficulty admitting their addiction to alcohol. Research on substance abuse cessation has demonstrated that most patients do not suddenly leap from denial into active recovery, but rather proceed over time through five *stages of change* (Table 14–2).[40] Each patient must be assessed for his or her current stage regarding cessation of substance abuse and assisted to make the transition from the current to the next desired stage in a linear progression. The alternative (e.g., asking a patient in denial to enter intensive treatment immediately) is unrealistic and likely to disappoint both patient and provider. Intervention with the help of a significant other or family members can often make the pivotal difference. Family members often need education about the disease's potential effects on them as well, including the tendency to feel frustrated and hopeless about recovery. A brief meeting that covers the potential benefits of Al-Anon support can have lasting benefits for both family and patient.

REFERRAL AFTER HOSPITALIZATION

Brief intervention in general medical practice is a well-developed, effective technique.[9] Even brief contact with a specialist addiction consultant has been shown to yield

TABLE 14–2 Stages of Change and Treatment Objectives

STAGE OF CHANGE	TREATMENT OBJECTIVE
Precontemplation (i.e., denial)	Cultivate rapport through repeated contact to promote patient's self-examination
Contemplation (awareness of problem)	Review substance use losses and potential risks, such as detailed teaching about hematologic and liver abnormalities and prognostic implications with continued drinking
Preparation (intends behavioral change, seeks treatment)	Anticipate treatment benefits, promote sense of self-efficacy and optimism for recovery
Action (cessation and treatment or self-help participation)	Facilitate entry to treatment and contingency plan in the event of dropout
Maintenance (ongoing avoidance of relapse cues)	Plan for relapse prevention via longitudinal treatment and recovery treatment and recovery activity (i.e., self-help group participation)
Relapse (resumption of substance use)	Support rapid reconnection with treatment system

improvement rates in 30% to 50% of patients months after hospitalization, and this is more effective with those who have no prior psychiatric illness and addiction treatments and good social function and resources.[6] Compared with general consultation psychiatrists, specialist addiction nurse consultants were found to double the rate of patient follow-through and completion in rehabilitation (40% versus 88%, $P < .001$).[7] Addiction psychiatry consultation to hospital physicians should assist with diagnosis, intervention, pharmacologic management, and post–acute care referral. At the Massachusetts General Hospital (MGH), a centralized intake procedure has been available to conduct objective, multidimensional assessment and protocol-driven referral. Consultants tell each alcoholic patient about the types of treatment programs available in the community.

Alcohol dependence causes diverse disruptions in people's self-awareness, communication skills, capacity for relationships, sense of purpose in life, and spirituality. Alcoholics Anonymous (AA) and similar approaches that examine the broader character, lifestyle, and spiritual issues have a record of successful accomplishments and accessibility. Visits on the inpatient unit from AA volunteers may be particularly helpful when patients are ambivalent about accepting their physician's recommendation for alcoholism treatment. Such personal contact increases the likelihood that the patient will attend the AA program. Once the community resources have been identified and their differences described, the patient is advised of the optimal choice.

Despite the severity of their drinking problem, some alcoholics reject intensive approaches as too restrictive or stigmatizing. In this event, a *contingency contract* in which the patient may begin a less-intensive treatment is helpful, but if improvement does not follow within 4 to 6 weeks, the patient agrees to enter the recommended treatment (e.g., inpatient rehabilitation or a halfway house). When this plan is supported by family members, patients often follow through to a successful treatment episode.

Two decades ago, it was common policy at the MGH to insist that the patient make the first contact with the treating agency; however, only approximately one in five patients actually made contact with treatment. After the introduction of a *central intake model*, referral completion rates increased to 58%. Key features of central intake include directly assisting patients with access to treatment, helping patients to call programs, subsidizing transportation to treatment program interviews, obtaining concrete services to diminish treatment obstacles (such as homelessness or lack of child care), and motivational interviewing. Motivational interviewing is a directive, patient-centered counseling for eliciting behavioral change by helping to explore and resolve ambivalence to change.[41] With this brief technique, the provider assesses the patient's losses and risks in detail, helps the patient recognize the underlying cause as substance abuse, and uncovers ambivalence about the potential value of treatment. By avoiding a threatening style of confrontation about denial, motivational interviewing has been found to enhance motivation for recovery.[41]

Studies of treatment outcome show that up to two thirds of patients who enroll in therapeutic programs improve[42] in terms of abstinence or reduced amount of drinking. Pressures to shorten lengths of stay, while improving patient follow-through, are stimulating creative strategies. Examples include intensive case management, home nursing, counseling visitation, and predischarge initiation of pharmacotherapies (such as disulfiram, naltrexone, or selective serotonin reuptake inhibitors [SSRIs]).

Disulfiram (125 to 250 mg orally daily), an aversive agent when combined with alcohol, has reduced subsequent drinking days in chronic alcoholics by approximately 50%.[43] If a patient drinks alcohol after taking disulfiram, the disulfiram–ethanol reaction produces flushing, hypotension, headache, nausea, and vomiting. Naltrexone (50 mg orally daily), an opiate antagonist, has no adverse reaction with alcohol and has produced similar reductions in drinking days presumably through diminished reward from alcohol.[44,45] Because both agents have slight hepatotoxic risk themselves in addition to the risks from chronic ethanol use, liver function studies are helpful at baseline and then at 1, 3, and every 6 months thereafter.

Selective serotonin reuptake inhibitors have produced only modest drinking reductions—independent of antidepressant effects—at typical antidepressant doses, presumably through an anticraving effect, which may be more effective in patients with depression and early-onset type alcoholism.[46,47] These agents are gaining renewed interest as adjuncts to a comprehensive psychosocial recovery plan. If corroborated data indicate the existence of a comorbid psychiatric syndrome, and a treatment plan with expected good prognosis for abstinence can be put into place, studies support initiation of an SSRI antidepressant for co-occurring major depression, mood stabilizers for bipolar illness, buspirone for generalized anxiety, and third-generation antipsychotics for schizophreniform disease.[48]

The disposition of patients with an acute or chronic alcohol syndrome is clinically complicated and increasingly subject to economic pressures because of managed care. This requires multidimensional assessment to optimize the use of treatment resources.[49] The key dimensions of assessment are specified by the Patient Placement Criteria of the American Society of Addiction Medicine.[50] They include:

- Acute intoxication or withdrawal potential
- Biomedical conditions and complications
- Emotional and behavioral conditions or complications
- Treatment acceptance or resistance
- Relapse potential
- Recovery environment

These dimensions help determine both acute treatment needs and prognosis, and their use can inform the managed care review process as well.[51] All active problem areas among these dimensions must be addressed in the treatment plan to achieve a good likelihood of success.[52]

15 Drug-Addicted Patients

John A. Renner, Jr., M.D.
Julie D. Ross, M.D., Ph.D.
David R. Gastfriend, M.D.

The number of patients treated for substance abuse–related problems in the United States has grown steadily in the last decade. In fact, between 1997 and 2002, the number of emergency department (ED) visits for drug-related events increased by more than 24%.[1] Clinical presentations in this domain are also becoming more complex. More than 55% of the drug-related problems seen in EDs in the first half of 2002 involved use of multiple drugs. In 37% of these cases, drug dependence was identified as the primary problem; 20% of the cases involved individuals seeking drug-induced psychic effects, and 20% involved suicide attempts. Successful treatment of this expanding group of patients requires that clinicians improve their skills in the management of substance-related problems. Although most physicians feel comfortable treating the symptoms of substance abuse, it has been our experience that they are historically reluctant to deal with the core disease process, and little effort is made to refer patients for substance abuse treatment. The chronic, relapsing nature of substance abuse inspires cynicism and resignation and is inappropriately thought to imply that substance abuse treatment is not helpful. Because most clinicians fail to appreciate that the relapse rate for other common chronic medical disorders (e.g., diabetes, hypertension, asthma) exceeds that for substance abuse disorders, they do not treat substance abuse patients with comparable therapeutic diligence.[2] The policy at the Massachusetts General Hospital (MGH) is to ensure that problems related to substance abuse are addressed with the same degree of compassion and persistence that is directed to other common relapsing medical disorders. This chapter contains material to aid clinicians in the prompt recognition and effective management of patients with drug-related problems. The treatment of concurrent medical and surgical problems should always be seen as an opportunity for intervention regarding the underlying substance abuse problem.

STIMULANTS

Cocaine Abuse

After alcohol, cocaine continues to be the leading drug of abuse in terms of the frequency of ED contacts, general hospital admissions, family violence, and other social problems. The Drug Abuse Warning Network ED data for 2006 reported 548,608 visits related to cocaine, compared with 577,521 alcohol-related visits.[3] Acute users experience intense euphoria that is often associated with heightened sexual desire and improved sexual function. These rewards are often followed by a moderate to severe post-cocaine depression that sets the stage for further cocaine use.

The signs and the symptoms of acute cocaine intoxication are similar to those of amphetamine abuse. Typical complaints associated with intoxication include anorexia, insomnia, anxiety, hyperactivity, and rapid speech and thought processes ("speeding"). Signs of adrenergic hyperactivity (e.g., hyperreflexia, tachycardia, diaphoresis, and dilated pupils responsive to light) may also be seen. More severe symptoms (e.g., hyperpyrexia, hypertension, and cocaine-induced vasospastic events such as stroke or myocardial infarction) are relatively rare among users but are fairly common in the ED. Patients may also manifest stereotyped movements of the mouth, face, or extremities. Snorting cocaine may produce rhinitis or sinusitis and, rarely, perforations of the nasal septum. "Crack" is a highly-addictive freebase form of cocaine that is sold in crystals; it can be smoked, and freebasing (i.e., inhaling cocaine alkaloid vapors) may produce bronchitis. Grand mal seizures are another infrequent complication of cocaine use. Patients also describe "snowlights" (i.e., flashes of light usually seen at the periphery of the visual field).

The most serious psychiatric sequelae associated with chronic cocaine use is a cocaine-induced psychosis (frequently manifested by visual and auditory hallucinations, paranoid delusions, and violent behavior). Tactile hallucinations, called "coke bugs," involve the perception that something is crawling under the skin. Cocaine-induced psychosis may be indistinguishable from amphetamine psychosis, but it is usually shorter in duration.

Management

Cocaine abusers can be seen in any medical or surgical setting. Cocaine abuse became common among affluent young people in the early to mid-1980s; however, with the availability of packaged, smokable cocaine, or crack, in low-cost doses, all classes and racial groups have become potential users. Occasional cocaine use does not require specific acute treatment, unless a life-threatening overdose has occurred. Most large doses are metabolized within 1 hour by enzymes in the blood and liver. While the patient is awaiting metabolism, intubation and assisted breathing with oxygen may be necessary. Stroke has been reported, and death can be caused by ventricular fibrillation or myocardial infarction. The cardiac status of a cocaine user should therefore be monitored closely. IV diazepam should be used to control convulsions.

Chronic cocaine use produces tolerance, severe psychological dependency, and physiologic dependence marked by irritability, anhedonia, low mood, and anxiety.[4] Many cocaine-dependent individuals follow a cyclical pattern of 2 or 3 days of heavy binge use, followed by a withdrawal "crash." Use is resumed in 3 or 4 days, depending on the availability of cash and the drug. A gradual reduction in use of cocaine is almost never possible. Detoxification is accomplished by the abrupt cessation of all cocaine use, usually through restricted access (e.g., incarceration, the loss of funds or contacts). Withdrawal symptoms begin to resolve within 7 days; specific medical treatments are rarely indicated. The value of medication for withdrawal symptoms has yet to be confirmed. Drugs that enhance central nervous system (CNS) catecholamine function may reduce craving, although they are of limited benefit clinically and have not been proven efficacious in double-blind, placebo-controlled trials. The major complication of withdrawal is a severe depression with suicidal ideation. If this occurs, the patient usually requires psychiatric hospitalization.

For the cocaine addict, the compulsion to use is overwhelming. We have seen some patients who continued dealing drugs from their hospital rooms after near-fatal injuries, and others who injected cocaine through a region of intensely painful cellulitis that occasioned the admission. For this reason, an actively using cocaine-dependent patient who has been hospitalized should have a drug screen performed after any behavioral change, particularly after receiving visitors or leaving the floor. The patient's urine should be examined for cocaine metabolites or, preferably, all drugs of abuse.

All cocaine abusers should also be referred for individual or group counseling; participation in twelve-step self-help programs should also be strongly recommended. Similarly, family members or significant others should be referred separately to Al-Anon because they may gain insights that may help them eliminate systemic support for the patient's further drug use. Manual-guided cognitive-behavioral therapy has been shown as efficacious in the treatment of cocaine dependence.[5] Once compulsive cocaine use has begun, it is almost impossible for the user to return to a pattern of occasional, controlled use. Such individuals are also likely to develop problems with alcohol and other drugs. For that reason the goal of treatment should be total abstinence from cocaine and all other drugs.

Amphetamine Abuse

Stricter federal controls on the production and distribution of amphetamines have greatly reduced the number of amphetamine abusers. Routine medical evaluation may uncover the most common type of amphetamine abuse seen in the inpatient setting. Historically, this involves a patient who began using amphetamines to control obesity and later became a chronic amphetamine abuser. The patient quickly develops tolerance and may use 100 mg or more daily in an unsuccessful effort to control weight. This amphetamine abuse can be treated by abruptly discontinuing use of the drug or by gradually tapering the dose, whichever is more acceptable to the patient. In either case, the patient should be shown a more appropriate program for weight control.

A more serious problem involves the patient who develops a severe psychological dependence on amphetamines and who may present the same symptoms that are seen in younger street-drug abusers. Amphetamine and methamphetamine (speed) accounted for 16,215 ED visits in the first half of 2002.[1] Among amphetamine users, the signs and symptoms of acute amphetamine intoxication are similar to those described in the section on cocaine abuse.

The other classic syndrome, seen in either acute or chronic amphetamine intoxication, is a paranoid psychosis without delirium. Although typically seen in youth who use IV methamphetamine hydrochloride, it can also occur in individuals who use dextroamphetamine or other amphetamines orally on a chronic basis. The paranoid psychosis may occur with or without other manifestations of amphetamine intoxication. The absence of disorientation distinguishes this condition from most other toxic psychoses. This syndrome is clinically indistinguishable from an acute schizophrenic episode of the paranoid type, and the correct diagnosis is often made only in retrospect, based on a history of amphetamine use and a urine test positive for amphetamines. Intramuscular (IM) haloperidol is effective in the acute management of this type of substance-induced psychosis.

Treatment

Amphetamines can be withdrawn abruptly. If the intoxication is mild, the patient's agitation should be handled by reassurance alone. The patient should be "talked down," much as one would handle an adverse reaction to D-lysergic acid diethylamide. If sedation is necessary, benzodiazepines are the drugs of choice. Phenothiazines should not be used because they may heighten dysphoria and increase the patient's agitation. Hypertension will usually respond to sedation with benzodiazepines. For severe hypertension, we recommend vasodilation through the use of phentolamine; β- or mixed α- and β-adrenergic blockers (e.g., propranolol, labetalol) should be avoided because they may exacerbate stimulant-induced cardiovascular toxicity.

Most signs of intoxication clear in 2 to 4 days. The major problem is appropriate psychiatric management of post-amphetamine depression. In mild cases this depression is manifested by lethargy and the temptation to use amphetamines to increase energy. In more serious cases the patient may become suicidal and require inpatient psychiatric treatment. The efficacy of antidepressants in such cases has not been adequately documented. Even with support and psychotherapy, most patients experience symptoms of depression for 3 to 6 months after the cessation of chronic amphetamine abuse.

CLUB DRUGS

In the 1980s and 1990s, there was a significant increase in the abuse of so-called club drugs, primarily 3,4-methylenedioxy-methamphetamine (MDMA; Ecstasy), γ-hydroxybutyrate (GHB), and ketamine. MDMA has both amphetamine-like and hallucinogenic effects. It was initially used experimentally to facilitate psychotherapy, but its use was banned after it was found to be neurotoxic in animals. At higher doses, it produces distorted perceptions, confusion, hypertension, hyperactivity, and potentially fatal hyperthermia. GHB (sodium oxybate) is a

CNS depressant that has been approved by the Food and Drug Administration (FDA) for the treatment of narcolepsy (Xyrem). In overdose it can produce coma and death; it has also been identified as a "date-rape" drug. Another agent, ketamine, has been used as an anesthetic; it can produce delirium, amnesia, and respiratory depression when abused. The treatment for overdoses of all these drugs is primarily symptomatic.

NARCOTICS

Heroin-related ED visits have steadily increased in the last decade. The abuse of narcotic analgesics, primarily oxycodone (OxyContin), almost doubled between 1997 and 2002.[1] In addition, more than 31% of acquired immunodeficiency syndrome (AIDS) cases in the United States are related to the use of injection drugs.[6] As a result, the treatment of opiate dependence is becoming commonplace on medical and surgical units. Proper management of such patients necessitates knowledge of FDA regulations, appropriate techniques for using opiate substitution therapy, and community treatment resources.

The classic signs of opiate withdrawal are easily recognized and usually begin 8 to 12 hours after the last dose. The patient generally admits the need for drugs and shows sweating, yawning, lacrimation, tremor, rhinorrhea, marked irritability, dilated pupils, and an increased respiratory rate. More severe signs of withdrawal (e.g., tachycardia, hypertension, nausea, vomiting, insomnia, abdominal cramps) occur 24 to 36 hours after the last dose. Untreated, the syndrome subsides in 5 to 10 days. Similar withdrawal symptoms are seen in patients addicted to methadone, but they may not appear until 24 to 30 hours after the last dose, and they abate over 2 to 4 weeks, owing to its longer half-life. Patients addicted to oxycodone may experience a particularly severe and prolonged withdrawal syndrome and may require high doses of opiates to achieve adequate control.

FDA regulations define opiate substitution therapy (either methadone or buprenorphine maintenance) as any treatment with an approved opiate that extends beyond 30 days. Methadone maintenance clinics may extend detoxification treatment from 30 to 180 days if the briefer detoxification program is not successful. Addicts cannot be placed in methadone maintenance programs unless they show physiologic evidence of current addiction (i.e., withdrawal signs) and can document a 1-year history of addiction. The only exceptions to this rule are pregnant addicts; addicts who are hospitalized for the treatment of a medical, surgical, or obstetrical condition; and formerly addicted individuals who have just been released from prison. Under these regulations, the physician has the option of providing opiate substitution therapy to any addict for the duration of the pregnancy or the period of hospitalization required to treat the primary illness. At MGH, we strongly recommend that such treatment be continued until the addict has fully recovered from the presenting illness and that the addict then be referred to a maintenance clinic or a program for detoxification treatment.

In addition to methadone, other options for opiate substitution therapy include buprenorphine, a long-acting partial opiate agonist. Buprenorphine attenuates withdrawal symptoms by partial activation of the opioid receptor, and it can be used in the treatment of addicts who meet *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition, criteria for opiate dependence. When dispensed in a sublingual tablet in combination with naloxone, it has minimal potential for IV abuse and has been demonstrated effective for maintenance treatment.[7] It has been approved for use in the office-based treatment of opiate dependence and provides an attractive alternative to methadone treatment for higher-functioning addicts and individuals with short-term histories of opiate dependence. L-a acetylmethadol (LAAM), a synthetic opiate with a duration of action of 48 to 72 hours, was once used for maintenance treatment of opiate dependence and was withdrawn from the U.S. market in 2003 after the FDA required a black box warning because of cardiac-related adverse events related to prolongation of the QTc interval. LAAM is no longer available as a treatment in the United States.

If a patient is actively participating in an opiate substitution program on admission to the hospital, the methadone or buprenorphine dose should be confirmed by inpatient staff and should not be changed without consultation with the outpatient physician responsible for the patient's treatment. Under no circumstances should such a patient be withdrawn from drugs unless there is full agreement among the patient, the hospital physician, and the outpatient clinic staff on this course of action. Such detoxification is rarely successful, particularly if the patient is under stress from a concurrent medical or surgical condition. Withdrawal from drugs may complicate the management of the primary illness. The option of detoxification should not be considered until the patient has fully recovered from the condition that necessitated hospitalization.

Patients on long-term opiate substitution therapy should continue daily oral methadone treatment while hospitalized. If parenteral medication is necessary, methadone can be given in IM doses of 5 or 10 mg every 8 hours. This regimen should keep the patient comfortable regardless of the previous oral dose. An alternative method is to give one third of the daily oral dose as an IM injection every 12 hours. As soon as oral medication can be tolerated, the original oral dose should be reinstated.[8]

Establishing the appropriate dose of methadone for a street addict is a trial-and-error process. Because the quality of street heroin is never certain, the addict's description of the size of the current habit is of minimal value. The safest guide to dosage is to monitor the patient's pulse, respiration, and pupil size ("The eyes never lie"). After the presence of withdrawal is documented, the patient should receive methadone 20 mg orally. Only if the patient is known to be a heavy user should the starting dose be as high as 30 mg. A relatively young patient or a patient who reports a small habit can begin treatment with 10 mg orally. If vital signs have not stabilized or if withdrawal signs reappear after 2 hours, an additional 5 or 10 mg can be given orally. It is rare to give more than 60 mg during the first 24 hours. Successful long-term outpatient maintenance treatment generally requires doses in the range of 60 to 120 mg, although lower doses may be adequate to control withdrawal symptoms in the hospital. Prolongation of the QTc interval has been shown to occur in patients treated with methadone either for opioid substitution therapy or

pain management. Torsades de pointes has been reported in patients treated with more than 300 mg of methadone per day. The risk for a cardiac arrhythmia is thought to be higher in patients with preexisting cardiac disease and in those taking multiple medications that may affect cardiac conduction. Such patients should be monitored with an electrocardiogram (ECG) before starting methadone or before any significant dose increase.[9]

CASE 1

A 17-year-old woman was admitted for an evaluation of fever of undetermined origin and associated epigastric distress. She requested large doses of methadone and claimed to have a heroin habit costing $200 per day. Further history revealed that she and her husband had been addicted for less than 3 months, and both were relatively naïve heroin users. After she began to show signs of opiate withdrawal, she was given methadone 10 mg orally; an additional 5 mg was given 10 hours later, when her respiratory rate was again noted to be more than 18 breaths per minute. The following day she remained comfortable after a single dose of 15 mg. Later it was discovered that she had regional enteritis. Given the short history of opiate abuse in this patient, she would likely be an appropriate candidate for office-based detoxification treatment with buprenorphine once her medical problems were stabilized.

Addicts should be maintained on a single daily oral dose that keeps them comfortable and keeps their heart rate and respiratory rate within the normal range. The dose should be reduced by 5 or 10 mg if the patient appears lethargic. If the street-drug addict is to be withdrawn from drugs immediately, the methadone dose can be reduced by 10% to 20% a day. If the drug habit has been maintained in the hospital for 2 or more weeks or if the patient has been using methadone before admission, detoxification should proceed more slowly. The dose can be reduced by 5 mg per day until 20 mg per day is reached. Further dosage reduction should occur more slowly if the patient is unable to tolerate the withdrawal symptoms. Clonidine, an α_2-adrenergic agonist, suppresses the autonomic symptoms of withdrawal and can be used as an alternative withdrawal medication. Clonidine should not be substituted for methadone until the methadone dose has been reduced to 20 mg per day. After an initial oral dose of 0.2 mg, patients usually require doses in the range of 0.1 to 0.2 mg every 4 hours. The total daily dose should not exceed 1.2 mg. Patients on clonidine should be monitored closely for side effects, particularly hypotension and sedation. In an inpatient setting, the clonidine dose can be reduced and discontinued over 3 to 4 days.[10,11] A transdermal clonidine patch is often applied on the third day. Supplemental doses of lorazepam can also be used to moderate withdrawal-related anxiety. Use of clonidine does not adequately suppress the subjective symptoms of withdrawal as does use of methadone and buprenorphine, and rates for successful completion of opiate detoxification with clonidine are almost 65% lower than those reported for buprenorphine.[12]

Buprenorphine has been efficacious for the short-term inpatient detoxification of opiate addicts. Patients can be stabilized using sublingual doses of 2 to 4 mg, and these doses can usually be tapered and discontinued over 2 to 4 days. An alternative protocol uses 0.3 to 0.6 mg of IM buprenorphine for 3 to 5 days, with a transdermal clonidine patch applied on the second day.[13] Addicts typically report that a buprenorphine detoxification is more comfortable than detoxification with either methadone or clonidine. Long-term buprenorphine treatment and maintenance, similar to the methadone model, has been more effective for long-term sobriety than have short-course detoxification protocols (as might be standard on inpatient dual-diagnosis units).[14]

Chances for successful withdrawal treatment are enhanced if the patient is aware of the dose and is able to choose the withdrawal schedule within limits established by the physician. By involving the patient in the treatment process and using a flexible withdrawal schedule, the physician can keep withdrawal symptoms to a tolerable level. Rigid adherence to a fixed dosing schedule is less likely to achieve success, and it may lead to premature termination of treatment.

Other less frequently used techniques permit rapid inpatient detoxification from opiates but require more intensive medical management. The addict is first stabilized on clonidine, as described previously. On the second treatment day, naltrexone 12.5 mg is added and then increased later that day and the following days up to a single dose of 150 mg by the fourth day. A supplemental benzodiazepine is also given for agitation and insomnia. At the end of 5 days, there are no further withdrawal symptoms and the patient can be discharged directly to an outpatient naltrexone program.[11,15] A more rapid experimental protocol using high doses of opiate antagonists given under general anesthesia permits completion of detoxification in 24 to 48 hours.[16] This approach has not been adequately evaluated in randomized clinical trials, and it cannot be recommended at this time.

Although techniques that permit a safe, rapid, and medically effective detoxification from opiates seem highly attractive in an era of managed care, clinicians must understand that detoxification alone is rarely successful as a treatment for any addiction. Unless opiate addicts are transferred to a long-term treatment program, relapse rates following detoxification are extremely high. The resulting costs to the patient, to society, and to the health care system far outweigh any savings realized from a rapid and supposedly cost-effective detoxification protocol.

Another common problem in the management of opiate-dependent patients is determining the appropriate dosage of an analgesic for patients receiving opiate substitution therapy.

CASE 2

A 28-year-old woman was hospitalized for the treatment of acute renal colic. Approximately 4 years earlier, she had been hospitalized for similar symptoms that subsided after she passed a kidney stone. During the year before her second hospitalization, the patient was in a maintenance program in which she received methadone 60 mg per day. She was doing well in treatment, and for the last 6 months was working regularly as a secretary. A psychiatrist was asked to see the patient because she was threatening to sign out of the

hospital. She claimed that she was not obtaining relief from her pain and that she wanted heroin to treat herself. The nurses described her as constantly complaining, demanding, and attempting to get additional doses of narcotics. A review of her chart revealed that she was receiving doses of morphine 5 mg, approximately half the usual analgesic dose in such situations, with strict orders not to repeat the dose sooner than every 4 hours because of her history of drug abuse. Her physician assumed that she would require lower doses of morphine because she was taking methadone.

After the consultation the physician accepted the psychiatrist's recommendation that the usual dose of morphine 10 mg be given every 2 hours as circumstances required because the patient would probably metabolize any narcotic more rapidly than normal. This regimen effectively controlled the patient's pain, and she suddenly became more cooperative. There was no recurrence of behavior that had been interpreted as manipulative or any other management problems. She passed several renal stones 2 days later and was discharged. Her physician had not realized that her so-called demands and manipulations were legitimate requests for effective analgesia.

The analgesic effect of methadone is minimal in maintenance patients, and, at best, it lasts only 6 to 8 hours. If pain control is required, addicts should be given standard doses of other narcotics in addition to methadone. Because of cross-tolerance, a patient on maintenance narcotic therapy metabolizes other narcotics more rapidly and may require more frequent administration of analgesics than might a nonaddicted patient. Pentazocine, buprenorphine, and other partial opiate agonists–antagonists are contraindicated for such patients. Because of their action at the opioid receptor, these analgesics produce withdrawal symptoms in regular users. If a patient on the buprenorphine–naloxone combination tablet requires additional narcotic analgesia treatment, he or she can be given supplemental opioids. However, higher-than-usual narcotic doses will be required to overcome the partial antagonist action of buprenorphine. Alternatively, such a patient can be switched to methadone and managed as described previously.

Opiate overdoses are treated with 0.4 mg/ml of IV or IM naloxone. Naloxone doses can be repeated every 2 minutes, as needed, up to a total dose of 1 to 2 mg. Patients who do not respond after 20 minutes should be treated for a combined drug overdose. Because of the long duration of action of methadone, overdoses of this drug often require an IV naloxone drip.

Discharge planning should be initiated as quickly as possible after admission. For patients who are not already in treatment, several weeks may be required to arrange admission to a drug-free residential program or an opiate substitution therapy program. Because a serious illness usually causes an addict to reexamine his or her behavior and possibly choose rehabilitation, the physician in the general hospital should emphasize the need for long-term treatment while the hospitalization is still fresh in the patient's mind. No patient should be discharged while still receiving methadone unless he or she is returning to a maintenance program or specifically refuses detoxification. Even when a physician discharges a patient for disciplinary reasons, medical ethics necessitate that the patient be withdrawn from methadone before discharge. Hospital physicians cannot legally prescribe methadone to maintain a habit or to withdraw from a habit on an outpatient basis.

BENZODIAZEPINES

Patterns of Chronic Use Versus Abuse

Benzodiazepines can produce dependence, especially when used in high doses for prolonged periods. Up to 45% of patients who receive stable, long-term doses show evidence of physiologic withdrawal. Withdrawal symptoms, which are usually the same in both high-dose and low-dose patients, include anxiety, insomnia, irritability, depression, tremor, nausea or vomiting, and anorexia. Seizures and psychotic reactions have also been reported in a few cases. The more common symptoms are similar to those seen during withdrawal from all the sedative–hypnotic drugs, and they may often be difficult to distinguish from the symptoms for which the benzodiazepine was originally prescribed. In general, withdrawal symptoms abate within 2 weeks.

Benzodiazepines with a rapid onset of action (e.g., diazepam, alprazolam) seem to be sought out by drug abusers and are generally presumed to have a greater potential for abuse than benzodiazepines with a slower onset of action (e.g., oxazepam). Nonetheless, there is relatively little evidence for the abuse of benzodiazepines when they are prescribed for legitimate medical conditions. Ciraulo and colleagues[17] found that the use of benzodiazepines, even among former alcoholics, was similar to that of other psychiatric patients. A study of alcoholics conducted at the Addiction Research Foundation of Ontario found that 40% were recent users of benzodiazepines and that there was a 20% lifetime incidence of anxiolytic abuse or dependence.[18] Although these studies suggest that concerns about the abuse of benzodiazepines by alcoholics may be exaggerated, the problem is real. Because some evidence suggests that benzodiazepine administration may increase the motivation of chronic alcoholics to drink, patients must be monitored carefully, and benzodiazepines should never be a first-line treatment in chronic alcoholics.[19]

It is important to distinguish between a drug abuser who uses benzodiazepines primarily to get high, often deliberately mixing them with alcohol and other drugs of abuse, and an individual who takes benzodiazepines appropriately under medical supervision. In both cases, the user may develop physiologic and psychological dependence. Such dependence, in and of itself, is not evidence of drug abuse. Unless there is evidence of dose escalation, deliberate use to produce a high, or a dangerous state of intoxication, there is no reason to assume that chronic benzodiazepine users are abusers. Even though clonazepam is the only benzodiazepine with an indication for long-term use, common medical practice supports the merit of the continued use of benzodiazepines in some individuals with chronic medical and psychiatric conditions.

CASE 3

A 68-year-old retired teacher was admitted for evaluation of severe gouty arthritis. His internist requested a psychiatric consultation regarding the management of long-term chlordiazepoxide use. The patient had been a heavy drinker before retirement, but he had been sober for the last 5 years. Approximately 2 years after becoming sober, he developed complaints of severe anxiety and was started on a regimen of chlordiazepoxide 25 mg three times per day. Two attempts had been made to reduce or eliminate the medication, but the anxiety symptoms returned. The patient expressed a strong desire for continued medication, and he became fearful that he might resume drinking. The symptoms were well controlled when regular treatment with chlordiazepoxide was resumed. After reviewing the case, the psychiatrist determined that the patient was dependent on the chlordiazepoxide but that there had been no escalation of dose or other signs of abuse. The medication continued to be effective in controlling his anxiety. The consultant recommended that he be continued on his current dose of chlordiazepoxide.

Overdose

Flumazenil, a specific benzodiazepine antagonist, reverses the life-threatening effects of a benzodiazepine overdose. An initial IV dose of 0.2 mg should be given over 30 seconds, followed by a second 0.2 mg IV dose if there is no response after 45 seconds. This procedure can be repeated at 1-minute intervals up to a cumulative dose of 5 mg. This treatment is contraindicated in individuals dependent on benzodiazepines (after long-term use) or those taking tricyclic antidepressants because flumazenil may precipitate seizures in these patients.[20,21] When flumazenil is contraindicated, benzodiazepine overdoses should be handled similarly to other sedative–hypnotic overdoses (see next section).

Withdrawal

When clear evidence of benzodiazepine abuse exists or when the patient desires to stop use of these medications, it is important that detoxification occur under medical supervision. During the withdrawal process, patients should be warned to expect a temporary increase in anxiety symptoms. The simplest approach to detoxification is a gradual reduction in dose that may be extended over several weeks or months. When a more rapid inpatient detoxification is desired, dosage reduction can be completed within 2 weeks. For some patients, this rapid withdrawal process produces an unacceptable level of subjective distress. An alternate approach is to switch to a high-potency, long-acting benzodiazepine such as clonazepam. Most patients seem to tolerate detoxification on clonazepam quite well. Because of the prolonged self-taper during detoxification, patients experience a smoother course of withdrawal with a minimum of rebound anxiety.[22,23]

Withdrawal from high-potency, short-acting benzodiazepines (e.g., alprazolam) has been particularly problematic. A rapid tapering of these drugs is often poorly tolerated by patients, and a switch to equivalent doses of a long-acting benzodiazepine may mitigate acute withdrawal symptoms. We recommend that clonazepam be substituted for alprazolam, at a dose ratio of 0.5 mg of clonazepam for each 1 mg of alprazolam. Clonazepam should then be continued for 1 to 3 weeks. A drug taper is not always required, although abrupt discontinuation of even a long-acting agent, such as clonazepam, can be associated with a withdrawal syndrome that includes seizures. Adverse events tend to occur several days after discontinuation, and a 2- to 3-week taper is usually adequate.

Supplemental medication is of little use during benzodiazepine withdrawal; β-adrenergic blockers (propranolol) and α-adrenergic agonists (clonidine) offer no advantage over detoxification using benzodiazepines alone. Although they tend to moderate the severity of physiologic symptoms, they are ineffective in controlling the subjective sense of anxiety, and they do not prevent withdrawal seizures. Buspirone has no cross-tolerance for the benzodiazepines and does not control withdrawal symptoms from this class of drugs.

SEDATIVE–HYPNOTICS

Abuse

Use of CNS depressants accounts for high rates of ED visits related to suicide attempts and accidental overdoses (consequent to recreational use and self-medication). Although benzodiazepines have become the most commonly abused sedative–hypnotic in the United States, there are still areas where the nonmedical use of barbiturates, such as butalbital (Fiorinal and Esgic), and carisoprodol (Soma), and other sedative–hypnotics (e.g., methaqualone, glutethimide) causes serious clinical problems.

A person intoxicated by other CNS depressants typically presents with many of the same diagnostic problems that are associated with alcohol intoxication. Slurred speech, unsteady gait, and sustained vertical or horizontal nystagmus, or both, that occur in the absence of the odor of alcohol on the breath suggest the diagnosis. Unfortunately, drug abusers frequently combine alcohol with other sedative–hypnotic drugs. The clinician may be misled by the odor of alcohol. The diagnosis of mixed alcohol–barbiturate intoxication can be missed unless a careful history is taken and blood and urine samples are analyzed for toxic drugs. The behavioral effects of barbiturate intoxication can vary widely, even in the same person, and may change significantly depending on the surroundings and on the expectations of the user. Individuals using barbiturates primarily to control anxiety or stress may appear sleepy or mildly confused as a result of an overdose. In those seeking to get high, however, a similar dose may produce excitement, loud and boisterous behavior, and loss of inhibitions. The aggressive and even violent behavior commonly associated with alcohol intoxication may follow. The prescribed regimen for managing an angry alcoholic can also be used for the disinhibited sedative–hypnotic abuser.

As tolerance to barbiturates develops, there is not a concomitant increase in the lethal dose, as occurs in opiate dependence. Although the opiate addict may be able to double the regular dose and still avoid fatal respiratory depression, as little as a 10% to 25% increase over the usual daily dosage may be fatal to the barbiturate addict whose

tolerance has narrowed the therapeutic window. Thus a barbiturate overdose should always be considered potentially life-threatening, especially for a drug abuser.

In overdose a variety of signs and symptoms may be observed, depending on the drug or the combination of the drugs used; the amount of time since ingestion; and the presence of complicating medical conditions (e.g., pneumonia, hepatitis, diabetes, heart disease, renal failure, head injury). Initially the patient appears lethargic or semicomatose. The pulse rate is slow, but other vital functions are normal. As the level of intoxication increases, the patient becomes unresponsive to painful stimuli, reflexes disappear, and there is a gradual depression of the rate of respiration; eventually, cardiovascular collapse ensues. Pupillary size is not changed by barbiturate intoxication, but secondary anoxia may cause fixed, dilated pupils. In persons who have adequate respiratory function, pinpoint pupils usually indicate an opiate overdose or the combined ingestion of barbiturates and opiates. Such patients should be observed carefully for increased lethargy and progressive respiratory depression. Appropriate measures for treating overdoses should be instituted as necessary. Patients should not be left unattended until all signs of intoxication have cleared.

Because there is no cross-tolerance between narcotics and barbiturates, patients receiving methadone maintenance who continue to abuse sedative–hypnotics present special problems. If a barbiturate overdose is suspected, the methadone-treated patient should be given a narcotic antagonist to counteract any respiratory depression caused by methadone. We recommend naloxone hydrochloride (Narcan) 0.4 mg IM or IV because it is a pure narcotic antagonist and it has no respiratory depressant effect even in large doses. If the respiratory depression does not improve after treatment with naloxone, the patient should be treated for a pure barbiturate overdose. Supportive measures include maintenance of adequate airway, mechanical ventilation, alkalinization of the urine, correction of acid–base disorders, and diuresis with furosemide or mannitol. Severe overdose cases may require dialysis or charcoal resin hemoperfusion.[21]

Withdrawal

The sedative–hypnotic withdrawal syndrome can present a wide variety of symptoms (e.g., anxiety, insomnia, hyperreflexia, diaphoresis, nausea, vomiting, and sometimes delirium and convulsions). As a general rule, individuals who ingest secobarbital 600 to 800 mg daily for more than 45 days develop physiologic addiction and show symptoms after withdrawal. Minor withdrawal symptoms usually begin 24 to 36 hours after the last dose. Pulse and respiration rates are usually elevated, pupillary size is normal, and there may be postural hypotension. Fever may develop, and dangerous hyperpyrexia can occur in severe cases. Major withdrawal symptoms, such as convulsions and delirium, indicate addiction to large doses (secobarbital 900 mg or more daily).

Because of the danger of seizures, barbiturate withdrawal should be managed only on an inpatient basis. Grand mal seizures, if they occur, are usually seen between the third and seventh days, although some reported cases occurred as late as 14 days into a medically controlled detoxification. Withdrawal seizures are thought to be related to a rapid drop in the blood barbiturate level. Treatment therefore should be carefully controlled so that barbiturates are withdrawn gradually with minimal fluctuation in the blood level, which theoretically decreases the danger of seizures. Treatment with phenytoin does not reliably prevent seizures caused by barbiturate withdrawal.

Delirium occurs less frequently than do seizures; it rarely appears unless preceded by seizures. It usually begins between the fourth and sixth days of withdrawal and is characterized by both visual and auditory hallucinations, delusions, and fluctuating levels of consciousness. The presence of confusion, hyperreflexia, and fever helps distinguish this syndrome from schizophrenia and other non-toxin-related psychoses.

Treatment for Withdrawal

Several techniques are available for managing barbiturate withdrawal. The basic principle is to withdraw the drug from the addicting agent slowly to prevent seizures. First, the daily dosage that produces mild toxicity must be established. Because barbiturate addicts tend to underestimate their drug use, it is dangerous to accept the patient's history as completely accurate. Treatment should begin with an oral test dose of the short-acting barbiturate pentobarbital (200 mg). If no physical changes occur after 1 hour, the patient's habit probably exceeds 1200 mg of pentobarbital per day. If the patient shows only nystagmus and no other signs of intoxication, the habit is probably approximately 800 mg per day. Evidence of slurred speech and intoxication and no sleep suggests a habit of 400 to 600 mg per day. The patient can then be given the estimated daily requirement divided into four equal doses administered orally every 6 hours. Should signs of withdrawal appear, the estimated daily dosage can be increased by 25% following an additional IM dose of 200 mg of pentobarbital. After a daily dose that produces only mild toxicity has been established, phenobarbital is substituted for pentobarbital (30 mg phenobarbital equals 100 mg pentobarbital) and then withdrawn at a rate of 30 to 60 mg per day (Table 15–1).[24] An alternative method is to treat withdrawal symptoms orally with 30 to 60 mg phenobarbital hourly, as needed, for 2 to 7 days. After the patient has received similar 24-hour doses

TABLE 15–1 Equivalent Doses of Common Sedative–Hypnotics

GENERIC NAME	DOSE (mg)
Barbiturates	
Phenobarbital	30
Secobarbital	100
Pentobarbital	100
Benzodiazepines	
Alprazolam	1
Diazepam	10
Chlordiazepoxide	25
Lorazepam	2
Clonazepam	0.5-1
Others	
Meprobamate	400

for 2 consecutive days, the 24-hour stabilizing dose is given in divided doses (every 3 to 6 hours). A gradual taper is then instituted as described previously. At MGH, we recommend this latter method because the use of a long-acting barbiturate produces fewer variations in the blood barbiturate level and should produce a smoother withdrawal.

Inpatient Management and Referral

Sedative–hypnotic users, like many other substance users, can present a variety of psychological management problems. Effective treatment requires a thorough evaluation of the patient's psychiatric problems and the development of long-term treatment plans before discharge. Treatment for withdrawal or overdose presents an opportunity for effective intervention in the patient's self-destructive lifestyle. Patients who abuse drugs have a reputation for deceit, manipulation, and hostility. They frequently sign out against medical advice. It is rarely acknowledged that these problems are sometimes caused by clinicians who fail to give appropriate attention to the patient's psychological problems. Most of these difficulties can be eliminated by effective medical and psychiatric management. The patient's lack of cooperation and frequent demands for additional drugs are often the result of anxiety and the fear of withdrawal seizures. This anxiety is greatly relieved if the physician thoroughly explains the withdrawal procedure and assures the patient that the staff knows how to handle withdrawal and that adverse effects will not occur if the patient cooperates with a schedule of medically supervised withdrawal.

Physicians sometimes fail to realize that the patient's tough, demanding behavior is a defense against a strong sense of personal inadequacy and a fear of rejection. Addicts have been conditioned to expect rejection and hostility from medical personnel. The trust and cooperation necessary for successful treatment cannot be established unless physicians show by their behavior that they are both genuinely concerned about the patient and medically competent to treat withdrawal. Physicians can expect an initial period of defensive hostility and testing behavior and should not take this behavior personally. Patients need to be reassured that their physician is concerned about them.

If the patient manifests signs of a character disorder and has a history of severe drug abuse, the setting of firm limits is necessary to ensure successful detoxification. Visitors must be limited to those individuals of known reliability. This may mean excluding spouses and other relatives. Urine should be monitored periodically for illicit drug use. Family counseling should be started during hospitalization and should focus on the family's role in helping the patient develop a successful long-term treatment program. Hospital passes should not be granted until detoxification is completed; however, passes with staff members as escorts should be used as much as possible. An active program of recreational and physical therapy is necessary to keep young, easily bored patients occupied. Keys to successful inpatient treatment are summarized in Table 15–2.

The story of a 21-year-old man who was hospitalized after having a grand mal seizure illustrates several of the problems that may occur.

TABLE 15–2 Inpatient Management and Referral

KEYS TO SUCCESSFUL INPATIENT TREATMENT
Perform a psychiatric evaluation.
Develop a long-term treatment plan.
Demonstrate explicit concern and expertise.
Expect testing behavior.
Set appropriate limits.
Limit and monitor visitors.
Supervise passes.
Monitor urine for illicit drug use.
Encourage ward activities and recreation.
Initiate family–network therapy.
Treat with respect.

CASE 4

The son of an eminent attorney described several years of episodic barbiturate and alcohol use and admitted to 3 months of daily barbiturate use after dismissal from college for failing grades. Three days before the patient's seizure, his father discovered that he had been ingesting secobarbital tablets taken from the medicine cabinet. The patient agreed to stop using barbiturates but did not realize that he was addicted. After admission to the hospital, the patient became a management problem. He demanded additional medication and refused to obey hospital regulations. Twice he left the floor without permission, and on one occasion he returned obviously high. A discussion with his physician turned into an angry shouting match. The patient denied any unauthorized drug use and insisted that he be permitted to leave the unit. He threatened to file a lawsuit for violation of his civil rights. When seen by the psychiatric consultant, the patient was hostile and provocative. He denied having any psychiatric problems and suggested that his physician was trying to have him committed to a psychiatric hospital.

The patient's hostility disappeared after the psychiatrist indicated that he had no interest in committing him but was concerned that his arguments with his physician and the nurses were interfering with his medical treatment. Once reassured that the psychiatrist did not think he was crazy, he admitted his fear of having more seizures. He did not know what to expect during detoxification and was too frightened to admit his fears to his physician. He finally admitted that he was meeting friends in the hospital cafeteria and they were giving him additional drugs. A meeting was then arranged between the patient and his physician. The physician explained the detoxification procedure in detail, including possible causes of seizures and the need for diagnostic tests. The patient was relieved to receive this information and readily agreed to appropriate limitations on visitors and hospital passes. The remainder of his hospitalization passed without incident, and he agreed to continue seeing the physician after his discharge.

Because treatment for detoxification or an overdose rarely cures an addict, referrals for long-term outpatient or residential care should be made early in the treatment process. Ideally, the patient should meet the future therapist before discharge. Alcoholics Anonymous and Narcotics Anonymous are useful adjuncts to any outpatient treatment

TABLE 15–3 Equivalent Doses of Narcotic Pain Medications

GENERIC NAME	DOSE (mg)
Morphine	10
Oxycodone (Percocet, OxyContin)	5-10
Hydrocodone (Vicodin, Lortab)	10
Meperidine (Demerol)	100
Hydromorphone (Dilaudid)	2.5
Methadone	5
Heroin	10

program. If transferring to a halfway house or residential program, the patient should move there directly from the hospital. Addicts are not likely to execute plans for follow-up care without strong encouragement and support.

MIXED-DRUG ADDICTION

Increasing numbers of patients are addicted to varying combinations of drugs, including benzodiazepines, cocaine, alcohol, and opiates. Accurate diagnosis is difficult because of confusing, inconsistent physical findings and unreliable histories. Blood and urine tests for drugs are required to confirm the diagnosis. A patient who is addicted to both opiates and sedative–hypnotics should be maintained on methadone while the barbiturate or other sedative–hypnotic is withdrawn. Then methadone can be withdrawn in the usual manner. Dose equivalents of narcotics are provided in Table 15–3.

Behavioral problems should be dealt with as previously described. Firm limit-setting is essential to the success of any effective psychological treatment program. Some patients who overdose or have medical problems secondary to drug abuse, such as subacute bacterial endocarditis and hepatitis, are not physiologically addicted to any drug despite a history of multiple-drug abuse. Their drug abuse behavior is usually associated with severe psychopathology. These patients should receive a thorough psychiatric evaluation and may require long-term treatment.

16 Functional Somatic Symptoms, Deception Syndromes, and Somatoform Disorders

Ilana M. Braun, M.D.
Donna B. Greenberg, M.D.
Felicia A. Smith, M.D.
Ned H. Cassem, M.A., Ph.L., M.D., S.J., B.D.

Called by Lipowski[1] "the borderland between medicine and psychiatry," somatization presents an important challenge to psychiatrists. It is defined as experiencing and reporting of physical symptoms for which there are no discoverable organic causes. Kellner[2] noted that 60% to 80% of the general nonpatient population experiences one or more somatic symptoms in any given week and that, when a patient approaches a physician with a somatic complaint, no organic cause can be found between 20% and 84% of the time. The most common somatic symptoms include palpitations, chest pain, headache, fatigue, and dizziness. For patients with functional symptoms, the strategy of pursuing a medical cause with invasive diagnostic procedures, unnecessary surgeries, and misdirected drug trials can be life-threatening, and the unwarranted costs of these measures strain limited medical resources.

The approach to patients with a host of unexplained symptoms must be thorough and include: taking a history (medical, psychiatric, psychosocial, and family), performing a physical examination, listing current medications, and obtaining appropriate laboratory tests. Because symptoms can occur in the context of serious medical illness, a systematic differential diagnostic approach is required; one of the first questions asked by a clinician should be "What organic disease could account for these symptoms?" Reading both the current and often formidable old medical records is indispensable. A psychiatrist may be the first clinician to diagnose a physical disease because the patient's personality, behavior, affect, or odd cognition has distracted the primary physician and other consultants from the task at hand. Table 16–1 lists diagnoses likely to produce functional somatic complaints.

DIFFERENTIAL DIAGNOSIS OF FUNCTIONAL SOMATIC SYMPTOMS

Depressive Disorders

Somatoform disorders should not be the first consideration when evaluating a patient whose physical symptoms seem out of proportion to objective findings. Major depressive disorder (MDD) is far more commonly a source of physical findings. Indeed, 75% of primary care patients with MDD or panic disorder seek treatment from their physicians for exclusively somatic symptoms.[3,4] This is likely the case for several reasons. First, the vegetative symptoms of MDD are physical in nature; they include insomnia, fatigue, anorexia, and weight loss. Second, depressed patients report more functional somatic symptoms (aches and pains, constipation, dizziness, and the like) than do other patients. Among primary care patients in an American health maintenance organization,[5] disabling chronic pain was present in 41% of those with MDD compared to 10% of those without MDD. Those patients with both chronic pain and MDD tended to have more severe affective symptoms and a higher prevalence of panic disorder. Even across cultures, the majority of patients with MDD spontaneously report only somatic symptoms; when pressed, however, 89% will also offer psychological symptoms.[6]

When MDD is diagnosed in the context of unexplained bodily complaints, depression should be treated promptly. Ordinarily both affective and somatic symptoms abate with psychological treatment, although, as shall be discussed, sometimes only the mood improves, leaving functional somatic symptoms still to be managed. (For further coverage of affective disorders, see Chapter 9.)

Anxiety Disorders

Anxiety frequently co-occurs with functional somatic symptoms, distorting the cognitive appraisal of somatic symptoms and making even benign bodily sensations seem ominous and alarming. Anxious patients tend to catastrophize normal physiologic sensations and ailments. As noted in Chapter 13, many of the symptoms of panic disorder are somatic; they include dyspnea, palpitations, chest pain, choking, dizziness, paresthesias, hot and cold flashes, sweating, faintness, and trembling. As a result, patients in the midst of a panic attack may fear that they are unable to breathe or that they are dying. Panic disorder is far more prevalent among patients with medically unexplained symptoms than was once thought (especially in cardiology,

gastroenterology, and neurology practices).[7] Anxiety is also one of the most common features of MDD.[8]

When co-morbid with pain, anxiety can lower the pain threshold dramatically. In fact, some patients cannot distinguish anxiety from pain ("No, I am not frightened; I hurt!"). Health care providers must be on guard against mistakenly attributing the marked discrepancy between pain complaints and objective findings to other conditions, for instance drug abuse or a personality disorder (see later).

Substance Abuse Disorders

Physicians should always consider the diagnosis of alcohol abuse in a patient with multiple, vague somatic symptoms. Whether the patient consciously conceals alcohol dependency or fails to make the connection, the diagnosis may be elusive. Information from the patient's family may help ("What he calls headache and chest pains, Doctor, I call a hangover."). Because alcohol abuse systematically disrupts sleep, patients may begin using sedative–hypnotic substances as well. Insomnia, morning cough, pains in the extremities, dysesthesias, palpitations, headache, gastrointestinal (GI) symptoms, fatigue, bruises—none are strangers to the alcoholic. The effects of other addictive drugs may be similarly confounding. (See Chapters 14 and 15 for the diagnosis and treatment of substance abuse disorders.)

Psychotic Disorders

Patients with psychotic depression may have somatic delusions (such as the conviction that one's abdominal organs are decomposing). Such patients are much more likely to be misdiagnosed as having schizophrenia than a physical illness. The somatic delusions of schizophrenia are generally so bizarre and idiosyncratic (e.g., that foreign bodies are inside an organ or orifice, or that body parts are missing or deformed) as to be easily recognized. But when a patient with schizophrenia complains of a functional symptom that is not of delusional proportions (e.g., a headache or weakness), psychosis may be missed. Making such a diagnosis with a thorough psychiatric history and examination is ordinarily no problem. Patients with schizophrenia can also have conversion symptoms (e.g., hemiparesis). In such a case, the proper diagnosis is of a conversion symptom in a patient with schizophrenia, not "conversion disorder."

Organic Mental Disorders

Somatizing cannot be localized to either a specific brain structure or a particular neurotransmitter system; however, patients with organic brain disease can have functional somatic complaints. The clinician's careful examination will detect cognitive dysfunction that may have gone unnoticed.

Personality Disorders

Although included in the differential diagnostic list of Table 16–1, personality disorders do not "cause" functional somatic symptoms. Rather, for the patient with an Axis II disturbance, the somatic symptom is a means to an end. For the individual with an antisocial personality, pain may be a means to get narcotics, to get out of work, or to escape trial. For the person with a dependent personality, functional weakness gains the attention and nurturance of others.[9] The borderline patient's somatic symptoms can become the focus for physicians and nurses, who may engage in a sadomasochistic struggle with the patient. The process begins with a helping relationship and ends with the rejection of a disappointed and outraged patient accused of wrongdoing. The "end" for this patient is the emotionally charged (usually hostile) relationship, and the failure to palliate the symptoms means to the patient that the physician simply does not care enough. Sometimes symptoms are reinforced by personality styles. Somatic symptoms are exaggerated by patients with a histrionic personality and may be the object of such intense fixations by those with compulsive, paranoid, schizotypal, and schizoid personalities as to make these patients take on a hypochondriacal character.

Factitious Disorders

Factitious illness is also on the differential of functional somatic symptoms. It is a complicated disorder that is marked by the conscious production of symptoms without clear secondary gain beyond assumption of the sick role; in fact, these patients often put their health at considerable risk. They may fake, exaggerate, intentionally worsen, or simply create symptoms. They do not admit to self-harm, but rather hide it from their doctors. The paradox, then, is that those with factitious illness come to health care providers requesting help, but intentionally hide the self-induced cause of their illness.

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) describes three subtypes of factitious disorder: that with predominantly physical signs and symptoms, with predominantly psychological signs and symptoms, and with combined psychological and

physical signs and symptoms. Finally, factitious disorders not otherwise specified (NOS) includes the notable example of factitious disorder by proxy, or Munchausen syndrome by proxy (see later).

In *factitious disorder with predominantly physical signs and symptoms*, the most common presentation is that of a general medical condition. Examples of faked clinical problems run the gamut from fever, bleeding, hypoglycemia, and seizures, to more elaborate productions of cancers and infection with the human immunodeficiency virus (HIV).[10–14] Whereas the term *Munchausen syndrome* is often used interchangeably with the physical type of factitious disorder, the classic Munchausen syndrome is reserved for the most severe and chronic form of the disorder, which is marked by the following three components: recurrent hospitalizations, travel from hospital to hospital (peregrination), and *pseudologia fantastica*.[14] Pseudologia fantastica is the production of intricate and colorful stories or fantasies associated with the patient's presentation. It is a form of pathological lying characterized by an overlapping of fact and fiction (with a repetitive quality, grandiosity, or an assumption of the victim role by the storyteller).[15] In some cases, it may be difficult to determine whether these lies are delusions or conscious deceptions. Munchausen patients often make a career out of their illness. Serial hospitalizations render employment or sustained interpersonal relationships impossible. Moreover, patients who produce significant self-trauma or develop untoward complications from medical or surgical interventions become further incapacitated. The prognosis is generally poor in these cases, and patients may die prematurely from complications of their own self-injurious behavior or from iatrogenesis.

Whereas Munchausen syndrome is the most dramatic form of factitious illness, *common factitious disorder* is more frequently encountered.[15] As opposed to those with Munchausen syndrome, patients with common factitious disorder do not typically use aliases or travel from hospital to hospital, but rather frequent the same physician. They are well known in their health care system because of numerous hospitalizations. They still misrepresent symptoms and feign illness, but are not as prone to pseudologia fantastica. Although conflicting data exist with regard to whether factitious disorders are more common in males or females, some suggest that common factitious disorder is more prevalent in women. Other risk factors include being unmarried, being in one's thirties, having experience in the health care profession, and having a cluster B personality disorder. Munchausen syndrome, on the other hand, may be more frequently seen in men in their forties who are single and have antisocial traits.[15] The co-morbidity with personality disorders may result from a rigid defensive structure, poor identity formation, and prominent dependency needs.[16]

Typical hospitalizations for those who feign medical illness share common characteristics. First, patients often come to emergency departments (EDs) after hours (at night or on the weekend), when it is less likely that medical personnel familiar with their cases are available. Patients use medical jargon and generally know what diagnoses or conditions will merit hospitalization. Their histories are often quite dramatic and convincing, and such patients persuade their physicians to provide care by appealing to narcissistic qualities, such as omnipotence. Once hospitalized, treatments are marked by demands for specific interventions (e.g., surgery or particular medications) and by increasing needs for attention. When the demands are not met, patients become angry and may accuse staff of misdiagnosis and mistreatment. If staff uncovers the deception, strong countertransference feelings of hatred ensue. Patients are then rapidly discharged or elope from the hospital only to seek "treatment" at another facility soon thereafter.

The types of physical symptoms and diseases that have been faked are limited only by the imagination of those who feign them. Table 16–2 lists some common categories. Modern day laboratory tests and diagnostic modalities may be particularly useful in distinguishing factitious symptoms from true medical illness. For example, in the case of suspicious infection, polymicrobial culture results that indicate an uncommon source (e.g., from urine or feces) is highly suggestive. Those who inject insulin to produce hypoglycemia will have a low C-peptide level on laboratory analysis, whereas glyburide can be measured in the urine of those suspected of taking oral hypoglycemics. Laxative abuse to cause ongoing diarrhea is confirmed by testing for phenolphthalein in the stool.[17] Finally, diagnostic studies in cases of suspected thyrotoxicosis (from surreptitious ingestion of thyroid hormone) reveal elevated serum total or free thyroid hormone levels, undetectable serum thyrotropin levels, low serum thyroglobulin concentration, normal urinary iodine excretion, suppressed thyroidal radioactive iodine uptake (RAIU), absence of goiter, and absence of circulating antithyroid antibodies.[18]

Detection of other types of physical factitious illness may require more astute physical examinations or observational skills (not to mention catching the patient "in

TABLE 16–2 Typical Clinical Presentation of Factitious Disorder

TYPE	CLINICAL FINDINGS OR SYMPTOMS
Acute abdominal (laparotomaphilia migrans)	Abdominal pain; multiple surgeries may lead to true adhesions and subsequent bowel obstruction
Neurologic (neurologic diabolica)	Headache, loss of consciousness, seizure
Hematological	Anemia from bloodletting or use of an anticoagulant
Endocrinological	Hypoglycemia from exogenous insulin; hyperthyroidism from exogenous thyroid hormone
Cardiac	Chest pain or arrhythmia
Dermatologic (dermatitis autogenica)	Rash; skin erruptions
Febrile (hyperpyrexia figmentatica)	Thermometer manipulation to produce fever
Infectious	Wound infected with multiple organisms (often through fecal material)

Adapted from Viguera AC, Stern TA: Factitious disorders. In Stern TA, Herman JB, editors: *Massachusetts General Hospital psychiatry update and board preparation,* ed 2, New York, 2004, McGraw-Hill, pp 145-147.

the act"). For example, fever of unknown etiology may be caused by warming thermometers on light bulbs or radiators, or with a flame (though this is more difficult with the advent of the electronic thermometer). Hematuria may be produced by bloodletting from another body area (commonly from a finger prick) into the urine sample. Though finding suspicious cuts may be suggestive, direct observation may be the only way to prove factitious disorder in this instance. Likewise, with nonhealing wounds where self-excoriation or "picking" behavior is suspected, witnessing the act either directly or with the use of video monitoring is diagnostic. Of note, the latter brings up ethical considerations unless done with the consent of the patient. Finally, among the numerous other possible physical manifestations, those that rely on more subjective report (including joint or muscle pain, headache, renal colic, or abdominal pain) may be present for months or years before a factitious etiology is even considered, much less proven.

Although the majority of published cases of factitious disorder involve physical symptoms, some patients primarily feign psychological symptoms. Psychological complaints encompass a broad spectrum of symptoms (including depression, anxiety, psychosis, bereavement, dissociation, posttraumatic stress, and even homicidal ideation).[19–23] As with primarily physical symptomatology, separating the motive of playing the sick role from one of secondary gain (malingering) is difficult and often imperfect. In the case of factitious bereavement, for example, the patient may report a dramatic or recent loss of a child or other loved one with a display of emotion that invokes significant sympathy by medical treaters. When the truth is discovered, the reported deceased may either be still alive, have died long ago, or perhaps did not really play a major role in the patient's life.

Diagnostic Approach. As previously suggested, making the diagnosis of factitious illness is often difficult. However, there are several elements of a general strategic approach that may be helpful. When suspecting factitious illness as a cause for somatic symptoms, one should first obtain information from all pertinent collateral sources. These may include previous or current caregivers, family members, current and old medical records, and laboratory and diagnostic studies. Verification of the "facts" presented by the patient is critical. Next, one should look for historical elements suggestive of factitious disease. Some of these are outlined in Table 16–3. Recognition of typical presentations (including all of those outlined in Table 16–2) may provide further clues. When one is lucky enough to find medical paraphernalia or to observe the patient intentionally inducing his or her own symptoms, the diagnosis is assured. Of note, room and personal belonging searches without the patient's permission are controversial and, in many cases, considered an invasion of privacy. Before embarking on such an endeavor, it is prudent to consider the potential ramifications carefully and to seek legal counsel. There is no doubt, however, that in most cases the diagnosis relies on significant detective work based on a high level of suspicion.

True physical disorders (especially rare or unusual diseases with few objective findings) may mimic factitious disorders. It is essential to consider this possibility before prematurely diagnosing factitious illness. Somatization disorder (Briquet's syndrome) and conversion disorder (see later) may also be mistaken for factitious disorder. These diagnoses, however, are distinguished from factitious illness, in that their symptoms are not under voluntary control. Factitious illness may also be confused with malingering, in which symptoms are also intentionally feigned. Malingerers, however, produce symptoms for obvious secondary gain (often financial, legal, or drug seeking).

TABLE 16–3 Historical Elements Suggestive of Factitious Disorder and Malingering

Factitious Disorder
Multiple hospital admissions—"hospital shopping" or peregrination
Many forms of identification or hospital numbers under various names
Ease with medical jargon
Current or prior employment in a medically related field
Lack of verifiable history
Few interpersonal relationships
Early history of chronic illness
Unexplained physical findings, multiple scars, or both
Failure to respond to typical treatments
Co-morbid personality or substance abuse disorders
Malingering
Legal involvement (e.g., the patient is referred for examination by an attorney)
A significant discrepancy between objective findings and reported symptoms or disability
A failure to cooperate with the evaluation or prescribed treatment
The presence of an antisocial personality disorder

From American Psychiatric Association: *Diagnostic and statistical manual of mental disorders, fourth edition, text revision*, Washington, DC, 2000, American Psychiatric Association.

Treatment Approach. No specific psychiatric treatment has been shown to be effective in the management of factitious disorders. There are, however, a few principles that generally prove helpful. The first is to avoid confrontation, especially when making the diagnosis. Direct confrontation or accusation often results in defensiveness, increased elusiveness, or flight from the hospital. Moreover, confrontation appears to be ineffective in most patients; few of them actually admit to their deception.[12] Interventions that allow the patient to save face (which require significant skill to carry out) may be effective.[24] Being aware of negative countertransference is also essential if one is to avoid being judgmental or acting on the hostility so often evoked by these patients. Making an early diagnosis is one of the most important interventions, since an undiscovered diagnosis of factitious disorder exposes the patient to additional and potentially harmful interventions; avoiding iatrogenesis is a key element of treatment. Because this illness is often highly treatment-resistant, placing an emphasis on management over cure helps to reframe the treatment goals. Clear and open communication between the psychiatrist and medical and surgical colleagues is essential in this regard. Finally, legal interventions are sometimes prudent (and often

required), especially in cases of Munchausen syndrome by proxy, where children or the elderly are affected.

Factitious Disorder by Proxy

Factitious disorder not otherwise specified is reserved for disorders with factitious symptoms that do not meet criteria for factitious disorder. Factitious disorder by proxy, otherwise known as Munchausen syndrome by proxy, is perhaps the most notable of these and often presents as unexplained somatic symptoms. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) defines *factitious disorder by proxy* as "the intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care for the purpose of indirectly assuming the sick role."[25] The perpetrator in this case is most often the biological mother of a young child, although the elderly and those under the medical care of others are also at risk. The perpetrator deceives medical personnel by altering records, falsifying medical history, contaminating laboratory samples, or directly inducing injury or illness on the victim.[26] In a review of 451 cases of Munchausen syndrome by proxy, Sheridan found that victims are typically 4 years old or younger, with equal percentages of males and females. She further discovered that an average of 21.8 months elapsed between the onset of symptoms and diagnosis, and 6% of victims died.[27] Perhaps even more alarming is her finding that 61% of siblings had illnesses similar to those of the victims, and 25% of the victims' known siblings were dead.[27]

Much like general factitious disorder, the symptoms in factitious disorder by proxy are more commonly physical than psychological, and may involve any symptom within the scope of imagination. The most common presentations seem to be apnea, anorexia, feeding problems, diarrhea, and seizures.[27,28] These may be induced in a variety of ways, from smothering the child to feeding the child laxatives or ipecac. Perpetrators often have some medical training or exposure to the illness that affects the child (e.g., a mother who has a seizure disorder herself). Other clinical indicators or red flags include a patient who does not respond to appropriate treatments, symptoms that improve when the mother does not have access to the child, unexplained illnesses with other children in the family, a mother who becomes anxious when her child improves, or a mother who encourages invasive tests.[26]

As with all factitious illnesses, diagnosis may prove difficult unless one directly witnesses a perpetrator harming the victim. When the victim is a child or is elderly, both legal obligations and privacy rights may differ from those of a typical adult patient. This is particularly pertinent with regard to mandated reporting (which varies by state), as well as when video surveillance is proposed as a mechanism to uncover intentional harm. In general, whenever diagnostic or treatment strategies outside the usual standard of care are considered, it is best to consult with both professional medical and legal colleagues before undertaking them.

Treatment Approach

The first consideration once a diagnosis of Munchausen syndrome by proxy is made is that of protecting the victim. In many cases this means placing the child in a foster care situation (at least temporarily). Treatment then addresses both the victim and perpetrator. Although no effective treatment for victims has been established, it is generally thought that therapy to address co-morbid other psychiatric diagnoses is a good place to start. Therapy for perpetrators is generally the mainstay of treatment; however, because many perpetrators never admit to wrongdoing, this often proves difficult.

Malingering

The DSM-IV-TR describes malingering in the following manner: "The essential feature of malingering is the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior, for example, feigning illness while a captive of the enemy during wartime."[25] Table 16–3 outlines clinical indicators suggestive of malingering. Patients always have a clearly definable goal or external motivation for their behavior (this differentiates malingering from factitious disorders). Though the prevalence of malingering is unknown, it is thought to be more common in men than women and is often co-morbid with antisocial personality disorder. Settings where these conditions intersect (e.g., prisons) likely see a higher incidence.

Malingerers most often pick symptoms that are highly subjective and difficult to prove (or disprove). Vague pains, such as headache, tooth pain, or back pain, are common. The goal may be to obtain narcotics or to be placed on disability from work. The presence of a lawsuit after a reported injury should also raise suspicion that the patient is malingering. As with factitious disorders, the primary symptomatology of malingering may also be psychological in nature. Malingerers may report symptoms of anxiety or depression, and try to convince the examiner of how much their function is impaired and how much they are bothered by the symptoms. The malingerer may say something like this: "My panic attacks come back every time I go to work. All I want to do is to be able to work, but the panic won't allow me to. Please help me, doc."

The presence of clearly identified secondary gain is not absolute evidence of malingering—one must be careful not to miss the diagnosis of a true medical condition in this population. When malingering is suspected, however, objective tests are crucial. When these are normal, psychological testing may be in order. The Minnesota Multiphasic Personality Inventory–2 (MMPI-2) may pick up distortions or exaggerations in both physical and psychological symptoms.[29] Direct confrontation is not advised because this often results in the patient becoming angry and fleeing from treatment. Strategies that allow the patient to save face, for instance, suggesting that the illness will improve soon, are generally more successful. Avoiding iatrogenesis and remaining aware of one's own anger toward the patient (so as not to act on it) are also keys to appropriate treatment.

Somatoform Disorders

The somatoform disorders are characterized by bodily symptoms that suggest a physical disorder, but for which there are no demonstrable organic causes or known

physiological mechanisms severe enough to result in significant distress or functional impairment; there is also a strong presumption that the symptoms are linked to psychological factors or to conflict.

Conversion Disorder

Conversion disorder is perhaps the classic somatoform disorder; it involves a loss or change in sensory or motor function that is suggestive of a physical disorder but that is caused by psychological factors. Common signs and symptoms include paralysis, aphonia, seizures, disturbances of gait and coordination, blindness, tunnel vision, and anesthesia. The primary evidence for the psychological cause consists of a temporal relationship between symptom onset and psychologically meaningful environmental precipitants or stressors. A patient who developed conversion blindness, for instance, may have seen her husband with another woman before she complained of being unable to see. The conversion symptom is not under voluntary control, although the patient may be able to modulate its severity. A patient with a functional gait disturbance or a weak arm, for example, may, with intense concentration, be able to demonstrate slightly better control or strength. DSM-IV has eliminated pain and sexual dysfunction as conversion symptoms. Reviewing conversion, Ford and Folks[30] recommended that it be considered a symptom rather than a primary diagnosis. In children with conversion symptoms, the gender ratio is equal; in adults, conversion is two to five times more common in women than men.

Predisposing factors are important considerations for both diagnosis and treatment. A prior medical illness is a common source for the symptom. If a viral illness is accompanied by vertigo while a patient is under stress, the illness may bring secondary benefits of attention and support from loved ones. At a later time, when stress recurs, the symptom of vertigo may develop again, this time as a conversion symptom. By definition, the symptom is not intentionally produced or feigned. It is presumed that the unconscious secondary benefit of the condition that alleviates conflict sustains the condition. Patients with seizures, especially complex partial seizures (in which consciousness is preserved), are repeatedly exposed to a phenomenon that removes them from responsibility, evokes sympathy, and brings help from a loved one. Pseudoseizures commonly co-exist with true seizures and can be exceedingly hard to discriminate, particularly when the electroencephalogram (EEG) fails to demonstrate spiking activity or shows only nonspecific slowing. Epileptic and nonepileptic seizures can be temporally related, and in patients with partial seizures, organic ictal changes may also facilitate the development of conversion symptoms.[31]

Preexisting psychopathology is another factor that predisposes to conversion symptoms. The most common Axis I disorders associated with conversion are depression, anxiety, and schizophrenia. Axis II personality disorders (especially histrionic, dependent, and what was formerly known as passive-aggressive personality disorders) are common in these patients.

Conversion symptoms may be precipitated by exposure to others with specific symptoms. Such "figures of identity" may be psychologically important people in the patient's life (such as a parent who has just died), or may be strangers whose symptoms the patient observes under extreme and sudden stress, as occurs in mass psychogenic illness ("epidemic hysteria"). Extreme psychosocial stress is likely the most important of all precipitating factors. Some authors have presented evidence for a predominance of conversion symptoms, when unilateral, and on the nondominant side in females.[32,33] More recently, the tendency for motor and sensory symptoms to occur on the nondominant left has been questioned.[34]

Often, confidence in the diagnosis is based on demonstration that function is normal in the symptomatic body part. Depending on the deficit being investigated, electromyograms (EMGs), evoked responses of vision and hearing, slit lamp examinations, funduscopic examinations, retinoscopic examinations, pulmonary function tests, and barium swallows should be normal. This negative evidence is critical and requires meticulous review by the clinician. Positive evidence includes not only the psychological data but also any demonstration of normal function in the supposedly disabled body part. Detective work begins with close observation of the patient, including during periods when the patient is unaware of the observer's presence. In part, one is trying to distinguish the presentation from that of the malingerer. If the patient moves his or her arm normally when unaware of being observed and displays a frail arm when watched, the patient is most likely malingering.

The diagnosis of conversion cannot rest comfortably only on the absence of organic disease. Caution in diagnosing conversion symptoms is based on early reports that 13% to 30% of those with this diagnosis went on to develop an organic condition that, in retrospect, was related to the original symptom.[35] The rate of misdiagnosis of conversion has dropped; a recent report revealed only 4% who were subsequently found to have a documented medical illness.[36]

Functional brain imaging has added another dimension to the study of patients with conversion disorder; there have been reports of functional neuroanatomical abnormalities in patients with conversion (i.e., sensorimotor loss).[37] Black and co-workers[38] have summarized the lessons from neuroimaging, suggesting that conversion results from dynamic reorganization of neural circuits that link volition, movement, and perception. Disruption of this network may occur at the stage of preconscious motor planning, modality-specific attention, or right frontoparietal networks subserving self-recognition and the affective correlate of selfhood.[38]

Conversion symptoms are usually sustained, but sometimes only for a certain activity. The patient who cannot lift his leg adequately in walking may be observed to cross it over his good one during conversation. Deviation of the eyes toward the ground, no matter which side the "semicomatose" patient lies on, is functional, and sometimes demonstrates lack of an organic disorder.[39] One may lead the patient with functional blindness around obstacles (e.g., chairs); the patient with conversion usually avoids them (a malingerer is more likely to bump into them). Carefully watching the "blind" patient's eyes and face while quietly taking a roll of money out of one's wallet, or suddenly menacing (being careful to avoid creating a draft or noise) or making a face at the patient is another way to assess vision. Sensory testing on the patient in both prone and supine positions checks for consistency. A malingerer is more likely to become hostile and uncooperative during the examination, probably in the hope of shortening it.

Prognosis and Treatment. The literature supports an optimistic outlook for these patients, at least in the first few years. Folks and co-workers[40] recorded a complete remission rate of 50% by discharge in those with conversion disorder in a general hospital. However, the long-term course is less favorable, because a sizable fraction of these patients develop recurrent conversion symptoms (20% to 25% within 1 year). Unilateral functional weakness or sensory disturbance diagnosed in hospitalized neurological patients persisted in more than 80% (of 42 patients over a median of 12.5 years).[41] Patients with one conversion symptom may also develop other forms of somatization or eventually meet criteria for somatization disorder.

The most common form of treatment is to suggest that the conversion symptom will gradually improve. This ordinarily begins with reassuring news that tests of the involved body system show no damage and therefore that recovery is certain. Predicting that recovery will be gradual, with specific suggestions (e.g., vague shapes will become visible first; weight bearing will be possible and then steps with a walker; standing up straight will come before full steadiness of gait; strength in squeezing a tennis ball will be followed by strength at the wrist and then elbow joints; and feeling will return to the toes first) usually succeeds, provided that the diagnosis is conveyed with serene confidence and the suggestions provided with supportive optimism. Lazare[35] pointed out that the psychiatrist should also discuss the patient's life stresses and try to detect painful affects to assess the nonverbal interpersonal communication embodied by the symptom.

Confrontation is seldom helpful. Patients are particularly sensitive to the idea that an authoritative person has dismissed their suffering; their anger and sensitivity may be based on a history of abuse or neglect. Stonnington and associates[42] suggested that the best context for discussion of the diagnosis of pseudoseizure comes after the patient and the family have agreed that key representative events have been captured by video EEG monitoring.

Some patients sense that there is a relationship between the stressful psychosocial conditions and the conversion symptomatology. An approach acceptable to some of these individuals has been to say that the body, mysterious in many ways, can be smarter than we are; it may tell us something is wrong before we realize we need help. When the stress in our lives becomes excessive, especially when our nature is more to overlook it or to grit our teeth and prevail, our body, by its symptoms, may blow the "time-out" whistle, forcing us to stop, to take a rest, and to get some help. This approach invites the patient to greater insight.

Further intervention may not be necessary. However, if the conversion symptom persists, if the precipitating stress is chronic, or if there is massive secondary gain, resolution of the situation becomes a target of the intervention. Because the stresses are often social, couples or family therapy may be instrumental in achieving a final resolution. Treatment, for instance, for nonepileptic seizures, should consider risk factors, including perpetuating and triggering events. Co-morbid psychiatric diagnoses should be treated. Behavioral interventions, physical therapy, and reassurance are crucial, particularly for less verbal patients.[42]

Some hospitalized patients fail to improve with suggestion. Because they occupy a nonpsychiatric bed, they must be told that if they insist that they are not well enough to leave the hospital, transfer to a psychiatric hospital or to a psychiatric unit will be arranged. Symptoms that have not responded to earlier suggestion may then improve sufficiently to permit discharge. One would have to entertain in such a patient the possibility that the correct diagnosis is malingering. In general, a favorable outcome depends more on the patient's psychological strengths and on the absence of other psychopathology than on the specific nature of the conversion symptom itself.

Somatoform Pain Disorder

The predominant feature of somatoform pain disorder (termed simply *pain disorder* in DSM-IV) is chronic, severe, and preoccupying pain that has no adequate medical explanation. Either there is no medical disease at all, or the patient's pain is grossly disproportionate to demonstrable histopathologic findings. The pain is severe enough to warrant clinical attention and to impair role function. It is constant and often inconsistent with known neuroanatomical innervation. Psychological factors must be judged to play a significant role in the precipitation, maintenance, or exacerbation of the pain, but it is neither intentionally produced nor feigned. Pain is the subject of Chapter 18. Patients with somatoform pain disorder are often severely disabled by their symptoms, live like invalids, and work infrequently. They have long histories of medical care and many surgical interventions. They are often completely preoccupied with their pain and view it as the sole source of all their difficulties. Depression is commonly co-morbid with somatoform pain disorder.

In practice, the problem is often that organic causes of pain cannot be completely disregarded. Co-morbid medical illness, concerns about neuropathic pain, myofascial pain, or an undiagnosed medical problem, challenge the diagnosis of the psychiatric disorder. Questions about substance abuse and personality disorder complicate the picture. A multiaxial record of the data related to a patient may help clarify the course, treatment effectiveness, and relative contributions of medical and psychiatric data. Mayou and associates[43] have suggested a method of somatoform classification that would include medical diagnoses, the presence or absence of depressive or anxiety disorder, history of narcotic use, health beliefs, illness behavior, stressors, and social benefits (e.g., disability payments or unemployment). Each parameter could be followed over time to shed light on the patient's condition.

Treatment. The spectrum of reactions of these patients is likely to mimic that for conversion and the same therapeutic approach is recommended: Provide reassurance that the body parts in question appear to be normal (or no worse) and then suggest that the pain will gradually subside. Some patients can accept their manifest need to resolve the stress that has been uncovered in psychiatric consultation (and can be told that it is worth working on even if it does not appear to be related to the pain). Results of psychological testing can be presented to them as helpful evidence of the existence of concerns in their subconscious or unconscious mind. The "wisdom" of their body in warning them about

their stress, by means of pain, may be helpful as well. Early treatment of patients with this disorder is usually limited to individual, marital, or family therapy. If it has continued for a longer time, multimodal, behavioral, and more comprehensive approaches (including relaxation response training and physical therapy) are indicated. Attention to triggers and perpetuating factors is important.

Somatization Disorder

Originally termed *hysteria* or *Briquet's syndrome* and now given the DSM-IV designation of *somatization disorder*, this condition has been solidly established as clinically and epidemiologically distinct. It is a chronic syndrome of multiple, recurring somatic symptoms that are not explainable medically and are associated with psychosocial distress and with medical help–seeking behaviors. The disorder is much more common in women as compared to men. It tends to occur in those of low socioeconomic status, often in non-Caucasians who live rurally, and has a 1-year prevalence rate of 0.3% in the general population.[44–46] Of first-degree female relatives, 10% to 20% suffer the same disorder, whereas male relatives show an increased incidence of alcoholism and sociopathy.[47]

Women with this disorder tend to have histories as children of missing, disturbed, or defective parents, and of sexual or physical abuse.[48–51] The tendency to somatization has been linked to childhood trauma via insecure attachment and maladaptive patterns of interpersonal communication in seeking care.[52,53]

These women marry sociopaths more often than chance would predict, and they tend to be poor parents themselves.[48–50] Given these unfortunate circumstances, and their roughly 75% chance of having one or more additional psychiatric diagnoses (the most common being an affective or anxiety disorder, or drug and alcohol abuse[54]), it is no surprise that marital discord and unsatisfactory work histories are also common.

DSM-IV diagnostic criteria include at least the following: four different pain symptoms (e.g., headache; back, joint, extremity, or chest pain; painful urination, intercourse, or menstruation); two GI symptoms (e.g., nausea, bloating, diarrhea, and food intolerance); one sexual symptom (e.g., menstrual symptoms, erectile or ejaculatory dysfunction, or sexual indifference); and one pseudoneurological symptom other than pain (e.g., deafness, paralysis, a lump in the throat, aphonia, fainting, anesthesias, or blindness). The symptoms must be disproportionate to demonstrable medical disease and severe enough to result in medical attention or significant role impairment.

The diagnostic symptoms are numerous and can be cumbersome for the busy clinician. Othmer and DeSouza[55] have addressed the first problem by developing an abbreviated list of seven symptoms that can be employed to screen for the disorder. If two or more of the symptoms in their clever mnemonic (Table 16–4) are present, there is a high likelihood of somatization disorder. The presence of three symptoms accurately identified 91% of the patients with somatization disorder with a sensitivity of 87% and a specificity of 95%. However, despite this list of symptoms, the clinical diagnosis almost always requires review of past records; these tend to be voluminous, scattered among a host of hospitals, lost, or a combination of the three. In the absence of the chart, contact with prior treating physicians or family members may help in establishing the symptom count. Notoriously poor historians, these patients will be unable to recall past admissions or clinic visits, and they will deny a history of a symptom that the chart lists as a chief complaint on a past visit.

TABLE 16–4 Seven-Symptom Screening Test for Somatization Disorder

MNEMONIC	SYMPTOM	SYSTEM
Somatization	Shortness of breath	Respiratory
*D*isorder	Dysmenorrhea	Female reproductive
*B*esets	Burning in sex organ	Psychosexual
*L*adies	Lump in throat (difficulty swallowing)	Pseudoneurologic
*A*nd	Amnesia	Pseudoneurologic
*V*exes	Vomiting	Gastrointestinal
*P*hysicians	Painful extremities	Skeletal muscle

From Othmer E, DeSouza C: A screening test for somatization disorder (hysteria), *Am J Psychiatry* 142:1146-1149, 1985.

During the interview, the patient usually presents complaints in a histrionic fashion ("Why I bled so much—I've never seen so much blood!!—that I passed out on the bed and my family said I was in a coma for 3 days!"), with symptoms so exaggerated that a psychogenic cause may be suspected from the outset. The other consistent trait these patients possess is a peculiar communication style. Histories are vague and details are either elusive or downright inconsistent. Efforts at clarification may be fruitless and frustrating. ("Is your pain worse in the morning?" "Yes, and it's worse in the afternoon, too.") Emotional distress is openly expressed ("I'm not getting *anywhere*, Doctor! No one can tell me anything! What's happening to me?"), but if one tries to identify the emotion, for example, telling the patient she seems very anxious, that emotion is more likely to intensify ("Well, wouldn't anybody be? It's been a whole month and nobody—nobody, Doctor—knows what's going on with me!"). This type of response tends to drive the physician back to a cognitive search—onset, duration, radiation, intensifying or relieving factors—only to encounter once again the fogbound and trackless waste of imprecision, inconsistency, and lapsing memory.

Contemporary medicine's shift from clinical to economic priorities has only heightened attention to somatization disorder. Smith and associates[56] have documented that the typical patient with this disorder spends an average of 7 days per month sick in bed (compared with 0.48 days for the average person), and accrues (mostly unnecessary) annual hospital care rates many times higher than those of the average person in the population between the ages of 15 and 64 years. This happens despite their remarkably stable clinical course, with a 90% probability of not developing a new medical or psychiatric disorder in the subsequent 6 to 8 years following diagnosis. New evidence suggests that somatizing patients experience functional disability and role impairment equal to or greater than that associated with many major, chronic medical conditions.[57]

Treatment. The management of somatization disorder has been well formulated by Murphy.[58] It is best carried out by primary care physicians (PCPs) according to a conservative plan based on being a consistent care provider, preventing unnecessary or dangerous medical procedures, and inquiring in a supportive manner about the areas of stress in the patient's life. The last occurs during the physical examination, without inferring that the real cause for the increase in the patient's somatic complaints is psychosocial stress (which is what most authors believe). The basic goal is to help the patient cope with the symptoms rather than to eliminate them completely. In short, the aim is palliation, rather than outright cure. Psychotropic medication and prescription analgesics generally are not very helpful, except when used to treat a clear-cut, co-morbid psychiatric condition, such as major depression or panic disorder.

Smith and associates[59] codified treatment recommendations in a letter to the PCPs of somatization disorder patients. These included regularly scheduled appointments (e.g., every 4 to 6 weeks); a physical examination performed at each visit to look for true disease; the avoidance of hospitalization, diagnostic procedures, surgery, and the use of laboratory assessments, unless clearly indicated; and advice to avoid telling patients, "It's all in your head." In a randomized controlled trial (RCT), this intervention reduced quarterly health care charges by 53%, largely as a result of decreases in hospitalization.[60] Neither the health of the patients nor their satisfaction with their care was adversely affected by implementation of the advice.

Cognitive-behavioral therapy (CBT), when compared to standard medical care, has also reduced symptoms, ratings of disorder by evaluators, and health care costs. The intervention focused on stress management, activity regulation, emotional awareness, cognitive restructuring, and interpersonal communication.[61]

Undifferentiated Somatoform Disorder

The diagnostic criteria for somatization disorder are quite restrictive, and most chronic somatizing patients in medical practice do not cross this stringent threshold. In an attempt to provide a diagnostic home for such patients, DSM-IV now includes the entity *undifferentiated somatoform disorder*. This diagnosis requires one or more physical symptoms that persist for at least 6 months and are medically unexplained. Several researchers, including Kroenke and co-workers[62] and Escobar and associates,[63,64] have sought to define a more inclusive entity that requires fewer somatic symptoms than are required for somatization disorder, but that nonetheless identifies patients who have the clinical and behavioral features characteristic of the disorder. Multi-somatoform disorder is based on current unexplained symptoms. It requires three or more unexplained symptoms within the past 2 weeks out of a list of 15, along with a 2-year history of somatization. Escobar's abridged somatization disorder is based on at least six lifetime unexplained symptoms in women and four in men. Multisomatoform disorder has a high concordance with somatization disorder and perhaps a more efficient diagnostic algorithm. It is less correlated with abridged somatization disorder, but all three diagnoses are associated with similar medical utilization rates and declining physical function over a year.[65]

Hypochondriasis

While extensive research has crystallized the concept of somatization disorder, the nosology of hypochondriasis remains more ambiguous. Concern about health is common, and the point at which preoccupation becomes pathological is not always clear. Hypochondriacal thinking may occur in the form of a primary disorder or as a nonspecific correlate of other Axis I illnesses, including affective and anxiety disorders. Tendencies to amplify benign, unpleasant symptoms and to misconstrue them as pathological have both trait-like and state-like properties. In a study of a military population, Noyes and colleagues[66] found that personality measures, mainly neuroticism, explained much of the variance in hypochondriacal concerns. Based on evidence such as this, some nosologists have argued that hypochondriasis is better thought of as a personality disorder to be denoted on Axis II.[67]

DSM-IV identifies the predominant feature of hypochondriasis as a preoccupation with the fear or belief that one has a serious, undiagnosed disease. This concern is based on a misinterpretation of benign physical signs and symptoms as evidence of disease. Other diagnostic criteria include the absence of a physical disorder that accounts for the patient's symptoms; persistence of the disease fear or belief despite appropriate medical reassurance; clinically significant distress or role impairment; and duration of at least 6 months. By this definition, hypochondriasis is quite prevalent. It is found in approximately 5% of medical outpatients and occurs equally between the genders.[68]

Fundamentally, hypochondriasis represents an overconcern about illness and a fearful attitude toward one's health. Afflicted patients are absorbed by their bodies and preoccupied with their symptoms. Their assessment of their health becomes both a way of reacting to life's stresses and demands, and a nonverbal language for communicating with others. Such inclinations and beliefs share similarities with those of the somatizer. The cognitive style of the typical hypochondriac is obsessive, whereas the cognitive style of the typical somatizer is histrionic.

The origins of hypochondriasis are not fully understood. Both genes and early upbringing may serve as conditioning factors. There is evidence, for instance, that hypochondriacal patients tend to amplify and augment somatic and visceral sensations more than nonhypochondriacal patients.[69,70] Predisposing events in childhood include disease in the patient or in a family member, and adversity, including neglectful and abusive parents.[71] Context also plays a role. The onset of the syndrome can be triggered by illness or by the death of a loved one.

Prognosis and Treatment. Hypochondriasis can be a chronic and disabling disease. Barsky and Ahern[72] note a time course of approximately 11 years in the group they studied; Kenyon[73] found that among hospitalized patients with hypochondriasis, only 20% were judged as recovered or much improved at the time of discharge, and twice that many were either unchanged or worse than on admission. There may be some room for optimism, however, particularly when the illness has lasted less than 3 years and is not co-morbid with a personality disorder.[74]

When confronted with hypochondriasis, a treater's first step should be to screen for co-morbid affective and anxiety disorders (including obsessive–compulsive disorder [OCD]). These are likely easier to treat, and their resolution may greatly diminish or bring an end to exaggerated disease fears. Isolated hypochondriasis is more difficult to cure. Although there have been a few reports suggesting a role for selective serotonin reuptake inhibitors (SSRIs).[75–77] the most successful psychiatric interventions for primary hypochondriasis are cognitive, behavioral, and educational.[78,79] Barsky and Ahern[72] have recently shown that the treatment combination of education of the PCP and time-limited CBT for the patient improves a range of hypochondriacal symptoms, with modest treatment effect. The manualized treatment for the patient targets cognitive and perceptual mechanisms of illness, including *hypervigilance* to visceral experience, *beliefs* about symptom etiology, *context* in which the hypochondriasis occurs, sick role *behaviors*, and *mood*.

Patients with hypochondriasis tax the general physician. Such patients are difficult to reassure; their care is both time-consuming and expensive; and they often provoke strong negative reactions in their frustrated providers.[73] Psychiatrists can be instrumental in easing anxieties and offering management recommendations. An internist's goals when treating a hypochondriacal patient should be threefold[78]: to avoid unnecessary diagnostic tests and to obviate overly aggressive medical and surgical intervention; to help a patient tolerate the symptoms, rather than striving to eliminate them; and to build a durable doctor–patient relationship based on the physician's interest in the patient as a person and not just in the symptoms. Once a physician views his or her task as palliative, not curative, the doctor–patient relationship becomes less contentious and adversarial. Further, the patient is likely to loosen the grip on symptoms when he or she feels that the physician has acknowledged and accepted them as real.

Several practical measures may be helpful. The physician can forge a personal connection with the patient by paying particular attention to social history and by complimenting the patient on the ability to persevere despite great discomfort. Rather than providing as-needed appointments, the doctor can schedule meetings at regular intervals, thereby decoupling professional attention from symptom severity. Patients with hypochondriasis tend to develop iatrogenic complications and treatment side effects. This has given rise to the clinical maxim, "Don't just do something, stand there." In other words, the best medical interventions are modest, simple, and benign (e.g., heating pads, ointments, frequent physical examinations, vitamins, as well as the offering of tangible evidence of discomfort, including canes, braces, and elastic bandages).

Monosymptomatic Hypochondriasis and Body Dysmorphic Disorder

Monosymptomatic hypochondriasis refers to several distinct syndromes characterized by a single, fixed, false belief that one is diseased. The disease conviction is generally delusional and grossly disproportionate to any objective disease or deformity. This belief is tightly circumscribed; no other thought disorder is present; and the remainder of the patient's personality remains intact and unaffected.[80] *Body dysmorphic disorder* (BDD), is one of the most common of these syndromes, and it is singled out in the DSM-IV as a separate diagnosis under somatofom disorder.[81,82] Other forms of monosymptomatic hypochondriasis include the delusional belief that one is infested with a parasite or insect and the delusion that one emits an offensive odor (olfactory reference syndrome).

The patient with BDD believes he or she is physically misshapen and unattractive, although objective appearance is unremarkable. Self-reported prevalence of the disorder in the German population is 1.7%.[83] The defect or deformity in appearance is most commonly in the face, breasts, or genitals. The average age of onset for these patients is younger than age 20, with males and females equally represented. Typical males seek plastic surgeons with the conviction that their noses are too large or disfiguring. The typical female, convinced that her facial skin is "scarred," making her appearance grotesque, will seek a plastic surgery or dermatological consultation. BDD is commonly accompanied by a mood disorder (including atypical depression with rejection sensitivity), social phobia, OCD, and substance use disorders. The rate of suicidal ideation, suicide attempts, and completed suicide is notable,[84] and the course chronic with a remission rate probably lower than that reported for mood and anxiety disorders alone.[85]

Patients with delusions of infestation believe that parasites, insects, or vermin are under their skin, and as a consequence they have often severely excoriated themselves. These individuals tend to be in their mid-50s at onset, and approximately two thirds are women. They may complain of itching or tickling sensations and frequently produce bits of skin or hair as evidence of their infestation.

In olfactory reference syndrome, the patient is falsely convinced he or she emits a foul odor, for example halitosis, which offends others. The patient engages in elaborate rituals, such as frequent bathing and changes of clothing, and uses excessive amounts of perfume and deodorants. Olfactory reference syndrome is more common in men than women, and the typical patient is in his mid-20s.

The three forms of monosymptomatic hypochondriasis share certain clinical characteristics. Despite the encapsulation of their thought disorder, these patients are profoundly anguished about their symptoms, and their lives are severely disrupted. Their lives are completely devoted to the pursuit of medical and surgical remedies, and they tenaciously resist psychiatric referral or treatment. They are intensely ashamed and feel that they are under constant scrutiny and derision. This generally leads to profound social withdrawal and disability. Severe anxiety, paranoia, and depression are prevalent. Alcohol abuse is common, especially in younger males.

Treatment. SSRIs and clomipramine (a tricyclic antidepressant [TCA]) are the agents of choice in the treatment of BDD, with doses in the upper therapeutic range. BDD may remit along with major depression, but treatment often fails or is only partially effective. Olanzapine, but not pimozide, has been shown to be effective to augment fluoxetine.[86,87] Electroconvulsive therapy (ECT) has also been used successfully when the patient was frankly delusional.

These patients are difficult to treat, in part because they are so ashamed of their appearance and resistant to psychiatric help. Psychopharmacologic agents may be effective, but the patients are frequently unwilling to take them.

They do not believe that a psychotropic drug could correct a physical defect; or once begun on an agent, they may stop taking it without informing their physician.

Maintenance therapy is generally necessary.[81] Even with successful pharmacotherapy, most patients retain some concern about their problem, but its intensity is blunted sufficiently to permit them to lead more normal lives. One may never be able to get some patients to acknowledge the delusional nature of their symptom, even after significant improvement. Hard-pressed to justify the recommendation of a neuroleptic, the physician may even tell the patient that these insects or odors are best "cleansed" from within the system, hence the need for a drug. On the other hand, a few patients will accept the notion that the body is more vulnerable to parasitic infestation or odor generation during times of greater stress. When major depression is present in BDD, medication is more readily accepted.

Functional Medical Syndromes

Although somatoform disorders are characterized by complaints that seem far out of proportion to any abnormalities found, common functional medical syndromes also lack laboratory confirmation. Like the diagnoses in DSM-IV, these diagnoses depend on consensus criteria, description of symptoms, and a natural course of illness. There is substantial overlap in the phenomenology, epidemiology, and co-occurrence of these various syndromes.[88,89]

Chronic fatigue syndrome (CFS), fibromyalgia (FM), and irritable bowel syndrome (IBS) are three of the functional medical syndromes named for the dominant symptom complex. Those patients who seek medical care for functional medical syndromes are more distressed, depressed, and under more life stress than community residents who have the same symptoms but who never seek out a physician. Once the patient acquires a functional diagnosis (either by strict research criteria or by looser clinical criteria), that diagnosis is granted greater authority and legitimacy than a co-morbid psychiatric diagnosis. Physician and patient often collude to focus attention only on the somatic syndrome. A symptom (such as disturbed sleep) can be seen either as part of a medical or a psychiatric diagnosis. Whether the patient is diagnosed with a functional medical condition, mood disorder, or somatoform disorder depends on whether the key symptoms are attributed to the physical or psychiatric realms. The fact that the patient carries a functional medical diagnosis should not limit aggressive treatment of co-morbid psychiatric diagnoses.

The principles of care for somatoform disorders apply here as well. Rule out organic disease; diagnose and treat affective disorder, substance abuse, and the other psychiatric diagnoses. Knowing the patient, listening with respect for his or her suffering, setting limits, and keeping an ear for changes in medical complaints remain pivotal concepts. CBT is emerging from a number of rigorous intervention trials as an effective treatment for many of these syndromes.[90–92] The status of antidepressant pharmacotherapy for them has been systematically reviewed.[93]

Chronic Fatigue Syndrome

Many more patients complain of chronic fatigue without a medical cause than meet formal criteria for CFS. Fatigue itself is a vague symptom that requires exploration of exacerbating factors, timing, mood, and meaning. Patients with MDD have fatigue that is worse in the morning. They have difficulty initiating activity, as do patients with Parkinson's disease. Sometimes fatigue actually turns out on exploration to be agoraphobic avoidance of leaving home, or a tendency to avoid the risk of social embarrassment. Fatigue may also mean daytime sleepiness, seen in sleep apnea. Fatigue with dysphoria is central to a mood disorder. Apathy—lack of motivation and lack of dysphoria—is more characteristic of a neurologic disorder or hypothyroidism. Patients who value their productivity and strength are especially frustrated by fatigue, and its personal meaning will exacerbate the symptom.

By consensus, CFS is defined by several features: self-reported, clinically evaluated, unexplained, persistent or relapsing chronic fatigue with a definite onset that lasts more than 6 months. It is not due to exertion or relieved by rest, but it substantially reduces the patient's activities; and it includes four or more other symptoms (impaired memory or concentration, sore throat, tender cervical or axillary lymph nodes, muscle pain, multijoint pain without joint swelling or redness; new headaches, unrefreshing sleep, and postexertional malaise lasting more than 24 hours), which came after onset of fatigue.[94]

The formal diagnosis of CFS, like that of a somatoform disorder, requires exclusion of the common psychiatric diagnoses. Patients, according to the most recent research criteria, do not qualify if they have a fatiguing medical condition that has not yet resolved or if they use fatiguing prescription medications. A formal diagnosis of past or current MDD with psychotic or melancholic features, bipolar mood disorder, schizophrenia, delusional disorder, dementia, substance abuse within the previous 2 years, and anorexia nervosa or bulimia precludes a formal diagnosis of CFS.

The patient may have CFS and also have a co-morbid anxiety disorder, somatoform disorder, nonmelancholic depression, neurasthenia, multiple chemical sensitivity disorder, or FM. The challenge for the psychiatrist is to treat what can be treated using either psychopharmacologic or psychological approaches. Anxiety disorders and nonmelancholic depression remain potentially fatiguing aspects of the syndrome. The psychiatrist should consider the role of personality disorder or the possibility of bipolar disorder, a diagnosis not easily ascertained by history, especially when seen between flagrant episodes. Exploration of the description and meaning of the most prominent symptom is indicated.

Although fatigue may follow a viral infection, no single virus has been shown to cause persistent, debilitating CFS. In the primary care setting, patients with postinfectious fatigue after 6 months are more likely to have had fatigue and psychological distress before the infection.[95] A history of dysthymia and more than eight medically unexplained symptoms not already listed in CFS criteria may predict prolonged disability in CFS patients.[96]

Suggested screening laboratory tests include a complete blood count, a sedimentation rate, liver and renal function tests, calcium, phosphate, glucose, thyroid-stimulating hormone (TSH), and urinalysis. Further tests, such as a magnetic resonance imaging (MRI) scan of the head to search for multiple sclerosis, should be guided by clinical findings. Lyme disease, for instance, is unlikely to cause

fatigue as the only finding.[97] Acute mononucleosis in adolescence might produce a similar picture, but it is not likely later on in life. The acute diagnosis could be documented by antibody evidence of recent infection.

There is no specific medical treatment for formal CFS. The choice of antidepressant for co-morbid mood disorder depends on its capacity to improve sleep but limit sedation. Graduated aerobic exercise programs are important to improve physical conditioning. CBT programs increasingly appear to have established their effectiveness.[98,99] The goal is to help the patient achieve maximal function.

Fibromyalgia

Fibromyalgia is a syndrome of generalized muscle pain and tenderness at specific trigger points, detected by physical examination.[100] For diagnosis, pain must be bilateral, above and below the waist, and include the axial-cervical spine, chest, or lower back. Criteria require 11 of 18 (9 bilateral) trigger points. Secondary FM occurs with rheumatoid arthritis and Lyme disease.

Affective disorders are common among FM patients who seek out rheumatologists. The diagnosis of FM, originally associated with chronic fatigue and sleep disorder, now only includes pain and trigger points, according to the American College of Rheumatology; however, patients with FM, fatigue, and unrefreshing sleep may meet diagnostic criteria of CFS.

For FM, amitriptyline (25 to 50 mg/day) and cyclobenzaprine (10 mg at bedtime) (both TCAs) to relieve pain and improve sleep seem to work at least briefly in some fraction of patients.[101,102] There have been single RCTs of fluoxetine, duloxetine, and venlafaxine.

Irritable Bowel Syndrome

Functional GI disorders are recurrent medical syndromes without known biochemical or structural abnormalities. Irritable bowel symptoms occur in 15% to 20% of the population, but people with the disorder who seek medical help compose a major component, 25% to 50%, of referrals to gastroenterologists.[103] The disorder effects females more than males and, although its causes are unknown, does appear to have a genetic component.[104,105]

The international criteria for IBS include continuous or recurrent symptoms (for at least 3 months) of abdominal pain or discomfort relieved by defecation, or associated with a change in stool frequency or consistency *and* an irregular pattern of defecation at least 25% of the time (three or more of the following): altered stool frequency; hard, loose, or watery stool; straining, urgency, or feeling of incomplete evacuation; passage of mucus; and bloating or a feeling of abdominal distention.[106]

Those who visit physicians have more severe symptoms and are more likely to have co-morbid psychiatric diagnoses than those who do not. Mood disorder,[107] panic with agoraphobia (especially fear of leaving the house because of diarrhea),[108] history of childhood abuse, and neuroticism[109] are more prevalent among patients than among the general population.[110]

Again, diagnosis depends on criteria, natural history of illness, and absence of laboratory confirmation of another diagnosis. The clinical approach to IBS is similar to that for the somatoform disorders: rule out organic and psychiatric diagnoses. In the context of a relationship in which the physician continues to learn about the patient, the physician chooses somatic treatments that target the predominant symptom of pain, constipation, or diarrhea. A TCA has an analgesic effect at low doses but tends to cause constipation and be preferable for a patient with recurrent diarrhea. An SSRI seems the better choice for co-morbid panic disorder or OCD,[111] particularly in patients with constipation. Paroxetine is most studied of the SSRIs for this use and results have been mixed.[112] If the patient tends to have diarrhea, loperamide, a constipating agent, may be useful. Fiber and dietary adjustments may relieve constipation. The principles of pain management in IBS parallel the principles of management in somatoform pain disorder.

Cognitive-behavioral therapy and interpersonal psychodynamic therapy appear to be effective for improving well-being and quality of life.[113–115] Education about amplification of visceral symptoms and the vicious circle of anxiety, increased vigilance for symptoms, and resultant increase in symptoms and pain; relaxation training; and stress management techniques are helpful to both individuals and groups.

CONCLUSION

When one thinks of psychologically driven somatic symptoms, the somatoform disorders may be the first diagnostic category to come to mind. But among general hospital inpatients and outpatients, other psychiatric diagnoses (particularly affective disorders, anxiety disorders, and organic mental syndromes) are more likely to be discovered at the end of the history and examination. These require specific treatment, and when the psychiatric disorder remits, the somatic symptoms usually subside. The diagnostic tests we find helpful are the MMPI-2, an excellent screening device for conversion or a somatoform disorder, and Axis II parameters; projective tests, to help both physician and patient understand conflicts in the patient's life that may not be in the patient's awareness; and full neuropsychological test batteries, which delineate precise areas of cognitive deficiency (see Chapter 7).

In the case of complex medical patients, some have suggested that disorders defined solely by unexplained somatic symptoms should be described as a multidimensional functional medical diagnosis without reference to etiology. Disorders such as chronic pain, FM, or IBS would be listed as medical diagnoses. Somatic symptoms associated with depression would be classified with depression, and those associated with anxiety would be classified with anxiety. A multiaxial diagnostic system would allow anxiety disorders, anxiety and hypochondriasis, and specific illness fears to be listed together. Personality disorders, including those seen in somatization disorder, would be on a personality axis, and specific stressors (including difficult interactions with the health care system) could be specified. A multidimensional descriptive system for somatic symptoms should document the type and number of somatic symptoms and the nature of the acute, chronic, or recurrent course. Known organic disease pathology should be listed as well as health beliefs, illness behavior, associated psychiatric disorders, and social factors such as employment or social benefits.[43]

The treatment ultimately depends on the diagnosis. Smith and associates[56] have shown that an intervention with the PCP significantly reduced costly and potentially harmful medical interventions for somatizing patients without compromising the health or satisfaction of these patients. Psychological treatments such as CBT that focus on initiating and perpetuating factors improve the outcome.

17 Patients with an Eating Disorder

Anne E. Becker, M.D., Ph.D., Sc.M.
Jennifer J. Thomas, Ph.D.
Kristin S. Russell, M.D.
Esther Jacobowitz Israel, M.D.

Eating disorders are common among adolescent and young adult women and are associated with serious morbidity and mortality. Patients with eating disorders present a multidimensional clinical challenge in the general hospital setting. These disorders frequently have medical complications and go undetected in clinical settings, and the patients are often reluctant to seek or accept treatment. Patients with anorexia nervosa (AN), bulimia nervosa (BN), binge-eating disorder (BED), or atypical eating disorders (known as eating disorder, not otherwise specified [EDNOS]) almost always benefit from integrated multidisciplinary care, with a team that includes primary care and mental health clinicians as well as a nutritionist. Medical and nutritional stabilization are often clinical priorities in the general hospital setting and can enhance the effectiveness of the management of psychological and psychiatric dimensions of these disorders.

EPIDEMIOLOGY

Although their prevalence is highest in westernized and postindustrial societies, eating disorders appear to have a global distribution. Notwithstanding a previous clinical stereotype that associated eating disorders with affluent white girls and women, eating disorders are also prevalent among women of ethnic minorities in the United States. Rates among Latinos and non-Latino whites may be comparable, and rates among Native American women may exceed those among whites.[1,2] Moreover, rates of binge eating and BED may be elevated in black and Latino women compared with white women in both community- and clinic-based samples.[3–9] Whereas eating disorders and clinically significant disordered eating most commonly occur in the young adult female population, they also occur in men and boys, albeit at lower rates (5% to 15% of cases of AN and BN occur in males).[10] The lifetime prevalence of AN among individuals residing in the United States is 0.9% for women but just 0.3% for men.[11] Lifetime prevalence of BN is slightly greater, affecting 1.5% of women but just 0.5% of men.[11] The most prevalent eating disorder, BED, has a more equal sex distribution, with a lifetime prevalence of 3.5% in women and 2.0% in men.[11] The prevalence of BED in weight-treatment–seeking populations ranges up to 30%.[12,13]

Although various guidelines have been proposed to assess subthreshold eating disorders,[14–16] the consensus is that they are prevalent among United States girls and women, pose a risk for significant impairment and distress, and often feature psychopathology of commensurate severity to the officially recognized eating disorders.[17] Even higher prevalence rates are reported for specific individual symptoms (e.g., in 2007, 6.4% of adolescent girls in the United States reported purging, and 16.3% reported fasting in the past month to lose weight).[18] Although the clinical significance of isolated symptoms is debatable, substantial evidence supports the notion that subthreshold presentations are commonly precursors of full-syndrome eating disorders[19,20] and thus very likely part of a spectrum of eating disturbances.[14,15]

ONSET AND COURSE

The etiology of eating disorders is multifactorial with biological, psychodevelopmental, and sociocultural contributions to risk. AN and BN most commonly have an onset in adolescence; eating disorders are relatively rare in young children compared with postpubertal adolescents and young adults. Although AN can be seen in young children,[21] it is far less common (i.e., only 5%) in prepubertal girls.[22–25] Moreover, the onset of BN is usually in late adolescence,[23] and prepubertal bulimic behavior is reportedly uncommon.[26] Longitudinal twin data indicating that the heritability of eating disorder psychopathology increases substantially from early to mid adolescence raise the intriguing possibility that epigenetic processes—through which pubertal hormones trigger the phenotypic expression of latent genotypic vulnerabilities—may work in tandem with environmental ones to promote risk.[27] Finally, the onset of BED is typically in the early twenties.[4,28] Despite rapidly evolving pharmacologic and psychosocial treatment strategies for the eating disorders, approximately half of cases of AN and BN follow a chronic course,[29,30] and 43% of individuals with BED continued to be symptomatic in a 6-year longitudinal study of BED.[31] It is very common for individuals with AN, BN, or BED to transition from one diagnostic category to another during the course of their illness.[20] When diagnostic crossover occurs, trajectories typically feature movement away from restrictive eating patterns and toward binge eating or purging patterns, or both, at follow-up.[32,33]

In addition to their considerable prevalence, eating disorders are associated with serious medical co-morbidity and mortality. Eating disorders and substance abuse are associated with the highest risk of premature death among all

psychiatric illnesses.[34] The mortality rate from AN alone is 0.56% annually.[35] Moreover, AN is associated with an all-cause death risk five times what is expected, and BN with a risk nine times that expected. It is also important to note that whereas some of the deaths associated with AN were directly attributable to self-starvation, the mortality risk for suicide was 33 times the amount expected.[34] Because of the serious medical complications associated with eating disorders, patients often present to primary care, emergency departments, or hospital inpatient settings with an undisclosed or previously unrecognized eating disorder. Given that up to half of eating disorder may be undetected in primary care settings,[36–41] inpatient and outpatient medical and pediatric services provide significant opportunities to make a new diagnosis of an eating disorder and to initiate treatment. Furthermore, it appears that initiating treatment earlier in the course of the illness may improve outcome.[42]

DIFFERENTIAL DIAGNOSIS AND INITIAL ASSESSMENT OF EATING DISORDERS

Selection of an optimal treatment strategy for an eating disorder depends on an accurate diagnosis. Both identification and differential diagnosis of an eating disorder can be challenging. Differentiating between AN, BN, and EDNOS must address both substantial symptom overlap (Table 17–1) and crossover among diagnostic categories. Moreover, eating disorder symptoms can be masked by certain medical complaints, particularly those associated with gastrointestinal (GI) symptoms and weight loss, which can obscure an underlying or associated eating disorder. For example, some individuals attribute their restrictive diet to efforts to minimize severe bloating, nausea, or constipation, but a restrictive diet can, in fact, *cause* or contribute to these symptoms.[43] Patients sometimes initially present for medical care[44] and only come to psychiatric attention after an extensive medical evaluation has excluded a medical cause, unless an eating disorder is suspected on the basis of history. In other cases, the etiology of symptoms remains unclear and psychiatric consultation is sought to clarify contributions from an eating disorder or other mental illness. Using the same example, in the vast majority of such cases, GI symptoms caused by disordered eating often improve or remit with nutritional rehabilitation, psychiatric care, and conservative management.[43] However, it is always appropriate to consider the panoply of medical and psychiatric differential diagnoses that could contribute to symptoms. This is particularly true for unexplained weight loss in a demographic group not generally associated with AN, or for patients who do not clearly exhibit the excessive concern with weight associated with AN. But it is also true for patients with what appear to be classic symptoms of an eating disorder, given the frequent association between acute weight loss of medical origin and the onset of an eating disorder.

Clinical Detection of an Occult Eating Disorder

Clinical detection of an eating disorder can also be undermined by the limited capacity or motivation of patients to acknowledge and receive care for their illness.[45] Patients with AN are commonly reluctant to seek or accept treatment for their symptoms, and some even go to great lengths to avoid clinical detection of symptomatic behaviors or low weight. For instance, patients may avoid clinic visits, laboratory tests, or weighing. They may layer their clothing to give the appearance of normal weight, or, if they anticipate being weighed, they may "water load" (i.e., drink excessive quantities of water) or even tape weights to themselves to make their weight appear closer to normal. Individuals with BN also commonly postpone seeking treatment. For these reasons, individuals may come to medical attention for their eating disorder only after they arouse clinical suspicion on a medical or pediatric service, either by unexplained weight changes or by other medical symptoms, or when family members report concerns. For instance, family members might notice restrictive food intake (e.g., a girl becomes a vegetarian or vegan and progressively narrows food selections), secretive behavior concerning food (e.g., parents notice large quantities of food are consumed after the rest of the family has gone to bed, or cafeteria charges are very high on a term bill), or a pattern of excessively frequent bathroom use after meals.

Given the prevalence and associated mortality and morbidity of the eating disorders, clinicians should maintain appropriate vigilance for eating disorders in general hospital settings as well as an awareness that they can be difficult to detect. For patients with limited capacity or motivation to report symptoms, some probe questions can yield useful clinical data. These include questions about weight and dieting history. Frequent fluctuations in dieting and weight sometimes suggest restrictive or binge patterns of eating, or both. It is quite useful to ask patients their current and desired weights as well as what and when their minimum and maximum weights have been. This information can help to identify a range suggesting capacity for nutritional compromise. It can also help clinicians gauge how the patient's presenting weight compares to his or her healthiest and most compromised weights in order to develop reasonable clinical goals and a timeline for therapeutic intervention. Finally, an unrealistic or unhealthful desired weight can reveal body image disturbance, whether the patient desires to be unreasonably thin, and whether the patient and clinician are likely to negotiate successfully for mutual treatment goals. For younger patients whose parents are involved in their care, a question about desired weight is also useful as a probe to discover whether parental expectations are aligned with therapeutic goals. Psychoeducational information about appropriate weights for height can be reviewed with the patient and others involved in supporting participation in treatment.

When an eating disorder is identified or suspected, information about dietary patterns (such as meal skipping or food restriction) and inappropriate compensatory behaviors (e.g., vomiting, laxative or diuretic misuse, fasting, and excessive exercise) should be elicited. Questioning should be approached with sensitivity because patients are frequently embarrassed to discuss these behaviors. Data from participants in a national eating disorders screening program indicate that 91% of individuals who had not previously volunteered eating and weight concerns to a health professional ultimately disclosed such concerns when directly asked.[46] Clinicians should ascertain the presence

TABLE 17–1 Differential Diagnosis of Eating Disorders

	PHYSICAL SIGNS	COGNITIVE OR EMOTIONAL SIGNS AND SYMPTOMS	BEHAVIORAL SIGNS AND SYMPTOMS	ASSOCIATED DISTRESS OR IMPAIRMENT
Anorexia nervosa (AN)	Inappropriately low weight for height, age, and sex (e.g., BMI of ≤17.5 kg/m^2 or BMI of <85% expected body weight in an adult) Amenorrhea	Fear of weight gain or fatness Body image disturbance	No specific symptoms required to meet DSM diagnostic criteria Almost always associated with restrictive pattern of eating Associated with bingeing or purging behavior in 50% of cases	None specified under DSM-IV diagnostic criteria; in fact, individuals with AN are often in denial of the serious nature of their illness
Bulimia nervosa (BN)	BMI can range from normal to overweight; a diagnosis of AN would most likely be made for low-weight individuals with BN symptoms	Excessive impact of body shape or weight on self-evaluation Frequently excessively preoccupied with body shape and weight	Frequent and regular binge eating (at least twice weekly for at least 3 months) Frequent and regular inappropriate compensatory behaviors to prevent weight gain (e.g., purging, fasting, excessive exercise; at least twice weekly for at least 3 months)	None specified under DSM-IV diagnostic criteria, although many individuals are markedly distressed by their symptoms
Binge-eating disorder (BED)	No weight criterion, but overweight is commonly associated with BED	None required to meet DSM-IV diagnostic criteria, but weight and shape concerns are frequently present	Frequent and regular binge eating (on at least 2 days weekly) Binge eating often associated with • Eating rapidly • Eating alone • Eating while not hungry • Eating well past satiety to the point of discomfort No regular inappropriate compensatory behaviors to prevent weight gain	Marked distress about the binge eating is present
Eating disorder, not otherwise specified (EDNOS)	No weight criterion, but low weight is likely to shift the diagnosis to AN	All of the above are possible	All of the above are possible, but full-syndrome criteria for AN or BN would be mutually exclusive of the EDNOS diagnosis Can be associated with chewing and spitting out food and inappropriate compensatory behaviors after small or normal quantities of food as well	Distress can be present or absent

From American Psychiatric Association: *Diagnostic and statistical manual of mental disorders, fourth edition, text revision,* Washington, DC, 2000, American Psychiatric Association.

of the full range of possible behaviors; although many of these questions can be asked in a relatively straightforward manner, appropriate clinical discretion should be used in taking an inventory of compensatory behaviors. Although information on extreme dieting is readily accessible via the Internet and social networks, patient reports of learning about managing weight through withholding insulin (for those with insulin-dependent diabetes) are sobering. Health risks associated with extreme dieting and compensatory behaviors are not always obvious to patients or their parents, and appropriate education is essential.

Because clinical history does not always elicit accurate or complete data, collateral history, physical signs, observable behaviors, and longitudinal clinical course should be used when possible to augment evaluation. These potentially informative sources also have limitations. With the exception of low weight in AN, eating disorders can and do present without physical signs. Laboratory studies may yield data suggestive of purging or nutritional compromise but do not have sufficient specificity or sensitivity to be useful in screening. When suggestive physical signs are present—for example, parotid hypertrophy, excoriations on the dorsum of the hand (Russell's sign), or characteristic

dental erosion—they can launch further evaluation. Whereas collateral data can be helpful for establishing the presence of eating and weight concerns, family members may not be aware of or may not recognize symptomatic behaviors. If a patient does not endorse or disavows weight and shape concerns, observed behaviors (such as body checking in a mirror, excessive weighing, undue sensitivity to weighing, or evidence of behaviors undermining weight gain) can suggest the diagnosis.

Differential Diagnosis

For patients who are more forthcoming about their symptoms, the differential diagnosis is relatively straightforward. AN is characterized in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) by an inappropriately low body weight for height and age (the DSM-IV gives an example of a weight less than 85% of expected body weight, or body mass index [BMI] ≤ 17.5), a fear of fatness, some type of body image disturbance (e.g., excessive impact of body shape or weight on self-evaluation, feeling fat when actually thin, denial of seriousness of low weight), and amenorrhea (in women who have passed menarche) (see Table 17–1).[47] Heterogeneous rationales for food restriction are reported in Asian as well as Western populations, and the fear of fatness is sometimes not reported or not discernible,[48–50] so there may be cultural diversity in the presentation of AN. Moreover, the usefulness of amenorrhea as a diagnostic criterion for AN has been questioned.[51,52] AN occurs as two subtypes, restricting and binge eating/purging. In the latter type, individuals binge and/or purge in addition to maintaining their low weight; bingeing and/or purging occurs in approximately half of individuals with AN.

BN is characterized by regular binge eating and by inappropriate compensatory behaviors (both at least twice weekly for 3 months) to control weight. Like AN, BN is characterized by excessive concern with body shape or weight, which has a major impact on self-evaluation (see Table 17–1). BN can occur as one of two subtypes: purging (i.e., regularly inducing vomiting or using laxatives, diuretics, or enemas) or nonpurging (i.e., inappropriate compensatory behaviors that exclude the aforementioned methods, such as restrictive eating or excessive exercise).[47] The purging subtype is much more commonly seen in clinical practice. Although AN and BN can have substantial phenomenological overlap in symptoms (i.e., excessive concern with weight, binge or restrictive pattern eating, and purging), they are best differentiated by weight and menstrual function. Specifically, a low-weight individual with bingeing and purging and excessive concern with weight is likely to best fit diagnostic criteria for AN. Similarly, although menstrual abnormalities can occur in individuals with BN,[53] amenorrhea is required for a diagnosis of AN.

BED is primarily characterized by recurrent binge eating over a period of 6 months or more. A diagnosis of BED requires that binges (1) occur at least 2 days weekly for the past 6 months; (2) are associated with three or more of the following qualitative characteristics: rapid eating; eating past satiety to the point of discomfort; eating a large amount without being hungry; eating alone to avoid embarrassment by the amount one plans to eat; feeling disgust, guilt, or dysphoria after a binge; and (3) are accompanied by marked distress. A diagnosis of BED is excluded in the presence of AN, BN, or regular purging or inappropriate compensatory behaviors to control weight (see Table 17–1).[47] BED is frequently complicated by obesity. Hospital psychiatric consultation often does not initially identify a patient's BED unless there is a known history or there is a concern about obesity. For these reasons, clinicians should remember to ask about associated symptoms and should be especially vigilant for BED in certain populations of adult patients—for example, those with current obesity, a history of weight fluctuation and dieting, or a history of an eating disorder.

Approximately 40%[54] to 60%[55] of patients who present with an eating disorder do not meet full criteria for AN or BN, notwithstanding clinically significant psychopathology. These patients are diagnosed with EDNOS. Despite its designation as a residual category, EDNOS is associated with significant eating pathology, general psychopathology, and medical risk.[17] Common presentations of EDNOS include individuals who present with AN-like symptoms but do not meet the weight or amenorrhea criterion, and patients with BN-like symptoms who do not binge and purge at the requisite frequency or duration. EDNOS also includes distinct syndromes, such as BED, purging disorder (i.e., repeated purging in the absence of objectively large binge episodes),[56] and night eating syndrome (i.e., habitual and distressing nocturnal overeating associated with sleep disturbance).[57]

Because diet and fitness concerns are virtually socially normative and often appropriate in American society, it can sometimes be difficult to differentiate appropriate concern with diet, weight, and exercise from excessive concern. For instance, the prevalence of obesity in children is 12% and has more than doubled over the course of the last generation.[58] Moreover, the prevalence of obesity among United States adults has steadily increased over the past two decades,[59,60] with an estimated 65.7% of adults currently overweight and 30.6% obese.[61] Finally, obesity is associated with substantial medical and psychological complications in both children and adults, and it is the second highest cause of preventable death in the United States.[62] For these reasons, appropriate attention to diet, fitness, and weight is necessary, but the appropriate level of physical activity should be evaluated with regard to health and fitness guidelines, social context, and presence of an eating disorder. For example, physical activity that appears motivated by inappropriate weight goals or compensation for binges, that results in significant distress or impairment, that exceeds or violates coaching recommendations, or that cannot be adjusted for sickness or injury warrants concern as inappropriate. The administration of a brief self-report measure querying the personal, social, and cognitive impairment associated with disordered eating can also assist clinicians in evaluating whether potentially problematic behaviors are clinically significant.[63]

Because many patients with disordered attitudes about eating feel that even normal food intake is excessive, it is helpful to establish that binge episodes are consistent with the established definition in the DSM-IV.[47] Thus, for the purposes of meeting criteria for BN or BED, a binge includes both the consumption of an unusually large

amount of food in a discrete time period (i.e., 2 hours or less) and is associated with diminished control over eating.[47] Subjective binge episodes are distinguished from objective binge episodes (requisite to meet diagnostic criteria for BN or BED) by food consumption with loss of control that appears excessive to the patient but is not actually excessive for its context by objective standards.

Assessment of the severity and patterning of the binge eating is aided by requesting that a patient keep a self-monitored record of daily food intake. To do this, patients should be instructed to record the contents of each meal, snack, or binge directly after it is consumed. Patients are also directed to record the feelings they experienced before, during, and after consumption. Although this record will be generally less useful in the hospital setting given the limited dietary choices and rather structured setting, it can still yield useful diagnostic information. Food records are, moreover, a core intervention of cognitive-behavioral therapy for both eating disorders because such records provide a detailed picture of the patient's typical eating habits, thus aiding in diagnostic formulation and assessing treatment response, and they help patients increase real-time awareness of behaviors that may have previously seemed automatic and beyond their control. Once completed, patients can review food records with clinical staff to identify probable binge triggers (e.g., undereating earlier in the day or negative affective states) and behavioral solutions (e.g., eating a morning snack or engaging in pleasurable activities).

Clinicians should maintain vigilance for a broad spectrum of purging and other inappropriate compensatory behaviors in their assessment. Vomiting is the most common means of purging associated with eating disorders, but some patients also misuse laxatives, diuretics, enemas, stimulants, and other naturaceutical preparations purported to suppress appetite or otherwise aid weight loss in addition to or instead of vomiting. Clinicians should also inquire about fasting or dietary restrictions and exercise behavior as modes of preventing weight gain. A recent survey of health food stores, pharmacies, and grocery stores identified 248 laxative,[64] 167 appetite-suppressant, and 25 diuretic[65] products readily available over the counter. Thus, clinicians should bear in mind the plethora of purging possibilities when assessing a patient with a suspected eating disorder and inquire about prescription stimulants (e.g., methylphenidate), herbal supplements (e.g., senna or aloe vera), and so-called cleansing or detoxifying products (e.g., Evercleanse), in addition to more conventional over-the-counter laxatives and diuretics. Herbal product use for weight loss is widespread among women with an eating disorder; a recent study reported a lifetime prevalence of 64% and a 1-month point prevalence of 14.1% among women with an eating disorder ($N = 100$).[66]

Patients with co-morbid insulin-dependent diabetes should also be assessed for inappropriately withholding their insulin. This behavior places them at risk for diabetic ketoacidosis, as well as long-term complications of poorly controlled blood sugars, and may necessitate inpatient care for stabilization and safety. As noted earlier, assessment of this mode of purging or weight control should be made with special clinical discretion, because some patients have reported learning about this strategy for weight control during a clinical evaluation. Finally, some individuals with an eating disorder induce vomiting with syrup of ipecac. Again, the ready over-the-counter availability of this medication is often misleading for individuals who wish to use it to purge, and the Food and Drug Administration (FDA) has considered elevating it to prescription status because of its toxicity and potential for abuse.[67] Because chronic ipecac use can result in cardiomyopathy, myopathy, and death,[68–71] patients should be educated about its associated risk. Patients who have used it should be instructed to discontinue it immediately, and they should be evaluated for possible further medical investigation. Ongoing ipecac use is an indication for inpatient care, and patients assessed as unable or unwilling to discontinue use should remain hospitalized until they are able to abstain from this behavior.

Although there is substantial phenomenological overlap and some crossover between AN, BN, and BED, by definition, they are mutually exclusive diagnoses. As can be seen from the diagnostic criteria, binge eating can be present in all three disorders, and purging and fasting can each be present in AN and BN. In addition, overvaluation of shape and weight is one of the diagnostic criteria of BN, but it is also common in patients with BED,[72] so the presence or absence of purging behavior is the best criterion for differentiating the two disorders. Finally, individuals with BN sometimes have amenorrhea, but by definition, if they have an inappropriately low weight, they meet the diagnostic criteria for AN instead.

Medical and other psychiatric causes of poor appetite and weight loss (e.g., the anorexia of depression) or vomiting (e.g., secondary to achalasia) should be excluded with appropriate history, examination, and diagnostic tests. Medical illnesses that the practitioner needs to differentiate from eating disorders include endocrinologic disorders (such as diabetes mellitus and hyperthyroidism), brain tumors, cancer, occult infections, and GI disorders. Moreover, because all of the eating disorders are frequently co-morbid with mood and anxiety disorders, personality disorders, and substance abuse, a complete assessment of mental status and psychiatric history should be included in the evaluation. Finally, a careful assessment of suicide risk is essential, and clinicians should bear in mind the frequent association of suicidal ideation and attempts with eating disorders.

Weight Assessment

Evaluation of an eating disorder routinely includes weight assessment. Weight assessment is inexpensive, straightforward, and informative; it is not only integral to the diagnosis of AN but also necessary for therapeutic management across the spectrum of eating disorders. For some patients, weight management—or medical management of weight-related conditions and complications—is a central therapeutic concern. Weight and height should be measured during the initial assessment. These should be obtained in privacy and with sensitivity. In some cases, patients benefit from the option of not seeing or knowing their weight. The calculated BMI is the clinical standard for weight assessment for adults. The formula for men and women is as follows:

$$\text{BMI} = \text{height (in meters)} \div \text{weight (in kilograms)}^2$$

For children, the BMI generally increases with age, and therefore BMI centiles are a more accurate measure. They can be assessed by measuring height and weight and plotting on the U.S. Centers for Disease Control and Prevention BMI-for-age charts.[73]

Other methods for weight assessment for adults include comparing the patient's actual weight with expected body weight (EBW) as a percentage:

$$\%\text{EBW} = (\text{actual weight} \div \text{expected body weight}) \times 100\%$$

EBW can be estimated with one of the following formulas:

$$\text{EBW (women)} = 100\text{ lb for the first 5 feet} + 5\text{ lb / inch above 5 feet}, \pm 10\%$$

$$\text{EBW (men)} = 106\text{ lb for the first 5 feet} + 6\text{ lb / inch above 5 feet}, \pm 10\%$$

The EBW percentage is preferable for both scientific and clinical use, but the estimated EBW is more intuitive for patients and can be calculated by hand.

Obtaining an accurate weight is critical to care. Because some patients may attempt to disguise a low weight by adding weight through jewelry, clothing, and hidden items, weights should be measured with the patient in a hospital gown only. If water loading is suspected, patients can be asked to void prior to weighing; urine specific gravity may be informative if it is relatively low. Some patients endeavor to increase their weight by taking in calories prior to a weight check; fortunately, eating to promote weight gain is consonant with therapeutic goals.

INTERVENTIONS

Although acute treatment of medical complications, nutritional compromise, and associated acute psychiatric symptoms can begin in the general hospital setting, treatment duration is generally lengthy and is likely to eventually require transfer to a psychiatric specialty or outpatient setting. Therefore, the consulting psychiatrist has a critical role in establishing a diagnosis and the level of severity to guide inpatient management, disposition, and a comprehensive care plan. Additional potentially useful interventions in a general hospital setting include (1) education of the clinical staff caring for the patient; (2) patient engagement in treatment and psychoeducation; (3) identification of referral resources for either specialized inpatient eating disorder care or for an outpatient multidisciplinary clinical care team; (4) implementation of behavioral strategies to control symptoms, when appropriate; (5) initiation of pharmacotherapy, when appropriate; and (6) implementation of a plan for nutritional rehabilitation, as appropriate. Also, on occasion, a formal behavioral treatment protocol is implemented on a general medical or pediatric floor.

Education of the clinical staff on the general medical or pediatric service is essential for two main reasons. It ensures that a thorough targeted work-up is complete, and that nutritional and medical complications of restrictive eating, binge eating, and inappropriate compensatory behaviors are addressed. For example, potassium repletion for a patient with chronic vomiting or diuretic or laxative abuse and ensuing hypokalemia, or a suitable bowel regimen for a patient tapering off laxatives, can be prescribed. Moreover, monitoring and prophylactic treatment for refeeding syndrome can be implemented for patients with severe nutritional compromise in consultation and collaboration with other specialty care teams with relevant expertise in the hospital.

Psychiatric consultation can also assist staff in the management of countertransference feelings toward patients, which can range from rescue fantasies to anger. Many hospital staff may be unfamiliar or inexperienced in responding in therapeutically constructive ways to patients who evade or undermine their care. Moreover, because patients with eating disorders often function quite highly in some domains, staff may underestimate their pathology or spend excessive time in well-intentioned—but ineffective—efforts to talk the patient out of his or her choices. On the other hand, the helplessness that can be engendered in staff and the appearance that the patient is choosing the symptoms (e.g., not to eat or to purge, whereas the patient in the next bed may be wasting away from cancer or nauseated by chemotherapy) can lead to anger. Similarly, the frequency with which eating-disordered patients comment on treatment providers' own weight, appearance, and eating habits can promote self-consciousness among clinical staff.[74] Consultation can assist treatment providers in setting appropriate (nonpunitive) limits, formulating realistic expectations, and maintaining an empathic stance.

Engaging the Reluctant Patient

Several unique features of AN serve to maintain the illness; even if AN patients are able to recognize their symptoms as an illness, they commonly perceive substantial benefits associated with it.[75,76] For the patient who is unable to admit the extent of the symptoms or to acknowledge that symptoms are problematic, gentle confrontation is essential. Although AN patients commonly disregard or disavow even the most objective evidence of medical complications, they should still have the benefit of education about clinical signs that are worrisome, availability and efficacy of treatment, and the substantial risks of not pursuing treatment. In addition, psychoeducation of patients with AN, BN, and EDNOS is useful to clarify their diagnosis of an eating disorder for them, to discuss the serious medical and psychological risks associated with symptoms, and to convey available treatment options that will be beneficial in focusing appropriate energy toward an intervention.

Anticipation of patient ambivalence about engaging in treatment and relinquishing symptoms may be helpful to identify resources, strategies, and supports that can advance therapeutic goals. Collaboratively creating a cognitive–behavioral formulation that highlights the predictable and self-defeating links among eating-disordered behaviors can be especially illuminating for patients who perceive symptoms as disparate or uncontrollable. Many individuals with either AN or BN believe their symptoms have an important primary gain—controlling their weight. By definition, individuals with AN and BN unduly base their self-worth on their body shape, weight, and appearance. Sometimes, an initial experience of positive social feedback and self-efficacy is so reinforcing that it

induces them to continue to lose weight. Not infrequently, the restrictive eating gives way to bouts of binge eating, which in turn can segue to purging and other inappropriate compensatory behaviors. Not surprisingly, this cycle is generally ineffective in achieving the desired weight loss. For example, laboratory studies of binge eating and purging indicate that the majority of calories are retained in the digestive tract after vomiting[77] or laxative use.[78] When patients rededicate their efforts to restrict their diet—often in a pattern in which they bank their calories for the end of the day—their hunger later in the day may trigger a binge. This binge eating can be further complicated by a preoccupation with food—so extreme that many patients report a constant distraction concerning the tally of calories they have consumed or that they plan to consume during the day. Thus, a viciously self-reinforcing cycle ensues.

Individuals with eating disorders are not always aware of the substantial secondary gains of their symptoms. Many patients experience distraction and emotional numbing as a result of their restrictive and binge-pattern eating and purging behaviors. Studies utilizing ecological momentary assessment paradigms—in which patients record symptoms and moods in real time on palmtop computers—indicate that individuals with BN are at higher risk for binge eating and purging on days characterized by consistently high levels of negative affect or increasing negative affect throughout the day,[79] suggesting that binge eating may serve as a self-soothing mechanism to individuals who perhaps cannot readily access higher-level defenses. Thus, the behavioral symptoms eventually become a core coping strategy for many individuals with eating disorders. Whereas some patients are completely unaware of this function of their symptoms, others have a clear sense that they could not tolerate relinquishing them. Moreover, most patients are convinced that they will gain weight if they establish normal dietary patterns. For these reasons, patients are understandably reticent to disclose their symptoms and reluctant to embark on any treatment plan that they perceive will result in weight gain and deprive them of sometimes highly valued coping strategies. In addition, extremely low weight AN patients often manifest cognitive inflexibility that can undermine insight and therapeutic engagement.

Thus, engaging a patient in treatment for eating disorders is often challenging, because the patient may perceive this as a threat to all the gains he or she experiences from the symptoms. Others, especially those who engage in binge eating, may quite willingly enter treatment when the symptoms lose their efficacy or purpose in self-soothing, have unwanted weight gain effects, or are too time-consuming or expensive. In one study, individuals with BN reported spending an average of $1600 per year on binge food, and $240 per year on purging aides (such as laxatives, diuretics, and diet pills).[80] In addition, some patients finally seek treatment when their living situation (i.e., a roommate and shared bathroom) puts their secrecy in jeopardy or when they are confronted about their symptoms by someone who has adequate leverage to steer them to treatment for their problem.

For reluctant patients, motivational enhancement therapy (MET) may galvanize the therapeutic alliance and promote patient readiness. Eating disorders are notoriously ego-syntonic; patients who perceive treatment providers as forcing them to change may ironically become increasingly less willing to do so. The goal of MET is to cultivate cognitive dissonance between the patient's current eating disorder symptoms and future life goals. Rather than attempting to convince the patient to recover, the skillful MET therapist introduces nonjudgmental exercises that allow the patient to identify and verbalize his or her own arguments for change. Techniques, such as brainstorming the pros and cons of the eating disorder, imagining life 5 years from now with and without the eating disorder, and identifying inconsistencies between eating disorder symptoms and core life values (i.e., autonomy, friendship) can be effective to this end. Short-term group MET has been associated with increases in self-reported motivation[81,82] and reductions in premature termination[82] among individuals in treatment for eating disorders. MET techniques can be readily adapted for use in individual psychotherapy.

For general hospital inpatients reluctant to discuss or allow treatment of their symptoms, engaging the patient around mutually identified goals and identifying key points of leverage are first-line strategies. In many cases, the patient can be asked why he or she has agreed to meet or speak with the consultant and what he or she hopes to get out of it. Even if the patient provides a seemingly bleak reply (e.g., an AN patient hopes to get her parents "off her back," a BN patient would like to lose weight), the stated rationale can prompt the development of specific goals with which to ally with the patient, such as autonomy or health. In addition to informing the patient and family about medical complications and risks associated with the disorder, concrete evidence about adverse health impact (e.g., the results of a dual-energy x-ray absorptiometry [DXA] scan of the lumbar spine showing osteopenia, or of laboratory analysis indicating hypokalemia) can be presented as a strategy to motivate treatment engagement.

When appropriate, clinicians should work collaboratively with parents, teachers, coaches, or school administration to identify incentives for patients to meet therapeutic goals. For example, patients may be required to meet specific clinical benchmarks to be eligible to participate in school or extracurricular activities. In addition to considering local mandatory reporting requirements, voluntary notification of employers, regulatory boards, and school administrators should be discussed when there are concerns about occupational impairment and safety. Clinicians with preexisting good therapeutic alliance should be enlisted in establishing incentives as well.

Especially when motivation is in question and when adherence to treatment or risk of decompensation is high, a treatment agreement specifying interim goals as well as the patient's responsibilities provides clarity to the team and the patient. For example, the patient may be asked to agree to attend all appointments, to allow weighing and laboratory work at intervals specified by the team, and to consent to communication among all members of the treatment team. In addition, parameters to be used in considering intensification of care should be specified, so that if a patient's weight is unstable, all team members and the patient are in agreement about the point at which an increased intensity of care (e.g., adding a group, adding medication, or being admitted to an inpatient unit for eating disorders) is necessary. To be maximally therapeutic, treatment

nonnegotiable outcomes—such as inpatient hospitalization at low body weight—should have a sound rationale, be consistently implemented throughout treatment, not take the patient by surprise, and provide clear opportunities for the patient to prevent implementation by altering undesirable behaviors.[83]

Involuntary hospitalization[84] may be necessary when patients are at imminent risk for self-harm or are unable to care for themselves (e.g., as evidenced by ongoing untreated serious medical complications). Although compulsory treatment raises challenging ethical considerations, available data suggest that patients may gain an understanding of treatment necessity after engaging in care. For example, one study found that 43% of patients with an eating disorder, who initially denied the need for hospitalization, retrospectively admitted its necessity within 2 weeks of admission.[85] Another study reported that legally committed patients exhibit similar rates of weight restoration during inpatient hospitalization compared to their voluntarily admitted peers.[86]

By contrast, some patients appear very eager to begin treatment for an eating disorder. Although this eagerness can be genuine, it can also eventually be revealed to have been only superficial compliance.[87] An abrupt eagerness to address an eating disorder in the setting of an ongoing treatment may also be motivated by difficulty tolerating the intensity or emotional charge in other areas of the therapy. In other words, a change in therapeutic focus to eating behaviors provides a diversion. In such a situation, the consultant can address with the patient and treatment team whether adjunctive treatment is advisable and appropriately timed with respect to other treatment goals and priorities.

Considerations in Initiating Treatment

Goals of the inpatient hospitalization are guided by the severity and duration of the disease as well as its medical complications. Initial goals generally encompass stabilization of medical parameters and behavioral symptoms, safety and containment (when appropriate), and a plan for nutritional rehabilitation. Therapeutic interventions that address cognitive and behavioral symptoms are integral to enhancing motivation to engage in treatment, consolidating nutritional and medical recovery, enhancing capacity to tolerate weight and behavioral changes, and preparing the patient for continuing in a less intensive level of care treatment setting, such as residential care, partial hospitalization, or multidisciplinary team outpatient care.

Depending on clinical staffing, a behavioral protocol can be implemented on a general medical or pediatric service to promote refeeding or control inappropriate compensatory behaviors. Some services have standardized protocols, and in others the consulting psychiatrist and staff can develop a plan to meet the needs of individual patients. A description of such protocols is beyond the scope of this chapter, but they include medical and nutritional monitoring and may also include supervised regularly scheduled meals, expectations for participation in meal selection with a nutritionist, expectations for duration of meals, restrictions of bathroom trips within an hour of meals, privileges (e.g., leaving the floor) contingent on meeting a dietary plan and weight goals, and restriction of physical activity.

Some patients who have been hospitalized on a medical service because of complications of their eating disorder will benefit from, or require transfer to, an inpatient setting for specialty psychiatric care. Others who are well stabilized, or for whom the eating disorder was an incidental finding, will be discharged home for outpatient care. Table 17–2 shows criteria for inpatient-level care of patients with an eating disorder. Although psychotherapeutic care (with the exception of supportive or psychoeducational treatment) may not be feasible in the general hospital inpatient setting, behavioral treatment to support adequate dietary intake can be initiated, pharmacologic therapy—when appropriate—can be started, and an outpatient team can be assembled to ensure smooth transition in care.

There are well-established treatment approaches for patients with eating disorders that should inform and guide treatment planning. However, general hospital clinicians should bear in mind the potentially limited generalizability of findings from clinical trials in outpatient or specialty care settings to the patients admitted to their care. Flexibility may be required to meet the multifaceted treatment goals in a general hospital setting.

The utility and necessity of a multidisciplinary team approach to treatment for eating disorders is well established. Generally, treatment benefits from the inclusion of the primary care clinician, a nutritionist, and a mental health clinician or clinicians, although it is not essential that the clinicians comprising this team be in one program or institution. A clear demarcation of responsibilities and roles (e.g., who will monitor weight, if necessary, or who will monitor frequency of purging behaviors that may require medical monitoring) and frequent and open communication about the treatment plan, progress, and concerns is optimal. Clinicians should strongly encourage patient consent to communicate all clinical information relevant to treatment planning among members of the team and should carefully scrutinize how exceptions will have an impact on treatment. Because splitting and miscommunication are both strong possibilities in such treatment situations, the team should make every effort to reach a consensus about the treatment plan and contingencies for changes depending on patient progress or difficulties and should present a unified front to the patient.

When evaluating an ongoing treatment or the development of a new treatment plan, clinicians should bear in mind that medical, nutritional, and psychological goals are integral to treatment; sometimes, progress with psychological symptoms is predicated on medical and nutritional stabilization. Likewise, if psychological symptoms are not addressed, medical complications and nutritional compromise can recur. With respect to the mental health component of treatment, psychosocial therapies and pharmacotherapies both have a role, but the former appear to be more effective. Thus, pharmacotherapy is more appropriately used as an adjunctive treatment to psychotherapy or when access to psychotherapy is otherwise limited. Although case reports and open trials have provided emerging support for the potential pediatric efficacy of agents with better-understood therapeutic effects in adult populations, such as olanzapine in AN and fluoxetine in BN,[88] data on efficacy and safety for pharmacologic management of eating disorders in children are too limited to support general recommendations for pediatric populations.

TABLE 17–2 Clinical Signs and Criteria Warranting Inpatient-Level Care to Stabilize or Treat an Eating Disorder

DOMAIN	GENERAL SYMPTOM*	EXAMPLE†
Weight	Substantially low weight for height and age	<75%-85% expected body weight
	Rapidly falling weight	
Behavioral	Acute food or water refusal	
	Episodes of bingeing and purging of very high and/or escalating frequency	Bingeing and/or vomiting multiple times per day resulting in social or occupational impairment and/or serious medical complications; ongoing ipecac use; inappropriate withholding of insulin
	Compensatory behaviors likely to result in acute and severe medical complications	
Other medical compromise	Abnormal vital signs reflecting nutritional compromise	Severe hematemesis
	Severe medical complications	Severe neutropenia and/or thrombocytopenia
		Severe hypokalemia
		Uncontrolled type I diabetes
		Syncope
Psychiatric co-morbidity and risk of self-harm	Substantial risk of self-harm or suicide	
	Co-morbid psychiatric illness resulting in safety risk or seriously undermining treatment	Co-morbid substance use escalating in the setting of treatment for the eating disorder
	Inability to adhere to treatment plan that will sustain minimal level of safety	
Treatment-related	Lack of clinically meaningful progress in an outpatient setting resulting in social or occupational impairment or medical risk	An adolescent's low weight poses risk for decreased peak bone mass or short stature
	Necessity of close supervision to maintain symptom control	Sustained or persistent inability to eat without supervision or to abstain from intractable purging after food intake
	Previously agreed-on criterion for hospitalization based on patient history	Reaching a threshold weight at which the patient repeatedly has rapidly deteriorated

* These criteria may be sufficient but do not necessarily need to be present to indicate inpatient care.
† Weight, vital signs, metabolic, and other parameters for hospitalization are best interpreted in the context of the patient's overall health, medical and psychiatric history, support systems, and engagement in treatment.

Medical Intervention for Eating Disorders

Medical complications of eating disorders are common, can affect every organ system, and are potentially severe and even lethal (Table 17–3). Clinicians should be aware that complications are associated with behaviors that can occur across the spectrum of eating disorders. For example, they are associated with poor nutrition (both micronutrient and macronutrient deficiencies), underweight, overweight and obesity, bingeing, vomiting, misuse of prescription and over-the-counter medication and supplements (including ipecac, diuretics, laxatives, stimulants, insulin, and certain naturaceuticals), and excessive exercise.

Assessment for these possible sequelae, and their subsequent correction, is a necessary prerequisite to the management of the patient with an eating disorder. Clinical history and physical examination are routinely augmented with laboratory studies that screen and monitor associated medical conditions. Vital signs and weight require ongoing monitoring. Laboratory examination—including serum chemistries, complete blood count, bone densitometry, and electrocardiogram—is directed at detection of common and potentially life-threatening complications associated with poor nutrition and purging and other inappropriate compensatory behaviors. Common problems and the approach to their management are specified here. However, an exhaustive review of medical complications and treatment of the eating disorders is beyond the scope of this chapter.

Poor nutrition associated with a restricted diet and a low body weight in AN can result in a number of serious medical complications (see Table 17–3). Fluid and electrolyte disturbances require immediate attention. The correction of dehydration, hypokalemia, and metabolic alkalosis is a priority. Intravenous (IV) fluids and electrolytes sometimes need to be used to support these patients to improve these parameters. The optimal strategy for potassium repletion should consider the possibility of total body depletion in the setting of chronic vomiting, diuretic use, and laxative misuse.

Cardiac consequences of AN and BN may be asymptomatic or lethal. Dizziness, palpitations, orthostasis, or syncope may herald cardiovascular danger.[89] Myocardial hypotrophy occurs, often early, with reduced left ventricular mass and output.[90] Hypotension occurs early and orthostasis follows, possibly enhanced by volume depletion. Bradycardia is common in patients with AN, and it probably reflects cardiac impairment associated with reduced stroke volume. QT prolongation, which can be idiopathic in AN,[91] can also be a consequence of hypokalemia in AN and BN. Both QT dispersion and QT interval prolongation are predicted by both low BMI and weight loss in patients with eating disorders. These electrocardiographic

TABLE 17–3 Selected Important Medical Complications of Eating Disorders

Metabolic
Hypokalemia
Hyponatremia; hypernatremia
Hypophosphatemia; hyperphosphatemia
Ketonuria

Endocrine
Euthyroid sick syndrome
Amenorrhea, oligomenorrhea

Skeletal
Osteopenia/osteoporosis (rarely fully reversible)
Impaired peak bone mass

Developmental
Growth arrest; short stature
Delayed puberty; delayed menarche

Reproductive
Oligomenorrhea
Infertility
Miscarriage
Increased rate of cesarean sections
Increased risk for postpartum depression
Intrauterine fetal growth and birth weight
Decreased neonatal Apgar scores

Dermatologic
Acrocyanosis
Carotenemia
Brittle hair and nails
Xerosis
Pruritus
Lanugo
Hair loss

Cardiovascular
Decreased left ventricular mass
Decreased chamber size
Decreased contractility
Decreased stroke volume
Decreased cardiac output
Decreased exercise response
Increased ventricular ectopy
Pericardial effusion (small)
Bradycardia
Orthostatic and nonorthostatic hypotension
Dysrhythmias
ECG abnormalities (including QT interval prolongation and QT dispersion)
Acquired (reversible) mitral valve prolapse
Ipecac cardiomyopathy
Congestive heart failure

Gastrointestinal
Reflux esophagitis
Mallory–Weiss tear (usual cause of hematemesis)
Esophageal or gastric rupture (rare but often lethal)
Gastroparesis (often symptomatic)
Laxative abuse colon
Rectal bleeding
Superior mesenteric artery syndrome
Abnormal liver enzymes with fatty infiltration
Pancreatitis
Functional gastrointestinal disorders

Neurologic
Seizures
Myopathy
Peripheral neuropathy
Cortical atrophy

Immunologic
Blunted febrile response to infection
Impaired cell-mediated immunity

Hematologic
Bone marrow suppression

Renal
Renal calculi
Acute: azotemia
Long-term: renal failure from chronic hypokalemia
Secondary hyperaldosteronism

abnormalities require immediate medical intervention because they increase the risk of ventricular arrhythmia and sudden death.[92]

GI symptoms are common in patients with eating disorders. Constipation brought on by dehydration, or by long-term laxative abuse, often responds to stool softeners and to bulk-forming agents. These symptoms are sometimes accompanied by evidence of delayed gastric emptying and intestinal transit time. Although they may resolve with conservative treatment (including nutritional rehabilitation and establishing routine meals), they may also persist and exacerbate cognitive symptoms that maintain the eating disorder. Although GI signs and symptoms may in some cases be attributed to an eating disorder, primary GI illness should be evaluated in the entire clinical context.[93]

Gastric motility agents are not routinely recommended for alleviating these symptoms in AN patients.[94] Occasionally, marked dilation of the stomach can be seen in patients with AN or those with BN and BED and can augur a medical emergency. The placement of a nasogastric tube provides symptomatic relief with decompression and avoids the dire consequence of gastric rupture.[93]

Osteopenia and osteoporosis are among the most serious clinical concerns accompanying amenorrhea and weight loss in AN. The peak bone mass achieved as a young adult is the major determinant of bone density and fracture risk. AN is associated with markedly reduced bone density, especially at the lumbar spine, but also at the proximal femur and the distal radius. The importance of nutritional factors, lean body mass, and BMI in determining bone mass cannot be overstated. The duration of estrogen deficiency does not determine the severity of the osteopenia, and hormone replacement has not significantly increased bone mineral density in patients with AN,[95–97] and it may in fact be detrimental in that it creates a false sense of security from the monthly withdrawal bleeding without any tangible benefits to the bone. The primary therapy is weight gain. The most appropriate recommendations include a plan for nutritional rehabilitation, supplementation with 1500 mg/day of calcium and 800 IU/day of vitamin D. If the vitamin D level is low,

a higher dose can be given for 1 month. DXA scanning at the initial medical assessment of a patient with an eating disorder and at varying intervals every 12 to 24 months can assist in counseling those at high risk for fractures and bone loss. Bisphosphonates have been used in many conditions that lead to osteoporosis and have been considered for the bone loss of AN. Because data thus far are limited, and conflicting and long-term use of bisphosphonates has been associated with complications (including very rarely, osteonecrosis of the jaw) and with uncertain effects on future pregnancies, their use in treating patients with AN is currently not routinely recommended outside of clinical trials. Several experimental therapies are under investigation.

Medical therapeutic considerations for the comprehensive care of patients with BN, and with AN and EDNOS patients who purge, include a plan to monitor for and address the most common and serious medical complications, including hypokalemia and cardiac dysrhythmias. Potassium losses occur in the setting of chronic purging behaviors associated with either BN or AN (e.g., induced vomiting, laxative abuse, diuretic abuse). Laxative abuse results in diarrhea accompanied by cramping abdominal pain and, at times, rectal pain.[98] Fecal electrolyte losses can be very high as the daily output increases considerably. Large amounts of sodium may be lost, but hyponatremia is uncommon because of the concomitant loss of water. The resulting picture of dehydration with hypotension, tachycardia, postural dizziness, and syncope needs to be addressed acutely, usually with IV fluids and electrolytes. Chronic deficiency of sodium and water may lead to increased renin secretion and secondary hyperaldosteronism that may then become autonomous, persisting after the laxatives are removed, a pseudo-Bartter's syndrome. Hypokalemia, as a result of laxative-related losses and purging, may appear as generalized muscle weakness and lassitude. More profound levels of hypokalemia may be life-threatening with cardiac arrhythmias. Of particular note, hypokalemia can, and often does, appear asymptomatically, so patients with chronic losses through vomiting, laxative abuse, or diuretic abuse must be routinely monitored with serum electrolytes, even in the absence of symptoms. Hyperphosphatemia, hypermagnesemia, and hypocalcemia can also be seen as a result of excessive purging with laxatives. If motility is stimulated enough with the cathartic laxatives, absorption of nutrients may be impaired because of decreased transit time. Although laxatives may cause changes in the intestine itself, such as melanosis coli from pigment-laden macrophages in the submucosa of the colon secondary to anthraquinones, there does not appear to be any functional consequence to this. The "cathartic colon" has not truly been observed during the past few decades, presumably because the laxatives causing this are no longer in use.[99] However, the preference is to manage frequent complaints of constipation with stool softeners as opposed to cathartic agents (so as not to iatrogenically reproduce the purging behavior, promote caloric loss, or waste potassium). Polyethylene glycol solutions, and other osmotic agents such as lactulose, are used to ease evacuation.

GI symptoms are common in BN, and primary GI illness should be evaluated. GI symptoms most commonly seen in BN include bloating, flatulence, constipation, abdominal pain, and nausea. Although rare, gastric rupture has also been reported as a consequence of binge eating. Most of the GI symptoms associated with disordered eating improve with conservative management (nutritional rehabilitation).

Dental hygiene in eating-disordered patients with vomiting should also be addressed. Dental erosion and caries in patients with self-induced vomiting may occur because of the effects of gastric acid on teeth enamel. Preventive techniques to protect from further dental erosion include fluoride application, good brushing techniques, and even the use of mouth guards.[100] Patients who engage in vomiting should routinely be referred for dental care.

Patients who use ipecac to induce vomiting are at risk of a life-threatening cardiomyopathy caused by the emetine in this product.[101]

The comprehensive care of patients with BED includes addressing the medical co-morbidities and sequelae of the condition. Co-morbidities of BED include disorders associated with excess weight such as an elevated risk of type 2 diabetes, hypertension, cardiovascular disease, hypercholesterolemia, osteoarthritis, sleep apnea, gall bladder disease, and certain malignancies.

TREATMENT OF PATIENTS WITH ANOREXIA NERVOSA

Nutritional Rehabilitation

The most appropriate initial treatment strategy for patients with AN addresses weight restoration because of the serious medical consequence of low weight and poor nutrition. For example, the primary therapy for the amenorrhea associated with AN is nutritional rehabilitation. Most patients with eating disorders will recover menses within 6 months of reaching 90% of their ideal body weight.[102] A caveat to that is that menstrual recovery depends on attainment of optimal fat mass, and although some women may recover to normal body weight, they may have very little fat mass. Also, some girls may have undergone alterations in other neuroendocrine hormones, including cortisol, ghrelin, leptin, peptide YY, and adiponectin, all of which may be related to body fat but may also be independent of it.[103] Orthostasis has been observed to remit after several weeks, at about 80% of EBW in adolescents. However, a return to full health requires restoration of normal weight. Low BMI at referral predicts a poor prognosis[104,105] and is associated with significantly higher chronicity and mortality for patients with AN.[106] Relapse rises steeply as the percent of EBW at discharge falls, with 100% minimizing immediate relapse and readmission rising rapidly as discharge weight falls to 95%, 90%, and 85% of EBW.

Undernutrition is also suspected to underlie some of the neurocognitive features of AN that may contribute to poor treatment response. Clinical experience suggests that cognitive inflexibility (e.g., relating to overvalued ideas about body weight) may impede treatment efforts for AN. Indeed, subtle abnormalities in abstraction and cognitive flexibility have been substantiated in studies of individuals with AN.[107,108] It is noteworthy that some of the cognitive abnormalities in those with AN that manifested in attentional domain tasks have been shown to at least partially improve with weight gain.[109] Interestingly, dilated ventricles and sulcal widening on computed tomography (CT)

scans as well as global hypometabolism seen in resting positron emission tomography (PET) studies of patients with AN improve at least somewhat with weight gain.[109,110] However, some aspects of cognitive inflexibility do not improve with treatment[109] and may be endophenotypic of AN. Pretreatment neuropsychological assessment coupled with individualized feedback highlighting the link between general cognitive inflexibility (i.e., a hyperfocus on detail at the expense of the bigger picture) and specific eating disorder symptoms (e.g., preoccupation with nutritional information at the expense of overall nutritional health) has demonstrated preliminary promise for enhancing motivation for treatment of AN.[111]

For AN patients without severe nutritional compromise, weight management can begin in the outpatient setting with the implementation of nutritional counseling (to make adequate dietary selections) and behavioral reinforcement for meeting weight goals. For example, the reinforcement might be to keep the privilege of working as an outpatient or to participate in an extracurricular performance. The treatment team and the patient should identify a weight goal and a timetable for interim goals at the outset of treatment. Generally, a goal weight should be chosen that is appropriate for the height and at which medical complications, such as osteopenia and amenorrhea, are reversed. Guidelines for appropriate duration and level of exercise should be addressed and adjusted as the patient recovers the weight.

Patients with eating disorders are often reluctant to meet with a nutritionist, with the excuse that they already know all there is to know about nutrition. However, they are often overly preoccupied with minor details of nutrition (such as calorie counting or carbohydrate avoidance), and their dietary knowledge may emanate from dubious sources such as fad diet books or websites. Nutritional counseling can also be framed as an activity to assist judgment and motivation. Especially with underweight patients, establishing a caloric requirement and developing a dietary plan to meet the weight goals that are set are highly useful. Minimally, this plan includes three meals daily to establish expectations of eating in alignment with social norms and nutritional adequacy, and it generally includes snacks or caloric supplements (or both) as well. When such a plan is in place, if a patient is unable to gain weight (e.g., the patient requires more calories or more help to adhere to the plan or needs to reduce physical activity), the need for additional measures can be assessed.

If patients are severely underweight (e.g., less than or equal to 75% of expected body weight), are underweight and have rapid weight loss, or remain chronically underweight with medical complications and are unable to gain a reasonable amount of weight as an outpatient, they will require inpatient or partial hospitalization care. Patients may require or benefit from hospital-level care at a higher percent EBW or if he or she has, for example, ongoing psychosocial stressors, a history of a pattern of rapid decompensation, or medical compromise. An inpatient hospital setting for nutritional rehabilitation offers diagnostic and therapeutic opportunities. For example, it promotes assessment of and rapid response to medical complications, and it allows dietary intake to be more carefully monitored, purging and exercise to be controlled, and behavioral reinforcement to be more easily implemented. In addition, if the patient withstands all feeding efforts, nasogastric feedings or parenteral feedings can be considered when there is extreme malnutrition and recalcitrance to treatment. However, most patients can be refed orally at experienced programs, so nasogastric tube feeding or total parenteral nutrition is very rarely required. Patients who require inpatient-level care to gain weight, but who recurrently relapse after discharge, may be best served in a residential care setting for an extended period to achieve and stabilize an adequate weight.

Calories should be increased incrementally, but rapidly, to achieve desired weight gains of 1 to 2 pounds weekly for outpatients and 2 to 3 pounds weekly in hospital settings. Patients vary widely in their caloric requirements for weight restoration, but it is not unusual to require up to 4000 calories a day as refeeding progresses. The measurement of the metabolic rate by indirect calorimetry can be helpful in determining the metabolic needs of the patient and thus the caloric goals. However, measurement of resting energy expenditure (REE) is not widely available, so an estimate of energy needs is usually required. Generally, most hospitalized patients with an eating disorder require at least 1500 kcal/day to maintain weight. Their reduced REE may be as low as 800 to 1000 kcal/day, and maintenance requirements are 130% to 150% of the REE. Approximately 1 g of weight is gained for every 5 calories in excess of output, so 5000 extra calories beyond maintenance is necessary for a weight gain of 1 kg. Weight gain may occur rapidly at first because of fluid retention and the baseline low metabolic rate.[112] Intake levels usually begin at 30 to 40 kcal/kg (1000 to 1600 kcal/day). As the patient with an eating disorder begins to gain weight, metabolic demands increase, and the intake needs to be increased considerably to continue to achieve ongoing weight gain.

Great care needs to be taken during nutritional rehabilitation to avoid the refeeding syndrome, a potentially catastrophic treatment complication that can result in heart failure, delirium, and death in undernourished patients who are being renourished. In this syndrome, the demands that a refilled circulatory system places on a nutritionally depleted cardiac mass result in cardiovascular collapse. This can be seen whether the nutrition is provided orally, enterally, or parenterally.[113] Patients most at risk are those who are the most undernourished. A range of electrolyte derangements can occur during refeeding. Much of the pathophysiology of the refeeding syndrome has been related to the rapid increase of insulin on refeeding.[114] Feeding stimulates insulin release, which, in turn, increases the cellular uptake of phosphate, glucose, and water, as well as stimulating protein synthesis. Insulin also increases sodium and water reabsorption in the renal tubules. Prolonged starvation results in a reduced cardiac mass and output. During the refeeding, ventricular volume returns to normal while left ventricular mass remains reduced, potentially leading to fluid retention and congestive heart failure. Sodium and fluid retention compound this problem. Serum phosphate levels may drop precipitously, leading to depletion of phosphorylated compounds, with impaired energy stores resulting from a decrease in intracellular adenosine triphosphate, and tissue hypoxia secondary to reduced levels of erythrocyte 2,3-diphosphoglycerate. Phosphate

depletion, in turn, produces widespread abnormalities, including cardiac arrest and delirium.[115] Potassium and magnesium also become depleted during starvation. On refeeding, these are deposited intracellularly and serum levels may fall if no supplementation is provided. Although refeeding syndrome generally emerges during the first 2 weeks of refeeding, delirium associated with refeeding can occur even later in the course.

Therefore, nutritional rehabilitation of the severely malnourished patient requires close monitoring for refeeding syndrome; the greatest caution is required during the first weeks after commencing the nutritional support. Specifically, vital signs and physical examination for signs of edema or congestive heart failure should be followed closely during this period—and daily for at least a week. Some patients develop edema without heart failure and may, indeed, have a rapid weight gain in the first few days of refeeding. Phosphorus, magnesium, and serum electrolytes should be closely monitored during at least the first 2 weeks of refeeding (e.g., it is recommended that this begin within 6 to 8 hours of feeding, continue daily for a week, and then continue at least every other day until the patient is stable). Cardiac telemetry is recommended during the first 2 weeks, and subsequent monitoring for complications of refeeding should continue until the patient stablizes.[116–120]

Due to concerns regarding refeeding syndrome, patients are cautiously refed with incremental increases of 200 to 300 kcal/day every 3 to 4 days as tolerated and as determined by individual weight gain. As patients near their target weight, they frequently require large amount of calories, upward of 3000 calories/day. Energy needs may be greater in young, growing adolescents and it often becomes difficult for that group of patients to ingest enough energy to gain weight consistently. Supplements need to be provided. Sodium at 1 mmol/kg per day, potassium at at least 4 mmol/kg per day, and magnesium at 0.6 mmol/kg per day should be given. Phosphate, up to 1 mmol/kg per day intravenously, and oral supplements up to 100 mmol/day can be given to try to avoid the hypophosphatemia associated with refeeding. Extra calcium may need to be given because hypocalcemia may occur during phosphate supplementation. Thiamine should be provided because acute thiamine deficiency can occur with refeeding.[121] Folic acid, riboflavin, ascorbic acid, pyridoxine, and the fat-soluble vitamins A, D, E, and K should be supplemented as well.[122] Trace elements, including selenium, may also be deficient. A good rule of thumb is to provide a multivitamin with minerals on a daily basis.

Psychosocial Therapies

Psychotherapy for patients with AN is often undermined by the effects of starvation and low body weight on cognition. Low-weight patients are often preoccupied with food and weight and relatively rigid in their dietary behaviors. Even modest weight gain can sometimes result in a remarkable improvement in cognitive flexibility, which facilitates further insight and behavioral change. However, persuading a patient to accept any treatment is often challenging. In a recent randomized prospective study of cognitive-behavioral therapy (CBT) and fluoxetine, 46% of patients dropped out before the completion of the study (most citing dissatisfaction with treatment).[123]

A number of psychotherapeutic modalities have been studied in the treatment of AN, including CBT,[124] psychodynamic psychotherapy,[125] and interpersonal psychotherapy.[126] For adolescents with AN, however, manualized family-based treatment (FBT) of adolescent AN has the strongest empirical support. This three-phase treatment lasts approximately 1 year and is based on the premise that the patient cannot control her symptoms, and thus her parents must temporarily claim complete responsibility for her eating.[127] In phase one, parents are encouraged to correct the patient's malnutrition by enforcing a regimented and calorie-dense meal plan. After steady weight gain has been established, food choices are gradually returned to the patient during phase two, and the family is invited to explore the ways in which the AN has affected family dynamics. In the final phase, when the patient has reached a stable weight, therapy focuses on enhancing the patient's autonomy and orchestrating a smooth return to normal adolescent development. FBT has demonstrated superiority to individual psychotherapy for adolescent AN,[128] and longitudinal follow-up studies suggest that approximately three quarters of patients receiving FBT achieve good outcome (normal weight and menstruation) at 4-year[129] and 5-year[130] follow-ups. However, data support efficacy of FBT only for adolescents—not for adults—with AN, and it is less effective in patients with a longer duration of illness. Moreover, it can only be implemented for patients whose families are willing to participate in treatment.

There are fewer empirical findings to guide psychosocial treatment selection in adults with AN. Outpatient CBT was superior to nutritional counseling alone in preventing relapse among a group of AN patients who had recently achieved inpatient weight restoration.[131] However, nonspecific supportive clinical management (a combination of case management and supportive psychotherapy) was as effective as CBT and superior to interpersonal therapy (IPT) in improving global outcome (a combined index of weight gain and reductions in eating disorder psychopathology) among outpatients with AN.[132] Conflicting randomized controlled trial (RCT) findings have prompted preliminary exploration of novel adjunctive treatments to target specific aspects of anorexic psychopathology. For example, graduated mirror exposure and response prevention, when added to a structured body image group treatment, was associated with significant reduction in the Body Dissatisfaction and Maturity Fears Subscales and significant improvement in the Interoceptive awareness subscale of the Eating Disorders Inventory at 6-month follow-up.[133] Similarly, exposure therapy encouraging AN patients to habituate to an unfamiliar, energy-dense test meal contributed to increased caloric intake of the same test meal after inpatient weight restoration compared with historical controls.[134]

Pharmacologic Management

Because of the desirability of weight gain in the early treatment of AN, there has been interest in identifying pharmacologic agents that promote weight gain in

patients with AN. Most efforts to identify pharmacologic agents to treat the primary symptoms of AN have been disappointing. Studies investigating the efficacy of chlorpromazine, pimozide, sulpiride, clomipramine, clonidine, and tetrahydrocannabinol[135] in addressing the primary symptoms of AN have all yielded negative results. It is important to emphasize the limited role for pharmacologic management of AN (Table 17–4), because patients with AN are frequently intolerant of medication side effects. Because there are no medications approved by the FDA for the treatment of AN, the use of pharmacologic agents to treat primary symptoms of AN is not only of questionable therapeutic value but also off-label.

Although few pharmacologic treatment strategies have shown promise, very preliminary data suggest that olanzapine, an atypical antipsychotic with a serotonin–dopamine antagonist profile, may have short-term clinical benefit in combination with day hospital treatment for AN. In a 10-week, double-blind, placebo-controlled flexible dose trial (to 10 mg/day), olanzapine resulted in a greater rate of weight gain and a greater rate of decrease in obsessive thoughts.[136] There are insufficient data to support recommendations for efficacy of olanzapine outside of concomitant structured treatment or beyond 10 weeks or for other atypical antipsychotic medications.

Empirical support for efficacy of serotonin selective reuptake inhibitors in the treatment of AN is also quite limited. Sertraline (50 to 100 mg/day) may promote some beneficial cognitive changes (e.g., reduction of perfectionistic attitudes and sense of ineffectiveness) in patients with AN, but there was no evidence that it promoted significant weight gain in AN patients compared with placebo in an open, controlled study.[137] Citalopram may have some efficacy in improving depression, obsessive-compulsive symptoms, and impulsiveness in this population.[138] Fluoxetine has been studied for stabilization in weight-recovered patients with AN in two RCTs. One of these demonstrated some efficacy (when adjunctive to elective psychotherapy) at a dosage of 20 to 60 mg/day, whereas the other failed to show efficacy compared with placebo when added to CBT (at a target dosage of 60 mg/day).[139] Whereas fluoxetine may have a role in stabilizing weight-recovered patients,[140] it does not appear effective in addressing symptoms of AN in patients who are underweight (i.e., those who meet weight criteria for diagnosis).

AN is frequently co-morbid with other mental disorders that can benefit from medication management, although clinical experience suggests reduced efficacy of antidepressant therapy in the setting of low weight. Agents that promote weight loss or diminish appetite should be avoided if possible. In addition, when agents that can prolong the QT interval or cause orthostatic hypotension are deemed essential, they should be implemented with extra caution along with appropriate monitoring and instruction to the patient. Finally, medications that promote appetite or weight gain can have the inadvertent effect of triggering binge episodes and should therefore be used judiciously—and with full transparency to the patient—if indicated for other symptom targets for patients with AN.

TREATMENT OF PATIENTS WITH BULIMIA NERVOSA

Individuals with BN are often eventually sufficiently distressed to seek and accept treatment, even if they remain ambivalent about relinquishing specific symptoms. As with AN, multidisciplinary team treatment to ensure adequate attention to nutritional and medical issues should be negotiated with the patient at the outset of treatment. Psychotherapy, with appropriate medical and nutritional monitoring and intervention, is the first-line treatment for BN. Although psychotherapy would not typically be feasible in a general hospital inpatient setting, patients can be informed about therapeutic options and provided with referrals. Among psychotherapeutic interventions studied, CBT has the strongest evidence supporting its efficacy in the treatment of BN.[141] Despite the high efficacy of CBT for many patients, a meta-analysis demonstrated that recovery rates (based on intention to treat) for subjects undergoing CBT for BN were only 38%.[142] Therefore, response to previous treatment, chronicity, severity of symptoms, co-morbid medical and psychiatric illness, psychosocial function, treatment availability, and patient preferences and capacities should inform treatment selection as well.[143]

CBT for BN is available in a manual for standardized care and is designed for completion in approximately 20 weeks. The treatment is based on educating the patient with a cognitive model of how symptoms of BN are perpetuated. That is, patients are introduced to a model in which low self-esteem, weight and shape concerns, dieting, binge eating, and purging operate in a self-perpetuating cycle.[144] The patient is asked to self-monitor intake with a food record to identify individualized triggers for binge eating and purging, which may include undereating, breaking self-imposed food rules, and negative affective states. The CBT therapist assists the patient in developing a schedule of regular eating (three meals and two snacks daily), and uses the information gained in the self-monitoring records to help the patient design relevant stimulus control strategies, such as keeping trigger foods out of sight or reach, and engaging in pleasant activities to distract from urges to binge (e.g., talking on the phone, going for a walk, or listening to soothing music). The CBT therapist also assists the patient in gently challenging cognitive distortions that perpetuate the disorder (e.g., "I must be thin to be happy"), reducing the body-checking and avoidance behaviors that exacerbate body dissatisfaction, and cultivating aspects of self-evaluation other than shape and weight. Last, the patient develops a relapse-prevention plan by identifying stressful situations (that may trigger future symptoms), and problem-solving potential solutions.

Up to 62% of the improvement seen in CBT treatment of BN occurs within the first 6 weeks.[145] A limitation of CBT has been that those who do not recover often remain substantially symptomatic and impaired in other domains.[142,143] An enhanced version of CBT (CBT-E) addresses this issue. It features an increased emphasis on mechanisms such as overvaluation of shape and weight, and emotion dysregulation. It also has optional modules specifically designed to target the features commonly encountered in treatment-resistant BN, including mood intolerance, clinical perfectionism, low self-esteem, and interpersonal difficulties.[146]

TABLE 17–4 Pharmacologic Agents with Efficacy in Treating Primary Symptoms of AN, BN, and BED, as Demonstrated in RCT Data*

	DOSAGE	COMMENTS OR CAVEATS
Anorexia Nervosa†		
Olanzapine	2.5-10 mg/day	Short-term efficacy in greater rate of weight gain when combined with day hospital treatment Potentially undesirable side-effect profile: somnolence, postural hypotension, QT interval changes, and metabolic effects
Fluoxetine†	20-60 mg/day	Stabilization of weight-recovered patients (i.e., patients at >85% EBW) in combination with elective adjunctive therapy Combination with adjunctive CBT did not show efficacy in trial
Bulimia Nervosa§		
Fluoxetine	60 mg/day	Best studied; well tolerated; only agent with FDA approval for this indication
Sertraline	100 mg/day	Data limited to one small, short-term RCT
Topiramate	Up to 250 mg/day Up to 400 mg/day	Potentially undesirable side-effect profile: sedation and cognitive changes, weight loss, renal calculi Both studies started at 25 mg/day and titrated upward as tolerated
Ondansetron	24 mg/day in six divided doses	High cost Effective for patients with severe BN
Of Limited Clinical Use		
Fluvoxamine‡	Up to 300 mg/day in divided doses	Inconsistent results in two RCTs, grand mal seizures in some study participants on active drug, but causal association unknown
Imipramine	Up to 300 mg/day	Potentially undesirable side effect profile: effects on pulse, blood pressure, and QT interval that potentiate medical complication seen in BN (e.g., QT interval lengthening associated with hypokalemia) High lethality in overdose
Desipramine	Up to 300 mg/day	Potentially undesirable side effect profile: effects on pulse, blood pressure, and QT interval that potentiate medical complication seen in BN (e.g., QT interval lengthening associated with hypokalemia) High lethality in overdose
Trazodone	Up to 400 mg/day	Potentially undesirable side-effect profile: sedation
Naltrexone‡	200-300 mg/day	Potentially undesirable side effect profile: hepatotoxicity Effective for patients who had not responded to a trial of antidepressant pharmacotherapy
BED‖		
Sibutramine‡	15 mg/day	Effective in a multisite trial
Topiramate	25-400 mg/day	Effective for patients with BED + obesity in a multisite trial Potentially undesirable side-effect profile: sedation, cognitive changes, paresthesia
Sertraline	50-200 mg/day	Effective for patients with BED + obesity
Fluvoxamine‡	50-300 mg/day	Effective for patients with BED + obesity in a multisite trial
Citalopram	20-60 mg/day	Effective for patients with BED + obesity
Fluoxetine‡	20-80 mg/day	Effective for patients with BED + obesity
Atomoxetine	40-120 mg/day	Effective for patients with BED + obesity
Orlistat (in combination with reduced calorie diet)	120 mg tid	Significant binge remission may not be maintained at 3 months Examined effects on BED in obese patients Was not effective at this dose in combination with CBT

*With the exception of fluoxitine or BN, none of these is FDA-approved for an eating disorder and thus use in treatment of an eating disorder is considered off-label.

† Cyproheptadine and zinc excluded because of mixed support and/or limited data, and because they are not in routine clinical use for AN.

‡ Negative study RCT data were also published on this agent for this indication.

§ Bupropion, phenelzine, and isocarboxazid excluded because of their potential for serious adverse reactions; bupropion and monoamine oxidase inhibitors are contraindicated in patients with BN; flutamide excluded because of limited support for efficacy and potential for hepatotoxicity and teratogenicity.

‖ Zonisamide 100-600 mg/day excluded because it was not well tolerated in the study sample.

AN, Anorexia nervosa; *BED*, binge-eating disorder; *BN*, bulimia nervosa; *CBT*, cognitive behavior therapy; *EBW*, expected body weight; *RCT*, randomized controlled trial.

CBT-E is designed to be offered to patients with any eating disorder diagnosis. An RCT comparing CBT to wait-list control for BN and EDNOS patients found that over half the sample endorsed eating-disorder features less than 1 standard deviation above the community mean at 60-week follow-up, indicating that CBT-E may be even more efficacious than the original version.[147]

With regard to alternative psychotherapeutic modalities for BN, IPT is as effective but generally takes longer to achieve a result than does CBT, thus increasing the length of time the patient is exposed to bulimic symptoms.[141,148,149] Other therapies that have some empirical support for the treatment of BN include dialectical behavioral therapy,[150] psychodynamic psychotherapies,[151] guided imagery,[152] and guided self-change (incorporating a self-care manual).[153]

In their work with BN patients at risk for relapse to more harmful self-destructive behaviors (such as cutting, suicide attempts, and substance abuse), clinicians need to weigh the benefits and risks of postponing focused efforts to reduce behaviors associated with eating disorders that may pose less medical risk. For example, some patients benefit from interim therapeutic goals focused on developing effective and constructive coping strategies if abstinence from eating disorder symptoms would jeopardize sobriety or safety. These treatment teams must closely monitor the frequency and severity of purging and focus on other inappropriate compensatory behaviors, and address medical safety and adjust treatment as appropriate. Moreover, it may not be medically safe or therapeutically appropriate to postpone a treatment focus on restrictive eating, bingeing, or purging behaviors. When there is an urgency to address eating symptoms, but there is concomitant concern that this treatment may precipitate a relapse of other self-harm behaviors, psychiatric inpatient care may be warranted.

Pharmacologic Management

Augmentation with medication with demonstrated efficacy in BN may further reduce symptoms, and fluoxetine 60 mg/day appears to be beneficial in reducing symptoms for patients with BN who have not responded well to CBT or IPT.[154] Several pharmacotherapies have modest short-term efficacy for BN, but remission rates are low (see Table 17–4)[155] and medication management is generally considered as an adjunctive—rather than a first-line—strategy for the treatment of BN. Fluoxetine is the only FDA-approved agent for the treatment of BN, and use of other agents is therefore considered off-label.

The decision to augment a psychosocial therapy with medication in the treatment of BN hinges on co-morbid illness, severity, past response to medication, patient preference, and patient commitment to adherence to a medication regimen. Choice of medication is guided by side-effect profile, history of response, and expense, because the data are insufficient to support greater efficacy for any particular agent. However, data do support consecutive trials if a patient does not respond to the first agent. If an agent is prescribed, it is essential to ensure that the dosing schedule is arranged so that the drug is sufficiently absorbed before the purging behavior.

Fluoxetine 60 mg/day is the first-line pharmacologic agent in the treatment of BN. It has shown efficacy in the reduction of symptoms of BN compared with placebo in two large RCTs, is generally well tolerated among individuals with BN, and shows efficacy in maintenance therapy over the course of a year.[156–158] Monotherapy with fluoxetine has also been found more effective than placebo for treatment of BN in a primary care settting.[159]

Sertraline was found to be effective in reducing the number of binge eating and purging episodes among patients with BN in a small RCT.[160] Fluvoxamine was evaluated in two clinical trials with inconsistent findings. One of these trials reported grand mal seizures among some study participants on active drug, although causal association is unknown.[161,162]

Other classes of agents also show promise for the reduction of symptoms of BN. Topiramate was found to significantly reduce symptoms when compared with placebo in two 10-week RCTs.[163–165] In addition, although naltrexone is not in routine clinical use, one study demonstrated that it had short-term efficacy at 200 to 300 mg/day versus standard dosages (50 to 100 mg/day) for patients with BN who had not previously responded to antidepressant therapy.[166] One RCT demonstrated short-term efficacy of ondansetron (24 mg/day divided into six doses) in severely symptomatic BN.[167] The risk for hepatotoxicity associated with naltrexone and cost associated with ondansetron limit clinical use of either of these options, however. Similarly, a small RCT suggested efficacy of flutamide for reduction of binge episodes (but not vomiting) in BN. However, given limited support for its clinical use and the associated risk of teratogenicity and hepatotoxicity with this agent, it cannot be recommended for the management of BN.[168]

Likewise, although imipramine, desipramine, and trazodone have been found effective in reducing symptoms in patients with BN, their side-effect profiles limit their use in this clinical population.[169–174] Finally, several agents should not be used for the treatment of BN. The risk of serious adverse events associated with both bupropion (seizures) and monoamine oxidase inhibitors (spontaneous hypertensive crises) in patients with BN contraindicates their use for the management of BN.[135,175–177] The use of these medications to manage co-morbid depression in the setting of BN is relatively contraindicated as well and warrants careful consideration of risk-to-benefit ratios in the context of each patient's individualized needs.

TREATMENT OF PATIENTS WITH BINGE-EATING DISORDER

Patients with BED are often quite willing to seek and accept treatment because of their high levels of distress and their eagerness to combat the co-morbid obesity (if present). Although BED is a recently described nosologic category in the DSM-IV (currently defined with research criteria), there has been rapid progress in identifying effective psychosocial and pharmacologic treatment. Because BED is frequently co-morbid with obesity, and because obesity is believed to contribute to risk for BED, weight reduction is often a primary goal of treatment and, unlike in patients with BN, it can be pursued concurrently or sequentially depending on the clinical situation.[178]

CBT, the best-studied psychosocial intervention for BED, has the strongest empirical support in the reduction

of the hallmark feature of the syndrome, binge eating.[179] Because the disorders share features, CBT for BED is similar to that for BN, featuring self-monitoring of food consumption, normalization of eating, implementation of distraction techniques, challenging of cognitive distortions, and development of a relapse-prevention plan. In an RCT comparing CBT to pharmacotherapy for BED, 61% of patients who received CBT plus placebo and 50% of patients who received CBT plus fluoxetine abstained from binge eating after treatment. Both CBT treatments were superior to fluoxetine (22%) or placebo (26%) alone.[180] Unfortunately, despite good efficacy in the reduction of binge eating, CBT is not associated with significant weight loss in obese patients with BED.[179,181,182] For this reason, clinicians have attempted to modify and augment the CBT protocol with medications and other psychosocial strategies in an attempt to improve results. For example, patients who complete experiential cognitive therapy (which incorporates a nutrition group, virtual reality therapy, daily moderate physical activity, and group therapy focused on increasing motivation and assertiveness) demonstrate lower rates of bingeing than those enrolled in traditional CBT or nutrition groups. Similarly, the addition of moderate exercise to CBT alone is found to further decrease the frequency of bingeing.[183]

Alternatives to CBT have demonstrated efficacy for BED as well. Specifically, substantial reductions in binge eating in the first 4 weeks of behavioral weight loss (BWL) treatment predict further reductions not only in binge eating but also in BMI. This finding has prompted speculation about the potential efficacy of a stepped care model in which patients begin treatment with BWL and subsequently transfer to CBT only if they are unable to achieve rapid BWL response.[184] As seen in results of studies comparing them for patients with BN, group IPT is as effective as group CBT in terms of posttreatment and follow-up binge eating recovery rates (i.e., approximately half of patients recover).[185] However, those participating in CBT are typically able to achieve change more quickly, usually through decreasing dietary restraint.[182] Participants in dialectical behavior therapy groups adapted for BED demonstrate significantly higher remission rates at the end of treatment in comparison to wait-list controls.[186] Finally, self-help versions of CBT delivered by book or CD-ROM are superior to wait-list control in reducing binge eating among individuals with both BN and BED, but the comparative efficacy of self-help versus traditional therapist-led CBT remains unknown.[187]

Pharmacologic Management

Pharmacologic therapies for the treatment of BED are being rapidly identified, and several medications have demonstrated efficacy in reducing symptoms of BED, or of BED with obesity, in RCTs, as a single or as an adjunctive treatment (see Table 17–4). However, none of these medications has FDA-approval for this indication, and the majority of the studies have investigated only relatively short-term use of the medication (3 months or less). Moreover, for the majority of agents, little is known about maintenance of symptom reduction after the drug is discontinued. Two agents have established efficacy for the reduction of symptoms associated with BED in multisite placebo-controlled trials: sibutramine for patients with BED[188] and fluvoxamine[189] and topiramate for obese patients with BED.[190]

Other agents with demonstrated efficacy in at least one RCT for reducing the symptoms of BED are sertraline,[191] citalopram,[192] fluoxetine,[193] atomoxetine,[194] orlistat in combination with a reduced calorie diet,[195] and zonisamide.[196] However, zonisamide was not well tolerated in the study population, and, in the or list at study, there was no significant difference in the rates of BED in the treatmetn versus control group at 3-month follow-up.[195]

Notwithstanding the promise of the emerging evidence of efficacy for pharmacotherapy for BED, long-term outcome data are not yet available on which to base recommendations for maintenance therapy strategies for this disorder. Evidence supports CBT as superior to pharmacotherapy. Although augmentation of CBT with topiramate (dosage range, 25 to 300 mg/day) was more effective than placebo augmentation in achieving BED remission in obese adults,[197] and fluvoxamine 300 mg/day augmenting CBT was more effective than CBT alone in reducing eating disorder pathology (as measured by the Eating Disorder Examination score) in the short term for patients with BED,[198] the efficacy of augmentation with other medications is not established.[199,200]

Because of the prevalence of BED in the weight-treatment–seeking population, a high percentage of patients seeking gastric bypass surgery for weight control have comorbid binge eating.[201,202] The long-term impact of bariatric surgery on binge eating is still unclear, as empirical data are mixed. One methodological issue that may account for differential findings across studies is the problematic definition of *binge eating* in postsurgical patients who may not be able to consume large amounts of food but who nonetheless experience bouts of loss of control and distress. Taken together, the evidence suggests that some patients who present with frank presurgical binge eating or BED continue to exhibit loss-of-control eating after surgery, and that postsurgical loss-of-control eating is associated with less weight loss, greater weight re-gain, and poorer psychosocial outcomes.[203] However, presurgical BED should not be viewed as a contraindication for bariatric surgery, because many other patients cease binge eating after surgery and the majority of patients experience weight loss and improved health even if some weight is re-gained.[204] Instead, presurgical psychiatric evaluation should be used as an opportunity to provide education about realistic weight loss expectations, identify potential barriers to meal-plan compliance, and recommend binge eating treatment (e.g., CBT, medication) if indicated.

SUMMARY

At Massachusetts General Hospital, and in many general hospital settings, patients with eating disorders frequently present with a serious, chronic, medically complicated, or co-morbid illness. For patients with previously unidentified or untreated eating disorders, an inpatient admission can present opportunities both to develop and coordinate a multidisciplinary team and for discussions about nutrition and psychoeducation. Inpatient assessment should ascertain the scope and severity of cognitive and behavioral symptoms associated with the eating disorder as well

as other psychological risks and psychiatric co-morbidities. Assessment of nutritional compromise and medical complications of the weight and behavioral symptoms are also essential to therapeutic planning. Interventions typically include assisting the medical team to complete an appropriate diagnostic work-up and address potential medical and nutritional complications as well as develop a plan for any behavioral interventions to be implemented during the admission. Psychoeducation and engagement of the patient and determination of appropriate disposition and available resources are two further goals of psychiatric consultation. Finally, in some cases, behavioral strategies (to stabilize weight, or to modify inappropriate compensatory behaviors) and pharmacotherapy can be implemented or initiated in a general hospital setting.

18 Pain Patients

Shamim H. Nejad, M.D.
Menekse Alpay, M.D.

Of all human experience, pain is, as long as it lasts, the most absorbing; it is the only human experience that when it comes to an end, automatically confers a sense of relief and joy. Moreover, by its very nature it is solitary. However, the oddest thing about pain is that despite its intensity and its unequalled power over mind and body, it is difficult to recall when it is over.[1]

The International Association for the Study of Pain (IASP) has defined pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[2] This definition recognizes the fact that pain has both an acute nociceptive aspect and an emotional and psychiatric dimension; these factors suggest that psychiatrists have a significant role in the treatment of the pain patient. Conceptualizing pain in this manner underscores the fact that pain is an important and complicated sensation, one that can occur in a multitude of ways.

In this chapter, we review the pathophysiology of pain, along with common pain syndromes and terminology. In addition, the role of the psychiatric consultant in the psychiatric assessment and management of the pain patient will be discussed. Furthermore, we will outline general principles of pain therapy, including use of medications commonly used for pain management, and review approaches to the treatment of pain behavior.

PATHOPHYSIOLOGY OF PAIN

To understand pain one needs to know about the pathophysiology of nociception and to realize that the threshold, intensity, quality, time course, and perceived location of pain are determined by central nervous system (CNS) mechanisms.[3] For example, neurosurgeons have shown that interruption of the specific pain pathways often does not eliminate pain; numbness does not confer analgesia. Peripheral nerve damage can result in changes in the receptive fields and recruitment of neurons at multiple levels of the nervous system (from the dorsal horn to the brainstem and to the thalamus and cortex). Somatic therapies directed only at nociceptive input may be ineffective.[4]

Detection of noxious stimuli (i.e., nociception) starts with the activation of peripheral nociceptors (somatic pain) or with the activation of nociceptors in bodily organs (visceral pain). Somatic pain is usually well localized, attributable to certain structures or areas, and described as stabbing, aching, or throbbing. In contrast, visceral pain may be poorly localized, is not necessarily attributable to the involved organ (as is the case with referred pain), and is characteristically described as dull and crampy.

Tissue injury stimulates the nociceptors by the liberation of prostaglandins, arachidonic acid, histamine, and bradykinin. Subsequently, axons transmit the pain signal to the spinal cord (to cell bodies in the dorsal root ganglia; Figure 18–1).

Three different types of axons are involved in transmitting a painful stimulus from the skin to the dorsal horn. A-β fibers are the largest and most heavily myelinated fibers that transmit awareness of light touch. A-δ fibers and C fibers are the primary nociceptive afferents. A-δ fibers are 2 to 5 μm in diameter and are thinly myelinated. They conduct immediate, rapid, sharp, and brief pain (first pain) with a velocity of 20 m/sec. C fibers are 0.2 to 1.5 μm in diameter and are unmyelinated. They conduct prolonged, burning, and unpleasant pain (second pain) at a speed of 0.5 m/sec. A-δ and C fibers enter the dorsal root and ascend or descend one to three segments before synapsing with neurons in the lateral spinothalamic tract (substantia gelatinosa in the gray matter).

Substance P, an 11-amino-acid polypeptide that is the major pain neurotransmitter, is released from the fibers at many of these synapses. Capsaicin, which is extracted from red hot peppers, inhibits nociception by inhibiting substance P. Inhibition of nociception in the dorsal horn is functionally quite important. Stimulation of the A-δ fibers excites some neurons and inhibits others. This inhibition of nociception through A-δ fiber stimulation might explain effects of acupuncture and transcutaneous electrical nerve stimulation (TENS). The lateral spinothalamic tract crosses the midline and ascends toward the thalamus. At the level of the brainstem more than half of this tract synapses in the reticular activating system (in an area called the *spinoreticular tract*), in the limbic system, and in other brainstem regions (including centers for the autonomic nervous system). Another site of projections at this level is the periaqueductal gray (PAG; Figure 18–2), which plays an important role in the brain's endogenous analgesia system. After synapsing in the thalamic nuclei, pain fibers project to the somatosensory cortex, located posterior to the Sylvian fissure in the parietal lobe (Brodmann's areas 1, 2, and 3).[5]

Developments in imaging technology have been helpful in understanding the relationship between pain pathways and cortical and limbic areas. These findings might help explain the relationship among emotions, cognition, and pain modulation that we observe in clinical practice as heightened pain perception in depressed patients and high rates of depression in those with chronic pain. Functional imaging studies using functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) have shown that acute traumatic nociceptive pain

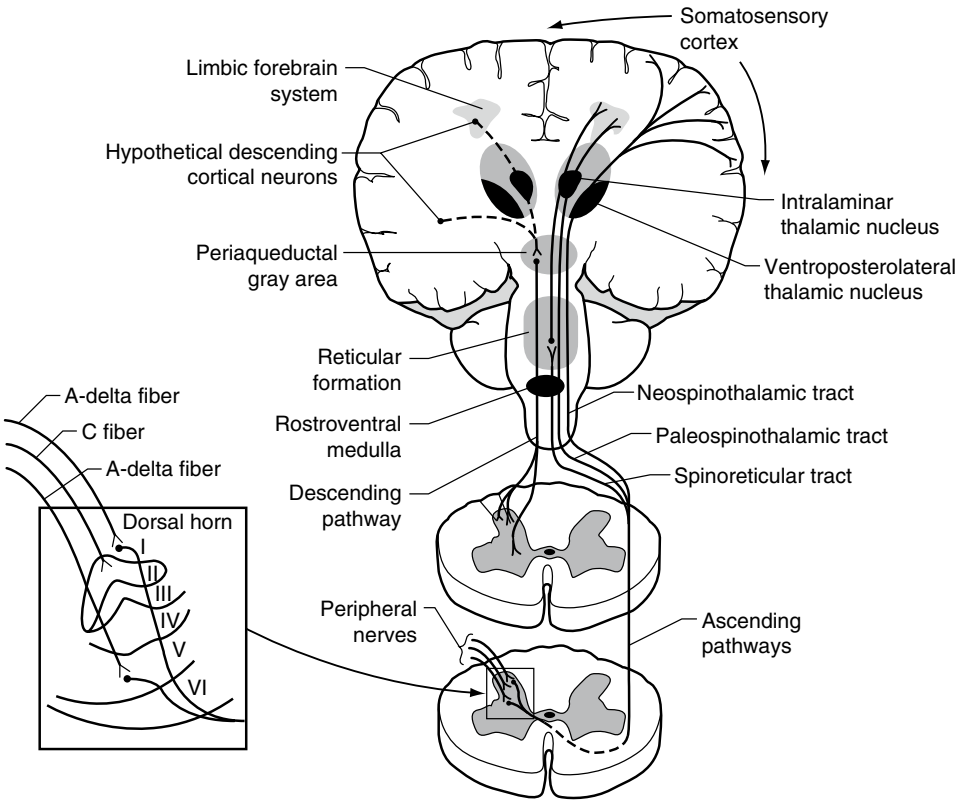

Figure 18–1. Schematic diagram of neurologic pathways for pain perception. *(From Hyman SH, Cassem NH: Pain. In Rubenstein E, Fedeman DD, eds.* Scientific American medicine: current topics in medicine. Subsection II. *New York, 1989, Scientific American, pp 1–17. Originally from Stern TA, Herman JB, editors:* Psychiatry update and board preparation, *New York, 2004, McGraw-Hill.)*

activates the hypothalamus and the PAG in addition to the prefrontal cortex (PFC), insular cortex, anterior cingulate cortex (ACC), posterior parietal cortex, primary motor and somatosensory areas, supplementary motor area (SMA), thalamus, and cerebellum.[6] Additionally, functional imaging studies have helped clinicians understand cognitive and emotional modulation of pain perception. Researchers have shown that with hypnotic suggestion the activity in the ACC depends on the intensity of the suggestion: The same stimulus with the suggestion of "highly unpleasant" induces significantly more ACC activation than when suggestions are less unpleasant.[7,8] In another study, when subjects were distracted during a painful stimulus, pain perception was attenuated in somatosensory regions and the PAG.[9] The short-acting opioid remifentanil and placebo analgesia have been shown to activate the ACC, which is rich in opioid receptors.[10] Analgesia induced by both opioids and placebos can be reversed with the opioid antagonist naloxone.[11] These findings suggest that cortical areas might exert control over lower brain areas involved in opioid analgesia.[10]

Endogenous analgesic systems involve at least 18 endogenous peptides with opiate-like activity in CNS (e.g., endorphins, enkephalins, and dynorphins). Different opiate receptors are involved in different effects of opiates. Mu receptors are involved in regulating analgesia, respiratory depression, constipation, and miosis. Mu receptors (located in the PAG, rostral ventral medulla, medial thalamus, and dorsal horn of the spinal cord) are mainly responsible for supraspinal analgesia. Kappa receptors are involved in spinal analgesia, sedation, and miosis. They are located in the dorsal horn (spinal analgesia), deep cortical areas, and other locations; pentazocine preferentially acts on these receptors. Delta receptors, like kappa receptors, mediate spinal analgesia, hypotension, and miosis. Enkephalins have a higher affinity for these receptors than do opiates. They are located in the limbic system, the dorsal horn, and other locations unrelated to pain. Delta receptors also mediate psychotomimetic effects (i.e., psychosis) in the CNS. Their effects are not reversed by naloxone, an opiate antagonist.[5]

In terms of anatomic organization, the centers involved in endogenous analgesia include, in addition to the PAG, the rostral ACC, amygdala, parabrachial plexus in the pons, and rostral ventromedial medulla.[10]

The descending analgesic pain pathway starts in the PAG (which is rich in endogenous opiates), projects to the rostral ventral medulla, and from there descends through the dorsolateral funiculus of the spinal cord to the dorsal horn. The neurons in the rostral ventral medulla use serotonin to activate endogenous analgesics (enkephalins) in the dorsal horn. This effect inhibits nociception at the level of the dorsal horn because neurons that contain enkephalins synapse with spinothalamic neurons.

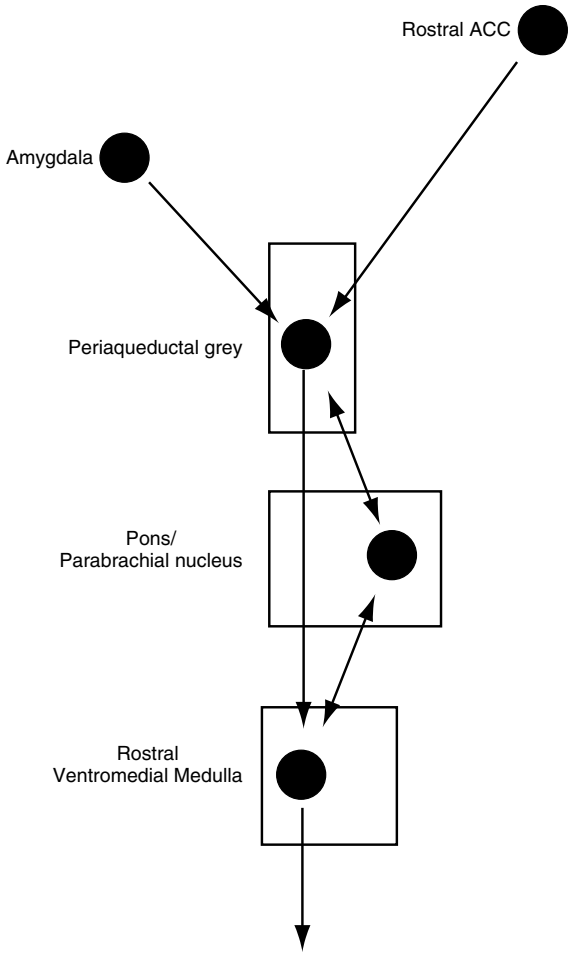

Figure 18–2. Endogenous opioid systems. *(From Petrovic P, Ingvar M: Imaging cognitive modulation of pain processing,* Pain *95:1–5, 2002.)*

Additionally, there are noradrenergic neurons that project from the locus ceruleus (the main noradrenergic center in the CNS) to the dorsal horn and inhibit the response of dorsal horn neurons to nociceptive stimuli. The effect of tricyclic antidepressants (TCAs) and other newer antidepressants is thought to be related to an increase in serotonin and norepinephrine that inhibits nociception at the level of the dorsal horn.[5]

PAIN TERMINOLOGY

Acute pain is usually related to an identifiable injury or to a disease; it is self-limited and resolves over hours to days or in a time frame that is associated with healing. Acute pain is usually associated with objective autonomic features (e.g., tachycardia, hypertension, diaphoresis, mydriasis, or pallor).

Chronic pain (i.e., pain that persists beyond the normal time of healing or lasts longer than 6 months) might have a neurologic origin. It has several features: lowered firing thresholds for spinal cord cells that modulate pain (triggering pain more easily); anatomic plasticity and recruitment of a wide range of cells in the spinal cord (so that touch or movement causes pain); convergence of cutaneous, vascular, muscle, and joint inputs (where one tissue refers pain to another); or aberrant connections (electric short-circuits between the sympathetic and sensory nerves that produce causalgia). Muscle pains often add to the pain experience. Vascular and other visceral mechanisms share features with neurologic mechanisms; however, these mechanisms involved are not mutually exclusive.[12,13] Table 18–1[14–26] summarizes the clinical implications of the mechanisms of chronic pain. Characteristic features include vague descriptions of pain and an inability to describe the pain's timing and localization. Unlike acute pain, chronic pain lacks signs of heightened sympathetic activity. Depression, anxiety, and premorbid personality problems are common in this patient population. Usually the major issue is a lack of motivation and incentive to improve. It is usually helpful to determine the presence of a dermatomal pattern (Figure 18–3), determine the presence of neuropathic pain, and assess pain behavior.

Continuous pain in the terminally ill tends to originate from well-defined tissue damage due to terminal illness (e.g., cancer). It is a variant of nociceptive pain. Stress, sleep deprivation, depression, and premorbid personality problems can exacerbate this pain.

Neuropathic pain is caused by an injured or dysfunctional central or peripheral nervous system; it is manifested by spontaneous, sharp, shooting, or burning pain that is usually distributed along dermatomes (see Figure 18–3). Neuropathic pain is often observed in deafferentation pain, complex regional pain syndrome (CRPS), diabetic neuropathy, central pain syndrome, trigeminal neuralgia, or postherpetic neuralgia.

Terms commonly used to describe neuropathic pain include *hyperalgesia*, an increased response to stimuli that are normally painful; *hyperesthesia*, an exaggerated pain response to noxious stimuli (pressure or heat); *allodynia*, pain with a stimulus not normally painful (e.g., light touch or cool air); and *hyperpathia*, pain from a painful stimulus with a delay and a persistence that is distributed beyond the area of stimulation.

CRPS, formerly known as reflex sympathetic dystrophy (RSD), is a syndrome of sympathetically maintained pain, or pain in an extremity that is mediated by sympathetic overactivity. The syndrome is usually caused by injury; however, the cause is unknown in approximately 10% of cases. Either microtrauma or macrotrauma (such as a sprain, a fracture, or a contusion) can cause it; iatrogenic causes include amputation, lesion resection, myelography, and intramuscular injections. CRPS may be related to disease, such as myocardial infarction, shoulder–hand syndrome, herpes zoster, cerebrovascular accidents, diabetic neuropathy, disc herniation, degenerative disc disease, neuraxial tumors or metastases, multiple sclerosis, or poliomyelitis. CRPS is divided into two types. In type I CRPS, which typically develops after minor trauma or fracture, no overt nerve lesion is detectable. In type II CRPS, a definable nerve injury is present. According to the diagnostic criteria set forth by the IASP, the diagnosis of CRPS can be made if the following criteria are met[27]:

TABLE 18–1 Chronic Pain: Nervous System Pathophysiology[14–26]

NEUROLOGIC MECHANISMS	PHYSIOLOGIC EFFECT	CLINICAL IMPLICATIONS
Neuroplasticity[14–15]	Recruitment of cortical and subcortical neurons so wide dynamic range cells can be activated by low-threshold mechanoreceptors Allodynia Allaesthesia	Early, concurrent, multimodal treatment of nociceptive, central, vascular, sympathetic, and psychiatric aspects of the pain Block glutamate, substance P Early use of anticonvulsants, membrane stabilizers, sympatholytics NMDA antagonists
NMDA excess and glutamate–GABA imbalance[16–19] Glutamate up, GABA down	Morphine tolerance Central hyperalgesia Hyperexcitability of peripheral and central pain cells	Normally nonpainful light touch, muscle and joint movements are painful Treatment options: benzodiazepines, baclofen, anticonvulsants, substance P antagonists, or other NMDA antagonists (e.g., ketamine), GABA agents
Neurotoxins[20]	Excitotoxic (e.g., quinolinic acid) neuropathy	AIDS pain: anticonvulsants, serotoninergic and noradrenergic agents, free radical scavengers
Opioid "off" mechanisms[21–22] Off cells in the medulla Morphine 3G and morphine up Side-effect intolerance	Hyperalgesia as narcotics increase (particularly intrathecal) Tolerance as morphine 3G increases Side effects greater than benefit	Maintain steady blood levels of narcotics, or decreased narcotic can increase pain Switch to a different narcotic if one does not work Trial off narcotics if narcotics not working
Sympathetic pain[15]	Mechanoallodynia, swelling Dystrophic changes	Sympathetic blockade and/or α-blocking drugs may be useful in CRPS, trauma, facial pain, arthritis
Monoamines (5-HT, NE, dopamine)[23–26]	5-HT increase lessens opiate analgesia 5-HT_1 dysregulation leads to vascular pain 5-HT_1 involved in affective disorders and suffering from pain	Full dosage, early use of antidepressant drugs, including tricyclics, SSRIs, and dopamine agonists, alone or in combination NE reuptake inhibitors (e.g., desipramine, venlafaxine) useful for pain whether depressed or not Pergolide and methylphenidate (Ritalin) are useful adjuvants
Psychiatric illness	Decreased sleep Decreased muscle relaxation Alienation, anxiety	Differential diagnosis of psychiatric conditions and appropriate treatments

5-HT, 5-hydroxytryptamine; *CRPS*, complex regional pain syndrome; *GABA*, gamma-aminobutyric acid; *NE*, norepinephrine; *NMDA, N*-methyl-D-aspartate; *SSRIs*, selective serotonin reuptake inhibitors.

- A preceding noxious event without (CRPS I) or with obvious nerve lesion (CRPS II)
- Spontaneous pain or hyperalgesia or hyperesthesia not limited to a single nerve territory and disproportionate to the inciting event
- Edema, skin blood flow (temperature) or sudomotor abnormalities, motor symptoms, or trophic changes are present on the affected limb, in particular at distal sites
- Other diagnoses are excluded

The clinical course (which can last up to 6 months) starts with an acute phase that involves pain, edema, and warm skin. Subsequently dystrophic changes dominate the picture with cold skin and trophic changes (3 to 6 months after the onset of the untreated acute phase). Irreversible atrophic changes (atrophy and contractures) eventually occur. Symptoms can improve with inhibition of sympathetic output; sympathetic blockade may be both diagnostic and therapeutic.[28]

Idiopathic pain, previously referred to as "psychogenic pain," is poorly understood. The presence of pain does not imply or exclude a psychological component. Typically, there is no evidence of an associated organic etiology or an anatomic pattern consistent with symptoms. Symptoms are often grossly out of proportion to identifiable organic pathology.

Jurisigenic pain results from perceived physical or emotional damage related to medical, personal, work, or product injury. Patients with this pain syndrome usually maintain the sick role for as long as possible to maximize financial return. It is important to recognize the existence of a conflict and to educate patients and attorneys; maintenance of a helping and neutral posture is critical.

Phantom-limb pain refers to severe and excruciating pain in the body part that is no longer present following amputation. The amputation of a limb is commonly followed by sensations that indicate that the deafferented body part is still present. These can include nonpainful phantom sensations such as specific positions, shape, movement, warmth, cold, itching, tingling, electric sensations, and other paraesthesias.[29] However, pain may also be present, and it occurs in 50% to 80% of all amputees.[30] Although this condition is most common after amputations of limbs, it can also occur

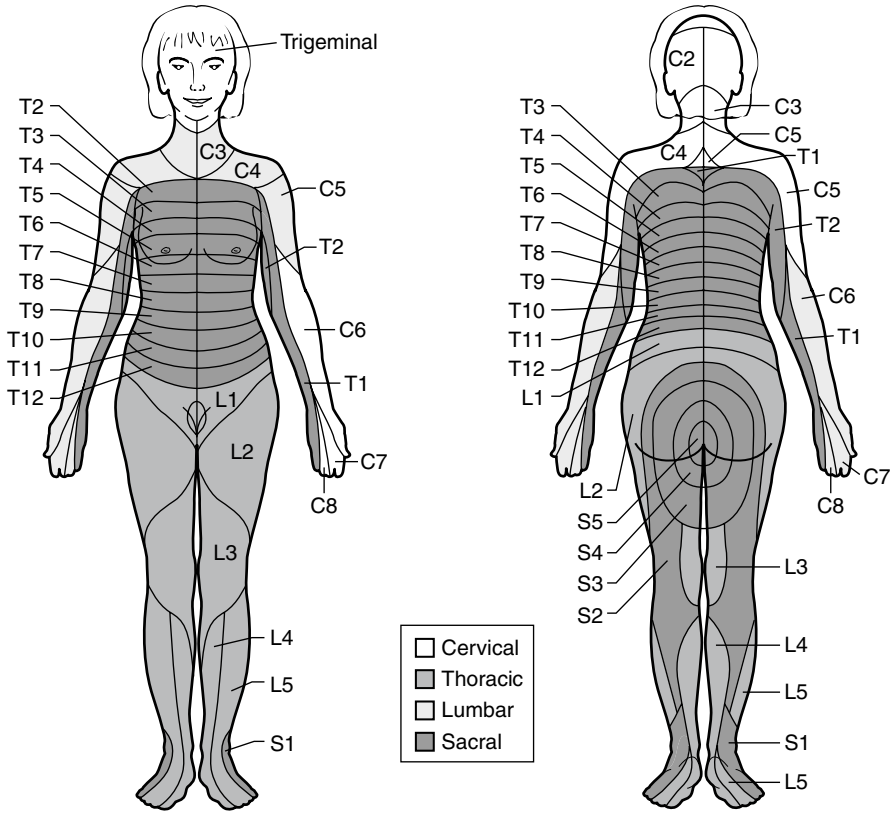

Figure 18–3. Schematic diagram of segmental neuronal innervation by dermatomes. *(From Hyman SH, Cassem NH: Pain. In Rubenstein E, Fedeman DD, eds,* Scientific American medicine: current topics in medicine. Subsection II. *New York, 1989, Scientific American; pp 1–17. Originally from Stern TA, Herman JB, editors:* Psychiatry update and board preparation, *New York, 2004, McGraw-Hill.)*

after the surgical removal of other body parts such as the breast, rectum, penis, testicle, eye, tongue, or teeth.[31] The pathophysiology of this pain is poorly understood; however, it is likely secondary to CNS[32–34] and peripheral (e.g., nociceptive input from the residual limb)[35] factors, with psychological factors influencing the course and severity of the pain.[36] Consistent with the impact of the psyche on pain, one study showed that it is possible to induce pain in an amputee by hypnotic suggestion.[37]

Myofascial pain can arise from one or several of the following problems: hypertonic muscles, myofascial trigger points, arthralgias, and fatigue with muscle weakness. *Myofascial pain* is generally used to describe muscle and connective tissue sources of pain. Myofascial pain can be a primary diagnosis (e.g., fibromyalgia) or, as more often is the case, a co-morbid diagnosis (e.g., with vascular headache or with a psychiatric diagnosis). Psychiatric symptoms are common in patients with muscle pain; other symptoms often include decreased energy, impaired sleep, and changes in psychomotor activity. Myofascial pain syndromes can involve muscle trigger points, hypersensitive skin, a subjective sense of swelling and numbness, somatoform pain disorder, affective and anxiety disorders, nonrestorative sleep, and pain of the head and neck. The diagnosis should be considered if there are multiple muscle trigger points in the temporalis, sternocleidomastoid, rhomboids, or trapezius muscles; if the person cannot get at least 5 hours of uninterrupted sleep; and if chronic fatigue is present.[38] Deficient stage 4 sleep is thought to underlie the lack of deep muscle relaxation, aching muscles, arthralgias, and general malaise.[39,40]

MEASUREMENT OF PAIN

The experience of pain is always subjective. Objective measurements of the patient's subjective response, however, are possible. Several sensitive and reliable clinical instruments for pain measurement are available. These include the pain drawing, the visual analogue scale, and categorical rating scales.

The pain drawing involves having the patient draw the anatomic distribution of the pain as it is felt in his or her body. The patient draws the outline of the body, labels where the pain is, and keeps this document as part of the medical record. The drawing serves as a clue to the anatomy of the problem, to the psychological state of the patient, and to the patient's level of knowledge.

The visual analog scale, a 100-mm scale with a 0 signifying no pain and 100 representing severe pain, is readily understood by most patients. It is also exquisitely sensitive to change; consequently the patient can mark this scale once a day or even hourly during treatment trials, if desired. Two separate scales can be kept for the least and the greatest pain. Concurrent scales for mood, overall progress, and

pain allow comparison of the relationship of pain to the total clinical picture, thereby rounding out the psychiatrist's understanding of the patient's syndrome.

Ad hoc categoric rating scales may be devised that comprise three to five categories for the ranking of pain severity.

THE PSYCHIATRY CONSULTANT AS PAIN PHYSICIAN

The Psychiatrist's Role

Physicians and patients alike seek knowledge, order, and relief when dealing with pain's chameleon-like manifestations; some of the common reasons pain patients or treating physicians seek consultation and treatment from psychiatrists are:

- To separate functional from organic factors. Unfortunately, the request to separate psyche from soma is often vexing. Through such consultations some physicians wish to absolve themselves of further responsibility.
- To resolve inconsistencies between symptoms and physical findings (or the lack thereof): "No anatomic lesion could account for this." The referring physician wonders if a psychiatric disorder or CNS pain is present or if he or she is missing something.
- To assess the patient for depression, anxiety, or some co-morbid disorder from the *Diagnostic and Statistical Manual of Mental Disorders*,[41] 4th edition, (DSM-IV) and the disorder's relation to the experience of pain.
- To address a patient's or physician's fear or misunderstanding of narcotics (e.g., use of high-dose narcotics, toxicity, and maintenance treatment).
- To determine if the use of psychopharmacologic agents might help alleviate pain and suffering.
- To satisfy the referring physician's personal desire to punish a "hateful" patient, one who will not take "yes" or "no" for an answer and who interferes with normal medical decision-making.

The psychiatrist begins with a clarification of the reason for the consultation, creates some initial hypotheses, and examines the patient. If possible, the psychiatric consultant should be brought into the case early on and introduced as a member of the medical team. The referring physician should take care to ensure that the patient does not interpret the referral as a sign that he or she is not believed, and the physician should state that a psychiatrist is routinely asked to evaluate patients with long-standing pain. When the referring physician is comfortable using the services of a psychiatrist, the patient typically accepts the examination without protest. When the psychiatrist is called in at the end of a long and frustrating stand-off, the patient typically balks.

Gathering Important Preliminary Information

The psychiatric consultant's job begins by answering five questions: Is the pain intractable because of nociceptive stimuli (e.g., from the skin, bones, muscles, or blood vessels)? Is the pain maintained by non-nociceptive mechanisms (i.e., have the spinal cord, brainstem, limbic system, and cortex been recruited as reverberating pain circuits)? Is the complaint of pain primary, as occurs in disorders such as major depression or delusional disorder? Is there a more efficacious pharmacologic treatment? Have pain behavior and disability become more important than the pain itself? Answering these questions allows the mechanism(s) of the pain and suffering to be pursued. Table 18–2 is a useful guideline to organize the questions, to test hypotheses, and to determine diagnosis.

Physical Examination

A psychiatrist's physical examination of the pain patient includes examination of the painful area, muscles, and sensation to pinprick and light touch (Table 18–3). The examination is essential to the psychiatric evaluation for pain and serves three purposes. First, examination of the patient allows better history-taking, therapeutic alliances, and integration of data; it also helps to eliminate the physical–mental dichotomy, which, left unspoken, often contributes to the patient's defensiveness. Second, the psychiatrist can search for signs of different types of pain and distinguish them from symptoms of a conversion disorder. Third, inconsistent findings suggesting a somatoform disorder may be uncovered.

Psychiatric Examination

Interviewing the patient with chronic pain demands close attention to both what was said and what was not said, as well as to mindfulness of the patient's style of discourse. Because patients with an extensive history of pain often delight in regaling the examiner with their odysseys through clinics, spas, and hospitals, it is helpful to ask them to write detailed accounts of their pain from its onset to the present. A detailed history of when and how the pain began, inquiring about the various treatments received, and the patient's relationships with other physicians are also important in the evaluation of the pain patient. Throughout the history, one should look for fluctuations in the course of the pain. Why did it improve? Did the medication help, or was it some other factor that proved palliative? In addition, one should explore the patient's past and present mental state and consider the family history and ethnic beliefs. Open-ended questions may include: "Have you ever suffered like this before? What do you do think about in the early morning hours when you cannot sleep? What do others think is the nature of the problem?" The psychiatrist also plays an important role in the treatment of the pain by his or her ability to recognize psychiatric conditions that can manifest with pain.

Diagnosis

Depression

Major depressive disorder (MDD) can be diagnosed by DSM-IV or similar research criteria in approximately 25% of patients who suffer from chronic pain. Recurrent affective illness, a family history of depression, and psychiatric co-morbidity (with anxiety and substance use) are often present. More often than not, depression predates the pain; overall, 60% to 100% of pain patients have depressive symptoms.

TABLE 18–2 Questions to Ask when Pain Persists

WHAT IS THE PROBLEM?	SELECTED DIAGNOSTIC CONSIDERATIONS	CONSIDER
Is there an ongoing physical disease? (e.g., infection, cancer)	MRI for anatomic pathology Gallium scan for infection ESR for infection, cancer PSA, CEA, p24 testing Pelvic, breast, prostate, gastrointestinal examination	Progression of disease Metastatic disease Visceral pain: adhesions, referred pain, central pain
Is there a problem with the use and response to narcotics? (misuse, lack of efficacy)	Central pain Narcotics masking a DSM-IV problem Narcotic dosing error or inconsistency Narcotic toxicity	Intravenous agents Antidepressants, anxiolytics, or sleep prescription Narcotic potency CYP 2D6 interaction: codeine or oxycodone with SSRI Meperidine toxicity
Is there a psychiatric disorder associated with pain?	Loss of all pleasure and mid or late insomnia Panic, depersonalization, benzodiazepine failure, anxiety	Depression often masked by narcotics or anxiolytics Co-morbid somatoform, mood, or anxiety disorders
Does CNS pain exist? (e.g., neuropathic pain)	not relieved by analgesics Hypochondriasis Increased sensory threshold, decreased pain threshold Nondermatomal distribution of pain Hyperpathia Allodynia, often narcotic resistant	Pain drawing and explanation helpful for diagnosis Sharp sensation perceived as light touch is common Light touch is painful and sustained and has a delayed crescendo Tuning fork and moving a hair examinations detect allodynia best
Is it a pain behavior syndrome?	Pain disorder (somatoform): rule out masked depression, drug abuse, physical or sexual abuse, missed physical disorder	Anger and anxiety: denied Counterdependent, demanding style Passive and endearing
Is the patient faking?	Malingering for drugs or disability benefits Factitious deception to maintain the sick role	Malingering or factitious disorders with physical symptoms are rare, much more likely to be something else
Is an unusual problem responsible for pain?	Muscle trigger points absent, deep sleep Laxative abuse, anorexia/bulimia Adhesions Hypoesthesia, allodynia Wasting illness, subcortical deficits, AIDS Conversion symptom, especially with pelvic, gastrointestinal, or head pain	Myofascial pain often is co-morbid with another pain syndrome Visceral pain is diffuse, nondermatomal, with sympathetic symptoms and can mimic DSM-IV Physical or sexual abuse history contributing to pain

CYP, Cytochrome P450; *ESR*, erythrocyte sedimentation rate; *MRI*, magnetic resonance imaging; *SSRI*, selective serotonin reuptake inhibitor.

TABLE 18–3 General Physical Examination of Pain by the Psychiatrist

PHYSICAL FINDING	PURPOSE OF EXAMINATION
Motor deficits	Does the patient give way when checking strength? Does the person try? Is there a pseudoparesis, abasia-astasia, or involuntary movements suggesting a somatoform disorder?
Trigger points in head, neck, shoulder, and back muscles	Are any of the common myofascial trigger points present, suggesting myofascial pain? Presence of evoked pain (such as allodynia, hyperpathia, or anesthesia) suggests neuropathic pain
Evanescent, changeable pain, weakness, and numbness	Does the psychological complaint preempt the physical?
Abnormal sensory findings	Detection of lateral anesthesia to pinprick ending sharply at the midline Presence of topographic confusion Presence of nondermatomal distribution of pain and sensation suggests either a somatoform or CNS pain disorder Presence of abnormal sensation suggests neuropathy or CNS pain
Sympathetic or vascular dysfunction	Detection of swelling, skin discoloration, or changes in sweating or temperature suggests a vascular or sympathetic element to the pain
Uncooperativeness, erratic responses to the physical examination	Detection of an interpersonal aspect to the pain, causing abnormal pain behavior, as in somatoform disease

Although some depressive syndromes are secondary to pain itself (e.g., an adjustment disorder with affective symptoms), many patients have major depression masked by denial or by medications that promote sleepiness. Denial of affect, particularly anger, is observed in nearly half of chronic pain patients referred to the Massachusetts General Hospital (MGH) Psychiatric Consultation Service. Diagnosing an affective illness when affect is minimized by the patient may be difficult, but the following tactics can be used to help ferret out affective illness.

One should ask questions about neurovegetative symptoms. Examples of questions to be posed include: How often do you wake from sleep at night? How long does it take you to return to sleep? Do you have early-morning awakening? When was the last time you really enjoyed yourself? Does food taste the same as it always has? Do you enjoy eating? What do you do for fun? Can you still smile? Do you have an interest in people, such as your grandchildren or friends? Do you have difficulty with decision-making? What do you do when you are angry? Do you sometimes feel you would rather be dead?

Clinicians should also evaluate the person's limbic (i.e., genuine and uncensored) response to emotionally charged stimuli. One should look for denial of any strong emotion, particularly anger or sadness, and note if the patient answers affective questions with affective responses or only with avoidance and denial. Denial, displacement, or suppression of emotions suggests psychopathology. One could ask questions such as "Can you laugh at a joke at your own expense? Can you acknowledge anger at yourself and others?" The Minnesota Multiphasic Personality Inventory (MMPI) may be of particular use in refining the differential diagnosis when denial or repression is suspected. Covert hostility is typically elevated, which adds some validity to the label of denier. The conversion V is present in about half of pain patients studied at MGH, and it occurs more often among those in denial. Patients with other chronic illnesses are more likely to have an inverted V configuration.

Anxiety Disorders

In the pain patient, denial of fear, worry, or nervousness is a more ominous sign than is the mere expression of modulated fear or worry about pain. Given that it is normal to worry about a painful threat to the body and the mind, pathologic denial of any anxious affect can suggest psychosis, hypochondriasis, conversion, factitious disorder, or personality disorder. Accordingly, the DSM-IV provides criteria to identify anxiety of sufficient intensity that can trigger or exacerbate pain. Inportant information may be gleaned by such questions as: Does the pain make you panic? Do you feel your heart beating fast, have an overwhelming feeling of dread or doom, or experience a sense of sudden high anxiety that overwhelms you?

Anxiety disorders are found in approximately 30% of patients with intractable pain (usually in the form of generalized anxiety or panic disorder). More than 50% of patients with anxiety disorders also have a current or past history of major depression or another psychiatric disorder. Alcohol and substance abuse are the most common co-morbid diagnoses; consequently, recognition and treatment of co-morbid depression and substance abuse are critical to long-term treatment outcome.

A variety of agents, including TCAs, selective serotonin reuptake inhibitors (SSRIs), serotonin–norepinephrine reuptake inhibitors (SNRIs), mirtazapine, and clonazepam, alone or in combination, improve panic, anxiety, and depression as well as neuropathic pain, muscle tension, and sleep. Anxiety that results from disruptions of body integrity, sense of self, or attachment to caregivers occurs in one third to one half of patients with chronic pain. Disruption in body integrity or sense of self can block efforts at physical and emotional rehabilitation and they require a pragmatic psychodynamic treatment. Anger is often linked to anxiety, although it is typically denied and expressed in terms of somatic symptoms. One can uncover affect quickly by holding up a clenched fist and asking the patient what he or she would do with it. The response will often be telling regarding denied anger. SSRIs are helpful with anger, anxiety, and mood disorders. Existential anxiety can increase when cancer is first diagnosed, when death nears, or when pain engenders feelings of helplessness. Spending time with the person, telling the truth, accepting the situation, and reconnecting with family members (parents and children) often decreases existential anxiety.

Somatization Disorder

The somatoform disorders (see Chapter 16) comprise a group of disorders in which complaints and anxiety about physical illness are the predominant clinical features. These complaints exist in the absence of sufficient organic findings to explain the pain. Pain may be present in somatization disorder, conversion disorder, hypochondriasis, and pain disorder. Somatoform disorders occur in 5% to 15% of treated patients with chronic pain, and somatizers account for 36% of all cases of psychiatric disability and 48% of all occasions of sick leave.[42]

Among somatizers, pain in the head or neck, epigastrium, and limbs predominates. Visceral pain from the esophagus, abdomen, and pelvis associated with psychiatric co-morbidity, especially somatoform disorders, can be challenging to diagnose.[43] Missed ovarian cancers, central pain following inflammatory disorders, and referred pain are often overlooked because of the nonspecific presentations of visceral pain. In one study, 64% of women with chronic pelvic pain reported a history of sexual abuse.[44] The two most common co-morbid conditions associated with somatoform disorders among MGH pain patients are MDD and anxiety disorders. Surprisingly, drug and alcohol abuse and personality disorders are not significantly associated with somatoform disorders. Patients with somatization disorder consume health care resources at nine times the rate of the average person in the United States.[45]

Sufferers from somatoform disorders often have painful physical complaints and excessive anxiety about their physical illness. Most of their pain complaints to physicians do not have a well-defined cause, and a psychiatric diagnosis is often particularly difficult to establish (Table 18–4).

Conversion Disorder

Conversion disorder may be manifested as a pain syndrome with a significant loss or alteration in physical function that mimics a physical disorder. Conversion symptoms can include paresthesia, numbness, dysphonia,

TABLE 18–4 Somatoform and Related Disorders

DISORDERS	DIAGNOSTIC TIPS
Somatization disorder	Pain in at least 4 different sites of the body, 2 GI symptoms (other than pain), 1 sexual symptom, and 1 pseudoneurologic symptom
Conversion disorder	Real disease and conversion symptoms often co-occur
	An undiagnosed medical condition might underlie the psychiatric diagnosis
	Deciding if psychological factors are a cause or a response is often impossible in patients with chronic pain
	Culturally determined stress responses, numbness, total body pain, weakness, abasia-astasia, fainting, voices, and nonepileptiform seizure activity are transient and not included as conversion disorders
Hypochondriasis	Transient hypochondriasis is particularly common in the elderly
	Psychosis and depression may be concealed because of the patient's fears
Pain disorder	Pain is enmeshed in Axis II problems and complicated by drugs (narcotics, benzodiazepines, or alcohol)
	Central and visceral pain, especially pelvic pain, can mimic somatoform disorders
	Pain can improve with psychotropic drugs or psychological techniques without having a psychiatric diagnosis
Malingering and factitious disorder	Pseudomalingering with dissociative features (Ganser syndrome) manifests with malingering, but it also underlies real psychiatric illness
	Some classify it as a conversion, dissociative, or factitious disorder

dizziness, seizures, globus hystericus, limb weakness, sexual dysfunction, or pain. If pain or sexual symptoms are the sole complaints, the diagnosis is pain disorder or sexual pain disorder rather than conversion disorder. Pain, numbness, and weakness often form a conversion triad in the pain clinic.

Psychological factors are judged to be etiologic for the pain when a temporal relationship between the symptoms and a psychosocial stressor exists—the person must not be intentionally producing the symptom. A mechanism of primary or secondary gain needs to be evident before the diagnosis can be confirmed. *La belle indifférence* and histrionic personality traits have little value in making or excluding the diagnosis of conversion. A conversion V on the MMPI denotes the hypochondriacal traits and relative absence of depression that accompany conversion. Evoked responses, an electromyogram (EMG), an electroencephalogram (EEG), MRI and PET scans, and repeated physical examinations are useful for identifying patients with misdiagnoses of hysteria.[46]

Hypochondriasis

Hypochondriasis involves the persistent erroneous belief that one has a serious illness. Generalized anxiety disorder and depression are the common causes of hypochondriasis-like presentations.[47] Head and orofacial pain, cardiac and gastrointestinal (GI) pain, and feelings of pressure, burning, and numbness are common hypochondriacal concerns. Therefore, attention to head and neck pathology, cancer, visceral pains, degenerative disorders, and CNS syndromes should be ongoing.

Care of the hypochondriac begins with a comprehensive differential diagnosis and becomes longitudinal; the persistence of vague complaints helps to rule out the most serious diseases and to set the stage for an alliance with the patient by demonstrating an open and critical mind. A pain drawing may help reveal psychotic somatic beliefs. The psychiatrist should reassure and not reject the patient; one should label behavior that produces more symptoms maladaptive or dangerous and should openly discuss psychodynamic factors.

Pain Disorder

Pain disorder is defined in DSM-IV as a syndrome in which the focus of the clinical presentation is pain that causes significant impairment in occupational or social function, marked distress, or both. Organic pathology, if present, does not explain the pain or the associated social and occupational impairment. Pain disorder has three diagnostic subtypes: psychological, nonpsychiatric, and combined. In psychological pain, psychological factors play an important role in the onset, severity, exacerbation, or maintenance of the pain. Nonpsychiatric pain is associated with a general medical condition. If psychological factors are present, they play only a minor role in the genesis of pain. This medical pain disorder is coded as an Axis III diagnosis.

Pain disorder, as it is currently known, has been variously named during different epochs. Examples of such labels include psychogenic pain disorder, somatoform pain disorder, and pain behavior.[48] When behavioral disability predominates, chronic pain syndrome is the behavioral description of this same syndrome. The meandering history of nomenclature is best understood as reflecting the mix of pain behaviors, as well as interpersonal and affective characteristics, that emphasize disability and entreat attention from others.

Psychological antecedents of this syndrome can include a history of physical abuse, counterdependent personal relationships, a family history of alcoholism, and a personal developmental history of attachment problems. Co-morbid diagnoses should be sought, particularly depression, anxiety, and substance abuse. Treatment must address the triad of self-defeating behavior, affective dysfunction, and psychodynamic conflicts, which causes poor coping, disability, and disruptive rehabilitation efforts. Common treatments and their reasons for possible failure are outlined in Table 18–5.

TABLE 18–5 Treatment and Reasons for Treatment Failure in Pain Disorder

PROBLEM	REASONS (NOT MUTUALLY EXCLUSIVE)	TREATMENT
Physical diagnosis	Ignorance, transference, narcissistic fears, or dishonesty Drug abuse	Clarify which demands are and are not ignored, sidelined, mistreated Refer, if at any impasse Possible drug abuse
Behavior is abnormal	Axis I DSM-IV not applied Relaxation, yoga, physical rehabilitation methods have not been used No common ground or treatment plan agreed to	Reassure the patient about normal suffering, coping, rehabilitation, and distinguish from Axis I symptoms, ensuring treatment
Self-esteem hurts more than does the body	Coping methods have not been addressed The physician–patient relationship has not been acknowledged as a treatment aspect Locus of control is thought to be external	Address the muted anger Identify denial, avoidance, rationalization, projection Interpret the unrequited wish for dependency versus self-control
High affective suffering	Major depression or mood disorder complicating general medical condition might not get addressed because of the somatic focus and the patient's fear of being psychiatrically dismissed	Treat the covert depression Identify the hateful patient's psychodynamics

Factitious Disorder with Physical Symptoms

Factitious disorder with physical symptoms involves the intentional production or feigning of physical symptoms. Onset is usually in early adulthood, with successive hospitalizations forming the lifelong pattern. The cause is a psychological need to assume the sick role, and the intentional production of painful symptoms distinguishes factitious disorder from somatoform disorders, in which intention to produce symptoms is absent. Renal colic, orofacial pain, and abdominal pain are three of the common presenting gambits in factitious disorder; of these, abdominal pain and a scarred belly herald the diagnosis most often. Despite the seeming irrationality of the behavior, those with factitious disorder are not psychotic.

Pain may be described as occurring anywhere in the body, and the patient often uses elaborate technical detail to captivate the listener with *pseudologia fantastica*. Narcotic-seeking behavior, multiple hospitalizations under different names in different cities, inconclusive invasive investigations and surgery, lack of available family, and a suave truculence are characteristic of this disorder. An assiduous inquiry into the exact circumstances of the previous admission and discharge leads to a sudden outraged discharge against medical advice. Typically, there is no effective treatment. If the patient is willing to receive care, however, psychotherapy is the treatment of choice, coupled with addiction treatment when there is underlying opioid abuse or dependence.

Malingering

In malingering, the patient fakes a complaint, although no pain is felt, because of an external incentive (e.g., to obtain money, drugs, or privilege or to avoid work). The conscious manipulation by malingerers precludes much diagnostic help from amytal interviews or hypnosis because the patient willfully withholds information. The malingerer typically refuses psychological tests; this raises suspicion even before a diagnosis is made. Even when the patient agrees to testing, the MMPI can be skewed to normality by the clever malingerer, although differences (more than 7 points) between obvious and subtle scale scores and high L, F, K scale scores (T >70) may be suggestive nonetheless. A mnemonic for suspicion of the diagnosis is WASTE (*w*ithholding of information; *a*ntisocial personality; *s*omatic examination inconclusive and changeable; *t*reatment erratic with noncompliance and vagueness; *e*xternal incentives exist, such as occur in a medicolegal context). The psychiatrist's familiarity with the neurologic examination is always useful, but it is critically important for the diagnosis of malingering when nonanatomic findings arise. Once an organic etiology has been ruled out, careful scrutiny of old records and calls to previous physicians might unearth evidence of similar behavior in the past. Similar to lying, malingering tends to be a character trait used in times of stress from early adolescence through the senium. Once malingering is revealed, psychotherapy can be offered; unfortunately, noncompliance is typical.

Dissociative States

Dissociation is commonly caused by psychological trauma, and it involves a disturbance or alteration in the normally integrative functions of identity, memory, or consciousness. Pelvic pain, sexual pain disorders, headache, and abdominal pain are the most common pain complaints in developmentally traumatized patients. Walker and associates[49] reported that in 22 women with chronic pelvic pain, 18 experienced childhood abuse. Of the 21 women selected as controls (i.e., without pelvic pain), 9 had childhood abuse ($P < .0005$). Dissociation, somatic distress, and general disability were more common in the group with pain. Denial makes the diagnosis of dissociative disorders in pain patients a longitudinal process, because truth is shared slowly with the physician and only when the patient can tolerate it. Signs of an underlying dissociative disorder are periods of amnesia, nightmares, and panic as well as anxious intolerance of close personal relationships.

Psychosis

Pain can also be a symptom of psychosis. This is a problem of misreporting a delusional symptom as a physical ailment, hence demonstrating the need for assiduous screening of delusional thinking. The diagnostic problems are fourfold.

First, DSM-IV profiles of schizophrenia, affective psychoses, and organic psychoses are not typical presentations for psychosis with pain; covert delusional thinking and anomie may be the only symptoms. Second, psychotic thinking may be masked by denial, rationalization, concrete thinking, and fear; historical anamnesis is the last thing the patient wants. Third, the last person the patient wants to see is a psychiatrist because the patient knows the pain "is not in my head." Finally, the pain belief is erroneously attributed to hypochondriasis. The psychiatrist must always consider pain as a delusional symptom when there is a bizarre, variable distribution to the symptom (best proven by getting the patient to draw a picture of the pain); when the patient is not eager to have the discomfort removed; and when the patient complains persistently with vagueness and a flat affect. The question "What have you learned from the other doctors" leads to no useful information.

GENERAL PRINCIPLES OF PAIN THERAPY

Pain Is Not Psychological by Default

The patient should not have his or her pain called "psychological" or "supratentorial" merely because it is not understood or because it is unresponsive to treatment. The physician should assure the patient that there is no question about the degree of suffering involved. Psychological factors might play a role, but this by no means diminishes either the quality or the quantity of pain the patient endures. Education about the close relation of psyche and soma in the CNS is often useful to establish an effective doctor–patient relationship.

Long-standing pain is difficult to assess largely because what we learn about pain is based on our concept of acute pain. The patient with acute pain moans, writhes, sweats, begs for help, and gives every appearance of being in great distress. Those nearby someone in acute pain typically feel an urge to help. When pain persists over days and weeks, the individual adapts to it, often without realizing. The patient becomes able to sit in the physician's examining room and complains of agonizing pain while giving little or no evidence of actually being in agony. This adaptation means that the pain has become bearable, although there seems to be no change in intensity. This may be accounted for by several explanations: The sensation may become intermittent, the CNS inhibits the pain, or the sufferer becomes more capable of using distraction. It is ironic that the capacity to adapt to severe pain is often the patient's undoing because it causes the examiner to doubt the patient's veracity. The sufferer now is in the position of having to prove that he or she is in pain. The patient feels himself or herself to be on trial. To counter this end, the physician must know the pathophysiology of pain and employ the full range of neurologic, pharmacologic, and psychological therapies available.

Care Does Not Only Involve Managing Symptoms

An important principle of pain management is to assure the patient that treatment will continue even if there is no immediate improvement. The physician should also guard against being affected by the patient's sense of discouragement. One of the fears expressed by many patients who suffer from chronic pain is that of abandonment; they believe that if they do not improve, the physician will no longer see them. In this case, an endless series of medications, without continuing examination, psychotherapy, or critical thinking, is tantamount to noninvolvement or to abandonment. Education about relaxation techniques, yoga, acupuncture, TENS, ultrasound, and massage all have their place in the therapeutic armamentarium. The value is not only in soothing the pain but also in helping the person to feel more in control, that is, less of a victim, and to become an active, educated participant while under the physician's care.

Placebo Response Accompanies a Variety of Syndromes

Few phenomena are as misunderstood as the placebo trial. A placebo trial shows whether or not the patient is placebo-positive; it does not prove that the pain is not real or that the person is either an addict or a malingerer. Similarly, it does not demonstrate that the patient would not benefit from an active medication. The trial is of no assistance in separating psychogenic from organic pain because the placebo response cannot be linked with any type of psychopathology. In fact, patients with depression, somatoform disorder, or other varieties of emotional disturbance are no more apt to be placebo responders than are so-called normal people.

Whether the pain is from a metastatic lesion or is part of a major affective disorder, relief is experienced by the placebo responder. Following surgery, about one patient out of three obtains pain relief from saline or from some other inert substance and is therefore considered placebo-positive. For instance, Evans and Hoyle[50] used sodium bicarbonate to treat patients suffering from angina pectoris. In 38% of their subjects, they found this agent to be as effective as nitroglycerin.

The time-worn custom of slipping in a few saline shots for morphine and calling the deception a placebo trial only demonstrates the ignorance of the perpetrator. If a shot of sterile saline is substituted for a dose of narcotics and the patient responds by obtaining relief, the nature of his or her pain will be questioned even though relief is based on the conditioned response. Moreover, placebo effect and true effects are not independent. The mechanism for the placebo response is possibly the endogenous opioid pain-inhibiting system and is therefore co-influenced by psychological expectation. Placebo analgesia has been shown to be reversed with the opioid antagonist naloxone.[11]

In a valid placebo trial, the inert substance must be given to the patient in a randomized manner along with the usual narcotic under double-blind conditions. Without this control, the placebo trial is useless. The only place for a placebo trial is an informed blinded experiment in which both the patient and the physician have discussed the intention and methodology and are in agreement to find the best treatment for a patient's pain disorder. One of the chief hazards of placebo use is that the patient may feel tricked if he or she discovers that a placebo has been administered. In this case, it is natural for the patient to feel

on trial and wrongly accused; there is no psychiatric fix for this error once it has occurred. The physician who ordered the placebo needs to discuss it with the patient.

Deafferentation Surgery Is Usually Not the Answer

An abiding principle in the treatment of chronic pain is to avoid surgery whenever possible. Few surgical procedures on the CNS are persistently definitive in the cure or control of pain, and most carry with them a tax that is sometimes worse than the pain itself. In particular, CNS pain is notoriously refractory to surgery that interrupts afferent pain pathways. The pain is often made worse by procedures (such as neurectomies, rhizotomies, tractotomies, and cordotomies). Surgery, with the one exception of cingulotomy, is not a treatment for depression that manifests as pain. A central procedure, such as cingulotomy performed stereotactically using radiofrequency lesions, may be useful for intractable pain, especially because it has a low risk of psychiatric and physical morbidity. Personality changes, mental dulling, and memory impairment are rare. Unfortunately, even when pain is reduced with cingulotomy, it can return within 3 to 6 months. To exemplify this multiform plasticity of pain, consider the following account of an extraordinary case.

CASE 1

RC, a 28-year-old mechanic, was thrown from his motorcycle en route to his wedding. Injury occurred to his brachial plexus and arm, requiring an amputation at the shoulder. He then developed severe phantom limb pain. Six months later, the stump was revised and a neurectomy performed; the pain, however, remained unaltered. The nerve was then severed further into the stump with similar result. An unsuccessful rhizotomy was then performed, followed by a chordotomy with the same outcome. He embarked on individual psychotherapy for a year, but there was no improvement. After six sessions of electroconvulsive therapy (ECT), the pain was only intensified. A higher cervical chordotomy was performed without success, and then a mesencephalic tractotomy; again, there was no relief. He next had both dorsomedial thalamic nuclei ablated using stereotactic electrocautery. He emerged from this procedure with his personality intact but still with his original pain. Then electrolytic lesions were made bilaterally in the inferior mesial quadrant of the frontal lobe in stages; still, the pain remained. Following this, he had a left radiofrequency amygdalotomy followed by a left cingulotomy. Nonetheless, the pain continued as before. The pain remained for 4 years after the accident, as pristine as it was 2 weeks after the injury.

Talking and Listening Are Helpful

A strategy to evaluate the feelings and behavior observed in the pain patient is as necessary as the strategy for evaluating physical aspects of the pain. The skill required is not only a matter of diagnosing the major psychiatric illnesses that can manifest with pain—these patients often have a maladaptive style of interaction that requires a different kind of interpretive skill—but also a question of the physician's ability to relate to the long-suffering pain patient who shows poor judgment of surgical risk, denies anger, and rapidly alternates between idealizing and denigrating the medical caretaker. The fluctuations of both mood and cooperation often encountered in the clinical interview are symptomatic of the patient's damaged self-esteem or his or her injured narcissism. Patients with chronic pain invariably feel damaged not only in the body part afflicted with discomfort but also in self-image and spirit, a phenomenon known as narcissistic injury.[51] The techniques for interviewing the narcissistically injured pain patient are designed to establish a working relationship. They allow an accurate medical history to be elicited, mistrust between physician and patient to be avoided, an effective treatment plan to be developed, and the outcomes through compliance and education to be enhanced.

The interviewer should allow the patient to tell his or her own story. An initial degree of catharsis may be helpful in decreasing the patient's anxiety and in giving the physician a sense of the patient's character. The physician must actively facilitate an alliance with the patient while still maintaining neutrality and avoiding misplaced sympathy. The patient's underlying feelings of fear, anger, resentment, and mistrust are best uncovered by asking how others view the situation, essentially a counterprojective method. This approach sometimes bares unpleasant affects without the use of intrusive questions from the physician. Labeling overt and covert roles assigned by the patient to the physician is an important early intervention. Specifically, this means that the physician should point out when the patient is attributing unrealistic curative powers to him or her or appears to believe that the physician is indifferent to the patient's suffering. The longer one waits to confront these fantasies, the less effective any intervention will be. Expression of affect should be encouraged, and the physician should help the patient express the feelings he or she is having but does not want to acknowledge. The physician's assertive pursuit of the patient's true feelings avoids giving the appearance of unqualified support to feelings that need expression. Too much support not only bypasses psychological problems but also can actually increase conflicted feelings over control, dependence, and frail self-esteem. The physician's kindness should not be allowed to become a problem for the patient.

Optimal care for intractable pain requires the ability to process neurologic and psychiatric data while delineating and responding to the phrase-by-phrase manifestations of suffering and pain behavior. In essence, being able to get patients to talk about what they are angry about is just as important as discussing their insomnia or disk herniation. Progress occurs with these needy, angry patients only when there is clear processing and separation of the reality-based facts of the case from unrealistic expectations. In that way, every clarification of an unrealistic idea can be an introduction to a more-realistic alternative. The overall goal is to improve the patient's self-awareness and capacity for insight, thereby gaining control.

MEDICATION FOR PAIN: ANALGESIA AND ADJUVANTS

Judicious and effective use of medicine in patients with chronic pain rests on the concise evaluation of the four main components of the pain complaint: nociceptive pain, and the CNS mechanisms of pain, suffering, and pain behavior.

In its most elemental form, the medical management of these four components employs opioids, anticonvulsants, antidepressants, and behavioral treatment. Nonsteroidal antiinflammatory drugs (NSAIDs), aspirin, and nerve blocks are often helpful in the early stages of these illnesses. Opioids are, however, the most effective medicine for these pains when the severity increases.

Nonsteroidal Antiinflammatory Drugs

The World Health Organization (WHO) has established a three-step guideline for pain treatment (Figure 18–4). Step 1 involves the use of NSAIDs, aspirin, or acetaminophen. Step 2 adds codeine to the NSAID, with other adjuvants (e.g., TCAs, other antidepressants, antiepileptic medications, and stimulants). Step 3 employs narcotics with adjunctive medication. Conceived for cancer pain, and reported efficacious in 90% of cancer patients, the three steps are a useful template for many kinds of acute pain, adjusted for the particular pain mechanism being treated. NSAIDs are useful for acute and chronic pain (e.g., inflammation, muscle pain, vascular pain, and posttraumatic pain), or when the physician wants to use a potent nonnarcotic analgesic. NSAIDs are generally equally efficacious and have similar side effects.[52]

Side Effects

Most NSAIDs can cause bronchospasm in aspirin-sensitive patients, induce gastric ulcers, interact with angiotensin-converting enzyme (ACE) inhibitors (thereby contributing to renal failure), precipitate lithium toxicity, and impair renal function in the long term. NSAIDs can elevate blood pressure in patients treated with β-blockers and diuretics. The exception to this general rule is the nonacetylated (nonaspirin) salicylates that do not inhibit the synthesis of prostaglandins. These include choline magnesium trisalicylate and diflunisal; these agents do not cause bronchospasm in aspirin-sensitive patients, precipitate renal failure, or inhibit platelet aggregation. Certain NSAIDs, however, have features that make some preferable over others in particular situations. The discovery of the enzyme cyclooxygenase (COX) isoforms 1 and 2 led to the increased use of selective COX-2 inhibitors. COX-2 tends to facilitate the inflammatory response selectively, and it has been argued that the use of new agents (paracoxib, etoricoxib, lumiracoxib, and celecoxib) might increase GI safety.[53]

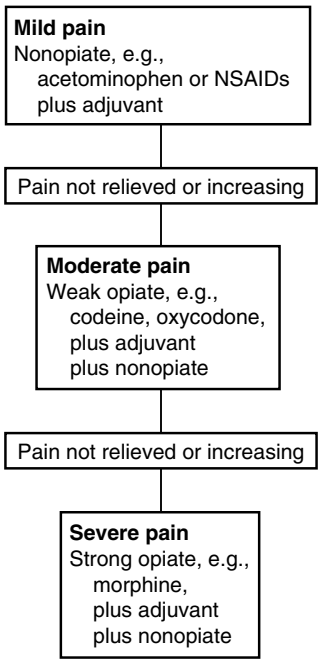

Figure 18–4. The analgesic ladder. *(From Borsook D, Lebel AA, McPeek B:* MGH handbook of pain management, *Boston, 1995, Little Brown).*

Based on currently available data, the U.S. Food and Drug Administration (FDA) has concluded that an increased risk of cardiovascularand cerebrovascular events has been demonstrated for all of the COX-2–selective NSAIDs (including rofecoxib, valdecoxib, and celecoxib).[53] Rofecoxib was voluntarily removed from the market in 2004 following the finding of increased cardiovascular events compared with placebo in a long-term study. Valdecoxib was voluntarily withdrawn from the market in 2005, after the FDA concluded that the overall risk-versus-benefit profile for the drug was unfavorable. Although an increased risk of cardiovascular events has also been demonstrated with celecoxib, the FDA has found that the benefits of celecoxib outweigh potential risks in properly selected and informed patients.

Special Features

Synergistic combinations of acetaminophen, aspirin, and caffeine (e.g., Excedrin) are the cornerstone for temporary relief of pain (e.g., headaches and muscle pain) and potentiation of the effects of narcotics. They do, however, have a limit on dosing and have only moderate potency; they are also not well tolerated by those who are very sick. NSAID variations then need to be considered. For a list of NSAIDs, see Table 18–6.

Choline magnesium trisalicylate (1000 to 1500 mg) is safe in aspirin-sensitive patients, and it does not prolong bleeding. Misoprostol can reduce GI erosions in patients on maintenance NSAIDs, but its use can be limited by diarrhea, pain, and flatulence in about one third of patients. Ibuprofen (800 mg) is a rapid-release agent that produces higher blood levels over the first half hour than the other preparations at equal dosage. Ketorolac (up to 30 mg every 6 hours) intramuscularly followed by oral dosing has a rapid onset and a high potency, enabling it to be substituted for morphine; 30 mg of ketorolac is equivalent to 10 mg of morphine. It should be used for no more than 5 days.

Extended-release preparations can be useful when long, steady analgesia and simple dose regimens are needed (e.g., nabumetone, oxaprozin, ketoprofen, piroxicam). Naproxen (375 to 500 mg twice a day with enteric-coated, delayed-release tablets) can be well tolerated over time. Ketoprofen (200 mg) extended-release tablets can be taken once a day, but they are not intended for patients with kidney disease or for those older than 75 years.

Ibuprofen works well as a narcotic adjuvant for bone pain. Naproxen (up to 1500 mg a day), but not flurbiprofen, has also had positive results for bone pain.

The newer COX-2 inhibitors may cause fewer GI problems compared to other NSAIDs. Celecoxib does not impair platelet function. Paracoxib, etoricoxib, and lumiracoxib are not currently available in the United States.

TABLE 18–6 Properties of Aspirin and Nonsteroidal Antiinflammatory Drugs

DRUG	DOSE (mg)	DOSAGE INTERVAL (h)	DAILY DOSE (mg/day)	PEAK EFFECT (hr)	HALF-LIFE (hr)
Aspirin	81–975	4	4500	0.5–1	0.25
Celecoxib	100–200	12	1200	1	11
Diclofenac	25–75	6–8	200	2	1–2
Diflunisal	250–500	12	1500	1	13

Fenoprofen	200	4–6	3200	1–2	2–3
Flurbiprofen	50–100	6–8	300	1.5–3	3–4
Ibuprofen	200–400	6–8	3200	1–2	2
Indomethacin	25–75	6–8	200	0.5–1	2–3
Ketoprofen	25–75	6–8	300	1–2	1.5–2.0
Ketorolac, oral*	10	6–8	40	0.5–1	6
Ketorolac, parenteral*	60 load, then 30	6–8	120	0.5	6
Meclofenamic acid	500 load, then 275	6–8	400	1	2–4
Mefanamic acid	500 load, then 250	6	1250	2–4	3–4
Nabumetone	1000–2000	12–24	2000	3–5	22–30
Naproxen	500 load, then 250	6–8	1250	2–4	12–15
Naproxen sodium	550 load, then 275	6–8	1375	1–2	13
Oxaprozin	60–1200	24	1800	2	3–3.5
Phenylbutazone	100	6–8	400	2	50–100
Piroxicam	40 load, then 20	24	20	2–4	36–45
Sulindac	150–200	12	400	1–2	7–18
Tolmetin	200–400	8	1800	4–6	2

Adapted from Borsook D, Lebel AA, McPeek B: *MGH Handbook of Pain Management*, Boston, 1995, Little, Brown.
*Use no longer than 5 days.

Opioids

Opioids help some cancer patients as well as those with non–cancer-related chronic pain.[54,55] Cancer pain is the most common indication for maintenance narcotics.[56] Acute, severe, and unremitting pain also requires opioid treatment, as outlined in the WHO analgesic ladder. At times, narcotics may be the only effective treatment for chronic, nonmalignant pain, such as the pain associated with postherpetic neuralgia, degenerative disorders, and vascular conditions.[57] Bouckoms and colleagues[58] demonstrated that long-term oral narcotics provide effective relief of nonmalignant pain in about two thirds of those treated. Nociceptive pain, absence of depression, and absence of any drug abuse were all significantly associated with efficacy of long-term narcotic treatment. Patients with neuropathic pain or major depression fared especially poorly; a bad outcome was four times more likely than a good outcome. Even when patients were carefully selected (i.e., with a lack of previous addiction or gross personality disorder), one third of patients developed abuse, tolerance, or addiction over a 3-year period. Even so, drug abusers with chronic pain can still benefit from physician-prescribed narcotics for their physical pain if it stops them from turning to illicit supplies. These patients might require specific nonnarcotic prescriptions for their neuropathy and depression if gains are to be made.

Narcotic Potencies

Codeine is a good narcotic for mild to moderate pain, but it has limited efficacy for severe pain. Morphine is the narcotic of choice for acute and chronic pain because it is well known and has a good safety profile. Beyond these starting points, the basic principles of narcotics are as outlined in Table 18–7.

Principles of Narcotics Administration

Potency and Administration

Potency and administration are consistent with the characteristics of the drug, its half-life, and absorption by different routes; such knowledge helps to ensure that the dosage schedule is consistent with these parameters.

Oral Potency

Oral potency must be high so that parenteral use can be avoided if possible. Methadone is a good first choice because of its oral potency and relatively slow clearance. Morphine, hydromorphone, and levorphanol may be useful alternatives for initial treatment. Once oral doses have been initiated and titrated to a satisfactory level (e.g., dosing of morphine or methadone every 4 hours), the analgesic effect needs to be sustained by minimizing fluctuations in blood levels and the variable effects of dosing schedules. Morphine sulfate controlled-release (MSC) is ideal for this homeostasis because it is released more slowly than conventional oral morphine. Furthermore, morphine's effect is not significantly affected by minor hepatic disease. Fifty percent of the morphine in MSC reaches the CNS after 1.5 hours, three times longer than it takes conventional oral morphine to reach the CNS. Steady state is reached with MSC in about 1 day. A steady state with MSC at any fixed dose and dosing interval has a lower maximum blood concentration than does conventional morphine, thereby reducing fluctuations in blood levels. MSC does not release morphine continuously and evenly, so that a dosing schedule of every 12 hours has more peaks and troughs than conventional oral morphine given every 4 hours. Chewing or crushing MSC further increases erratic release. MSC should not be given less than every 12 hours.

TABLE 18–7 Potencies and Special Features of Narcotics

DRUG	PARENTERAL (mg EQUIVALENT)	ORAL (mg)	DURATION (hr)	SPECIAL FEATURES
Morphine	10	30	4	Morphine sulfate controlled release has 12-hr duration
Codeine	120	200	4	Ceiling effect as dose increases, low lipophilic
Oxycodone	4.5	30	4	Oxycodone controlled release has 8-12-hr duration (10, 20, 40 slow release mg)
Hydromorphone	2	8	5	Suppository 6 mg = 10 mg parenteral morphine
Levorphanol	2	4	4	Low nausea and vomiting, low lipophilic
Methadone	5	10	2	Cumulative effect; day 3–5 decrease respiration
Meperidine	100	300	3	κ, proconvulsant metabolite, peristaltic slowing and sphincter of Oddi dysfunction
Fentanyl	0.1	25 μg SL	1 (patch 72 hr)	50 μg patch = 60 mg/day morphine IM/IV
Sufentanil	Not recommended	15 μg SL	1	High potency with low volume of fluid
Propoxyphene	Not available	325	4	High dose leads to psychosis
Pentazocine	60	150	3	κ, σ agonist-antagonist, nasal 1 mg q1–2h
Butorphanol	2	N/A	3 (IM), 2 (NS)	μ, κ, σ, agonist- antagonist, nasal 1 mg q1–2h
Buprenorphine	0.3	0.3	4–6	μ-partial agonism; κ-antagonism; can precipitate withdrawal in patients already on chronic opioids
Tramadol	Not available	150	4	μ-agonist, decreased reuptake 5-HT and NE, CYP metabolism
Nalbuphine	10	N/A	3	Agonist–antagonist

CYP, Cytochrome P450; *5-HT*, serotonin; *N/A*, not available; *NE*, norepinephrine; *NS*, nasal; *SL*, sublingual.

Avoid As-Needed Dosing

A steady state of narcotic blood level requires approximately four half-lives to achieve consistency, and a steep dose–response curve makes pain relief erratic (e.g., if one dose is missed, it can take 23 hours to return to therapeutic analgesia). Dosing on an as-needed basis makes steady relief impossible. It also predisposes the patient to drug-respondent conditioning and to subsequent behavior problems.

Toxicity

Morphine and dihydromorphone uncommonly cause toxicity and hence are prescriptions of choice. Even so, when glomerular filtration rate is poor and morphine or hydromorphone doses are high, toxicity can occur, even when equivalent doses of morphine are used without signs of toxicity. Meperidine hydrochloride should be avoided in difficult cases because of its short duration of action (2 to 4 hours) and because even at normal doses its principal metabolite (normeperidine) can cause irritability, auditory and visual hallucinations, agitation, confused thinking, disorientation, hypomania, paranoia, and muscle twitches, in addition to partial and generalized seizures.[59,60] This CNS excitement is more likely to occur in patients with malignancy or renal impairment or when the drug is given intravenously and the dose exceeds 300 mg/day for more than 3 days—all conditions in which there may be significant accumulation of the proconvulsant normeperidine with repeated dosing. Methadone, safe and effective for analgesia on day 2, can accumulate and cause significant respiratory depression by day 5. Troubleshooting checklists for opioids may be required when the basic principles mentioned have not worked.[61]

Are Opioids the Drugs of Choice in This Case?

Unduly long clinical trials and ongoing suffering may be avoided by giving the patient 10 mg of IV morphine as a single-blinded test dose. This is a diagnostic procedure designed to determine if narcotics will relieve the pain. If there is a positive result with relief of pain, one concludes that morphine works well enough to continue its use. A negative outcome might result in a repeat dose of morphine at 20 mg to ensure that it was not just tolerance that failed to produce a benefit at 10 mg. In a doubtful case, one can give 0.4 mg of IV naloxone to confirm the lack of an opioid effect on pain. If there is neuropathic pain, for example, opioids might not produce a good enough response at normal doses. In about 50% of patients with intractable pain, opioids do not have a good enough analgesic effect. In a minority, it is the anxiolytic effect rather than the analgesic effect that is helpful.

Dosing

Prescriber fear and ignorance are the usual reasons that analgesics are given at inadequate dosages and frequencies. Appropriate dosing requires knowledge of the potency and half-life of the drug. Common errors that occur at critical moments include failure to adjust the dosage when switching from parenteral to oral use (e.g., not tripling the dose of morphine when switching from IM to oral dosing); failure to administer the drug at longer intervals than its half-life (e.g., methadone's analgesic half-life is 6 hours; consequently, methadone is needed at least four times a day when it is given for pain, not once a day as when it is given for opioid addiction); and underdosing when beginning MSC

or fentanyl patches because both require at least 24 hours to reach steady-state (supplementary opioids are required for the first 24 hours).

Drug Delivery

An important question to bear in mind is whether the method of administration and type of opioid have been optimized. The most common problem in severe pain is the threefold to eightfold variability of IM absorption. This can be decreased by using agents that are hydrophilic (e.g., morphine, hydromorphone) rather than lipophilic (e.g., fentanyl, methadone, meperidine). When more-lipophilic agents, such as methadone, are used intramuscularly, injections into the deltoid rather than the gluteus muscle are preferable. If an erratic response occurs, it might be due to inconsistent drug delivery. Alternative methods include delivery of the drug intravenously, sublingually, intrathecally, ventricularly, or transdermally. For example, Kunz and colleagues described the innovative use of sublingual sufentanil, 25 mg every 3 minutes (for three doses) for severe but episodic pain.[62] The drug and route were preferable to patient-controlled analgesia (PCA), fentanyl sublingually, or MSC because the volume of fluid was small, speed of onset was within 1 minute, and the half-life was short (and therefore not sedating the rest of the day); in addition, the cost was comparable to PCA, albeit more expensive than sublingual fentanyl. The patient could get out of bed and remain alert and comfortable with a low-tech intervention that is ideal for hospice or for home care.

Tolerance or Excessive Sedation

The age of the patient is an important factor in the efficacy of the drug. The duration of effect can double as age increases; as it does, so does the analgesic effect in a 70-year-old versus a 20-year-old. Opioid adjuvants (e.g., methylphenidate) can decrease or increase (e.g., with antidepressants) sedation.

Mixed Agonists and Antagonists

Pentazocine and butorphanol are commonly used opioids because of their mixed antagonist–agonist properties. Not only are they less potent than standard opioids, but also, if combined with standard opioids during a period of transition, they can cause the patient to develop withdrawal symptoms, an acute confusional state, or even psychosis. Older people are particularly susceptible. Avoidance of mixing agonist opioid drugs with agonist–antagonist agents obviates this problem.

Addiction

The risk of opioid addiction in a general population of medically ill patients is approximately 0.3%. Therefore, considering the patient as an addict on the basis of difficulties with managing narcotics should be done cautiously. Acute sympathetic symptoms from drug withdrawal are more likely to be problematic than addiction per se. Rather than addiction, unrecognized depression alone or co-morbid with anxiety is a more common, immediate explanation for the excessive need for opiates.

Oxycodone has attracted significant attention in the media due to its addiction potential. Clinical practice and research trials show that it is a good medication for pain due to its efficacy, fairly good side-effect profile, and short onset of action. In patients who cannot tolerate or respond to other opioids it remains a good option.[63]

Opioid Adjuvants

Opioid adjuvants are indicated when toxic or pharmacokinetic factors limit further increases in the patient's opioid dosage or when pain remains uncontrolled by opioids in combination with other secondary treatments, such as decompression surgery, nerve blocks, or use of anxiolytic drugs. The choice of adjuvant should be individualized; one should aim for the simplest and most potent combination of drugs. The selection of the adjuvant depends on the symptoms associated with the pain; the character of the pain; and the physician's knowledge of any special issues, risks, drug interactions, or special mechanisms.

Guidelines for Narcotic Maintenance Adjuvants

Maintenance narcotics should be considered only after other methods of pain control have proven unsuccessful. Alternative methods vary from case to case but typically include NSAIDs; oral, transdermal, IV, intrathecal, or epidural opioids; membrane-stabilizing drugs; monoaminergic agents and local nerve blocks; nerve stimulation; and physical therapy.

Narcotics should not be prescribed for addicts unless there is a new major medical illness with severe pain (e.g., cancer or trauma). In such cases, a second opinion from another physician is suggested for all narcotics used for longer than 2 months. If narcotics are prescribed for longer than 3 months, the patient should have a second-opinion consultation, plus a follow-up consultation at least once per year. There should be one pharmacy and one prescriber designated as exclusive agents.

Narcotic dosage should be defined, as should expectations of what will happen if there are deviations from it. For example, abuse leads to rapid tapering of the drug and a detoxification program, if necessary. There should be no doubt that the physician will stop the drug.

Informed consent as to the rationale, risks, benefits, and alternatives should be documented. The course of treatment (in particular, the ongoing indications, changes in the disease process, efficacy, and the presence of abuse, tolerance, or addictive behavior) should be documented.

Justification for maintenance narcotics, given the mixed benefits and risks, involves humanitarian and public health principles. If narcotics are the only effective treatment for intractable suffering, they should be used for humanitarian reasons. The risk of episodic abuse may be justified in marginally reliable people with drug abuse histories and chronic pain if use of narcotics lessens disability and illicit drug use. For example, an IV drug addict with chronic pain might benefit from a methadone maintenance program for pain; furthermore, it may be an effective public health means of reducing the risk of acquired immunodeficiency syndrome (AIDS).

ANALGESIC ADJUVANTS

Pain may be refractory despite the most judicious application of traditional anti-nociceptive measures (such as surgery, nerve blocks, and use of opioids). Stimulants, neuroleptics, TCAs, benzodiazepines, anticonvulsants, antihistamines, peptides, and prostaglandin inhibitors also have roles as nonnarcotic pain treatment adjuvants[64] (Table 18–8).

TABLE 18–8 Analgesic Adjuvants

AGENT	DOSAGE	INDICATIONS	SPECIAL ISSUES
Prostaglandin Inhibitors			
	Variable, limited by side effects and medical co-morbidity	Metastatic bone pain Inflammation Vascular pain	NSAID risks: GI bleeding, kidney impairment
Neuroleptics			
Phenothiazines Butyrophenones	Antipsychotic D_2 receptor–blocking doses	Postherpetic pain Cancer pain Diabetic neuropathy Adjunct to TCAs Co-morbid anxiety or delirium	Haloperidol binds to opioid receptors Membrane stabilizing
Stimulants			
Methylphenidate Dextroamphetamine Pergolide	5–50 mg/day (t½:2–7 hr) 5–20 mg/day (t½:4–21 hr) 0.05 mg tid (t½:6–72 hr)	Postoperative pain and pain in pediatric and cancer patients respond well to combination of analgesic and stimulant	Stimulants decrease pain and sedation Appetite and cognition improve Methylphenidate shows better long-term efficacy than does amphetamine
Steroids			
Prednisone Methylprednisolone	15 + mg/day PO 15 mg/kg IV boluses	Bone metastases Brain swelling Spinal cord compression Anorexia and pain Sickle cell pain	Risks: mood lability, withdrawal, anxiety, insomnia, GI upset
Peptides			
Calcitonin	100–200 IU SC bid Nasal 200 IC/day	Paget's, metastatic, and myeloma pain	Intrathecal, nasal, and SC are used
Somatostatin	500 µg	Vascular headaches	Somatostatin inhibits SP
Capsaicin cream	.075%	Neuralgia, cancer pain Hyperalgesia, postherpetic neuralgia, cluster headache, CRPS, inflammatory dermatoses, itching secondary to dialysis, psoriasis	Capsaicin effect peaks 4–6 wk, for diabetes, postmastectomy, and arthritis pain
Antihistamines			
Diphenhydramine	150 mg	Narcotic adjunct	Decreased inflammation, 5-HT, NE, dopamine, muscle spasm, opiate clearance
Hydroxyzine	100 mg		Increased opiate binding
Benzodiazepines			
Clonazepam Lorazepam	1–4 mg/day 2–16 mg/day	Adjuvant tricyclics Allodynia	Not a substitute for diagnosis of depression or substance abuse
Antiepileptics			
Phenytoin	300-450 mg/day	Cancer pain	Paroxysmal pain responds best to antiepileptic drugs
Carbamazepine	400–1600 mg/day	Headaches, neuralgia	
Valproate	500–2000 mg/day	Central pain	
Gabapentin	900–1800 mg/day	Neuropathy	
Lamotrigine	100–300 mg/day	Migraine headaches	
Oxcarbazepine	300-1600 mg/day	Neuropathy	
Pregabalin	600-1200 mg/day	Neuropathy; PHN	
Topiramate	200-400 mg/day	Neuropathy	
Antidepressants			
Tricyclics			
Desipramine Imipramine	25–300 mg/day 25–300 mg/day	Neuropathy Postherpetic neuralgia	Burning Deafferentation pains respond best to the tricyclic drugs Increased side effects with amitriptyline

Continued

TABLE 18–8 Analgesic Adjuvants—*cont'd*

AGENT	DOSAGE	INDICATIONS	SPECIAL ISSUES
Selective Serotonin Reuptake Innibitors			
Paroxetine	20-60 mg/day	Diabetic neuropathy	
Citalopram	20-60 mg/day	Diabetic neuropathy	
Serotonin–Norephrinine Reuptake Inhibitors			
Duloxetine	60-120 mg/day	Diabetic neuropathy, fibromyalgia	
Venlafaxine	75-375 mg/day	Fibromyalgia	

CRPS, Complex regional pain syndrome; *5-HT*, serotonin; *GI*, gastrointestinal; *NE*, norepinephrine; *NSAID*, nonsteroidal antiinflammatory drug; *PHN*, postherpetic neuralgia; *SP*, substance P; *TCAs*, tricyclic antidepressants.

The type of pain is as important as its cause in guiding the choice of an adjuvant. The pain may be characterized as a constant aching somatic pain, as in a fracture, or as a paroxysmal burning deafferentation sensation, as in phantom limb pain. The primary cause of the pain, however, does not necessarily determine its type or character. For example, the pain of metastatic cancer may be either neuropathic or somatic (and might or might not respond well to NSAIDs). Neuropathic pain is often refractory to opioids, and it covers a diverse group of conditions, which range from herpetic neuralgia to atypical facial pain. Patients suffering from this type of pain might respond to anticonvulsants or TCAs. In the most difficult or ambiguous cases, a valuable technique is to use an IV dose of the drug to gain a rapid and accurate assessment of its effectiveness for the long term. IV morphine, lidocaine, and lorazepam can be used in this way to see whether or not any of these classes of drugs are worth pursuing.

Antidepressants for Pain

The mechanisms of action of TCAs are multiple and probably co-modulate the pain-relieving effect.[65] First, they have an effect in augmenting the descending periaqueductal spinal inhibitory control of pain mediated by serotonin and norepinephrine. In the spinal cord, the dorsolateral funiculus is a serotoninergic inhibitory descending spinal pain pathway that modulates 80% of the spinal analgesic effect of opiates. Second, they potentiate naturally occurring or administered opiates. For example, desipramine, 8-OH-amoxapine, and imipramine are twice as potent as amitriptyline and four times as potent as trazodone and clomipramine at binding to opiate receptors. Third, antihistamine and α-receptor effects may be important with regard to potentiation. Fourth, there may be membrane-stabilizing anesthetic, anti-kindling anticonvulsant effects, which can also give secondary symptom relief of insomnia or anxiety.

The pain relief obtained from antidepressants is often independent of their effects on mood or their alleviation of major depression.[66,67] In fact, the greatest response to antidepressants in patients with pain can occur in those who are not depressed.[68] Antidepressants as analgesics are best thought of as monoaminergic cell stabilizers rather than just antidepressants. Serotonin, norepinephrine, and dopamine all modulate pain via their actions in the periphery to the CNS.

Serotonin presents a paradox because more serotonin is not necessarily better, yet function must be intact for pain to be inhibited. One type of peripheral serotonin receptor, 5-HT_{1D}, is found in cerebral blood vessels. Sumatriptan, a selective 5-HT_{1D} antagonist, acts to produce vasoconstriction and migraine headache relief. The raphe and mesolimbic structures are important sites of subcortical serotonin receptors, mainly types 1A, 2A, and B. These areas modulate pain and mood—the neurobehavioral sites of action. Despite the important role serotonin plays in pain, there are a number of exceptions to the simplistic notion of more serotonin, less pain.[69] For example, buspirone, fluoxetine, and trazodone have all been shown to be ineffective in attenuating certain pain syndromes.[70–72]

Norepinephrine-modulating medications also have value in treating chronic pain. Desipramine (at an average dose of 200 mg daily) relieved pain in diabetic neuropathy, in both nondepressed and depressed patients,[73] and it also relieved postherpetic neuralgia.[74] Duloxetine, a serotonin–noradrenergic reuptake inhibitor (SNRI), has become the first antidepressant to have a specific pain indication for the treatment of painful diabetic neuropathy.[75] Duloxetine has also been studied in a number of large trials for the treatment of fibromyalgia and found to be efficacious not only in reducing pain but also in reducing tender points and stiffness scores, while also increasing the tender-point pain threshold when compared with placebo.[76] These results have also been reproduced by other SNRIs; milnacipran and venlafaxine also have been shown to be efficacious for the treatment of pain associated with fibromyalgia.[77,78]

Reviews of Efficacy

Earlier reports of Lindsay and Wycoff showed an efficacy of 70% to 80% for antidepressants for the treatment of chronic pain in patients with depression.[79] Stein and associates reported that amitriptyline (150 mg/day) was more effective than acetaminophen (2 g/day) in a controlled, double-blind study, with mild depression being one of the predictors of pain relief at the end of the 5-week study.[80] Blumer and Heilbronn showed twice the improvement (60%) in outcome and a halving of the dropout rate (25%) in pain patients treated with antidepressants.[81]

Pain syndromes that may be responsive to antidepressants include those associated with cancer, postherpetic neuralgia, arthritis, vascular and tension headaches, and facial pain. The literature reports a wide range of generally positive, but poorly designed, studies. Feinmann reviewed the 11 largest and best-designed studies on pain relief from antidepressants when depressive symptoms were present.[82] TCAs (e.g., amitriptyline hydrochloride) and monoamine oxidase inhibitors (MAOIs) (e.g., phenelzine sulfate) were used, and the results demonstrated that these antidepressant drugs were beneficial in treating chronic pain associated with depression.

A review by Goodkin and co-workers found that 37 of 53 trials (70%) of heterocyclic antidepressant drugs for chronic pain syndromes failed to meet minimum criteria for adequate design.[83] Of the remaining 16 trials that met design and protocol criteria, 7 evaluated headache pain and documented positive effects with low-dose regimens. Complicating these findings was that smaller than typical antidepressant doses were used in many studies. In this same review, another nonrandom series of 17 studies was selected, of which 5 (29%) met minimum design and protocol criteria (i.e., clear protocol, placebo-controlled, and defined outcome measurements); only two of the five trials showed positive results. One study was for low-dose amitriptyline in mixed pain syndromes, and the other study was for desipramine in postherpetic neuralgia. Max found that in 13 well-designed, randomized trials, antidepressants reduced pain in diabetic neuropathy and postherpetic neuralgia, particularly the SNRIs (e.g., imipramine, desipramine, and amitriptyline).[84]

Saarto and Wiffen, in a Cochrane-based review, reviewed available randomized clinical trials of antidepressants in neuropathic pain.[25] Sixty-one trials were included; they found that TCAs were effective. There was limited evidence for the effectiveness of the SSRIs based on current available data.

In a meta-analysis conducted to assess the efficacy of antidepressants in treating back pain in adults, antidepressants were more effective than placebo in reducing severity of pain, but not functional status in chronic back pain.[85] TCAs have been an option for patients with chronic back pain, but SSRIs have shown limited effectiveness. To date, SNRIs have not been studied for the treatment of chronic back pain.[26]

When is it worth trying a monoaminergic agent? A trial of an antidepressant medication is useful in any intractable pain condition, whether or not depression is present, because analgesic effects are at least partly independent from antidepressant effects. Furthermore, the size of the analgesic effect does not differ significantly in the face of depression.

There is no clear evidence for the superiority of any one antidepressant over any other. Amitriptyline, desipramine, and doxepin hydrochloride have been used most often in the clinical studies. Even though sedating and nonsedating properties of drugs have no significant association with analgesic effect, the antihistaminic profile of an antidepressant correlates with effect.[86] Potent serotonin reuptake blockade is not essential to pain relief; moreover, there is doubt about the efficacy of purely serotoninergic drugs for neuropathic pain (e.g., fluoxetine, zimeldine, and trazodone).[87,88] Buspirone does not appear to relieve pain. With the exception of paroxetine, all antidepressant drugs studied in placebo-controlled trials of neuropathic pain have some inhibition of norepinephrine reuptake (i.e., amitriptyline, desipramine, nortriptyline, imipramine, and maprotiline).[73] Venlafaxine has some agonist–antagonist opiate activity as well as norepinephrine, 5-hydroxytryptamine, and dopamine-reuptake effects, but it has yet to be rigorously proven as an analgesic.

Monoamine oxidase inhibitors may be particularly helpful in the attenuation of atypical pain associated with atypical depression. MAOIs and TCAs, however, can require a trial of at least 6 weeks for the full benefit to be evident.

Dopamine agonists can also augment analgesia. Dopamine has been associated with pain in clinical and experimental trials and has also been shown to comodulate opioid and substance P effects in the CNS. Psychostimulants can potentiate the effects of opioid analgesics.[89,90] Methylphenidate has been studied as adjuvant therapy for cancer patients receiving narcotics. In a randomized, double-blind, placebo-controlled crossover trial of 32 patients with advanced cancer receiving chronic opiate therapy, a statistically significant reduction in pain intensity and sedation was seen with the use of methylphenidate.[91] In another study of 50 patients with advanced cancer and opiate-induced sedation, 44 had a decrease in sedation after initiation of methylphenidate.[92] Patients with incident cancer pain (mild or no pain at rest, severe pain during movements) showed better pain control, and they tolerated higher doses of narcotics when narcotics were supplemented with methylphenidate.[93] A placebo-controlled trial demonstrated that the addition of oral methylphenidate resulted in improved cognitive function in 20 patients receiving continuous subcutaneous narcotics for cancer pain,[94] and similarly, 5 of 11 adolescent cancer patients receiving opiates exhibited improved interaction with family or decreased somnolence when methylphenidate was added to their medication regimen.[95]

Although it is classified as a dopamine reuptake inhibitor, bupropion also has noradrenergic activity. Evidence of its analgesic effect is still very limited, although in one double-blind, placebo controlled, crossover trial, 73% of 41 subjects with neuropathic pain obtained pain relief with bupropion treatment.

Monoaminergic agents in combination with clonazepam, valproate, or narcotics (for cancer pain) are often safe and desirable.

Although some patients respond to low doses of antidepressants for pain, a complete trial of an antidepressant in a pain patient requires a full dose of an antidepressant, the same as used in major depression. The placebo-controlled study of McQuay and associates found that low doses of antidepressants (amitriptyline 25 mg) did not have the efficacy of higher doses.[96] The best results in the largest number of people are obtained, however, when the usual antidepressant dosage of drug is used (e.g., 300 mg/day of imipramine hydrochloride or its equivalent). Other pointers include:

- Depression should not be rationalized as appropriate.
- Treatment of the depressed pain patient is no different from treatment of any other depressed patient.
- Education of the patient as to the rationale for antidepressant treatment is advised for good compliance.
- Maintenance treatment for 3 to 6 months is usually necessary for the best results.

Antiepileptic Drugs

Antiepileptic drugs (AEDs) have a long history of efficacy in the treatment of pain, especially neuropathic in origin, dating back to case reports for the treatment of trigeminal neuralgia with phenytoin in 1942 and carbamazepine in 1962.[97] Blocking abnormally high-frequency and spontaneous firing in afferent neurons, in the dorsal horn, and in the thalamus are the putative mechanisms for the efficacy of anticonvulsants with regard to pain. The consequence of blocking the hyperexcitability of low-threshold mechanoreceptive neurons in the brain lead to pain relief.[98]

Phenytoin, carbamazepine, valproic acid (VPA), benzodiazepines, and some of the newer AEDs including gabapentin, pregabalin, lamotrigine, topiramate, and oxcarbazepine are agents used to treat pain. These drugs have a number of shared cellular effects, which include antagonism of excitatory amino acids, gamma-aminobutyric acid (GABA)-receptor agonism, sodium and calcium pump stabilization, and antagonism of adenosine. Indirectly, they all antagonize the effects of excitatory amino acids, which are believed to kindle hyperexcitability of CNS neurons.

Phenytoin has been shown effective in alleviating pain associated with various neuropathies, particularly trigeminal, diabetic, and poststroke pain. Sharp, shooting, lancinating pain has been shown to respond especially well to this drug. It has more behavioral toxicity, however, and is less effective than carbamazepine, thus making it a second choice for analgesia.

Carbamazepine is generally superior to phenytoin for pain. The effect of carbamazepine on pain suppression is likely mediated by central and peripheral mechanisms. The ability of carbamazepine to block ionic conductance appears to depend on dosing frequency, which enables the drug to suppress the spontaneously active Aδ and C fibers responsible for pain without affecting normal nerve conduction. Since Blom reported the analgesic properties of carbamazepine for patients with trigeminal neuralgia in 1962, carbamazepine has been shown to be effective also for postherpetic pain, postsympathetic pain, diabetic neuropathy, multiple sclerosis, and assorted neuralgias.[99] Higher levels (8 to 12 μg/L) are typically necessary for optimal efficacy.

The first reports of VPA used in neuropathic pain appeared in the early 1980s. VPA prolongs the repolarization of voltage-activated Na^+ channels and also increases the amount of GABA in the brain, enhancing the activity of glutamic acid decarboxylase and inhibiting GABA degradation enzymes. VPA has been shown to decrease postherpetic neuralgia, episodic and chronic cluster headaches, migraine, and postoperative pain, as well as various neuralgias. It has also been demonstrated that VPA is effective in treating migraine headaches in two double-blind, placebo-controlled trials.[100,101] These demonstrations of efficacy in pain reduction are in addition to the traditional place for VPA in treating psychiatric disorders (bipolar and schizoaffective disorders). VPA sprinkles, in particular, are well tolerated and can substitute for carbamazepine and lithium in pain states, although no head-to-head comparisons have been completed.

Benzodiazepines have been controversial in the alleviation of pain, but they do have a definite place as safe and effective agents.[102] Combinations of benzodiazepines with antidepressants or opiates may be particularly useful clinically. IV lorazepam was superior to morphine, lidocaine, and placebo in a single-blind study of neuropathic pain[103]; however, these results were not reproduced in a randomized, double-blind trial in which lorazepam was less effective than amitriptyline in patients with postherpetic neuralgia.[104] Orally, clonazepam is the drug of choice. It binds more slowly to central than to peripheral benzodiazepine receptors, and it is synergistic with serotoninergic pain mechanisms, a factor that distinguishes it from other benzodiazepines. A useful diagnostic test for benzodiazepine-sensitive pain is to administer lorazepam 2 mg IV in a single-blind manner evaluated by visual analogue scale (VAS) monitoring. Positive results (greater than 3-cm decrease in VAS) signify relief of ongoing pain. If positive results are achieved, it is recommended to give sequential IV lorazepam doses to break the pain cycle (in severe cases) or clonazepam (e.g., 2 to 4 mg orally at bedtime, and 1 mg twice a day).

Of the new generation of AEDs used to treat neuropathic pain, gabapentin is perhaps the best studied. Developed as a structural GABA analogue, it has no direct GABAergic action. It is believed that gabapentin acts on the $\alpha_2\delta$ calcium channels. Gabapentin has relieved pain and associated symptoms in patients with peripheral diabetic neuropathy, postherpetic neuralgia, HIV-related neuropathy, and cancer-related neuropathic pain.[105–108] The dosages used in these studies typically ranged from 900 to 3600 mg daily in three divided doses. Additional studies are required to evaluate if gabapentin is efficacious in other pain states.

Topiramate works via multiple mechanisms, including prolongation of voltage-sensitive sodium channel inactivation, $GABA_A$ agonism, and non–*N*-methyl-D-aspartate (NMDA) glutamate receptor antagonism. Topiramate is useful in the treatment of trigeminal neuralgia, along with diabetic neuropathy. Like any of the newer AEDs, continued studies will be required to determine overall efficacy.

Oxcarbazepine is a keto-analogue of carbamazepine, with the analgesic mechanism likely due to inhibition of voltage-dependent sodium channels and also, to a lesser extent, potassium channels. Studies seem to show mixed results for the use of oxcarbazepine for diabetic neuropathy, but its efficacy seems to be similar to carbamazepine's in the treatment of trigeminal neuralgia. However, there are limited data regarding the efficacy and safety of this drug in the treatment of other neuropathic pain syndromes.

Pregabalin is a GABA analogue believed to exert its analgesic effect by binding to the $\alpha_2\delta$ subunit of voltage-gated calcium channels on primary afferent nerves and reducing the release of neurotransmitters from their central terminals. Evidence seems to show that pregabalin is effective for reducing the intensity of pain associated with diabetic polyneuropathy and postherpetic neuralgia.[109,110]

Lamotrigine is a direct glutamate antagonist that also inhibits sodium channels. Although initial case reports seemed to show some promise for use of lamotrigine in neuropathic pain states, most randomized, double-blind studies to date have not shown any significant efficacy.[111–115]

Sympathetic Blockade

Sympathetically maintained pain (SMP)—regardless of whether it is due to CRPS, opiate tolerance, hyperalgesia, inflammation, vascular headache, postherpetic neuralgia, trauma, facial pain, or arthritis—might respond to sympathetic blockade.[116] Sympathetic efferent fibers release norepinephrine, which in turn activates α-adrenergic receptors. Activation of these receptors, either directly or indirectly, excites nociceptors. Activity in the nociceptors then evokes pain and causes further discharge of nociceptors. α-Adrenergic receptor supersensitivity has been postulated as a likely mechanism for both the hyperalgesia and the autonomic disturbances associated with SMP.[117]

The clinician may consider the early use of sympathetic blockade in any chronic pain syndrome with features

of sympathetic dysfunction. SMP is diagnosed and treated using the method of injecting or transdermally applying an α-adrenergic blocking agent selected from the group consisting of an α_1-adrenergic antagonist, α_2-adrenergic agonist, or other drug that depletes sympathetic norepineprhine. One method to assess for SMP is to infuse 500 mL of half-normal saline before putting phentolamine into an ischemic regional block, and then administer phentolamine (10 mg IV over a 10-minute period). A positive test result is marked by relief of evoked pain stimulated by light touch or a tuning fork.[118] α-Blocking drugs (e.g., phentolamine and α-blocking antidepressants) and α_2-agonists (such as clonidine), given with or without opiates, are all potentially useful in patients with chronic pain. Intrathecal, epidural, and systemic administration of clonidine also produce analgesia, and clonidine is often useful in patients who have developed tolerance to opiates and who have some types of vascular or neuropathic pain.[119,120] Transdermal clonidine (0.1 to 0.3 mg/day) is sometimes useful in neuropathy, although the results of the treatment are mixed.

The mechanism of action of dexmedetomidine resembles that of clonidine, although its affinity for the α_2-adrenoceptor is approximately eight times that of clonidine[121] and it has a significantly higher α_2/α_1 selectivity ratio than does clonidine.[122,123] Besides its analgesic effects, its sedative effects are thought to be secondary to action on α_2-adrenoreceptors located in the locus ceruleus. Similar to clonidine, dexmedetomidine decreases the requirement for opioids in patients undergoing a variety of surgical procedures,[124] and in a clinical trial where it was administered as a single agent for sedation, it reduced by approximately 60% the number of patients who needed opioids to control pain.[125] Dexmedetomidine was approved in the United States in 2000 for up to 24 hours of pain treatment in surgical patients, and it is currently in clinical trials for the control of postoperative pain in thoracotomy patients.

β-Blockers are not efficacious in the treatment of sympathetically maintained pain except in their use for alleviating migraine headaches. Guanethidine, bretylium, reserpine, and phentolamine have been used successfully to produce a chemical sympathectomy.[126,127]

ADDITIONAL ASPECTS OF TREATMENT

Central Neuropathic Pain States

The clinical hallmark of central pain is that it persists without an obvious nociceptive stimulus; the physiologic goal of treatment is to stabilize hyperexcitable neurons. Table 18–9 outlines some clinical approaches to central pain.

TABLE 18–9 Pain Treatment

PAIN CHARACTERISTICS	WHAT TREATMENT IS NEXT?	COMMENTS
Nociceptive element present?	Nerve block for diagnostic and therapeutic reasons Imaging; MRI, looking for lesion	Even in pain that appears central (e.g., trigeminal neuralgia), nociceptive triggers can initiate pain and peripheral deafferentation
Allodynia present? (vibration, cold, or light touch)	Low-dose clonazepam (1–4 mg/day), if the person can tolerate benzodiazepines, alone or in combination with desipramine 50 mg at bedtime (up to 300 mg eventually, if necessary) Mexelitine 150–400 mg tid	Allodynia predicts response to clonazepam Clonazepam relaxes muscles and improves sleep and anxiety Membrane stabilizers are useful, but cardiotoxicity needs to be checked Peptides useful
Paroxysmal attacks? (lightning-like)	Antiepileptic drugs (AEDs) Carbamazepine 400–1600 mg/day (serum level 8–12 mcg/L) Valproate 500–2000 mg/day Gabapentin 300–1200 mg tid Lamotrigine 100–300 mg/day	Clonazepam should usually be tried first, but it works well synergistically with the AEDs listed Valproate for vascular headache Gabapentin: few drug interactions
Central pain? Allodynia Paroxysmal attacks Sharp perceived as light touch Decreased pain threshold Nondermatomal distribution of pain Hyperpathia	Definitive trial is a single-blind random assignment of IV lorazepam (2–4 mg) vs lidocaine (100 mg) vs morphine 10 mg, rated on a VAS IV amitriptyline 25 mg infusion as a test dose with VAS	Careful physical examination is essential Is sharp perceived as light touch? Light touch is painful, sustained, and has a delayed crescendo Tuning fork/moving a hair examination is best for allodynia
Co-morbid central pain? Vascular and myofascial pain	Valproate 250–2000 mg/day Physical therapy Monoaminergic prescription antidepressants Nasal calcitonin 200 IU/day Capsaicin 4–6 week trial Topical preparation (Zostrix)	Common in head, neck, and face pain Mixed results with SSRIs Rule out sympathetically maintained pain

Continued

TABLE 18–9 Pain Treatment—*cont'd*

PAIN CHARACTERISTICS	WHAT TREATMENT IS NEXT?	COMMENTS
DSM-IV psychiatric diagnosis? Rule out or treat	Co-morbid psychiatric and CNS pain: consider prescription with dual effects for pain and psychiatric diagnosis Benzodiazepine for allodynia and anxiety Antidepressants for neuropathy, depression, and anxiety Neuroleptics for neuralgia, anxiety, psychosis, and nausea Anticonvulsants and mood stabilizers for lancinating pain	Rule out depression and anxiety, consider mimics of central pain, such as somatoform, factitious, or psychotic disorders Pain drawing by the patient is a good tool to uncover psychosis and myofascial pain Rule out akathisia, restless legs syndrome

AEDs, Antiepileptic drugs; *CNS*, central nervous system; *MRI*, magnetic resonance imaging; *SSRIs*, selective serotonin reuptake inhibitors; *VAS*, visual analogue scale.

Carbamazepine has been shown to be among the most effective agents for some facial neuralgias, which can be so agonizing that some patients actually look forward to death. Within 24 hours of attaining steady state, it is effective in 80% of patients with trigeminal neuralgia, making it clinically superior to phenytoin. Other types of lancinating pain, such as postherpetic neuralgia, postsympathectomy pain, and posttraumatic pain, might also respond to AEDs. IV trials offer a quick, definitive way of identifying drug responders in complex or pressured situations.

For routine CNS pain, clonazepam is the best-tolerated anticonvulsant for pain syndromes, especially when allodynia is present. It facilitates both presynaptic and postsynaptic inhibition, increases recurrent inhibition, and decreases the firing rate of normal and epileptic neurons in the brain; it also enhances sleep, relaxes muscles and blood vessels, and treats panic. It is the drug that exemplifies the need to select prescriptions based not only on their efficacy and tolerability but also on their mechanisms of action for disease processes that have multiple pathophysiologies.

ECT has been used in long-standing pain accompanied by depression. The rationale is that treating the depression eases the suffering associated with pain. Unfortunately, ECT is effective for major depression, but it does not relieve pain. The assumption that there must be chronic depression with chronic pain and that it will be amenable to ECT is usually untenable.

Pain Behavior and the Use of Multidisciplinary Pain Clinics

Guidelines

Medicare guidelines offer one set of standards for multidisciplinary management of pain. The pain must be at least 6 months in duration (resulting in significant life disturbance and limited functioning), it must be attributable to a physical cause, and it must be intractable to the usual methods of treatment. Desirable characteristics for pain treatment facilities and standards of care in pain management have now been published in response to skepticism about cost, quality, control, and diversity of pain treatment facilities.[118] Quality-control guidelines developed by the Commission on Accreditation of Rehabilitation Facilities (CARF), under the umbrella of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), have led to the certification of more than 100 chronic pain-management programs nationwide. Behavioral treatments, however, are not primarily for pain relief; they merely extinguish the behavior associated with pain.[128] Furthermore, proof of the cost-effectiveness of inpatient multidisciplinary treatment is nascent and consequently still ill defined.

Reasons for Referral to an Inpatient Multidisciplinary Pain Clinic

Inpatient multidisciplinary pain clinics should be considered in the following circumstances:

- When the diagnosis of the physical and psychiatric pathology is already complete or is so obscure that intensive observation is necessary (e.g., malingering)
- When consultation from an independent physician who is an expert in the treatment of chronic pain is necessary to confirm that no single modality of outpatient treatment is likely to work
- When the patient has already obtained maximum benefit from outpatient treatments such as NSAIDs, nerve blocks, antidepressants, and simple physical and behavioral rehabilitation
- When intensive daily interventions are required, usually with multiple concurrent types of therapy, such as nerve blocks, physical therapy, and behavior modification
- When the patient exhibits abnormal pain behavior and agrees to the goals of improved coping, work rehabilitation, and psychiatric assessment
- When medications for pain relief are so complex or compliance management is so difficult that direct supervision of medical therapy is necessary
- When a self-medication program is required, typically with a written schedule of medications, a contract, and strategies mutually acceptable for patient and physician

Hypnosis

The use of hypnosis in chronic pain syndromes is well known. Self-hypnosis is particularly helpful, but only about one in four subjects is able to achieve a state of concentration of sufficient magnitude for lasting pain control. Hypnosis is a method worth considering, provided that the physician knows its limitations and how to apply it to the individual patient's needs.

Rehabilitation

Rehabilitation of patients who have chronic pain syndromes can require some combination of psychiatry, physical therapy, physiatry, behavioral psychology, and neurology. No special therapy, including exercise therapy, spinal manipulation, bed rest, orthoses, acupuncture, traction therapy, back schools, and epidural steroids, works well. Successful rehabilitation aims to decrease symptoms, increase independence, and allow the patient to return to work. A positive, rapid return to light-normal activities and work is essential if disability is to be minimized. Psychologically, this is the key to coping with acute trauma. Even with patients who experience low back pain, 50% of whom have a recurrence within 3 years of the initial episode, there is no evidence that a return to work adversely affects the course of the pain syndrome.[129]

Treatment of myofascial pain syndromes may be challenging. It involves restoration of stage 4 sleep, aerobic conditioning (which could include physical therapy or yoga), and avoidance of drugs, including caffeine and alcohol. Trigger point analgesia, behavioral modification of maladaptive sleep habits, and treatment of anxiety and depression may be necessary if chronic muscle pain is to be relieved. MAOIs are often effective. TCAs (e.g., desipramine and imipramine) can also be effective and are easier to use than MAOIs because dietary restrictions are not needed. Response to SSRIs has been unpredictable for myofascial pain; at times they provoke muscle spasms and do not help the myofascial pain.[130] Cyclobenzaprine and *S*-adenosylmethionine (SAMe), however, have resulted in some modest adjunctive efficacy.[131] Eight weeks is the duration of an optimal trial for any of these agents.

Education

Education is needed for the caregivers as well as the patient. In the past, medical professionals, be they physicians or nurses, viewed the patient who is in constant need of pain medication with suspicion. Physicians often underestimated the medication's effective dose, overestimated the medication's duration of action, and had an exaggerated notion of the danger of addiction. Rarely were physicians told to vary the amount of drug prescribed based on the patient's body weight, kidney function, and previous tolerance for the drug. The physician's ennui with failure, suffering, and death could also have led to flight from pain. When the amount of medication a patient requires for the management of pain becomes a cause célèbre on the ward, the consulting psychiatrist should call a meeting of the house staff, attending physicians, and nurses so that all biases and suspicions can be brought into the open. Medical personnel are far more apt to underestimate the amount of narcotic required for a given pain than to overestimate it. In either case, their opinions are usually based more on misinformation or folklore than on fact. Once these judgments are aired, the patient usually benefits.

Cognitive-Behavioral Therapies

Hypnosis and imagery conditioning to induce relaxation and pain control are consistently found to be more effective than cognitive-behavioral training.[132,133] Traditional hypnosis, autogenic exercises, yoga methods, and meditation are all useful paths to achieve those goals.

Coping and Psychotherapy

Coping with chronic pain always threatens two fundamentals of survival: attachment behaviors and intrapsychic defenses. To cope means to have people of quality around to fortify one's courage and to have adaptive defense mechanisms to negotiate the thoughts and feelings that arise in one's head. Helping the patient develop cognitive and behavioral coping skills is more effective for decreasing pain and psychological disability than is education alone.[134] Coping is also context dependent and is most effective when the focus includes the couple or family.[135,136]

The psychodynamic aspects of coping involve conflicts over autonomy and care. Old conflicts about nurturance suggest there may be mixed feelings about recovery. Shame can mimic depression, trigger conservation and withdrawal, and produce counterdependent behavior. Regression, some of which is normal, can be manifested as noncompliance, help-rejecting behavior, complaining, and behaviors akin to the metaphorical "cutting off your nose to spite your face." The hateful patient and the hateful physician are often compatriots in partnership with chronic pain, and a task of the psychiatrist is to clarify how these problems become played out in the physician–patient relationship. One should understand that the physician is a protective figure who is the recipient of both idealized and angry feelings when a cure is not forthcoming. Modern health care, with its fragmentation, multiple caregivers, and bureaucracies, guarantees rifts in the physician–patient relationship. To help the patient cope, the psychiatrist must be sensitive to the unconscious feelings of the patient and be prepared to manage denial and to employ family counseling, relaxation, exercise, physical rehabilitation, and pharmacotherapy, while still functioning as a teacher and physician. Wisdom, medicine, time, and hope are the professional's charge.

Patients with Neurologic Conditions I. Seizure Disorders (Including Nonepileptic Seizures), Cerebrovascular Disease, and Traumatic Brain Injury

Jeff C. Huffman, M.D.
Megan Moore Brennan, M.D.
Felicia A. Smith, M.D.
Theodore A. Stern, M.D.

The structure and function of the central nervous system (CNS) is altered by many neurologic disorders. Because the CNS controls affect, behavior, and cognition, neurologic disorders can lead to neuropsychiatric symptoms that resemble those found in primary psychiatric conditions. Therefore the general hospital psychiatrist is frequently called on to assess patients who have classic psychiatric symptoms caused by an underlying neurologic disease

In this chapter we will review the management of patients with neurologic conditions that are commonly associated with neuropsychiatric phenomena. We will discuss seizure disorders and describe the diagnosis and management of nonepileptic seizures (also known as *pseudoseizures*). Furthermore, we will outline the treatment of neuropsychiatric symptoms in patients with cerebrovascular disease and traumatic brain injury (TBI). Chapter 20 will discuss the management of neuropsychiatric conditions associated with movement disorders, demyelinating disease, and CNS neoplasm or infection.

THE MANAGEMENT OF PSYCHIATRIC SYMPTOMS IN PATIENTS WITH SEIZURE DISORDERS

Approximately half of all patients with seizure disorders have co-morbid psychiatric syndromes[1]; therefore the general hospital psychiatrist should have a working knowledge of seizure disorders and the neuropsychiatric syndromes that are commonly associated with these disorders. Patients with seizures may have psychiatric symptoms that occur during a seizure (*ictal* symptoms), immediately before or after a seizure (*periictal* symptoms), or between seizures (*interictal* symptoms).

It may be useful to begin with some definitions. A *seizure*, as defined by Schwartz and Marsh,[2] is an abnormal paroxysmal discharge of cerebral neurons sufficient to cause clinically detectable events that are apparent to the patient or an observer. Seizures can be *partial* (focal) or *generalized*; partial seizures are localized in one area of the brain, whereas generalized seizures result in abnormal electrical activity throughout the cortex. Patients with a chronic course of repeated, unprovoked seizures are said to have *epilepsy*.

Generalized seizures are subclassified into a number of subtypes.[3,4] *Tonic–clonic* (grand mal) seizures are the most common form of generalized seizure; they are characterized by a sudden loss of consciousness, followed by a brief tonic phase with contraction of skeletal muscles and an upward deviation of the eyes. A more prolonged clonic phase follows; this stage is characterized by rhythmic and symmetric jerking of the extremities. *Absence* (petit mal) seizures are characterized by brief (usually 5 to 10 seconds) lapses in consciousness and by motionless staring; these seizures occur primarily in children and are rare after puberty. *Myoclonic* seizures are characterized by brief and sudden muscle contractions that may occur unilaterally or bilaterally, singly or repeatedly; these are more commonly seen in children but may also occur in adults. Finally, *atonic* seizures ("drop attacks" or akinetic seizures) are characterized by sudden loss of muscle tone in the neck, upper extremities, or lower extremities.

Partial seizures are classified as *simple partial seizures* when consciousness is unaffected or as *complex partial seizures* when consciousness is altered. Partial seizures may secondarily progress to become generalized seizures. An aura before a generalized seizure (e.g., an unusual sensation before the onset of a convulsive seizure) is essentially a partial seizure that secondarily generalizes. Complex partial seizures (CPSs) deserve special mention, insofar as they are the most common type of seizure in adults[4] and are commonly associated with neuropsychiatric phenomena (especially when the seizures have a temporal lobe focus; in this case the syndrome is often called *temporal lobe epilepsy [TLE]).*

CPSs may involve sensory, affective, perceptual, behavioral, or cognitive symptoms. CPSs may include hallucinations of any sensory modality; they can be olfactory (e.g., a noxious odor, like burning rubber), gustatory (metallic or

other tastes), auditory, visual, or tactile in nature. The most common affective symptoms are fear and anxiety, although depression may also occur; rage is uncommon. Such affective symptoms usually have a sudden onset and offset.

Behavior during CPSs may also be abnormal; automatisms are common and may include oral or buccal movements (e.g., lip smacking or chewing), picking behaviors, or prolonged staring. Cognitive symptoms associated with CPS include *déjà vu* (a feeling of familiarity), *jamais vu* (a feeling of unfamiliarity), macropsia, micropsia, and dissociative, or "out-of-body," experiences. Patients with neuropsychiatric symptoms secondary to CPS may be mistakenly diagnosed with a primary psychiatric disorder because the symptoms of a CPS are often similar to those of psychiatric disorders, because CPSs are generally not associated with classic tonic–clonic seizure activity, and because the interictal (and even ictal) scalp electroencephalogram (EEG) may appear normal. Therefore the general hospital psychiatrist must be particularly astute in differentiating patients with CPS from those with primary psychiatric disorders.

In the following discussion, we outline the phenomenology and treatment of neuropsychiatric symptoms among patients with seizure disorders. We discuss ictal, periictal, and interictal neuropsychiatric symptoms and delineate how these symptoms differ from those seen in patients without seizure disorders. In addition, we discuss practical approaches to treatment.

Ictal Neuropsychiatric Phenomena

Ictal psychiatric symptoms are most commonly associated with partial seizures, although they can also occur with generalized seizures.[1] Anxiety, fear, and psychosis are the most common psychiatric symptoms experienced during a seizure. Anxiety or fear is a component of the aura in one third of patients with partial seizures[5]; the anxiety is often intense and may last throughout the course of the seizure. It may be most common in patients with right temporal foci.[6]

Such symptoms may resemble those of panic attacks, with autonomic symptoms, nausea, intense anxiety, and depersonalization. The clinical situation may be further confused by the fact that patients with epilepsy have high rates (approximately 20%) of co-morbid panic attacks[7]; therefore patients with epilepsy may have both ictal anxiety and interictal panic attacks that can be difficult to distinguish. The more circumscribed the symptoms are to associated seizure phenomena (e.g., automatisms or hallucinations during an episode, or confusion or severe lethargy after the event), the more likely it is that the anxiety is ictal.

Ictal psychosis is also common in patients with partial seizures. Ictal psychotic symptoms are most often associated with temporal lobe foci, but nearly one third of patients have nontemporal lobe foci.[8] Hallucinations during a seizure are much more likely to be olfactory or gustatory; auditory hallucinations (common in primary psychotic disorders) are less common. Paranoia is uncommon and usually short-lived. In contrast to patients with primary psychosis, consciousness is usually impaired during ictal psychosis, and affected patients are usually amnestic for the episode.[9]

Ictal depression is uncommon; it occurs as part of the aura in approximately 1% of patients with epilepsy.[10] Such depressive symptoms, as with other ictal symptoms, appear abruptly and without obvious psychosocial precipitants. Although depressive symptoms often disappear abruptly, some authors have noted that ictal depressed mood may extend beyond other ictal or postictal symptoms.[10,11]

Ictal aggression has also been reported, but it appears to be exceedingly rare (fewer than 0.5% of patients in one large series[12]). Furthermore, ictal aggression is poorly directed and does not involve significant interactive behavior; stereotyped shouting and pushing are among the most common manifestations. Patients rarely perform intricate, directed acts of violence during a seizure.

Determining whether anxiety, depression, or other psychiatric symptoms are ictal events or part of primary psychiatric conditions can be difficult. Table 19–1 describes some distinguishing characteristics of ictal and nonictal symptoms. In general, ictal symptoms are more often abrupt in onset and offset, occur in concert with other stereotyped manifestations of seizures (e.g., automatisms and jerking), and are frequently short-lived, usually lasting less than 3 minutes.[1] Furthermore, ictal symptoms are usually stereotyped; that is, a patient will not experience fear with one seizure and depressive symptoms with another—the pattern of symptoms will generally be the same.

In most cases, these factors should help the clinician to distinguish ictal psychiatric symptoms from primary psychiatric phenomena. However, complicating factors may be present, and partial status epilepticus may result in prolonged ictal psychiatric symptoms. Therefore the EEG remains a key tool for establishing whether symptoms are ictal.

Treatment of ictal psychiatric symptoms requires a careful evaluation. Primary psychiatric symptoms and ictal psychiatric symptoms are similar, frequently co-morbid, and have different treatment. Therefore careful clinical evaluation; EEG monitoring; and, when indicated, other diagnostic procedures (e.g., determination of prolactin levels) should be performed to distinguish these phenomena. Once symptoms have been identified as ictal, treatment of the associated psychiatric symptoms requires treatment of the seizure with anticonvulsants. Treatment of ictal psychosis with antipsychotics or ictal anxiety with non-anticonvulsant anxiolytics is generally not indicated. Nonpharmacological strategies, including close observation and measures to reduce the risk of falls or other injury, are crucial for patients whose seizure disorders remain active.

Periictal Neuropsychiatric Phenomena

The majority of periictal neuropsychiatric disturbances are postictal; they usually occur several hours after a seizure. Preictal symptoms can occur and include psychosis, mood changes, or aggression in the hours or minutes before a seizure.[13] These symptoms tend to increase until the onset of ictus[14] and, depending on the time course and nature of the symptoms, may be conceptualized as prodromes separate from the ictus or as ictal events (i.e., as a partial seizure).

Postictal symptoms are relatively common. Approximately 8% to 10% of patients with seizures have postictal psychiatric disturbances.[15] These psychiatric symptoms may occur in the context of a postictal delirium

TABLE 19–1 Differences Between Ictal and Nonictal Neuropsychiatric Symptoms

APPEARANCE OF SYMPTOMS	LENGTH OF SYMPTOMS	ASSOCIATED SYMPTOMS	PSYCHOTIC SYMPTOMS	CONSCIOUSNESS DURING EVENT	RECALL FOR EVENT	EEG DURING EPISODES	EEG BETWEEN EPISODES	POSTEVENT PROLACTIN LEVEL
Ictal Symptoms								
Sudden onset and offset	Usually < 3 minutes	Stereotyped ictal symptoms: rhythmic blinking, abnormal movements, unusual sensations, automatisms	Usually olfactory, gustatory, or tactile hallucinations	May be altered	Frequently none or limited	Almost always abnormal	Frequently normal	Often elevated
Nonictal Symptoms								
More often gradual in nature	Usually 20-30 minutes (panic attack); usually days-weeks (depression, psychosis)	Absence of blinking, jerking, automatisms	Usually auditory hallucinations; paranoia; common	Generally intact	Usually intact	Usually normal	Normal	Normal

or in the setting of clear consciousness. In general, postictal symptoms remit spontaneously and are often short-lived; in one study, symptoms lasted approximately 72 hours.[16] However, such symptoms may persist for days or even weeks, and patients with well-defined, prolonged postictal neuropsychiatric syndromes may be more likely to develop persistent interictal symptoms.

Psychosis is the most common postictal neuropsychiatric symptom, occurring in up to 7.8% of epilepsy patients[17]; such psychosis generally appears after a nonpsychotic postictal period of hours to days. It most commonly occurs in patients with CPSs that become secondarily generalized,[9] especially in those with temporal lobe or bilateral foci. Psychotic symptoms vary widely, and affective symptoms (depressive or manic) may also be present. Symptoms can include paranoid or grandiose delusions and hallucinations in a variety of sensory modalities; Schneiderian first-rank symptoms of schizophrenia are rare.[16] Symptoms tend to resolve spontaneously but recur an average of two to three times per year.[18] In a minority of patients, such symptoms become chronic.

Postictal depression is also associated with CPS but is less common than postictal psychosis.[19] Patients with postictal depression may have flattened affect and anhedonia more often than sadness, and postictal depression is commonly associated with delirium and other postictal cognitive disturbances.[20] Kanner and colleagues[19] found that symptoms last an average of 24 hours, although symptoms may be more prolonged.[11] In most cases, postictal depressive symptoms do not just represent a reactive response to the stress of having a seizure.

Other postictal symptoms are less common. Acute postictal anxiety is relatively infrequent and is usually associated with postictal depression.[19] Postictal mania and hypomania occur infrequently. Postictal aggression can also occur; it is generally associated with delirium, psychotic symptoms, or abnormal mood states.

The management of patients with postictal neuropsychiatric symptoms has a number of tenets. First, enhanced treatment of the seizure disorder is crucial; patients whose seizure disorders are poorly controlled appear to have a greater tendency toward postictal affective and psychotic symptoms. In addition to anticonvulsants for seizure prophylaxis, other psychotropic medications may be indicated, especially if symptoms are prolonged, present a risk to the patient or to others, or adversely affect the patient's ability to receive appropriate treatment. Such situations occur most commonly with psychosis; low doses of antipsychotics can reduce agitation and diminish psychotic symptoms. If such symptoms are limited to the postictal period, these medications can be discontinued once symptoms resolve, because the best prophylaxis against recurrence of psychosis is treatment with anticonvulsants to prevent seizures. Antidepressants are uncommonly indicated for depressive symptoms limited to the postictal period.

In addition to medications, behavioral treatments can be instituted to facilitate coping and to maintain the patient's safety. Such interventions may include the use of restraints or sitters, frequent reorientation, or the presence of familiar family members. Finally, it is important to know the patient's postictal pattern of symptoms to prepare caregivers and family members for what lies ahead. Seizures and their neuropsychiatric sequelae are commonly stereotyped; that is, patients tend to have the same postictal symptomatology from seizure to seizure. If a patient is known to become psychotic or dangerous after a seizure, the treatment team can be prepared with antipsychotic treatments or other safety-enhancing measures.

Interictal (Chronic) Neuropsychiatric Phenomena

Psychiatric syndromes are also common in the period between seizures; patients with seizure disorders have chronic psychiatric disorders at substantially higher rates than do those in the general population. Depression, anxiety, and psychosis are all common, with depressive disorders being the most prevalent. In contrast, interictal hypomanic or manic symptoms are uncommon.

Interictal depression is common and can be disabling. Rates of depression and suicide among patients with epilepsy are four to five times greater than those in the general population,[1,21,22] and up to 80% of patients with epilepsy report having some feelings of depression.[23,24] A constellation of biological and psychosocial factors likely coalesce to result in these elevated rates of depression, but risk factors for depression that are specific to seizure disorders include poor seizure control and CPS,[25,26] especially with left-sided temporal lobe seizure foci. In fact, suicide may be 25 times more likely among patients with TLE than among those in the general population.[27]

Furthermore, this relationship between depression and seizures may be bidirectional. History of depression has been associated with the onset of seizures, given that a history of depression increases (by threefold) the risk of developing a seizure disorder.[20,28] Some have hypothesized that depression and epilepsy share neurotransmitter abnormalities (e.g., reduced noradrenergic, dopaminergic, and serotonergic activity), and that these shared abnormalities may explain the link between the two conditions.

The symptoms of interictal depression are often distinctive. Atypical features are common,[23] and many patients have depressive symptoms that are more consistent with dysthymia than with major depression. Furthermore, these dysthymic symptoms are often interrupted by symptom-free periods that can last for hours or days.[29] Blumer and associates[30] have described a clinical syndrome called *interictal dysphoric disorder*, which is characterized by interictal dysthymic symptoms with intermittent irritability, impulsivity, anxiety, and somatic symptoms.

Interictal anxiety disorders vary in frequency. Anxiety symptoms are more common in patients with epilepsy than those in the general population, and, of the anxiety disorders, panic disorder appears to be the most common. Interictal panic disorder is present in approximately 20% of patients with epilepsy,[7] with symptoms that differentiate the panic attacks from the feelings of panic that occur during a seizure. Other anxiety disorders, such as generalized anxiety disorder (GAD) or obsessive–compulsive disorder (OCD), are less common.[1]

Interictal psychosis can be intermittent (with brief, recurrent episodes), but more commonly it is continuous and chronic. Psychotic symptoms are approximately 10 times more likely to occur in patients with epilepsy.[31]

Psychosis is more common in patients with CPS (especially those with TLE) and in those with multiple seizure types, a poor response to treatment, or a history of status epilepticus.[32] Clinically, interictal psychotic symptoms most often consist of paranoid delusions with associated visual or auditory hallucinations. Affective blunting, a lack of motivation, and catatonia are also common.[32] Compared with patients with primary schizophrenia, patients with interictal psychosis have a greater preservation of affect and more visual hallucinations.

Finally, some evidence supports an interictal personality change among patients with TLE. The TLE personality syndrome, described primarily by Gastaut and co-workers[31] and by Geshwind,[33] has features that include moral rigidity, hyperreligiosity, hypergraphia, hyposexuality, and hyperviscosity ("a sticky personality"). However, this concept remains controversial, with other authors[34] refuting the existence of such a syndrome.

The management of interictal psychiatric phenomena is similar to the treatment of primary psychiatric disorders. However, there are a number of special considerations in this population. Given that most interictal psychiatric symptoms are more common when seizures are poorly controlled, effective treatment with anticonvulsants is of vital importance. Treatment of psychiatric symptoms associated with epilepsy should also include behavioral and educational interventions that reduce the risk related to their seizure disorder (e.g., having family ensure that depressed patients take their anticonvulsants or keeping manic or psychotic patients from driving when this is unsafe).

Treatment of psychiatric symptoms with psychotropics is frequently indicated, but the effects of these agents on the seizure threshold should be considered. Treatment of epileptic patients with antidepressants has been controversial, given the propensity of some antidepressants to increase the risk of seizure. However, the risk of seizure with most antidepressant agents is quite small when these agents are used at standard doses.[35] Citalopram,[36] sertraline,[35,36] venlafaxine,[20] and tricyclic antidepressants (TCAs)[30] have all been used successfully in patients with epilepsy without significantly exacerbating the underlying seizure disorder.

Given their relative safety with regard to seizure exacerbation and their overall safety and tolerability, selective serotonin reuptake inhibitors (SSRIs) should be considered as first-line treatment for patients with interictal depression. In general, starting with a low dose and increasing the dose gradually should minimize the risk of seizure in these patients. In general, bupropion and maprotiline should be avoided because these agents are more strongly associated with the development of seizures. Among the TCAs, clomipramine may be associated with a greater risk of seizure and should probably be avoided as well.[37] Monoamine oxidase inhibitors (MAOIs) have not been associated with an elevated risk of seizure, although they have not been studied in patients with seizure disorders. Finally, electroconvulsive therapy (ECT) can be used to treat patients with epilepsy and severe depression[38]; ECT appears to increase the seizure threshold,[39] and it has been used safely in patients with epilepsy.[40]

Patients with anxiety disorders can be treated with antidepressants or with benzodiazepines; buspirone, sometimes used for the treatment of GAD, can lower the seizure threshold and generally is not recommended for this population.[41] Interictal psychosis can be treated with antipsychotics. It appears that all antipsychotics may modestly lower the seizure threshold; however, low-potency antipsychotics, such as chlorpromazine, may have greater effects on the seizure threshold than higher-potency agents.[42,43] Furthermore, clozapine has been associated with an elevated seizure risk and, in general, should be avoided. Therefore atypical antipsychotics, such as risperidone, or high-potency typical antipsychotics, should be used when needed. Again, titrating the dosage slowly and using the lowest effective dose should minimize the risk of seizure in this population.

In sum, virtually any psychiatric symptom can occur with any type of seizure at any time before, during, or after the seizure. However, anxiety is most common during a seizure, psychosis is most common postictally, and depression is the most common chronic symptom between seizures. Virtually all symptoms are more common in patients with CPS than with other types of seizure disorders. Treatment of ictal phenomena involves treatment of the seizure, whereas postictal and interictal phenomena may require the use of antipsychotics, anxiolytics, or antidepressants for optimal symptomatic relief. Careful attention to the patient's safety is always an important consideration (whether from seizure or suicidality), and a knowledge of the patient's pattern of symptoms associated with their seizures helps caregivers and family members prepare for sequelae.

NONEPILEPTIC SEIZURES

Patients who appear to be having epileptic seizures may, in fact, be having abnormal movements as the result of another medical or neurologic problem or, most often, as a consequence of psychological factors (e.g., a conversion reaction). These events, called *nonepileptic seizures (NESs)* and also referred to as *psychogenic seizures* or *pseudoseizures*, pose a common and important problem. Patients with NESs have convulsive events more frequently and are more significantly disabled by these events than are those with true seizure disorders.[44] Even after a diagnosis of NESs has been made, affected patients continue to be disabled by recurrent convulsive events.[45]

The general hospital psychiatrist is frequently called on to assess patients suspected of having NESs. Knowledge of the epidemiology, differential diagnosis, clinical features, and relevant diagnostic studies that may suggest the presence of NESs can significantly facilitate making the diagnosis. Once the diagnosis of NESs is suspected, it is just as important for the psychiatrist to be able to discuss the diagnosis of NESs with the patient in a way that is validating, reassuring, and supportive.

NESs are common; they are seen in approximately 10% of outpatients with intractable seizure disorders and in approximately 20% of patients with intractable seizures referred to epilepsy monitoring units.[46,47] About three quarters of those with NESs are women, and they most often exhibit symptoms when they are between the ages of 15 and 35.[45] A history of sexual abuse is common among patients with NESs, occurring in at least 25% of those with the condition.[48–51] Further complicating the picture is the fact that patients with NESs often have true seizure disorders as well, with roughly 25% of patients with NESs also having true seizures.[52]

TABLE 19–2 Differential Diagnosis of Nonepileptic Events

General Medical Conditions
Transient ischemic attack (TIA)
Complicated migraine
Syncope
Hypoglycemia
Parasomnia (e.g., rapid eye movement [REM] behavior disorder or night terrors)
Narcolepsy
Myoclonus (from metabolic disturbance)
Psychiatric Causes
Conversion disorder
Somatization disorder
Dissociative disorder
Panic disorder (simulating partial seizures)
Volitional Deception
Factitious disorder (goal is to maintain the sick role)
Malingering (goal is to obtain secondary gain, e.g., disability income)

NESs are associated with general medical conditions, deceptive acts, and unconscious productions of symptoms that appear to be epileptic seizures. Table 19–2 displays a number of conditions that can be mistaken for epilepsy. Of these conditions, unconscious, psychologically mediated convulsive activity (essentially conversion seizures) are the most common,[46] and we will focus on this etiology of NESs. Other causes of functional somatic symptoms, such as factitious disorder and malingering, are more extensively covered in Chapter 16.

Clinical Considerations

In this section, we discuss methods for making a clinical diagnosis of NESs. For the purposes of this discussion, we will assume that medical and neurologic causes of NESs have been ruled out and that the etiology of the NESs is psychogenic (i.e., conversion disorder).

Although all features suggestive of NESs (discussed later) can also occur in true seizure disorders, certain clinical features of the periictal and convulsive phases are more suggestive of NESs. That said, a single clinical feature taken in isolation should not be used to confirm a diagnosis of NESs. Most NESs simulate generalized tonic–clonic (GTC) seizures. The more features that deviate from the usual characteristics of a GTC seizure, the more likely it is that the event is a NESs. Therefore it is useful to know the usual characteristics of GTC seizures. Careful observation throughout the seizure can be very useful in the diagnostic assessment.

GTC seizures usually are sudden in onset; although there may be an aura before the seizure, there is usually a sudden loss of consciousness, followed by a brief tonic period of less than 30 seconds. A more prolonged period of convulsive, clonic activity follows. This activity is characterized by bilateral, symmetrical, and rhythmic jerking of the upper and lower extremities; trunk activity and pelvic thrusting are uncommon. Loss of continence, tongue-biting, and other injuries may occur. The patient remains unconscious and unresponsive throughout the event and is amnestic for the episode. After the event the patient may be confused or drowsy or complain of headache; the patient is rarely completely lucid in the immediate postictal period. Most GTC seizures are quite brief, lasting less than 3 minutes, and they have a stereotyped pattern in a given individual.

Table 19–3 lists the clinical features that suggest NESs. The gradual onset of a seizure, responsiveness during the seizure, pelvic thrusting, asymmetrical clonic activity, and lucidity immediately after the event indicate that the event may not be epileptic. It should be emphasized again that certain types of seizure are marked by symptoms that appear to suggest NESs. For example, simple partial seizures may involve asymmetrical jerking with preserved consciousness. CPS can manifest with only behavioral or psychiatric symptoms. Frontal lobe seizures may cause pelvic thrusting. Automatisms during partial seizures may result in acts that appear volitional. However, combinations of atypical features suggest that NESs are the more likely diagnosis.

A number of diagnostic procedures can be performed to aid in the diagnosis of NESs. The two most useful of these are video-EEG monitoring and so-called provocative testing. The use of video-EEG monitoring allows one to correlate EEG changes (or the lack thereof) during a convulsive event. If a patient experiences a typical event and the EEG remains normal, this suggests NESs, especially when there are other clinical features that are inconsistent with epilepsy. However, it should be noted that both complex and simple partial seizures may give rise to normal EEGs in 10% to 40% of cases.[46,53] The EEG capture of multiple events reduces the likelihood of such false-negative EEG findings.

TABLE 19–3 Features that Suggest Nonepileptic (Conversion) Seizures

Historical Features
History of sexual abuse
History of other unexplained neurologic symptoms occurring during stress
Seizures despite multiple adequate trials of anticonvulsants at therapeutic levels
Features of Event
Events occur with suggestion/provocation
Gradual onset and offset of symptoms
Responsiveness during event
Weeping, speaking, or yelling during the event
Asymmetrical clonic activity
Head bobbing or pelvic thrusting
Rapid kicking or thrashing
Prolonged duration of symptoms (> 3 minutes)
No EEG abnormalities during the event
Postevent Features
Lucid during immediate postictal period
Able to recall event
Lack of incontinence, tongue biting, or physical injury despite numerous events
Postictal prolactin is normal
Neuropsychological testing suggestive of conversion symptoms

In addition to using video-EEG monitoring, use of suggestion or provocative stimuli can induce a seizurelike event during EEG monitoring. Provocative stimuli include injection of normal saline or placement of a tuning fork on the head after a suggestion has been given that the procedure will likely cause a seizure. It is crucial that EEG monitoring be done during these procedures because true epileptic seizures can also be more frequent during periods of stress and patients may have both epileptic and nonepileptic events. Much discussion has ensued about the ethics of deception under these circumstances; researchers have found that such provocative testing can be approached honestly with the patient with high rates of suggestibility and little adverse effect on the patient–physician alliance.[54,55]

In addition, a number of other ancillary studies can be used when considering a diagnosis of NESs; prolactin levels have been measured, given that prolactin levels typically rise during seizures, possibly due to disruption of hypothalamic inhibition of prolactin release during a seizure. This rise is maximal within the first 30 minutes after a seizure. However, in more than 10% of patients with GTC seizures, 30% of patients with temporal lobe seizures, and 60% of patients with frontal lobe seizures, prolactin is not elevated.[56] Cragar and colleagues,[56] in their review of the literature, found that a rise in prolactin is suggestive of epilepsy but that a failure of prolactin to rise is less predictive of NESs. Other diagnostic laboratory values, such as creatine phosphokinase (CPK), may be even less sensitive and specific, especially when taken in isolation.

Neuropsychological testing can be a useful adjunct to a clinical and laboratory evaluation. Such testing can provide information about co-morbid psychiatric diagnoses, personality styles, and tendency toward conversion reactions. Some studies demonstrate that patients with NESs, when compared with patients with epilepsy, exhibit less objective evidence of cognitive impairment and are more likely to show impairments that are a function of poor effort rather than real deficits.[57,58] Also, some studies of patients with NESs using the Minnesota Multiphasic Personality Inventory (MMPI) report an association with the "conversion V" profile with elevations in scales 1 (Hs, hypochondriasis), 3 (Hy, hysteria), and 2 (D, depression).[56] However, such testing cannot definitively make or exclude a diagnosis of NESs, and there is significant overlap of results, particularly on cognitive testing, between patients with NESs and those with epilepsy.[59]

In short, making a definitive diagnosis of NESs can be difficult. There are characteristic features of epidemiology, clinical events, laboratory values, and EEG monitoring that may suggest NESs, but for each individual thought to have NESs, there are others in whom true epilepsy can result in a diagnosis of NESs. However, a thorough evaluation using each of these domains—with EEG-video monitoring being perhaps the best diagnostic test—can help the psychiatrist determine whether NESs are more or less likely.

It is important to allow for the possibility that one's diagnosis of NESs may be incorrect. Patients with NESs typically have symptoms that are quite convincing for epileptic seizures; conversely, patients diagnosed with conversion symptoms are found to have an organic syndrome related to the supposed conversion symptom roughly 20% of the time.[60] This should not prevent clinicians from moving forward on the basis of their clinical findings but should simply serve as a reminder to maintain an open mind about the diagnosis.

General medical providers often feel that once the diagnosis of NESs has been made, treatment is over. However, fortunately *and* unfortunately, treatment is truly just beginning. After the diagnosis is made, patients with NESs continue to have frequent and disabling NESs events; only about 30% will stop having convulsive events.[45,61] However, early diagnosis is associated with better outcome,[61] and presentation of the diagnosis and a treatment plan in a way that is acceptable to the patient is critical.

Table 19–4 lists the important features of NESs diagnosis and the treatment plan for patients with the disorder. In general, the tenets of revealing the diagnosis are similar to those outlined for conversion disorder in Chapter 16. First of all, the diagnosis should be framed in a positive way: It is tremendously reassuring that these events are not due to abnormal electrical discharges in the brain, and there is no need to take anticonvulsant medications and deal with their side effects.

If a patient feels as if he or she is being told that there is nothing wrong, it can be useful to emphasize that although there is not a *structural* or *electrical* abnormality present, it is clear that there is an abnormality of *function* of their nervous system that will require integrated treatment. Furthermore, the physician should make it clear that he or she understands that these events are having a significant impact on the patient's life and obviously require ongoing efforts to reduce their negative impact.

Next, the physician should describe the impact of mood, anxiety, and stress on these symptoms and inform the patient that reduction of these symptoms is absolutely imperative to help the patient improve his or her function and quality of life. However, rather than simply making a referral to a psychiatrist, the physician should also emphasize that the patient will continue to see his or her neurologist or primary care physician on a regular basis as a crucial part of the treatment. The regularity of this follow-up is important: The patient should have an appointment with the caregiver regardless of whether he or she is having active symptoms, thus disconnecting the link between symptoms and medical attention.

Finally, suggesting to the patient that his or her symptoms are likely to improve gradually over time can be helpful. As with pain management, the goal of treatment should be to optimize function and quality of life rather than focusing on the total absence of symptoms.

CEREBROVASCULAR DISEASE

Given that cerebrovascular accidents (CVAs) result in brain areas with reduced or absent function, it is not surprising that abnormalities of affect, behavior, and cognition are common after a CVA. This section discusses the prevalence, diagnosis, and management of patients with psychiatric symptoms after a CVA.

Each year 795,000 people suffer new or recurrent stroke[62]; more than half of them suffer from significant poststroke neuropsychiatric sequelae.[63] Such neuropsychiatric sequelae of strokes have been recognized for decades. More than 50 years ago, both Kraeplin[64] and Bleuler[65]

TABLE 19–4 Guidelines for Presenting a Diagnosis of Nonepileptic Seizures and Developing a Treatment Plan

Presentation of the Diagnosis

1. Frame the diagnosis in a positive way: Symptoms are not due to abnormal electrical activity, and risks of anticonvulsants need not be undertaken.
2. Explain that symptoms are likely due to a problem with the *function* of the nervous system, rather than electrical or structural abnormalities.
3. Explain that these symptoms are common and are likely to improve gradually over time. Give specific suggestions regarding how they will improve (e.g., episodes will become less prolonged, then become less frequent, then have fewer symptoms during each episode, and so forth).
4. Acknowledge the disability that such symptoms have caused and the importance of developing a treatment plan that will improve the function of the nervous system and reduce disability.
5. Introduce the idea that anxiety, stress, and mood significantly affect the frequency and severity of these events and that reduction of these symptoms is crucial in the patient's treatment.
6. Describe a treatment plan that includes integrated, consistent treatment from providers in psychiatry, neurology, and primary care.

Treatment Plan

1. The treatment plan should include as much psychiatric care as the patient will allow. Weekly psychotherapy to assess unconscious motivation, to allow psychoeducation, and to provide support is ideal.
2. Psychotropic medications should be used to treat co-morbid psychiatric symptoms (e.g., associated with major depression).
3. Regular follow-up from other caregivers is a key component of the treatment plan. Appointments should be scheduled at regular intervals, whether or not the patient is symptomatic, and patients should receive positive reinforcement (and not a decrease in frequency of follow-up) when symptoms subside.
4. Physical examinations should be done regularly, but diagnostic studies should be avoided unless clearly indicated.
5. Despite the diagnosis of nonepileptic seizures, all caregivers should remain vigilant for the possibility that an organic diagnosis has been missed or that nonepileptic seizures and epilepsy are both present.

noted an association between cerebrovascular disease and depressive illness. Ironside,[66] in 1956, was the first to describe pathologic crying and laughing associated with cerebral infarction, now a well-described poststroke syndrome termed *pseudobulbar affect*. Despite the high incidence of these disorders and their frequent description in the literature, acute emotional and behavioral sequelae of stroke go largely unrecognized and untreated.[67]

Neuropsychiatric syndromes caused by stroke can be conceptualized on the basis of lesion location. Whereas our understanding of brain circuitry has become much more sophisticated than prior models postulating that certain cortical lobes performed specific cognitive functions, it remains true that lesions in specific cortical areas are more likely to cause characteristic cognitive and neuropsychiatric deficits. For example, strokes in the left frontal lobe are more likely to result in a nonfluent aphasia, and strokes affecting the right parietal lobe most frequently cause anosognosia, an unawareness of illness or of neurologic deficits. Table 19–5 provides a list of some correlations between neuropsychiatric deficits and lesion locations.

Neuropsychiatric syndromes caused by strokes can also be discussed with regard to symptomatology. The following section discusses poststroke depression, mania, psychosis, anxiety, and other common neuropsychiatric sequelae of stroke.

Poststroke Depression

Poststroke depression (PSD) is the prototypical acute psychiatric manifestation of stroke. It is common; approximately 20% of patients meet criteria for major depression in the poststroke period, and another 20% meet criteria for minor depression.[68–70] Stroke-associated depression may reduce survival and increase the risk of recurrent vascular events.[71,72] Risk factors for PSD include a history of depression, prestroke functional impairment, living alone, poststroke social isolation, and possibly female gender.[73]

Both biological and psychological theories of etiology have been studied. Biological hypotheses include lesion location (e.g., of the left frontal region and left basal ganglia),[69,74,75] neurotransmitter mechanisms (decreased serotonin and norepinephrine), inflammatory cytokine-mediated (increased interleukin [IL] 1-β, IL-18, and tumor necrosis factor [TNF] -α), and gene polymorphism mechanisms (e.g., short variant of serotonin transporter gene–linked promotor region).[76] Psychological factors, largely related to the various functional and personal losses associated with stroke, also contribute to the development of PSD. The correlation between location of stroke and the likelihood of developing PSD has been controversial; some studies have demonstrated positive correlations, and a large meta-analysis of 143 studies by Carson and co-workers[77] found no correlation between lesion location and the risk of PSD.

PSD is associated with significant long-term negative effects on social function, motor abilities, and quality of life.[78–80] Moreover, the negative effect of depression on functional impairment continues well beyond the period of abnormal mood symptoms.[81] Such extended functional disability may be due to poor initial rehabilitation efforts by patients with PSD that limit the recovery of strength and mobility.

Diagnosis of PSD is straightforward in many cases, although certain situations can make diagnosis quite challenging. A number of nondepressive neurologic stroke sequelae may resemble symptoms of depression. Patients with expressive aprosodias have monotonous speech that may make them appear sad or withdrawn, and their affect

TABLE 19–5 Correlations Between Cortical Lesion Location and Neuropsychiatric Symptoms

CORTICAL AREA	POTENTIAL NEUROPSYCHIATRIC SYMPTOMS
Frontal Lobes	
Orbitofrontal region	Disinhibition, personality change, and irritability
Dorsolateral region	Executive dysfunction: poor planning, organizing, and sequencing
Medial region	Apathy and abulia
Left frontal lobe	Nonfluent (Broca's) aphasia, poststroke depression (possibly)
Right frontal lobe	Motor dysprosody
Temporal Lobes	
Either side	Hallucinations (olfactory, gustatory, tactile, visual, or auditory), episodic fear, or mood changes
Left temporal lobe	Short-term memory impairment (to verbal or written stimuli), fluent (Wernicke's) aphasia (left temporoparietal region)
Right temporal lobe	Short-term memory impairment (nonverbal stimuli; e.g., music), sensory dysprosody (right temporoparietal region)
Left parietal lobe	Gerstmann's syndrome (finger agnosia, right/left disorientation, acalculia, and agraphia)
Right parietal lobe	Anosognosia, constructional apraxia, prosopagnosia, and hemineglect
Occipital lobes	Anton's syndrome (cortical blindness with unawareness of visual disturbance)

may appear blunted. The presence of anosognosia (neurologically mediated unawareness of illness usually associated with right parietal lesions) may look like denial associated with depression, and this symptom can itself lead to frustration and anger when others insist that the patient has a problem that he or she simply cannot recognize. Finally, aphasias can make the diagnosis of depression—or any diagnosis—more difficult because of the difficulty of communicating with such patients. By being aware of these potential neurologic sequelae and by carefully using criteria from *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[82] with particular attention paid to depressive symptoms that overlap less with concurrent medical and neurologic symptoms (e.g., feelings of guilt, worthlessness, hopelessness, and suicidality), in most cases the psychiatrist can verify the presence or absence of PSD.

Despite the significant consequences of PSD (both because of underdiagnosis[67] and the fear of intolerable side effects from antidepressant medications), it is often undertreated. However, early and effective treatment of depression is perhaps even more crucial in this patient population than it is in other populations, given the need for full mobilization for occupational and physical therapy and other functional retraining early in the course of recovery.

A number of placebo-controlled trials have demonstrated that antidepressants are effective in the treatment of PSD. SSRIs[83–86] and nortriptyline[87] have been shown to relieve symptoms of PSD; another study of nortriptyline found that treatment of depression resulted in improved cognitive outcome.[88] A study by Robinson and associates[89] found that nortriptyline was more effective than either fluoxetine or placebo in treating PSD and improving functional outcomes.

Studies of PSD have found disruptions of both noradrenergic and serotonergic pathways[85]; the effectiveness of venlafaxine was demonstrated in a case series by Kucukalic and colleagues,[90] and only 2 of 30 patients studied had mild elevations in blood pressure, which would be a side effect of concern with venlafaxine in poststroke patients. Psychostimulants have also been used in the treatment of PSD. Retrospective studies using psychostimulants (methylphenidate and dextroamphetamine) to treat PSD found these medications to be effective, with response rates of 47% to 80%.[91,92] Response to psychostimulants was rapid (usually within 48 hours), and adverse events were rare. However, unlike SSRIs and TCAs, psychostimulants have not been studied under placebo-controlled, double-blind conditions for the treatment of PSD.

ECT also appears to be an effective treatment for PSD, with high rates of response and low rates of medical complications.[93] ECT is more extensively discussed in Chapter 33. In addition to the somatic treatments of PSD, group and family psychotherapy have also been reported to safely and effectively treat PSD.[94,95] There are few randomized and controlled trials of individual psychotherapies for PSD. One study found that problem-solving therapy reduced the incidence of depression and also delayed the time to onset, compared to placebo, for poststroke patients.[96] Another study found no significant difference between cognitive-behavioral therapy, attention placebo, and standard care.[97] More studies are needed in this area.

Administration of psychiatric medications to at-risk populations to prevent the onset of psychiatric illness is an increasingly popular area of study. Several recent studies have evaluated whether antidepressant medication can prevent PSD.[96,98–100] Although initial studies demonstrated differences in rates of depression in poststroke patients who received medication compared to placebo, they were not statistically significant and were underpowered.[98,99] A more recent and methodologically sound study by Robinson and associates[96] evaluated 176 nondepressed patients within 3 months of stroke and randomized them to three groups, a double-blinded escitalopram and placebo group and a nonblinded problem-solving therapy group. Rates of major and minor depression were statistically significantly lower for both escitalopram and problem-solving therapy, though escitalopram remained significant only with an intention-to-treat analysis. The potential clinical impact of these studies is impressive, but more studies are needed to definitely direct clinical care.

For most patients with mild to moderate PSD, SSRIs are the treatment of choice, given their proven efficacy, favorable side effect profile, and cardiovascular safety. However, TCAs, despite higher rates of side effects than SSRIs, might also be considered first-line agents for PSD because of their potentially superior efficacy. For more severe depression

that impairs decision-making capacity, nutritional intake, or ability to participate in rehabilitation, psychostimulants should be strongly considered; methylphenidate or dextroamphetamine can be started at 2.5 to 5 mg in the morning, and a protocol for dosing and patient monitoring can be followed (Table 19–6). ECT can also be considered in patients with incapacitating depression. Prophylactic treatment with antidepressants to prevent depression is supported by preliminary studies and may be prudent in patients with numerous risk factors; careful analysis of risks and benefits for the individual patient is still required.

Other Poststroke Psychiatric Phenomena

Other psychiatric syndromes than occur in the poststroke period include anxiety, mania, and psychosis. Poststroke anxiety is common, and usually arises in concert with PSD. Approximately one fourth of patients meet criteria for GAD (except for duration criteria) in the acute poststroke period; at least three fourths of these patients with poststroke GAD symptoms have co-morbid depression.[101,102] Poststroke anxiety has a negative impact on the functional recovery of stroke victims and has been associated with impairment in activities of daily living (ADL) up to 3 years after the event.[102] The functional impairment of PSD and poststroke GAD appear to be additive, insofar as patients with both GAD and PSD have greater ADL impairment at follow-up than those with isolated PSD.[103]

Poststroke mania occurs in fewer than 1% of patients.[3] Symptoms of poststroke mania are similar to those of primary mania (with flight of ideas, pressured speech, a decreased need for sleep, grandiosity, and associated psychotic symptoms). Lesions in the right orbitofrontal cortex, right basotemporal cortices, dorsomedial thalamus, and head of caudate appear to be associated most often with poststroke mania.[104–109] Stroke in the right hemisphere, compared with the left, has led to increased serotonin binding, and it is hypothesized that this may result in poststroke mania.[110]

Poststroke psychosis is also uncommon, occurring at a rate of approximately 1% to 2%.[111] Such patients usually have right temporoparietal lesions and a high rate of associated seizures.[111,112] This suggests that temporal lobe damage that leads to CPS and to associated psychosis may account for symptoms in a significant percentage of these patients.

Finally, there are two other clinical neuropsychiatric syndromes that are common in the poststroke period. The first is termed *catastrophic reaction*, a collection of symptoms involving patient desperation and frustration. This syndrome is relatively common; rates of poststroke catastrophic reaction are 3% to 20%.[113,114] Catastrophic reactions are strongly associated with PSD, with roughly three quarters of patients with catastrophic reaction having PSD.[114] Catastrophic reactions are also associated with a personal and family history of psychiatric disorders.[113]

Catastrophic reactions also appear to be associated with anterior subcortical lesions and with left cortical lesions.[113–115] Given the strong association of catastrophic reactions and depression, some feel that such a reaction is a behavioral symptom of depression (provoked by anterior subcortical damage) rather than a discrete syndrome. Others feel that catastrophic reactions result from damage to left hemispheric areas involved in the regulation of emotions related to social communication.[114]

The second of these clinical syndromes is *pseudobulbar affect*, also termed *pseudobulbar palsy*. This syndrome (which consists of frequent and easily provoked spells of laughing or crying) occurs to some degree in approximately 15% of poststroke patients.[116,117] The pathophysiology is unknown but is thought to involve frontal release of brainstem emotional centers.[118] It is usually seen in a mild form, with brief fits of crying or laughing linked with appropriate changes in mood; however, in more serious cases it may involve frequent and spontaneous fits of laughing and crying inappropriate to the context. It can cause embarrassment, curtailment of social activities, and a decreased quality of life.[119]

Treatment of these poststroke phenomena generally parallels the treatment of primary psychiatric syndromes. Poststroke anxiety can be treated like any primary anxiety syndrome. SSRIs are effective in the treatment of a variety of anxiety disorders, including GAD, and, given that most patients with poststroke anxiety have co-morbid PSD, these agents are often the treatments of choice. Benzodiazepines can also be given for isolated anxiety, but they can lead to ataxia, sedation, and paradoxical disinhibition; therefore they must be used with caution in this population. Furthermore, these agents do not treat co-morbid depression.

Treatment of poststroke mania follows the same rules as does the treatment of primary mania: Mood stabilizers and adjunctive antipsychotic medications or benzodiazepines are used to control symptoms. Treatment studies of poststroke

TABLE 19–6 Guidelines for the Use of Psychostimulants to Treat Depression

1. Consider possible (relative) contraindications to psychostimulant use:
   (a) history of ventricular arrhythmia
   (b) recent myocardial infarction
   (c) congestive heart failure with reduced ejection fraction
   (d) poorly controlled hypertension
   (e) tachycardia
   (f) concurrent treatment with MAOIs
2. Initiate treatment with morning dose of 5 mg methylphenidate or dextroamphetamine (2.5 mg in frail elderly or medically tenuous patients).
3. Check vital signs and response to treatment in 2-4 hours (the period of peak effect).
4. If the initial dose is well tolerated and effective throughout the day, continue with a single daily morning dose.
5. If the initial dose is well tolerated and effective for several hours, with a loss of effect in the afternoon, give the same dose twice per day (in the morning and the early afternoon).
6. If the initial dose is well tolerated but is without significant clinical effect, increase dose by 5 mg per day until a clinical response is achieved, intolerable side effects arise, or 20 mg dose is ineffective (i.e., a failed trial).
7. Continue treatment throughout the hospitalization; stimulants can usually be discontinued at discharge.

mania have found lithium, valproic acid, carbamazepine, neuroleptics, and clonidine variably efficacious, though none of these treatments has been examined in placebo-controlled, double-blind trials for this condition.[105,110,120–122] Poststroke psychosis can be treated symptomatically with antipsychotics. However, anticonvulsants (especially valproic acid and carbamazepine) should be used when psychotic symptoms are the result of CPS, because psychotic symptoms should improve with better seizure control.

Finally, pseudobulbar affect and catastrophic reaction may respond well to antidepressants. A few trials of TCAs and SSRIs, some of which were placebo-controlled, have demonstrated efficacy in reducing symptoms of pseudobulbar affect.[123–126] Symptoms of catastrophic reaction may also improve with antidepressant treatment of co-morbid PSD.

In short, psychiatric symptoms after stroke are common and have a significant impact on the long-term outcome of poststroke patients. Awareness of neurologic symptoms that may mimic psychiatric illness (e.g., anosognosia) and careful diagnostic interviews can allow accurate diagnosis and prompt treatment. In general, psychiatric symptoms secondary to stroke are treated in the same way as are nonstroke-related psychiatric syndromes with similar symptoms.

THE MANAGEMENT OF PATIENTS WITH TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is a leading cause of death and disability in the United States; nearly 1.4 million head injuries occur every year.[127] Of these, approximately 235,000 result in hospital admission, and between 50,000 and 60,000 result in death.[127,128] Permanent neuropsychiatric disabilities affect an estimated 80,000 to 90,000 patients who suffer a TBI.[128] Of this group, psychosocial and psychological impairments lead to substantial disability and cause significant stress to their families.[129] The consulting psychiatrist plays an important role in the evaluation and treatment of these patients. In this section the epidemiology and pathophysiology of TBI will be addressed; this will be followed by a discussion of the clinical features and treatment of the affective, behavioral, and cognitive aspects of TBI.

Epidemiology

Disorders that result from TBI are more common than are any other neurologic disease except for headache.[129] Falls cause 28% of TBIs, and motor vehicle accidents (20%), assaults (11%), having one's head struck against an object (19%), other trauma (13%), and unknown trauma (9%) account for the remaining TBIs.[127] Among adults, alcohol is a contributing factor in 40% to 56% of cases.[127,129,130] The highest rates of hospitalization and death after TBI are found in persons older than 75 years.[127] Individuals who have had one brain injury are three times as likely, compared with the general population, to sustain a second, and after a second TBI the risk of another is 10 times higher.[128] It should be noted, however, that even more mild TBIs (i.e., without an associated hospital stay) may result in neuropsychiatric sequelae.

Pathophysiology

TBI can be divided into primary and secondary brain injuries. Primary injury consists of focal and diffuse lesions. Focal TBI generally results from a blow to the head that produces cerebral contusions or hematomas. Epidural hematomas, subdural hematomas, and cerebral contusions are all types of focal lesions. The location, size, and progression of the injury determine resultant morbidity and mortality.[130] Most injuries occur in the polar temporal lobes and on the inferior surface of the frontal lobes as a result of contact with the bony prominences along the base of the skull, often a result of a coup–contrecoup mechanism of injury.[129,131] All are diagnosed by computed tomography (CT) scanning or magnetic resonance imaging (MRI) of the brain. An epidural hematoma is usually caused by head trauma that is associated with a lateral skull fracture and with tearing of the middle meningeal artery and vein and therefore is most often located in the temporal or temporoparietal region.[130,132] There is often loss of consciousness followed by a period of lucency, and then neurologic deterioration. Prompt surgical evacuation of the hematoma is essential. Subdural hematoma is more common than epidural hematoma and generally results from tearing of a bridging vein between the cortex and a venous sinus. Much of the force of an impact is often transmitted to the brain, and the underlying brain injury actually determines the outcome in approximately 80% of cases.[130] Treatment also involves surgical evacuation. Finally, traumatic cerebral contusion is often associated with an initial bout of unconsciousness, generally followed by recovery. Edema may cause fluctuations in the level of consciousness, seizures, or focal neurologic signs.[132] Surgery is rarely undertaken for cerebral contusions.

Diffuse lesions, or *diffuse axonal injury*, is seen more commonly in injuries that involve rapid acceleration, deceleration, or rotational forces.[133] The sites most prone to such injury are the reticular formation, basal ganglia, superior cerebellar peduncles, limbic fornices, hypothalamus, and corpus callosum.[129] Patients who suffer diffuse axonal injury have high rates of morbidity and mortality. The diagnosis, often missed on CT, may be made by use of diffusion-weighted MRI, which is sensitive to the axonal swelling seen after injury. Lack of radiographic evidence of injury does not translate into an absence of damage. Deficits in arousal, attention, and cognition (i.e., processing speed) often result from diffuse axonal injury.

Whereas primary brain injury (focal and diffuse) results from mechanical injury at the time of the trauma, secondary brain injury is caused by the physiologic responses to the initial injury. This is thought to involve a cascade of events, with edema and hematomas leading to increased intracranial pressure, which leads to compression and deformation of surrounding brain tissue and further damage. Neuronal damage is also mediated by release of neurotoxic substances. Although a full discussion of each of these is beyond the scope of this chapter, each substance must be considered when evaluating the status of a brain-injured individual in the acute care setting.

Clinical Presentation

TBI is often divided into three categories according to the severity and the duration of altered mental status; however, there is no definitive breakdown of specific types of sequelae that may be affiliated with each. Whereas more severe injuries are often thought to have more persistent and pervasive consequences, there are certainly instances of significant morbidity even with mild TBI. The severity of the injury is classified by the Glasgow Coma Scale (GCS; Table 19–7). Mild head injury correlates with a GCS score of 13 to 15, moderate injury with a GCS score of 9 to 12, and severe head injury corresponds to a GCS score of less than 8. Lower scores are associated with more severe injury and poorer recovery outcomes.[128]

Other factors that may increase morbidity include the following: lower intelligence quotient (IQ), a concomitant substance abuse disorder, older age, and a history of brain injury.[129] Moreover, the DSM-IV[82] suggests the following criteria to establish the severity of injury significant enough to cause postconcussional disorder, a diagnosis under research (two of the following): (1) a period of unconsciousness lasting more than 5 minutes; (2) a period of posttraumatic amnesia that lasts longer than 12 hours after the closed head injury; or (3) new seizures (or a marked worsening of a preexisting seizure disorder) that occurs within the first 6 months after the closed head injury. Diagnostic criteria for this disorder also include cognitive disturbances and three or more of the following[80]: fatigue; disordered sleep; headache; vertigo or dizziness; irritability or aggressivity; anxiety, depression, or affective lability; changes in personality; and apathy or lack of spontaneity.

These features are representative of the three major categories of neuropsychiatric sequelae that may be seen with TBI: cognitive impairment, changes in personality and behavior, and Axis I psychiatric disorders (e.g., mood, anxiety, and psychotic disorders). Each of these is outlined briefly.

Cognitive Impairment

Cognitive difficulties in acute care settings following TBI may be due to the brain injury itself, delirium, or other factors.[134] As recovery progresses, deficits related to the TBI (e.g., attentional impairment, associated with the reticular activitating system and prefrontal white matter) become more apparent.[135] Impairments in language and executive function (those skills necessary for independence in the world) as well as memory often follow TBI.[135] Examples of executive dysfunction include poor planning, impaired abstraction, and difficulties with calculations.[129,131] Neurocognitive testing is essential to further specify and quantify deficits. Moreover, neuropsychological testing is invaluable in designing an individualized rehabilitation program to meet the specific needs of each patient.

TABLE 19–7 Glasgow Coma Scale

Eye Opening

Flexor response	3
Extensor response	2
None	1

Personality Changes

Personality change due to TBI is a DSM-IV[82] diagnosis characterized by a persistent personality disturbance that represents a change from the individual's prior personality; it is a direct consequence of the injury and is not better explained by delirium, dementia, or another Axis I disorder. The disturbance must also cause clinically significant distress or impairment in occupational or social function.[82] The terms *frontal lobe syndrome* and *organic personality syndrome* are often used to describe these personality changes.[136] Personality changes and behavioral manifestations often include labile affect, disinhibition, poor social judgment, apathy, lewdness, loss of social graces, perseveration, aggressive behavior, paranoia, and inattention to personal hygiene. In a 30-year follow-up study of patients with TBI, Koponen and colleagues[137] found that 23% of injured adults manifested an Axis II diagnosis. These changes may be a direct result of the TBI but also may be exacerbated or caused by delirium, seizures, or use of medications or substances. When evaluating personality changes, the physician should note that the patient may have little insight into the change, so including supportive family members in the evaluation and planning of treatment is essential. Additionally, families may need significant support to cope with changes present in their loved ones.

Mood and Anxiety Disorders

As many as 40% of patients with TBI will develop an Axis I disorder, most commonly major depression, an alcohol-use disorder, panic disorder, a specific phobia, or a psychotic disorder.[137] Depression occurs in 26% to 77% of those with mild TBI, whereas higher rates of depression are associated with more severe injuries.[138–141] These individuals have higher risk because of the neuroanatomic and physiologic changes that occur and because of lost capabilities, changes in roles, and financial and other losses that have occurred.[142] Premorbid substance abuse, poor functioning, lower education, and an unstable work history predict depression after TBI.[143,144] Because there may be significant overlap with cognitive impairment and personality changes, the diagnosis must be made with care. Major depression is associated with poor outcome across multiple domains[139]; this makes its early diagnosis and treatment particularly important. Prominent signs and symptoms include fatigue, distractibility, anger, irritability, and rumination.[138] Neuropsychological testing may be helpful in these individuals. Finally, there is an increased risk of suicide after TBI; up to 15% of individuals make a suicide attempt in the 5 years after TBI.[129] In this population, intense despair, hopelessness, worthlessness, and loss of sense of integrity,

as well as relationship breakdown and isolation, contribute to the risk for suicide.[142,145] The combination of depression and disinhibition associated with frontal lobe injury is also thought to contribute to higher rates of suicide.[129]

Mania has also been shown to occur more often after TBI than it does in the general population.[141] Predisposing factors may include a family history of affective illness, right temporal lobe lesions, and right orbitofrontal cortex injuries; unfortunately, consensus is lacking.[129,141] Furthermore, seizures seem to be more common in this group[141]; this makes the EEG an important diagnostic tool following TBI. For this reason, anticonvulsant medications are the preferred mood stabilizers after TBI (see treatment section).

Regarding anxiety disorders after TBI, GAD and posttraumatic stress disorder (PTSD) appear to be the most common.[141–147] OCD, specific phobias, and panic disorder have also been reported.[140,148] GAD is co-morbid with depression in approximately 11% of patients.[129] There is some evidence that early intervention with cognitive-behavioral therapy for acute stress disorder may prevent PTSD after mild TBI.[146] Other investigators have shown a relationship between impaired memory of the traumatic event and lower rates of PTSD[147]; however, more research is needed in this area.

Psychosis

Psychosis as a consequence of TBI is thought to be relatively rare. Although some authors doubt that a correlation exists,[141] others argue that psychosis may appear immediately after brain injury or years later (with rates between 0.7% and 9.8%).[149] Frontal and temporal lobe injuries are associated with psychosis, as are posttraumatic seizures.[150] Cognitive impairment and behavioral changes (already described) may mimic the symptoms of schizophrenia. Because individuals with schizophrenia have also been found to have a higher incidence of brain injury than those in the general population,[150] it may be true that head injury predisposes these individuals to schizophrenia. Alternatively, it may be that individuals who are already predisposed to schizophrenia have a higher incidence of brain injury for other reasons. More research is needed in this area.

Treatment

Treatment of neuropsychiatric sequelae of TBI is best accomplished with a comprehensive, multidisciplinary, rehabilitative approach. This may include psychiatric, neurologic, psychological, behavioral, occupational, and vocational evaluations.[129] Specific brain-injury centers are best equipped to undertake this; however, not all communities have such resources. Psychiatric evaluation and consultation generally focus on several areas of intervention: pharmacological, behavioral, cognitive, and social (family support). These are discussed in the following section.

Pharmacology

Generally, medications effective for primary psychiatric disorders in non-TBI patients are similarly effective in TBI patients. Because brain-injured patients are often more sensitive to certain medications and their side effects, several guidelines should be considered. The principle of "start low, and go slow" is wise; being overly cautious may lead to inadequate medication trials if therapeutic doses are not achieved or medications are not given sufficient time to work. Slow titration as tolerated by side effects and an adequate duration of trials should be the goal.

Although treatment of depression and anxiety in patients with TBI follows the same principles as those for the treatment of depression and anxiety in the general population, careful attention should be paid to medication side effects. Medications with a high potential for lowering the seizure threshold, causing sedation (typically mediated by antihistamine effects), and inducing anticholinergic side effects and hypotension (usually mediated by peripheral alpha antagonism) should be avoided or used with great care if no better alternative exists. TCAs and bupropion, which both lower seizure threshold, are generally avoided. SSRIs are usually well tolerated. Several studies (only one of which was a randomized controlled trial) with citalopram, fluoxetine, and sertraline have demonstrated improvements in mood and aggression.[151–154] Psychostimulants may be employed for depressive symptoms (irritability, apathy, and depressed mood), cognitive symptoms (arousal, processing speed, and attention), and fatigue,[155,156] although paradoxical dysphoria, agitation, and paranoia may be seen in the brain-injured patient.[129] Improvements have also been seen in depression, anxiety, irritability, and aggression with buspirone; it has a more favorable side effect profile and less abuse potential than benzodiazepines.[157–159] Propranolol (a β-blocker) has been shown to reduce the intensity of agitation and aggression following TBI.[149] ECT remains a good option and is often underutilized. Care should be taken to assess memory and cognitive dysfunction before recommending ECT, given the potential side effects of this treatment.

Mania should be treated using standard agents. However, neurotoxicity from lithium may develop at higher rates in patients with TBI[129]; anticonvulsant mood stabilizers, such as valproic acid or carbamazepine, may be preferable. For patients with co-morbid seizures, anticonvulsants are the treatment of choice.

Neuroleptics are frequently used for agitation and aggression in TBI patients, as well as psychosis. The use of neuroleptics in this population is controversial given research, largely conducted on animals, that indicates they interfere with neural plasticity and are associated with longer posttraumatic amnesia and worse outcomes.[155,160,161] That said, there is also evidence that antipsychotics may be effective for the management of agitation and aggressive behavior.[162] Because brain-injured patients are at increased risk for extrapyramidal symptoms (dystonias, akathisias, and parkinsonian side effects),[129] high-potency agents should be used with care and atypical antipsychotics are generally preferred over typical antipsychotics. Antipsychotics with significant anticholinergic side effects (e.g., clozapine and low-potency typical agents) and antipsychotics that lower the seizure threshold, such as clozapine, should be monitored carefully.

Finally, benzodiazepines and barbiturates should be used sparingly in patients with TBI on account of their potential for causing paradoxical disinhibition, sedation, and worsening of cognitive and motor impairments.[155] If rapid sedation is desired in an agitated patient, low doses may be used with caution.

Behavioral, Cognitive, and Social Interventions

Once deficits related to TBI have been delineated, a comprehensive plan of treatment can be instituted. Behavioral treatments are helpful for the management of maladaptive social behaviors (including aggression) and personality disorders. For patients with prominent mood or anxiety symptoms, who are easily agitated, or who have low thresholds to anger and aggression, environmental modification (e.g., increasing structure, simplifying tasks, reducing or increasing stimulation, and removing triggers and irritations) helps reduce symptoms.[163] Specific cognitive rehabilitation programs may be helpful, depending on individual deficits. These deficits are best assessed by administration of neuropsychiatric testing. Teaching about stress management and coping skills may also be particularly useful. Finally, psychotherapeutic and social interventions, including family education and supportive therapy, may prove useful given the sense of loss and distress often felt by family members and by loved ones.

CONCLUSION

Traumatic brain injury is an important cause of neuropsychiatric disability in the United States. A thorough assessment of mood, anxiety, personality change, and cognition should be a routine part of postinjury screening. The consulting psychiatrist plays an important role in the evaluation and treatment of these patients. Prompt diagnosis and treatment, as well as appropriate referral using a multidisciplinary approach, greatly benefit patients and their families.

Theodore A. Stern, M.D.

Chapter 19 discussed the epidemiology, diagnosis, and management of neuropsychiatric symptoms associated with seizures, strokes, and traumatic brain injuries (TBI). In this chapter, we extend such discussion to other neurologic conditions. We discuss neuropsychiatric symptoms associated with movement disorders, multiple sclerosis, connective tissue diseases, brain neoplasms, and central nervous system (CNS) infections; as in the last chapter, the focus will be on phenomenology, diagnosis, and the practical management of patients with such symptoms.

MOVEMENT DISORDERS

Movement disorders are characterized by abnormalities in the extrapyramidal motor system that result in progressively impaired regulation of voluntary motor activity in the setting of normal strength. Depending on the particular illness, as well as on the stage of the disease, a patient can exhibit hyperkinetic, involuntary movement or hypokinetic, impoverished motor activity. These clinical features reflect dysfunction or degeneration of subcortical gray matter structures, known as the *basal ganglia*. Three movement disorders discussed in the following sections—Parkinson's disease, Huntington's disease, and Wilson's disease—are associated with particularly high psychiatric co-morbidity, ranging from mood and thought disorders to dementia. These disorders pose a particular diagnostic challenge for psychiatrists, for in each case, behavioral symptoms can reflect the primary pathophysiology of the disease, psychologic reactions to debilitating illness, or both. Treatment can be equally challenging, for although medications used to treat the underlying neurologic process can also induce psychiatric symptoms, certain treatments directed at psychiatric symptoms can worsen the movement disorder.

Parkinson's Disease

Parkinson's disease (PD), a neurodegenerative disorder characterized by the clinical triad of resting tremor, rigidity, and bradykinesia/akinesia, affects up to 2.5% of the geriatric population, although its onset in young adults has also been reported.[1] The pathophysiology of PD likely reflects both genetic and environmental influences; it involves loss of dopamine neurons in the midbrain substantia nigra, with subsequent downstream effects in striatal, frontal, and cingulate regions and disruption of cortical–basal ganglia–thalamic circuitry. Postmortem examination can reveal the presence of Lewy bodies as well as the degeneration of noradrenergic neurons in the locus ceruleus, cholinergic neurons in the nucleus basalis, and serotonergic neurons in the dorsal raphe nucleus.[2] Antiparkinsonian medications potentiate dopamine transmission as well as modulate the dopamine–acetylcholine balance in the basal ganglia. The mainstay of treatment is the dopamine precursor levodopa, usually given with carbidopa (which inhibits peripheral metabolism of dopamine). Other useful agents include dopamine agonists (e.g., bromocriptine, pramipexole, and ropinirole), inhibitors of dopamine metabolism (e.g., monoamine oxidase B inhibitors, such as deprenyl and selegiline, and the catecholamine transferase inhibitor tolcapone), anticholinergics (e.g., trihexyphenidyl and benztropine), and amantadine.

Psychiatric disturbances in PD are common and multifactorial. These complications, which encompass dysregulated mood, psychosis, and cognitive impairment, can be primary to the underlying neurodegenerative process or secondary to its pharmacological treatment; in some cases, they may be engendered or exacerbated by the psychologic stress of experiencing a severe, progressive illness. The following sections will discuss the more common psychiatric

sequelae of PD and review approaches to management, bearing in mind that in most cases, well-controlled clinical trials establishing safety and efficacy have yet to be conducted.

Depression in Parkinson's Disease

The reported occurrence of depression in PD ranges widely, possibly because of variations among diagnostic instruments and disease-defining criteria, but in many studies, incidence of clinically relevant depressive symptoms is approximately 35%.[3] Indeed, early PD is often mistaken for depression, given the sizable overlap in clinical phenomenology between the two disorders. Features common to both disorders are summarized in Table 20–1. According to the Global Parkinson's Disease Survey conducted by the World Health Organization, even among patients with established diagnoses of PD, depression was recognized by clinicians in only 1% of cases.[4] The same study indicated that among all measured factors, including severity of motor disability, depression accounted for the greatest impairment in quality of life (QoL).

Given the mixture of potential neurobiological, pharmacological and psychosocial substrates that could account for mood disorders in patients with known PD, careful consideration should be given to differential diagnosis. Depressive features thought to be related to the underlying neuropathology of PD have been well characterized and likely reflect altered monoamine transmission in the brain regions described earlier. In contrast to primary major depressive disorder, patients with parkinsonian depression primarily exhibit anhedonia, anxiety, and sleep disturbance, with far less prominent guilt, irritation, and psychotic features. Although suicide attempts are rare, suicidal ideation is common.[5] Alterations in mood can parallel the "on–off" phenomenon related to abrupt changes in motor activation[6]; depression associated with the "off" period can be reversed with acute administration of levodopa.[5] However, the degree of depression does not usually correlate with either severity of motor symptoms or duration of PD.[2] Caregivers should also bear in mind the possibility that depressive symptoms in PD might alternatively reflect dysthymia, an adjustment disorder, or (rarely) bipolar disorder.[7]

TABLE 20–1 Symptoms Common to Parkinson's Disease and Major Depression

Motor
Bradykinesia/psychomotor retardation
Masked facies/restricted affect
Stooped posture
Cognitive
Impaired memory
Impaired concentration
Indecisiveness
Vegetative
Decreased energy
Fatigue
Impaired sleep
Appetite changes
Somatic
Physical complaints

From Damier P: The role of dopamine, serotonin, and noradrenaline in Parkinson's disease. In Wolters ECH, Scheltens PH, Berendse HW, editors: *Mental dysfunction in Parkinson's disease II*, Utrecht, 1999, Academic Pharmaceutical Productions.

Few controlled studies have examined the safety and efficacy of antidepressant medications in patients with PD and depression. Several reports suggest some benefit from use of dopamine agonists. The D_2 and D_3 receptor agonist pramipexole, which appears to provide significant antidepressant effect when used as an adjuvant in refractory major depressive disorder (MDD) and bipolar disorder,[8–10] has also shown some promise in treating depression among patients with PD.[11–14] Selegiline, a selective type B monoamine oxidase inhibitor (MAOI) originally developed as an antidepressant, has been used to slow the progression of motor decline in PD. Limited studies have not consistently demonstrated an antidepressant effect for selegiline in PD.[15,16] The most widely used treatments for depression in PD are tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs). A single double-blind study indicated a greater effect of nortriptyline (up to 150 mg per day) than placebo in improving depressive symptoms in PD patients[17]; similar results have been obtained with imipramine and desipramine in smaller studies.[18,19] Given their particular efficacy in improving sleep as well as their mild anticholinergic action, TCAs can be especially useful in the PD population; at the same time, though, elderly PD patients are at greater risk for TCA-induced adverse effects, including delirium, cardiac arrhythmias, orthostatic hypotension, and urinary retention.[5] Several SSRIs, which exhibit an improved safety profile compared to TCAs, ameliorated depression among PD patients in open-label trials and case reports.[20] To date, there have been two randomized comparison studies looking at the treatment of depression in PD with use of SSRIs and TCAs. One study conducted by Antonini and associates[21] assessed the effect of 3 months of treatment with low-dose sertraline (50 mg daily) and low-dose amitriptyline (25 mg daily). Patients taking both medications had significantly reduced Hamilton Depression Rating Scale scores, however only sertraline accounted for a significant benefit in QoL. In another study, a randomized, placebo-controlled trial was conducted evaluating the efficacy of citalopram and desipramine.[22] After 14 days, patients taking desipramine showed an improvement in the Montgomery-Asberg Depression Rating Scale (MADRS) when compared with citalopram and placebo, and after 30 days, both medications showed significantly improved MADRS scores when compared with placebo. Mild adverse side effects were twice as frequent in the desipramine group than in the groups receiving citalopram and placebo.

There are also conflicting reports about SSRI-induced exacerbations of motor symptoms in PD.[23] Caution must also be exercised when prescribing both an MAOI and an SSRI or (especially) a TCA, given the risk of serotonin syndrome.[24] Efficacy of newer antidepressants in PD (including norepinephrine and combined serotonin and norepinephrine reuptake inhibitors) is plausible but remains to be studied.[25–27]

Although not supported by well-controlled studies, electroconvulsive therapy (ECT) appears to be effective in improving depression among PD patients.[28] One

retrospective study described a similar benefit of ECT among 25 patients with parkinsonism and 25 age- and gender-matched patients without neurologic co-morbidity.[29] Two studies have also indicated a transient improvement in motor symptoms among PD patients receiving ECT for depression.[29,30] However, the same studies also reported that PD patients demonstrate an increased vulnerability to ECT-related mental status changes, including delirium. There is increasing evidence that transcranial magnetic stimulation (TMS) may improve both the depressive and motor symptoms in PD, via effects on brain monoamine levels.[31–33]

Psychosis in PD

Psychotic features are also common, occurring in as many as 20% to 30% of cases, and are multifactorial in PD patients.[34,35] Especially prominent in patients with dementia, psychotic symptoms are often manifest initially as illusions or as "friendly" visual hallucinations (e.g., beloved relatives or animals). With time, hallucinations typically progress to include frightening or threatening images (e.g., insects or snakes) and paranoid delusions, often involving persecution or spousal infidelity.[34–36] As in depressive syndromes among patients with PD, consideration should be given to several potential etiologies. Psychotic features were recognized as part of the natural course of PD in up to 10% of patients before the advent of antiparkinsonian medications,[35] potentially related to altered subcortical dopamine transmission and to diffuse Lewy body pathology.[37] Both dopamimetic and anticholinergic medications given to alleviate motor symptoms can induce psychosis in PD. Dopaminergic agents can provoke a subacute psychotic disorder (perhaps akin to the putative role of dopamine in primary psychoses); there is no apparent relationship between dose, duration, or plasma levels of dopamine agonists and the incidence or severity of psychosis.[38,39] Anticholinergic agents can induce a toxic delirium with associated autonomic dysfunction (e.g., tachycardia, mydriasis, and priapism). Other factors predisposing PD patients to psychosis include cognitive deterioration, preexisting psychiatric diseases, infection or other medical illness, and dehydration.[35] Of note, virtually all patients with PD eventually exhibit cognitive impairment,[40] with the presence of Lewy bodies being the most consistent pathological correlate of dementia in this population.[3]

Optimal management of psychosis in PD is highly dependent on consideration of differential diagnosis, as detailed in Table 20–2. Once other causes of mental status alteration have been ruled out, the next step is to reduce or eliminate anti-PD medications in order of their most psychotogenic and least antiparkinsonian effects (i.e., anticholinergic and other agents) followed by dopamine antagonists, and finally levodopa/carbidopa. Nighttime psychosis can often be alleviated by reduction or discontinuation of bedtime medications.[34] Finally, treatment with antipsychotics can be attempted. The best-studied antipsychotic for use in PD is clozapine, an atypical antipsychotic associated with virtually no extrapyramidal symptoms (EPS).[41,42] Poewe and Seppi[20] reviewed several case reports with a total of 432 patients receiving clozapine for psychotic symptoms in PD and found significant benefit in approximately 85% of patients; similar results were obtained in two recent placebo-controlled trials, which also yielded no evidence of motor decline attributable to clozapine.[41,43] In most cases, the dose of clozapine used (e.g., 50 mg) was much lower than the dose typically used in schizophrenia. The use of clozapine is associated with life-threatening agranulocytosis in 1% to 2% of cases, necessitating weekly white blood cell count monitoring; no leukopenia-related deaths have been reported in PD patients.[20] Of the second-generation antipsychotics, quetiapine has the closest structural resemblance to clozapine. Numerous open-label studies of quetiapine for the treatment of psychosis in PD have been reported, two of which were retrospective studies. One study found that 35 of 43 PD patients showed significant improvement in their psychotic symptoms when treated with quetiapine, and only five patients experienced a mild deterioration in motor function.[44] In another study, 78 of 106 PD patients treated with quetiapine at a movement disorders center took quetiapine for a mean duration of 15 months, with 82% experiencing partial or complete resolution of psychosis.[45] Mild motor worsening was reported over 15 months by 32% of patients, and these patients tended to have more advanced dementia. Several double-blind trials of quetiapine in PD have been conducted, with mixed results.[46–48] Overall, quetiapine appears to be less effective than clozapine for the treatment of psychosis in PD. However, unlike olanzapine and risperidone, no declines in motor function reported in PD patients have required hospitalizations. In addition, quetiapine does not carry an increased risk of agranulocytosis, and does not mandate the monitoring required with use of clozapine. Therefore, despite

TABLE 20–2 Stepwise Management of Psychosis in Parkinson's Disease

I.	**Consider etiologies unrelated to PD or anti-PD medications and treat accordingly**
	Medications: antihistamines, anticholinergics, benzodiazepines, antispasmodics, narcotics, and corticosteroids
	Metabolic, electrolyte, or fluid-related abnormalities
	Infection
	Alcohol, benzodiazepine, or opiate withdrawal; Wernicke's encephalopathy
	Hypoxia
	Stroke or intracranial hemorrhage
	Hypertensive encephalopathy
	Seizure
II.	**Reduce anti-PD medications**
	Reduce or discontinue anticholinergic medications, amantadine, or MAOIs; then
	Reduce or discontinue dopamine agonists; then
	Reduce levodopa
III.	**Consider a trial of antipsychotics**
	Treatment of choice: clozapine
	Next line: quetiapine, olanzapine
	Last resort: risperidone, low-potency typical antipsychotics

From Cantello R, Gill M, Riccio A et al: Mood changes associated with "end-of-dose deterioration" in Parkinson's disease, *J Neurol Neurosurg Psychiatr* 49:1182–1190, 1986; Kuzuhara S: Drug-induced psychotic symptoms in Parkinson's disease. Problems, management and dilemma, *J Neurol* 248(suppl 3):11128–11131, 2001.

the lack of efficacy of the medication in randomized, placebo-controlled trials, because of its tolerability, efficacy in several open label studies, clinicians still use quetiapine as one of the first-line treatments for psychosis in PD. A randomized, controlled trial (RCT) that assessed the use of the atypical antipsychotic, olanzapine, in PD patients with psychosis was stopped prematurely because of exacerbation of motor symptoms in the olanzapine group[49]; although no improvement in psychosis was observed in this study, several open-label and case studies have documented amelioration of psychotic symptoms with olanzapine.[50,51] With regard to risperidone and the typical antipsychotics, given their propensity toward inducing EPS and parkinsonian symptoms in patients with primary psychosis, these medications should only be used as a last resort in PD.

Other Neuropsychiatric Aspects of PD

Patients with PD suffer from a variety of other neuropsychiatric problems, including dementia, behavioral disorders, sleep pathology, and anxiety. As previously mentioned, there is significant clinical and neuropathologic overlap between PD and dementia with Lewy bodies (DLB), although it remains to be determined whether one or several concurrent etiologies are at work.[3] Whether as a function of age or primary disease progression, the frequency of dementia and cognitive impairment increases with PD duration.[52] PD patients, especially men, can exhibit a marked increase in libido and hypersexual behavior as a result of levodopa treatment.[53] Excessive daytime sleepiness, sleep attacks, and parasomnias also occur with increased frequency in PD patients; these symptoms can be treated effectively with sleep hygiene, intermittent use of nonbenzodiazepine hypnotics, and occasionally with a reduction in dopamimetics.[54] Finally, especially in PD patients with co-existing depression, anxiety disorders can significantly detract from quality of life[55]; although no randomized studies have been conducted to assess pharmacological intervention, citalopram has demonstrated good anxiolytic effect in an open-label study of depressed PD patients.[56]

Huntington's Disease

An autosomal dominant disorder occurring with a frequency of 4 to 8 per 100,000, Huntington's disease (HD) is characterized by progressive choreiform movements, dementia, and neuropsychiatric symptoms. The usual course involves initial presentation in the fourth and fifth decades of life, with gradual deterioration and death occurring within 10 to 15 years.[57,58] Although expression of neurologic and psychiatric symptoms is variable, the underlying disease process reflects a single mutation on chromosome 4p16.3.[59] Expansion of CAG repeats beyond the usual number (wild type, approximately <37) and results in an elongated huntingtin protein, which (because of a variety of putative mechanisms) induces neuronal death.[60] The neuronal population most severely affected includes gamma-aminobutyric acid (GABA)-ergic medium spiny striatal neurons, causing decreased inhibitory output to the substantia nigra and globus pallidus; some cortical neurons in layers III and VI also appear to be directly affected.[61] Accordingly, disruptions in dorsolateral prefrontal–subcortical, orbitofrontal, and medial prefrontal–thalamic circuitry may underlie respective alterations in executive function, mood, and response inhibition.[62]

In his description of the disorder, Huntington himself noted a "tendency to insanity and suicide."[63] Indeed, HD appears to incorporate a spectrum of psychopathologies, including mood, anxiety, and psychotic symptoms. In a prospective study of 52 HD patients, Paulsen and coworkers[64] described neuropsychiatric symptoms in 98% of subjects, with dysphoria, agitation, and irritability occurring most frequently (65% to 69%); 52% exhibited anxiety symptoms, whereas 13% demonstrated hallucinations or delusions. Symptoms did not correlate with dementia or chorea-scale ratings or with disease duration. Notably, suicide risk in HD was as high as 12.7%, and findings showed that frequency of suicidal ideation doubled from 9.1% in at-risk persons with a normal neurologic examination to 19.8% in at-risk persons with soft neurologic signs. Suicidal ideation increased to 23.5% in persons with "possible" Huntington's disease.[64,65] Of 102 HD patients evaluated by Dewhurst and associates,[66] 42 exhibited depressive symptoms, and 50% were described as delusional (12 had hallucinations). Another large study indicated the presence of MDD in 28 of 88 HD patients, with bipolar disorder diagnosed in an additional 8 cases.[67] Although in the latter study the onset of affective symptoms preceded chorea and dementia by an average of 5.1 years, De Marchi and Mennella[68] similarly concluded that psychotic symptoms often emerged significantly earlier than motor dysfunction in HD. These studies, as well as others that described clustering of psychiatric symptoms in specific HD families, suggested that affective and psychotic symptoms in HD may be primary expressions of the disease process.[68] As always, though, medical causes of new-onset psychiatric symptoms in HD patients should first be ruled out; particular consideration should be given to alcohol withdrawal, because ethanol abuse has been reported in up to 24% of men with HD.[69]

As in PD, there are few well-controlled trials that establish the efficacy of treatment strategies for psychiatric problems in HD. The observations of Rosenblatt and LeRoi[70] suggested that SSRIs are well-tolerated in HD patients with depression and perhaps are safer than TCAs, given the vulnerability of HD patients to anticholinergic delirium, sedation, and falls. They also reported that SSRIs are useful in managing the irritability, aggression, apathy, and obsessiveness often seen in those with HD. ECT can be useful to treat severe or psychotic depression in HD, although again the risk of ECT-induced delirium must be weighed.[71] For treatment of psychotic symptoms in early HD, small doses of high-potency neuroleptics (e.g., haloperidol) should be considered; these medications are also useful for management of chorea and motor tics. However, in more advanced HD, when parkinsonism and dystonia are more likely to occur, atypical antipsychotics (e.g., quetiapine and clozapine) are preferable.[70,72]

Wilson's Disease

Wilson's disease (WD) is a rare, autosomal recessive disorder of copper metabolism with an incidence of 12 to 30 per 1 million.[73] Mutations on chromosome 13q14 result in altered function of apoceruloplasmin, a copper-transporting

protein[74]; subsequent toxic accumulations of copper in the liver, brain, and other organs lead to progressive hepatic and neuropsychiatric dysfunction. Onset usually occurs in the first four decades of life, with a mean onset at age 17.[75] Low serum ceruloplasmin and high urinary copper levels are diagnostic; associated neuroimaging findings include increased signals in the putamen, lenticular nuclei, ventral or lateral thalamic nuclei, subcortical white matter, lamina tecti, and caudate nuclei.[76] Atrophy of the hemispheres or brainstem was evident in 68% of patients with neurologic symptoms, but in only 6% of neurologically-asymptomatic patients.[76] Functional neuroimaging often shows reduced striatal glucose metabolism and reduced *N*-acetylaspartate levels in the globus pallidus.[77,78]

Initial clinical presentation can be divided among predominantly hepatic, neurologic, or psychiatric symptoms with roughly equal frequency. Liver-related presentations include hepatitis and cirrhosis, whereas neurologic presentations most commonly involve dysdiadochokinesia and dysarthria[79]; tremor, spasticity, rigidity, or chorea in the absence of sensory changes can also occur. Psychiatric symptoms are varied, but personality change and incongruous behavior are the most frequently described.[80] A prospective study of MDD in WD indicated an incidence of 27%, although it remains unclear whether this reflects primarily a reactive or biological process.[79] Case reports of secondary mania have also been reported with WD.[81–83] Psychotic symptoms are seen infrequently, but catatonia can occur in 8% of patients with other neurologic manifestations of WD.[84] Kayser-Fleischer rings, which reflect copper deposition in the corneal limbus, occur much more frequently with neuropsychiatric than with hepatic presentations.[79]

Given the clinical heterogeneity with which WD can present, a high degree of clinical suspicion is important in making the diagnosis and therefore in establishing treatment. Moreover, treatment with copper-chelating and depleting agents (e.g., penicillamine and zinc) is only effective during the first few years of illness, so early intervention is essential.[75] Improvement in psychiatric symptoms has been less well studied than neurologic recovery, but incongruous behavior and psychosis appear to respond better than irritability and depression.[85] There have been no controlled evaluations of adjunctive psychotropic medications in WD, although there are reports of increased sensitivity to neuroleptic-induced EPS.[86]

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic disorder of white matter in the brain and spinal cord, characterized pathologically by inflammatory demyelination of axonal sheaths and by gliosis. The illness is disseminated in space and time (i.e., it affects different locations within the CNS and is manifested by separate symptomatic attacks). Neurologic dysfunction frequently involves changes in vision (e.g., blurred vision, alteration of color perception, and diplopia), spastic paresis, hypoesthesia and paresthesia, ataxia, and bladder or bowel dysfunction.

Epidemiology

Multiple sclerosis affects approximately 300,000 to 350,000 people in the United States.[87] The disease usually becomes manifest between the ages of 18 and 50 years. Most cases (80%) are of the relapsing–remitting type; episodes of dysfunction last for several weeks and they are followed by substantial or complete improvement. Some patients remain well for decades. The prevalence of the relapsing–remitting type of MS is roughly twice as high in women than in men. Primary progressive MS, which is characterized by a steady neurologic decline, more often affects men.[88]

Etiology

The pathogenesis of MS remains enigmatic. Its inflammatory white matter changes are thought to be immune-mediated. The absolute risk of disease for a first-degree relative of an MS patient is less than 5%, but is still approximately 20 to 40 times higher than the rate in the general population. Several linkage studies have shown an association between major histocompatibility complex (MHC) alleles and other genes related to the immune system. Infectious agents and other environmental factors may also contribute; however, no causal link has yet been established.[89]

Psychiatric Changes

Cognition

Cognitive changes occur in 45% to 60% of patients with MS.[90] The impairment is often not readily apparent; it is frequently missed by bedside cognitive screening, such as with the Mini-Mental State Examination (MMSE).[91] Systematic psychologic testing has shown impaired memory function within the first 5 years of diagnosis in at least half of afflicted patients.[90,92] In most studies, cognitive decline was not significantly correlated with physical impairment or depressed mood, and there has been no association with the duration of disease.[90] However, cognitive deficits have been shown to be detrimental to the QoL and productivity in patients with MS, and in particular, neuropsychologic deficits having a large impact on QoL.[93] Dramatic worsening of cognitive function that occurs during an acute episode may remit completely over several months, as described in a case series by Franklin and colleagues.[94]

Mood and Behavior

MS greatly increases the risk for development of an underlying mood disorder. The lifetime prevalence of a major depressive episode for patients with MS is roughly 50%.[95–98] Several studies describe a higher incidence of depression in MS patients compared to those with other chronic neurologic disorders[99,100]; patients with prominent plaque formation in the cerebrum were more likely to be depressed than were patients with solely spinal involvement and comparative physical disability.[98] Furthermore, the risk of bipolar disorder is 2 to 13 times higher for MS patients than for those in the general population.[96,101] Population studies in Denmark and Canada showed a 2- and 7.5-fold increase of suicide risk, respectively, for patients with MS compared to the general population. The Danish investigators found that suicide was most likely during the first 5 years after diagnosis was made.[102,103] Fatigue is also a problem for 80% to 97% of MS patients.[104] Paradoxically, symptoms of fatigue are inversely proportional to the degree of brain injury as measured on MRI.[105]

Intermittent emotional expression disorder (IEED) is a neurologic phenomenon that occurs in the absence of

subjective emotional lability and has been reported in 10% to 20% of patients with MS.[106,107] Previously referred to as pseudobulbar affect (PBA) or pathologic crying (PLC) and laughing, case reports have implicated varied neuroanatomic regions in the development of IEED, including areas of the prefrontal cortex, cerebellum, and the brainstem.[108,109]

Psychosis

Although symptoms of psychosis in patients with MS tend to be rare, the belief that psychosis is not increased in MS was recently challenged in a study by Patten and colleagues.[110] They found rates of psychosis of 2% to 3% in MS compared with 0.5% to 1% in the general population. An MRI study of psychotic MS patients reported more extensive lesions in the temporal horns compared to other MS patients.[111,112]

Sexual Dysfunction

Up to 70% of MS patients experience sexual dysfunction.[113] Both genders experience decreased libido, orgasmic dysfunction, and decreased genital sensation. The incidence of these symptoms may be higher in men, who also describe difficulty with erection and ejaculatory dysfunction.[114] Women report decreased vaginal lubrication and decreased vaginal sensation.[115] Sexual dysfunction is a common contributor to marital problems for MS patients.

Iatrogenic Neuropsychiatric Changes

Corticosteroids, which are used in high doses to treat MS exacerbations, are known to induce insomnia, irritability, mood lability, and maniform psychosis.[116] Minden and colleagues[117] described a higher incidence of steroid-associated mania or hypomania in MS patients with a history of depression.

Concerns that interferon-beta may induce or exacerbate depression were raised after the first controlled clinical trial of interferon-beta-1b and follow-up data reported one completed suicide and four suicide attempts in the active treatment group.[118,119] This association, however, was not replicated in subsequent trials of interferon-beta-1a and interferon-beta-1b.[120,121] Prospective studies of MS patients during interferon-beta therapy suggest that patients with a recent depressive episode may experience a recurrence of their symptoms after initiation of interferon treatment; a family history of mood disorder by itself was not an independent risk factor for depression during interferon treatment.[122,123]

Treatment

Neuropsychiatric changes associated with MS are primarily treated in the same way as neuropsychiatric changes in other types of psychiatric patients.

Depression, which is the strongest predictor of poor quality of life in MS patients, responds well to treatment with antidepressants and psychotherapy.[124] Cognitive-behavioral therapy, and therapies focused on developing problem-solving skills, are more effective than are insight-oriented approaches.[122,125,126]

Fatigue may be improved by aerobic exercise, timed rest periods, improved sleep, and avoidance of heat. Often patients with MS-associated fatigue require pharmacologic treatment. Amantadine (100 to 200 mg/day) and modafinil (200 to 400 mg/day) have both been effective in controlled trials. If fatigue recurs despite continuing treatment with amantadine, drug holidays may restore its efficacy.[125,127,128]

Patients with a history of steroid-induced mania have been treated acutely and prophylactically with lithium, carbamazepine, olanzapine, quetiapine, risperidone, haloperidol, and chlorpromazine before and during the treatment with steroids to prevent the recurrence of a manic or psychotic episode.[129–133] IEED has also been shown to improve with use of TCAs, SSRIs, along with dextromethorphan/quinidine.[109]

Few studies have addressed the treatment of sexual dysfunction. Foley and colleagues[134] reported a successful pilot study involving couples counseling. Male patients with MS who have erectile dysfunction may benefit from sildenafil, 50 to 100 mg, administered 1 hour before intercourse. Because sildenafil can enhance the effect of nitrates, which produce severe hypotension, this combination should be avoided.[135] Often it is appropriate to refer patients with sexual dysfunction to a urologist or gynecologist with expertise in this area.

Cognitive dysfunction can be treated with rehabilitation, which focuses on retraining and developing compensatory strategies.[136] Acetylcholinesterase inhibitors have been evaluated in patients with MS, with most research attention focusing on donepezil. A double-blind, placebo-controlled RCT with 69 MS patients showed that donepezil improved objective memory performance on list learning, as well as subjective ratings and clinician ratings of memory abilities.[137,138] Amantadine, though commonly used to treat fatigue in MS, has not been shown to have any effect on treating the cognitive deficits in MS.[139] In another RCT of 38 patients with MS, no effect on cognition was appreciated with use of ginkgo biloba. However, a trend was noted for improved performance on the Stroop test, which measures resistance from interference and processing speed.[140]

CONNECTIVE TISSUE DISEASES

Connective tissue diseases (also known as collagen vascular diseases) are characterized by inflammation, small vessel damage, and serosal surface inflammation; they cause a constellation of symptoms ranging from arthritis to severe, multisystem illness. Although the etiology of many connective tissue diseases is unknown, autoimmune processes have been implicated in most cases. Neuropsychiatric presentations of connective tissue disease are variable and can reflect the primary disease process, psychologic stress related to the illness, or side effects of medications. The following sections will discuss neuropsychiatric manifestations and treatment approaches for common connective tissue diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), Sjögren's syndrome, and other rheumatologic disorders.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease with multiorgan involvement primarily affecting adult women, in particular African American women in their third through fifth decades of life.[141] Non-CNS manifestations of the disease are varied and include malar or discoid rash, arthritis, proteinuria, hematologic disorders, photosensitivity, oral ulcers, and serositis. The diagnosis is made by satisfying minimal criteria as established by the

American Rheumatological Association, as well as by the presence of serum autoantibodies, including antinuclear antibodies (ANA), as well as anti-DNA, anti-Smith, and anti-RNP antibodies.[142]

Neuropsychiatric manifestations of SLE (NP-SLE) occur in reportedly 14% to 75% of patients and can be divided into focal and nonfocal signs (Table 20–3).[143] Not surprisingly, whereas focal signs have been correlated with macroscopic CNS pathology at autopsy (including infarction, hemorrhage, and thrombosis), patients with nonfocal signs exhibit more subtle findings, such as encephalomalacia, arteriolar infarction, and fatty infiltration. Clinically, there has been inconsistent evidence to support a relationship between emergence of NP-SLE symptoms and changes in biological markers, largely because it is unlikely that one pathogenic mechanism is exclusively causal in the variety of syndromes seen in NP-SLE. Primary mechanisms likely include vascular occlusion and hemorrhage, autoantibody-mediated effects (antineuronal antibodies), choroid plexus dysfunction, cytokine effects, neuroendocrine–immune imbalances, and direct neural tissue injury via oxidative stress, excitatory amino acid toxicity, and matrix metalloproteinase injury.[144] Antineuronal antibodies are felt to have a significant role in NP-SLE pathogenesis, and various antibodies have been found in the serum of SLE patients. A subset of anti–double-stranded DNA antibodies cross-react with a consensus sequence present in the ligand-binding region of the CNS *N*-methyl-D-aspartate (NMDA) receptor, NR2.[144] These receptors are responsible for the binding of glutamate, the primary excitatory amino acid of the brain. Furthermore, antibodies against ribosomal P proteins have been linked to psychiatric manifestations of SLE. Shoenfeld and colleagues[145,146] have reported experimental depression induced by anti–ribosomal P, pointing to limbic and olfactory areas in the pathogenesis of depression and CNS involvement in SLE. Anti–ribosomal P positivity and the titer of these antibodies have been correlated with clinical disease activity in both adults and children, although the validity of these results continue to be debated.[147]

Although many patients with CNS manifestations exhibit cerebrospinal fluid (CSF) abnormalities (e.g., elevated protein, immunoglobulin G [IgG], and immunoglobulin M [IgM]),[148] and most demonstrate electroencephalographic (EEG) abnormalities (e.g., diffuse slowing),[149] neither test appears to be sensitive or specific. MRI studies can be useful, but abnormal findings often do not correlate with clinical changes.[150]

Psychiatric symptoms in SLE are varied and occur with an unpredictable course. They can reflect primary effects of SLE, secondary metabolic abnormalities, side effects of treatment (steroid treatment or withdrawal in particular), or psychologic reactions to illness.[151] Depressed mood can occur in 41% to 70% of patients,[152] although the exact prevalence is difficult to determine because of a lack of standardized diagnostic criteria; other mood-related symptoms can include lability, irritability, and anger.[150] Although the prevalence of psychotic symptoms was initially reported at greater than 50%,[153] many of these patients may have in fact exhibited delirium; a more recent study employing a more standardized diagnosis indicated an incidence of 5%.[154] Cognitive impairment, with specific impairment in concentration and attention, occurs quite frequently, perhaps in as many as two thirds of SLE patients.[155]

Because of the heterogeneity of symptomatic presentations of NP-SLE, the general hospital psychiatrist will often face the problem of deciding whether symptoms are due to SLE itself, or secondary to another primary etiology (including a psychiatric one). It is essential to consider the timing of symptom emergence in relation to medication changes, and new physical or laboratory findings. If NP-SLE is suspected, the first priority is identification and treatment of exacerbating factors, such as hypertension, infection, and metabolic abnormalities. Immunosuppression is the cornerstone of the management of NP-SLE and may rely on high-dose glucocorticoids, cyclophosphamide, or azathioprine. Immunosuppressant agents are usually used in combination with glucocorticoid therapy, and often adjunctive medications (e.g., dopamine antagonists, antidepressants, and antiepileptic drugs) will be used for optimal clinical and symptomatic response.

TABLE 20–3 Presenting Features in Systemic Lupus Erythematosus

	CNS	
NON-CNS	**FOCAL**	**NONFOCAL**
Malar rash	Seizure (generalized, partial)	Headache
Discoid rash	Hemiplegia	Delirium
Photosensitivity	Cranial neuropathy	Psychosis
Oral ulcers	Transverse myelitis	Mood disorders
Arthritis	Peripheral neuropathy	Cognitive dysfunction
Serositis (pleuritis, pericarditis)	Abnormal movements	
Renal disorder (proteinuria, casts)		
Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, thrombocytopenia)		

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a common and debilitating disease of unknown etiology that causes symmetrical inflammation of the joint synovium. Symptoms usually begin in the hands, with sparing of the distal interphalangeal joints; morning stiffness is common. Extraarticular manifestations occur in more than three fourths of patients and can involve the heart (e.g., pericarditis, cardiomyopathy, and valvular lesions), lungs (e.g., pleurisy, fibrosis, and pneumoconiosis), eyes (e.g., scleritis and iridocyclitis), and peripheral nervous system. Rheumatoid factor is a sensitive, although nonspecific, diagnostic test.

Although there is a high (40% to 50%) prevalence of depressive symptoms in RA, it is unclear whether these reflect the underlying disorder or a secondary psychologic reaction to the disease[156]; treatment should include both analgesics and adjunctive antidepressants or psychotherapy.[151] Of particular concern, though, is the potential for psychiatric complications related to RA treatment. The rare ability of salicylates to cause delirium and psychosis has been known since 1965.[157] Nonsteroidal antiinflammatory drugs (NSAIDs) have been reported to cause paranoia, depression, hallucinations, and delirium,[158] and can also increase plasma lithium levels by decreasing its renal clearance.[157] Finally, as mentioned previously, the use of corticosteroids has been associated with manic and psychotic symptoms as well as delirium.

Sjögren's Syndrome

Sjögren's syndrome, a chronic inflammatory disorder characterized most commonly by keratoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), and xerosis (dry skin), can also be associated with focal neurologic symptoms, movement disorders, spinal cord involvement, along with nonfocal symptoms that include encephalopathy, cognitive dysfunction, and neuropsychiatric abnormalities. Neuropyschiatric symptoms (anxiety, depression, hypochondriasis, cognitive dysfunction, and reduced concentration and attention) are common and may represent as early manifestation of the disease. Malinow and colleagues[159] reported psychiatric disturbances in up to 60% of patients examined. Drosos and co-workers[160] found a significantly higher level of introverted hostility and higher scores for paranoid ideation, somatization, and obsessive-compulsiveness when compared with healthy subjects. Psychiatric symptoms influencing QoL have been studied and have shown that patients with Sjögren's syndrome had a significantly higher scoring rate for possible clinical anxiety and for possible clinical depression versus controls.[161] When compared with patients affected by RA, patients with Sjögren's syndrome complained more commonly of low mood, irritability, headache, gastrointestinal symptoms, and impaired concentration and memory performance. In addition, patients with Sjögren's syndrome appear vulnerable to cognitive dysfunction (ranging from mild problems with attention and concentration to severe dementia).[159]

Treatment of Sjögren's symptoms, both glandular and extraglandular, is generally supportive, with use of steroids and other immunosuppressants reserved for severe, systemic cases.[162] Caution should be exercised when using anticholinergic medications, because these can exacerbate glandular symptoms.

Other Connective Tissue Diseases

Several other connective tissue diseases are sometimes associated with neuropsychiatric sequelae, but these phenomena have not been extensively described. End-stage scleroderma can cause delirium as a consequence of renal or hepatic failure.[163] Fibromyalgia has been associated with sleep disturbance, hypochondriasis, and depression.[164] Finally, vasculitides (e.g., temporal arteritis) can cause transient blindness, cerebral ischemia, delirium, and stroke.[165]

BRAIN TUMORS

Brain tumors may originate in the CNS, where they are derived from neuroepithelium, glia, or meninges (a *primary brain tumor*), or may be metastases from tumors in another locations in the body (a *secondary brain tumor*).

Epidemiology

Each year, roughly 16,500 patients in the United States are diagnosed with a primary brain tumor. In addition, approximately 120,000 individuals experience morbidity resulting from brain metastases of a systemic neoplasm. In adults, more than one half of the primary brain tumors are gliomas (i.e., tumors derived from the interstitial tissue of the nervous system). High-grade tumors, predominantly glioblastoma multiforme, constitute up to 80% of the gliomas. Unfortunately, the prognosis associated with glioblastomas remains poor; even with treatment, few patients survive longer than 1 year. Meningioma, a slow-growing tumor of the meninges, is the second most common CNS tumor; it accounts for about 20% of cases. Unlike glioblastomas, meningiomas can be cured with surgery or controlled by use of radiation. Although primary CNS lymphomas represent only 1% of adult brain tumors, their incidence has tripled during the past 20 years. Advances in high-dose chemotherapy, with or without radiation therapy, have increased the median survival of patients with these tumors to at least 40 months. In children, the two most common brain tumors are low-grade astrocytic or glial tumors and medulloblastomas. Meningiomas in children occur infrequently.[166–168]

Neuropsychiatric Changes Associated with Brain Tumors

All brain tumors can produce changes in affect, behavior, cognition, and perception. Upon initial presentation, mental status changes are most often seen in those with lymphoma (61%) and high-grade gliomas (40% to 60%) and less frequently seen with meningiomas (21%).[166] Most of these mental status changes are typically associated with infiltration of the tumor into the frontal and temporal lobes, and are rarely associated with occipital and parietal tumors.

Mood

Alterations in mood lead to anxiety, depression, fatigue, irritability, anger, and full-blown mania, especially with lesions of the ventral frontal and temporoparietal cortices.[169–171] Symptoms inconsistently correlate with lesion size and location. Prospective studies have shown both higher rates of depression with left-sided tumors[172] and no effect based upon hemisphere involvement.[173] One crucial distinction to make is between depression and abulia. *Abulia* or *akinetic mutism* (manifested by reduced spontaneity of speech, motion, and goal-directed behavior and by the absence of despair, sadness, or crying) is distinct from depression.[174] Tumors that cause abulia most frequently invade and affect the frontal lobes. Caplan and Ahmed[175] described bedside testing suggestive of abulia. This involves asking a patient to give lists of common objects, such as animals, fruits, or

vegetables. The abulic patient will often produce only two or three items. Another strategy is to ask the patient to count out loud from 1 to 20 and then backward from 20 to 1. Abulic patients often stop in the middle of the task, and then will either lose interest in the task, or take significantly longer than the normal (10 to 20 seconds) to complete the task. Patients with depression may also fail to pay full attention to these tasks, but with prodding their behavior changes. Delirious patients may be unable to respond appropriately; in contrast to abulic patients, they often exhibit other cognitive deficits, such as disorientation. Fluctuations in performance over time, a hallmark of delirium, is not anticipated in abulic patients, whose lack of persistence and effort is more stable.

Psychosis

Perceptual disturbances are caused by mass lesions that impinge directly on the auditory, visual, tactile, or olfactory pathways (located in the temporal and occipital cortices), the brainstem, and the base of the frontal lobes. Less frequently, brain tumors cause hallucinations indirectly through increased intracranial pressure. Paranoid ideation and other delusions are also associated with lesions of the temporal lobes.[169,170]

Cognition

When cognitive testing is performed on patients with frontal and temporal lobe tumors, measurement of memory, attention, language, and executive functions shows significant impairment in at least one area of function in most patients assessed immediately after the diagnosis. Verbal fluency and learning are most often impaired in patients with left-sided tumors.[172,176] Tucha and colleagues[177] found only a weak correlation between self-reports of cognitive dysfunction (of 139 brain tumor patients) and formal neuropsychologic assessment.

Iatrogenic Neuropsychiatric Changes

Neuropsychiatric changes are commonly caused by cancer treatments. Dexamethasone, which frequently relieves headaches and improves cognitive function by reducing brain edema, is known to induce insomnia, irritability, mood lability, and maniform psychosis.[116] Whole brain irradiation may cause sudden, transient cognitive changes. In addition, a delayed-onset subcortical dementia, thought to be related to delayed white matter necrosis, has been reported between 6 months and 20 years after radiotherapy.[178,179] Memory impairment also occurs more frequently in patients who receive high doses of radiation and in patients older than 60 years.[180,181] Combined radiotherapy and chemotherapy increase the risk of neurotoxicity. Reports of cognitive dysfunction in adults with primary brain tumors treated exclusively with chemotherapy are few and far between. Long-term follow-up studies of patients with primary CNS lymphoma suggest that chemotherapy alone does not contribute to cognitive impairment.[182,183]

Tumor resection or *debulking* often produces neuropsychiatric improvement, once the postsurgical edema has resolved; however, it carries the risk of creating lesions in functional brain areas. Careful preoperative mapping of target regions with the help of conventional and functional MRI reduces the morbidity surrounding eloquent brain areas.[184]

Treatment

The consulting psychiatrist may be called to help with the treatment of mood and behavior symptoms in patients with brain tumors. Such symptoms may be sequelae of tumor invasion into the patient's brain, tumor-related brain edema, or neurotoxic side effects of treatments. In addition, the psychiatrist can help the patient and family members to cope with and adapt to a devastating illness.

Psychopharmacologic Interventions

Clinical depression is best treated with SSRIs, such as citalopram, sertraline, paroxetine, or fluoxetine. Use of TCAs and bupropion may lower the seizure threshold and thus should be avoided (unless the patient has a therapeutic level of an anticonvulsant medication). Abulia and apathetic depression respond best to psychostimulants.[185] Methylphenidate or dextroamphetamine are usually given in the morning and around lunch time. Administration later in the day should be avoided because it may cause insomnia.

Anxiety, especially surrounding the initial diagnosis and before procedures or imaging studies, responds well to low doses of benzodiazepines (such as lorazepam or clonazepam), given two to four times per day. Acute psychosis, due to the tumor, postoperative delirium, or use of steroids, is treated best with high-potency dopamine antagonists (e.g., haloperidol) or second generation serotonin–dopamine antagonists (e.g., risperidone, olanzapine). Chlorpromazine and clozapine may lower the seizure threshold and create anticholinergic symptoms and are best avoided. Mania after initiation of dexamethasone treatment is often short-lived and quickly controlled with antipsychotic medications. If prolonged treatment with steroids is necessary and is accompanied by intolerable mood swings, lithium or valproic acid can help stabilize the patient. These medications can also be prescribed prophylactically to patients with a history of bipolar disorder, or with a previous episode of steroid-induced mania, before a future course of dexamethasone.[129,186]

Psychosocial Interventions

Supportive psychotherapy (conducted individually or in a group) may be helpful to both the patient and his or her family. Patients struggle with vulnerability and mortality; they wonder "Why me?" Patients may redefine the meaning and priorities of their life and ponder their legacy left behind. A patient with young children may want to make a recording or to leave a picture album or a letter, which can be addressed to his or her children for when they are older. Family members often struggle with the patient's decline in function and behavior that may be induced by the tumor. Studies have repeatedly shown that caregivers tend to give lower estimates of patient QoL and hope than do patients themselves.[187,188] Cognitive rehabilitation,

originally developed for patients with traumatic brain injuries, can help to improve function and dysphoric mood in patients with brain tumors.[189]

PARANEOPLASTIC LIMBIC ENCEPHALITIS

The description of limbic encephalitis is attributed to Brierley and co-workers,[190] who in 1960 reported 3 patients with "subacute encephalitis of later adult life, mainly affecting the limbic areas." Corsellis and colleagues[191] used the term "limbic encephalitis" to describe a series of patients with severe memory loss, and memory loss with dementia in association with bronchial carcinoma. The authors also reviewed previously reported cases and established for the first time a relationship between limbic encephalitis and systemic cancer.

The classic syndrome includes rapid development of irritability, depression, sleep disturbances, hallucinations, along with seizures and short-term memory deficits.[192] Patients may seem to be quietly confused, making repetitive statements, and sometimes with episodes of staring, along with psychomotor or partial seizures that predominate over generalized seizures. Encephalitis associated with *N*-methyl-D-aspartate receptors (NMDAR) typically occurs in young women, who for a few days after a flu-like illness develop anxiety and other mood disorders, which progress to severe behavioral and personality disturbances, delusions, or disorganized thinking, paranoid ideation, and hallucinations.[192] They may eventually also develop symptoms similar to catatonia and remain with eyes open, unresponsive to visual threats, mutism, increased muscle tone, or dystonic posturing.[193] These symptoms are generally associated with seizures, a decline of the level of consciousness, central hypoventilation, autonomic instability, and dyskinesias. Agitation is generally unresponsive to usual pharmacologic interventions, and may necessitate intubation.

After excluding a viral etiology, the next diagnostic question is whether the suspected limbic encephalitis is paraneoplastic or not. Sixty percent to 70% of paraneoplastic encephalitis cases present neuropsychiatrically, before the detection of the tumor.[194] Patients may have CSF inflammatory findings (e.g., pleocytosis, increased protein concentration, increased IgG index, and oligoclonal bands), EEG abnormalities (focal or generalized slowing, or foci of epileptic activity in one or both temporal lobes), MRI changes (hyperintense signal in the medial aspect of the temporal lobes), and antineuronal antibodies. These antibodies are directed against two broad categories of antigens: intracellular (Hu, Ma2, CV2/CRMP5, and amphiphysin) and cell membrane antigens (voltage-gated potassium channels [VGKC], NMDAR, along with others expressed in the neuropil of the hippocampus and cerebellum that have yet to be characterized).

In cases where a tumor is found in association with a possible paraneoplastic disorder, removal of the tumor is critical for neurologic improvement and stabilization.[195] Unfortunately, most limbic encephalitides related to intracellular antigens do not improve, and at best stabilize, after tumor removal and immunotherapy. There are anecdotal cases of patients that improve with tumor removal, coricosteroids, IV Ig, or plasma exchange. In contrast, limbic encephalitis associated with cell membrane antigens is significantly more responsive to immunotherapy (IV Ig, plasma exchange, coricosteroids, cyclophosphamide, rituximab).[196] Control and removal of the tumor for this group of patients seems to be required not only for more rapid response but to attain full recovery.[192]

CNS INFECTIONS

Infections of the CNS must be considered in the differential diagnosis of both acute and chronic neuropsychiatric symptoms. Manifestations of CNS infections may involve the entire gamut of neuropsychiatric disorders, including delirium, psychosis, mania, depression, dementia, catatonia, behavioral changes, agitation, or anxiety.[197–199] The consequence of missing a CNS infection may contribute to increased morbidity and a devastating outcome for the patient. The general hospital psychiatrist plays an important role in ensuring that such diagnoses are considered and evaluated. The following section will first describe the signs and symptoms that should prompt a more thorough medical evaluation in this regard. This will be followed by a discussion of specific types of CNS infection most likely to be seen by the psychiatric consultant. These include meningitis and encephalitis due to bacteria, viruses, and parasites.

Because CNS infections may present with such a wide array of neuropsychiatric symptoms, the diagnosis may not be readily apparent. However, certain clues suggest that neuropsychiatric symptoms are due to a medical illness rather than a primary psychiatric disease (Table 20–4).

Moreover, the presence of fever, nuchal rigidity, headache, visual changes, or focal neurologic signs puts CNS infection atop the list of possible etiologies. Work-up may then include serum laboratory tests, CSF analysis, CT scan or MRI scans of the head, and an EEG. These will be discussed in more detail later, with each of the specific types of infection.

Bacterial Meningitis

Bacterial meningitis often presents with a constellation of signs and symptoms, including fever, headache, lethargy, confusion, vomiting, irritability, and a stiff neck.[200,201] Focal neurologic abnormalities and seizures may also be observed. Although a complete discussion of etiological

TABLE 20–4 Factors Suggestive of Medical Illness

Sudden onset of symptoms
Absence of prior psychiatric history
Vital sign abnormalities
Disorientation
Younger or older age (younger than 12 years or older than 40 years)
Immunocompromised host
Concurrent physical symptoms
Focal neurologic signs
Nonauditory hallucinations

From Reeves RR, Pendarvis EJ, Kimble R: Unrecognized medical emergencies admitted to psychiatric units, *Am J Emerg Med* 18(4):390–393, 2000.

agents is beyond the scope of this chapter, the most common pathogens include *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. The propensity of infection with specific pathogens varies according to age of the patient and with the following factors: neurosurgical procedure, immunocompromised state, alcoholism, systemic illness, cancer, and head trauma.[201,202] Bacteria may enter the subarachnoid space via hematogenous spread, which generally begins in the nasopharynx. Alternatively, bacteria may invade the meninges directly through structural defects. Because of the diffuse nature of bacterial involvement, confusion and altered sensorium are typical manifestations. Focal findings often suggest a localized cerebritis or abscess.[201]

Bacterial meningitis is diagnosed by lumbar puncture, which should be performed at the earliest suspicion, given high rates of mortality. Table 20–5 illustrates typical CSF findings for different types of CNS infections. CSF should also be sent for culture to identify specific organisms involved. Other diagnostic measures include a complete blood count (CBC), which may show leukocytosis or leukopenia. An EEG is most commonly marked by generalized slowing. Brain imaging is most helpful in instances where an abscess or focal disease is suspected.

Intravenous antibiotics are the mainstay of treatment for bacterial meningitis. Although specific agents will not be discussed here, the standard practice involves starting broad coverage and then narrowing the range once an etiologic agent is discovered. Corticosteroids may also be used for patients with cerebral edema or with high levels of bacteria in the CSF.[202] Neuropsychiatric side effects of steroid treatment should be closely monitored. Early diagnosis of meningitis greatly improves outcome; however, despite intervention, bacterial meningitis may be fatal in an estimated 20% to 30% of cases.[200,201]

Viral Meningitis

Viral meningitis is commonly referred to as *aseptic meningitis* because of characteristic aseptic CSF. Diagnosis is made by lumbar puncture (see Table 20–5), and care must be taken to exclude fungal or mycobacterial etiologies, because these may take days or weeks to grow in culture medium. Viruses generally infect the subarachnoid space and leptomeninges with rare involvement of the brain parenchyma.[202,203] Clinical features most commonly include a triad of fever, meningismus, and vomiting. Irritability, clouding of consciousness, and lethargy are less frequent.[203] Focal neurologic signs, seizures, or more severe presentation suggests encephalitis.

Viral meningitis is most often caused by the enterovirus family; however, the most common single causal agent is mumps.[200] It often affects young adults in the late summer or early fall. Herpes viruses and human immunodeficiency virus (HIV) infection may also produce viral meningitis and is discussed separately. The course of aseptic meningitis is usually benign, and treatment involves supportive measures. Fatalities are extremely rare, as are long-term sequelae. However, at least one study suggests that viral meningitis in adults may result in underdiagnosed mild cognitive impairment, especially in areas of nonverbal learning and cognitive speed.[199] Neuropsychologic testing may prove to be beneficial in this regard.

Herpes Simplex Virus Encephalitis

Herpes simplex virus (HSV) is the most frequent and potentially dangerous cause of sporadic and focal encephalitis in the United States. Mortality rates are estimated at 10% to 40% with similar rates of significant sequelae.[200,202] HSV typically invades the inferior frontal and anterior temporal lobes via cell-to-cell spread along branches of the trigeminal nerve.[200,204] Because of its predisposition for these locations, typical presentations include behavioral disturbances, personality changes, aphasia, memory loss, and dementia. Fever and headache are also frequently present.

Definitive diagnosis of HSV encephalitis may be difficult, because brain biopsy is the gold standard, and CSF often does not reveal the presence of virus. However, brain imaging by CT or MRI may demonstrate inflammation and edema in characteristic temporal and frontal areas. An EEG with periodic sharp waves in the temporal regions should also raise concern for HSV infection. In cases in which there is a high index of suspicion, treatment with acyclovir is started empirically, because delay increases the risk of mortality.

Human Immunodeficiency Virus Infection

Central nervous system infections related to HIV may result from meningitis due to HIV itself, or from superimposed infections due to an immunocompromised state. Moreover, the differential diagnosis of neuropsychiatric disturbance in patients with HIV infection or AIDS may result from a variety of factors. These include primary psychiatric illness, primary effects of HIV infection of the CNS, opportunistic infections, and side effects of medications used to treat HIV-related illnesses.[205] Because HIV infection is described in detail elsewhere in this book, only a short overview is provided here.

TABLE 20–5 Typical CSF Findings with CNS Infections

	CELL TYPE PREDOMINANCE	GLUCOSE	PROTEIN (mg/dl)
Bacterial meningitis	Polymorphonuclear cells	Low	>150
Viral meningitis	Lymphocytes	Normal	<100
Tuberculous meningitis	Lymphocytes	Low	>150
Syphilitic meningitis	Lymphocytes	Low	<100
Herpes simplex encephalitis	Lymphocytes	Normal	<100

From Andreoli TE, Bennett JC, Carpenter CC et al: *Cecil essentials of medicine,* ed 4, Philadelphia, 1997, Saunders; Sagar SM, McGuire D: Infectious diseases. In Samuels MA, editor: *Manual of neurologic therapeutics,* ed 6, Philadelphia, 1999, Lippincott Williams & Wilkins.

In brief, of the two categories of CNS infection seen with HIV infection (meningitis due to HIV itself and CNS opportunistic infections), meningitis usually runs a more benign course. HIV meningitis is marked by a syndrome of fever, headache, acute confusional state, meningeal irritation, and cranial nerve palsies (especially cranial nerve VII).[201] This often occurs at the time of HIV seroconversion as a complication of the flu-like illness experienced by approximately one third of HIV-infected people.[205] The CSF generally reveals a mononuclear pleocytosis, and the symptoms generally resolve spontaneously. Meningitis, encephalitis, and abscesses caused by opportunistic infections are generally more serious, and they signify worsening of the immune status. Others include cryptococcal meningitis, HSV encephalitis, varicella-zoster encephalitis, cytomegalovirus encephalitis, and cerebral toxoplasmosis. In addition, progressive multifocal leukoencephalopathy (PML) occurs in up to 5% of patients with AIDS. It is caused by the reactivation of the polyomavirus JC (JCV) in immunocompromised individuals. The mortality rates for those with HIV PML have fallen dramatically from approximately 90% to between 30% and 50%.[206] Classically, patients with PML present with a subacute onset of neurologic deficits, corresponding to one or multiple CNS lesions on neuroimaging, which is restricted to white matter changes. Typical symptoms associated with PML can be diverse, and are related to the location and extent of CNS injury in the brain. The most prominent symptoms are clumsiness and progressive weakness, along with visual, speech, and behavioral changes. In HIV-positive patients, highly active antiretroviral treatment (HAART) is the only effective therapeutic option for PML. There have been several case reports suggesting that mirtazapine may be potentially useful in treating PML in HIV-infected patients receiving HAART. The efficacy of mirtazapine therapy may be through its antagonist properties at $5HT_{2A}$ receptors, the putative receptors for JCV infection of oligodendrocytes.[206] Mirtazapine likely acts by preventing the spread of JCV infection to additional glial cells rather than by direct antiviral properties.

In general, organic causes of psychiatric symptoms should be at the top of the list of possible causes in people with HIV infection or AIDS, especially at later stages of the illness.

Tuberculous Meningitis

Tuberculous meningitis is important to consider in patients who present with confusion, especially in those with a history of pulmonary tuberculosis, alcohol abuse, homelessness, HIV infection, or chronic steroid treatment.[201] It is caused by a rupture of latent parameningeal tubercles, which remain dormant in the subarachnoid space from earlier exposure. Tuberculous meningitis is characteristically subacute with symptoms generally present for up to 4 weeks at the time of presentation. Clinically, one sees headache, fever, meningismus, and delirium most frequently. Papilledema and ocular palsies are also notable. CSF usually reveals low glucose levels and mononuclear predominance (see Table 20–5). Acid-fast smears may be initially negative, though they are an aid in early diagnosis when positive. Definitive diagnosis may be delayed, given that *Mycobacterium tuberculosis* may take up to 4 weeks to be cultured, and only 50% to 65% of patients have a positive purified protein derivative (PPD) skin test or chest x-ray evidence of prior exposure to tuberculosis.[202,203] Treatment is therefore initiated with antituberculous medications when the level of suspicion is high while awaiting culture results. Once a diagnosis is established, treatment continues for 4 to 10 months. Recurrences may develop because of poor compliance. Even with treatment, mortality is significant, at about 30%.[201]

Syphilitic Meningitis

The incidence of syphilis is rising globally, partly because of the increased transmission in HIV patients and other high risk groups.[207] Neurosyphilis occurs when *Treponema pallidum* invades the CNS and is reactivated up to years later. Because neurologic symptoms rarely appear until at least the secondary stage of the disease, earlier detection of syphilis infection is essential to prevent long-term sequelae. The serologic test for syphilis (STS) or Venereal Disease Research Laboratory (VDRL) test is used for large screening programs, but the fluorescent treponemal antibody (FTA-ABS) is much more sensitive and should be used when suspicion is high. There are several categories of neurosyphilis that occur when *T. pallidum* enters the CNS (including meningeal and parenchymal). Patients may exhibit confabulation, dysarthria, impaired judgment, and psychosis.[199] *General paresis* refers to dementia associated with parenchymal neurosyphilis; it had been a common cause of admission to psychiatric facilities. *Tabes dorsalis*, also of the parenchymatous type, results from chronic infection, and it causes a progressive sensory neuropathy. Other complications of neurosyphilis include communicating hydrocephalus, lightning pains (associated with tabes dorsalis), Charcot joints, parenchymal or meningeal gummas, and spinal pachymeningitis.[202] Treatment is with penicillin; however, once later stages of neurosyphilis are reached, full recovery is not expected.

Lyme Meningitis

Lyme disease is caused by *Borrelia burgdorferi*, a spirochete transmitted by ticks primarily on the Atlantic coast of the United States and in parts of the West and Midwest, as well as parts of western Europe. Lyme is the major vector-borne infection in the United States, and in endemic areas (as listed earlier), the attack rate may be as high as 2% to 3%.[208] Initial presentation is marked by *erythema migrans*, an expanding skin lesion at the location of the tick bite. Because there is a typical central clear region, the lesion has been called the *bull's eye* lesion.[208] If untreated, Lyme disease may progress to a subacute or chronic meningitis marked by lymphocytic predominance in the CSF. Serological tests are generally positive for Lyme as well; however, during late neurologic disease, CSF serology may be negative. Of particular note, patients with Lyme disease may have a false-positive test for syphilis (and vice versa) because of cross reactivity.[202]

Particular neuropsychiatric sequelae from Lyme disease have been noted to include paranoia, dementia, psychosis, mania, panic attacks, depression, anorexia, obsessive–compulsive disorder, and cognitive impairment.[209,210] Depression has been reported to be as high as 26% to

66%.[209] Other studies suggest that impairment in verbal memory is significant.[210] However, more recent studies suggest that long-term sequelae may not be as common as initially suspected, and that the psychiatric sequelae (listed previously) may not be caused by Lyme disease in a majority of patients.[211,212] Nevertheless, prompt diagnosis and treatment with doxycycline is important to prevent long-term complications that may occur.

Parasitic Meningitis

Parasitic infections are an important cause of meningitis, especially in immunocompromised hosts and in certain areas of the world. Although the scope of such organisms is too large to discuss fully in this chapter, one organism is of particular note because of increasing reemergence in the United States and other developed areas of the world.

Neurocysticercosis is caused when the larval form of *Taenia solium* (pork tapeworm) infects the CNS. The parasite is typically ingested from undercooked pork, and later eggs from the tapeworm residing in the human gut make their way to the CNS. Though autoinfection is possible, more commonly eggs are passed on by fecal–oral transmission by food handlers and such. Cysticercosis is endemic in rural Latin America, Asia, and Africa, and immigration has recently caused a reemergence of the disease in the United States (California, Texas, and the Southwest United States are particularly affected).[212–214]

Neurocysticercosis may present in a number of ways depending on the part of the CNS involved. The main clinical manifestations are seizures, headache, and focal neurologic deficit. Hydrocephalus may contribute to acute presentations of psychosis and delirium. A more chronic picture of depression and dementia is also seen.[212,214] Definitive diagnosis is by brain biopsy; however, CT or MRI often shows the characteristic cysts. Treatment for neurocysticercosis depends on clinical presentation. Anticonvulsants are the mainstay for seizures. Steroids may be used for edema, whereas shunting is used to manage hydrocephalus. Standard antidepressants and neuroleptic medications are used for psychiatric manifestations. Anthelmintic medications are standard as well; however, no controlled trial has established definitive doses or durations of treatment.[214]

CONCLUSION

Infections of the CNS may cause both acute and chronic neuropsychiatric symptomatology. Presentation may be quite varied; it includes delirium, psychosis, dementia, depression, behavioral changes, and mania, among others. The general hospital psychiatrist plays an important role in safeguarding patients from medical diagnoses that may be missed because of psychiatric manifestations. This introduction to the more commonly seen CNS infections and their neuropsychiatric sequelae should provide a starting point for such consultations and evaluations.

21 Catatonia, Neuroleptic Malignant Syndrome, and Serotonin Syndrome

Gregory L. Fricchione, M.D.
Anne F. Gross, M.D.
Jeff C. Huffman, M.D.
George Bush, M.D., M.M.Sc.
Theodore A. Stern, M.D.

Each of the syndromes described in this chapter involves a complex interaction of motor, behavioral, and systemic manifestations that are derived from mechanisms that are not fully clear. What *is* clear is that neurotransmitters, such as dopamine (DA), gamma-aminobutyric acid (GABA), and glutamate, are of major importance in catatonia and neuroleptic malignant syndrome (NMS), whereas serotonin (5-hydroxytryptamine [5-HT]) is a key to the serotonin syndrome (SS). Many now believe that NMS represents a catatonic state that results from the use of DA-blocking medications. These syndromes have symptoms and treatments that overlap.

As our psychopharmacologic armamentarium grows and as drugs with potent effects on modulation of monoamines proliferate, the diagnosis and management of these complex disorders becomes even more important. How can we approach such complicated clinical syndromes? Use of vignettes should help to clarify issues of diagnosis and treatment.

CATATONIA

CASE 1 Catatonia

A 42-year-old man with a long history of complex partial seizures and a history of a left temporal lobectomy had intermittent seizures despite the use of phenytoin and other antiepileptics. After admission to the hospital following a seizure, he developed catatonic withdrawal. After administration of IV lorazepam, he became alert, agitated, and aggressive; moreover, he was paranoid, and reported nihilistic and religious delusions. After several more doses of lorazepam, a higher dosage of phenytoin, and a dose of an atypical antipsychotic (risperidone), his psychosis gradually dissipated. At that point, he was able to state that he felt alone and dissociated, and he was unsure whether he even existed. "I feel separated from the human race, like I am on another planet," he said.

Definition

The catatonic syndrome comprises a constellation of motor and behavioral signs and symptoms that often occurs in relation to neuromedical insults. Structural brain disease, intrinsic brain disorders (e.g., epilepsy, toxic–metabolic derangements, infectious diseases), a variety of systemic disorders that affect the brain, and idiopathic psychiatric disorders (such as affective and schizophrenic psychoses) have all been associated with catatonia.[1–3] Catatonia was first defined by Karl Kahlbaum, who, in 1847, published a monograph that described 21 patients with a severe psychiatric disorder.[4] It was among the first studies in the area of mental illness to use the symptom-based approach of Sydenham to diagnose disorders without a known etiopathogenesis.[1]

Kahlbaum believed that patients with catatonia passed through several phases of illness: a short stage of immobility (with waxy flexibility and posturing), a second stage of stupor or melancholy, a third stage of mania (with pressured speech, hyperactivity, and hyperthymic behavior), and finally, after repeated cycles of stupor and excitement, a stage of dementia.[4]

Kraepelin,[5] who was influenced by Kahlbaum, included catatonia in the group of deteriorating psychotic disorders named dementia praecox. Bleuler[6] adopted Kraepelin's view that catatonia was subsumed under severe idiopathic deteriorating psychoses, which he renamed the schizophrenias.

Kraepelin and Bleuler both recognized that catatonic symptoms could emerge as part of a mood disorder (either mania or depression). It also was well known that catatonia developed secondary to neurologic, toxic–metabolic, and infectious etiologies. These states were considered phenomenologically indistinguishable from primary psychogenic catatonias.

Nevertheless, catatonia was overly associated with schizophrenia until the 1990s as a result of a nosological misconception. Thanks in large part to the work of Fink and Taylor,[7] the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), finally included new criteria for mood disorders with catatonic features, and for catatonic disorder secondary to a general medical condition, as well as the catatonic type of schizophrenia.[8] Catatonia, whether a consequence of medical illness, major depression, mania, a mixed affective disorder, or

schizophrenia, is diagnosed when the clinical picture includes at least two of the following:

- Motoric immobility, as evidenced by catalepsy (including waxy flexibility) or stupor
- Excessive motor activity, apparently purposeless and not influenced by external stimuli
- Extreme mutism or negativism, characterized by an apparently motiveless resistance to all instructions or by maintenance of a rigid posture against attempts to be moved
- Peculiarities of voluntary movement, such as the voluntary assumption of inappropriate or bizarre postures, stereotyped movements, prominent mannerisms, or grimacing
- Echolalia or echopraxia

Epidemiology and Risk Factors

The incidence of catatonia in the general psychiatric population varies according to study design and diagnostic criteria. Nevertheless, prospective studies on patients hospitalized with acute psychotic episodes place the incidence of catatonia in the range of 7% to 17%.[9] In patients who suffer from mood disorders, occurrence rates have ranged from 13% to 31% over the past century. Catatonia appears commonly in people with bipolar disorder.[10] Others at particular risk include patients with mixed manic episodes and those with severe mood disorders.[9] Some have contended that the incidence of catatonia has diminished in cases of schizophrenia, but here, too, diagnostic and study design variations over the decades make this interpretation problematic.

Catatonia is a nonspecific syndrome associated with a variety of etiologies.[9] Neuromedical "organic" etiologies account for 4% to 46% of cases in various series. This underscores the need for a thorough neuromedical workup when catatonic signs are present. Personality disorders or conversion disorder is cited as etiologic in 4% to 11% of cases of catatonia. Catatonia is idiopathic in 4% to 46% of cases in various case series.

Subtypes of Catatonia

Subtypes of catatonia include catatonic withdrawal (characterized by psychomotor hypoactivity) and catatonic excitement (characterized by psychomotor hyperactivity), and these may alternate during the course of a catatonic episode. Kraepelin identified a "periodic" catatonia with an onset in adolescence characterized by intermittent excited states, followed by catatonic stuporous stages and a remitting and relapsing course.[11] This disorder was further elaborated upon by Gjessing[12] in 1932. In 1934, Stauder[13] described lethal catatonia, distinguished by the rapid onset of a manic delirium, high temperatures, and catatonic stupor; it has a mortality rate of greater than 50%.

Although a genetic predisposition has not been clearly identified for catatonia, there appears to be a dominant gene effect for families with periodic catatonia.[14] The disease locus for periodic catatonia appears to map to chromosome 15q15.[14] However, in one family the locus was mapped to chromosome 22q13, affecting the gene *WKL1*. *WKL1* codes for a cation channel found in limbic and dorsal striatal tissues, suggesting that periodic catatonia may be associated with mesolimbic and nigrostriatal changes.[15] More recently, single-nucleotide polymorphisms for the gene *MLC1*, which was thought to be a risk gene for schizophrenia, also located on chromosome 22q13, has been associated with periodic catatonia, but not with general schizophrenia or bipolar disorder.[16] Interestingly, a recent study identified a shared-susceptibility chromosome region on chromosome 15 between catatonia, schizophrenia, and autism, and the authors argued that catatonia may represent an intermediate phenotype in schizophrenia and autism.[17]

In 1986, Mann and associates[18] reviewed the world's literature on lethal catatonia, dating back to the pre-neuroleptic era. Cases from the pre-neuroleptic era classically began with a period of intense motor excitement, which lasted uninterrupted for an average of 8 days. These patients often acted in a bizarre and violent fashion, refused to eat, and displayed intermittent mutism, posturing, catalepsy, and rigidity that alternated with their excitement. They manifested thought disorders with disorganized incoherent speech and experienced delusions and hallucinations. During the hyperactive stage, their fevers rose rapidly, and they were diaphoretic and tachycardic. This stage would be followed by exhaustion, characterized by stupor and high body temperatures.

Terminal rigidity and posturing were noted in Stauder's series of 27 lethal catatonia cases,[13] although others reported cases of flaccidity.[19] Some cases in the pre-neuroleptic era were characterized by catatonic stupor and rigidity in the absence of an early excitement phase. Pre-neuroleptic–era lethal catatonia was fatal in more than three out of four cases.

For Kraepelin, lethal catatonia was a syndrome with various neuromedical and psychiatric causes; the review by Mann and co-workers[18] of 292 cases since 1960 supports this concept. Most of the patients in this series received neuroleptics at some point during their treatment. Of those, 60% died. The classic hyperactive form of catatonia was found in 69% of the cases. Patients either presented with catatonic excitement or it developed early on. High fever, altered consciousness, autonomic instability, anorexia, electrolyte imbalance, cyanosis, and associated catatonic signs (e.g., posturing, stereotypies, and mutism) were present from the early stages. Stupor typically followed the early hyperactive state, but 31% of patients with lethal catatonia presented with stupor. Once stupor and rigidity emerge, patients with catatonic stupor act like those with NMS, which also has a substantial mortality rate.[19] Indeed, the symptoms of predominantly stuporous patients with catatonia were clinically indistinguishable from those with NMS.

Clinical Features and Diagnosis

Signs and symptoms of the catatonic syndrome are outlined in Table 21–1 (the Modified Bush–Francis Catatonia Rating Scale). A key is to differentiate catatonia from other syndromes with similar manifestations but with different etiologies (Table 21–2).[20–42] When assessing the etiology of the catatonia, the psychiatrist should consider secondary causes of catatonia related to underlying neurologic, toxic, or metabolic abnormalities, as well as primary psychiatric causes.

In addition to routine studies to identify neuromedical causes of catatonia, the clinician can obtain a metabolic panel; serum and urine toxicologies; an infectious-disease

TABLE 21–1 Modified Bush–Francis Catatonia Rating Scale*

Catatonia can be diagnosed by the presence of two or more of the first 14 signs listed below.

1. Excitement	Extreme hyperactivity, and constant motor unrest, which is apparently nonpurposeful; not to be attributed to akathisia or goal-directed agitation
2. Immobility/stupor	Extreme hypoactivity, immobility, and minimal response to stimuli
3. Mutism	Verbal unresponsiveness or minimal responsiveness
4. Staring	Fixed gaze, little or no visual scanning of environment, and decreased blinking
5. Posturing/catalepsy	Spontaneous maintenance of posture(s), including mundane (e.g., sitting/standing for long periods without reacting)
6. Grimacing	Maintenance of odd facial expressions
7. Echopraxia/echolalia	Mimicking of an examiner's movements/speech
8. Stereotypy	Repetitive, non–goal-directed motor activity (e.g., finger-play, or repeatedly touching, patting, or rubbing oneself); the act is not inherently abnormal but is repeated frequently
9. Mannerisms	Odd, purposeful movements (e.g., hopping or walking on tiptoe, saluting those passing by, or exaggerating caricatures of mundane movements); the act itself is inherently abnormal
10. Verbigeration	Repetition of phrases (like a scratched record)
11. Rigidity	Maintenance of a rigid position despite efforts to be moved; exclude if cogwheeling or tremor present
12. Negativism	Apparently motiveless resistance to instructions or attempts to move/examine the patient; contrary behavior; doing the exact opposite of the instruction.
13. Waxy flexibility	During reposturing of the patient, the patient offers initial resistance before allowing repositioning, similar to that of a bending candle
14. Withdrawal	Refusal to eat, drink, or make eye contact
15. Impulsivity	Sudden inappropriate behaviors (e.g., running down a hallway, screaming, or taking off clothes) without provocation; afterward, gives no or only facile explanations
16. Automatic obedience	Exaggerated cooperation with the examiner's request or spontaneous continuation of the movement requested
17. *Mitgehen*	"Anglepoise lamp": arm raising in response to light pressure of finger, despite instructions to the contrary
18. *Gegenhalten*	Resistance to passive movement that is proportional to the strength of the stimulus; appears automatic rather than willful
19. Ambitendency	The appearance of being "stuck" in indecisive, hesitant movement
20. Grasp reflex	Per neurologic examination
21. Perseveration	Repeatedly returns to the same topic, or persistence with movement
22. Combativeness	Usually aggressive in an undirected manner, with no, or only facile, explanation afterward
23. Autonomic abnormality	Abnormal temperature, blood pressure, pulse, or respiratory rate, and diaphoresis

Modified from Bush G, Fink M, Petrides G et al: Catatonia—I: rating scale and standardized examination, *Acta Psychiatr Scand* 93:129–136, 1996.

*The full 23-item Bush–Francis Catatonia Rating Scale (BFCRS) measures the severity of 23 signs on a 0 to 3 continuum for each sign. The first 14 signs combine to form the Bush–Francis Catatonia Screening Instrument (BFCSI). The BFCSI measures only the presence or absence of the first 14 signs, and it is used for case detection. Item definitions on the two scales are the same.

work-up, including human immunodeficiency virus and rapid plasma reagin testing; and autoimmune screening (erythrocyte sedimentation rate, C-reactive protein, antinuclear antibodies). A personal and family history of psychiatric illness is important but not diagnostic. Research on regional blood flow has shown basal ganglia asymmetry with left-sided hyperperfusion, hypoperfusion in the left medial temporal area, and decreased perfusion in the right parietal cortex. During working memory tasks and with emotional–motor activation, the orbitofrontal cortex appears to be altered in several cases studied with functional magnetic resonance imaging (fMRI).[43] However, none of these experimental findings are diagnostic.

Under the category of secondary causes, some now argue that there should be a catatonia subtype associated with delirium, which would include excited forms (as can occur in "delirious mania") and stuporous forms (as often seen in cases of encephalitis). Delirious mania is a syndrome with acute onset of excitement, grandiosity, emotional lability, delusions, and insomnia characteristic of mania and the disorientation and altered consciousness characteristic of delirium, as well as fever, tachycardia, hypertension, and tachypnea. It is often associated with catatonia and can often look like excited or malignant catatonia. Fink argues that when catatonic signs predominate, this syndrome may be classified as excited catatonia, whereas if catatonic symptoms are less prominent, the syndrome should be identified as delirious mania.[44] The diagnostic evaluation, including careful assessment for catatonic symptoms, is essential; the use of lithium and neuroleptics, common medications for the treatment of mania, may worsen the catatonic symptoms and lead to NMS. In fact, Fink argues that electroconvulsive therapy (ECT) is the treatment of choice for patients with delirious mania.

When catatonic symptoms are associated with a stuporous state in the setting of delirium, limbic encephalitis must be considered as a potential cause.[45] Limbic encephalitis has an acute to subacute onset, and it is associated

TABLE 21–2 Potential Etiologies of the Catatonic Syndrome

Primary: Psychiatric
Acute psychoses
Conversion disorder
Dissociative disorders
Mood disorders
Obsessive–compulsive disorder
Personality disorders
Schizophrenia

Secondary: Neuromedical
Cerebrovascular
- Arterial aneurysms
- Arteriovenous malformations
- Arterial and venous thrombosis
- Bilateral parietal infarcts
- Temporal lobe infarct
- Subarachnoid hemorrhage
- Subdural hematoma
- Third ventricle hemorrhage
- Hemorrhagic infarcts

Other Central Nervous System Causes
Akinetic mutism
Alcoholic degeneration and Wernicke's encephalopathy
Cerebellar degeneration
Cerebral anoxia
Cerebromacular degeneration
Closed head trauma
Frontal lobe atrophy
Hydrocephalus
Lesions of thalamus and globus pallidus
Narcolepsy
Parkinsonism
Postencephalitic states
Seizure disorders*
Surgical interventions
Tuberous sclerosis

Neoplasm
Angioma
Frontal lobe tumors
Gliomas
Langerhans' carcinoma
Paraneoplastic encephalopathy
Periventricular diffuse pinealoma

Poisoning
Coal gas
Organic fluorides
Tetraethyl lead poisoning

Infections
Acquired immunodeficiency syndrome
Bacterial meningoencephalitis
Bacterial sepsis
General paresis
Malaria
Mononucleosis
Subacute sclerosing panencephalitis
Tertiary syphilis
Tuberculosis
Typhoid fever
Viral encephalitides (especially herpes)
Viral hepatitis

Metabolic and Other Medical Causes
Acute intermittent porphyria*
Addison's disease
Cushing's disease
Diabetic ketoacidosis
Glomerulonephritis
Hepatic dysfunction
Hereditary coproporphyria
Homocystinuria
Hyperparathyroidism
Idiopathic hyperadrenergic state
Multiple sclerosis
Pellagra

Idiopathic
Peripuerperal
Systemic lupus erythematosus*
Thrombocytopenic purpura
Uremia

Drug-Related
Neuroleptics (typical and atypical): clozapine and risperidone* (all neuroleptics have been associated)
Non-neuroleptic
- Alcohol
- Anticonvulsants (tricyclics, monoamine oxidase inhibitors, and others)
- Anticonvulsants (e.g., carbamazepine, primidone)
- Aspirin
- Disulfiram
- Metoclopramide
- Dopamine depleters (e.g., tetrabenazine)
- Dopamine withdrawal (e.g., levodopa)
- Hallucinogens (e.g., mescaline, phencyclidine,* and lysergic acid diethylamide)
- Lithium carbonate
- Morphine
- Sedative–hypnotic withdrawal
- Steroids
- Stimulants (e.g., amphetamines, methylphenidate, and possibly cocaine)

Modified from Philbrick KL, Rummans TA: Malignant catatonia, *J Neuropsychiatry Clin Neurosci* 6:1–13, 1994.
*Signifies most common medical conditions associated with catatonic disorder from literature review done by Carroll BT, Anfinson TJ, Kennedy JC et al: Catatonic disorder due to general medical conditions, *J Neuropsychiatry Clin Neurosci* 6:122–133, 1994.

with confusion, cognitive impairment (including short-term memory dysfunction), seizures, and also, at times, with catatonia. Etiologies of limbic encephalitis include infectious, autoimmune, paraneoplastic, and idiopathic causes. Neuroimaging (MRI) and lumbar puncture (sometimes revealing a pleocytosis) with cerebrospinal antibody titer studies may be helpful in determining the diagnosis. Idiopathic encephalitis has sometimes been called encephalitis lethargica. Recently, several cases of limbic encephalitis in young women have been associated with ovarian teratomas that generate autoantibodies to NMDA receptors,[45] and a testicular teratoma was also associated with limbic encephalitis.[45] These cases respond well to removal of the teratoma, as well as to immunosuppressive

therapies. Therefore, if a patient presents with symptoms of limbic encephalitis, a healthy level of suspicion should be maintained for a gonadal tumor, and abdominal and pelvic imaging (computed tomography, MRI, positron-emission tomography, or pelvic ultrasound) should be considered.

Fortunately, although no one test can confirm a diagnosis of catatonia, some studies (e.g., an electroencephalogram [EEG], neuroimaging of the brain, optokinetic and caloric testing) may help establish the etiology.

An EEG read as normal might be consistent with primary catatonia, and although psychiatric patients may have diffuse, nonspecific changes on the EEG, this finding is found most often in patients with secondary catatonias. Also, catatonia may emerge as both an ictal and a postictal phenomenon. Plum and Posner[46] pointed out that those with idiopathic primary catatonia, as opposed to catatonia associated with structural neurologic disease, have normal optokinetic responses, normal pupillary responses, and ocular nystagmus on cold caloric tests. Patients with hysterical stupor, when turned on their sides, will elicit a downward gaze, as if resulting from gravity.[47] Neuroimaging, especially MRI of the brain, should be obtained, although a negative result does not rule out a neuromedical etiology. Creatine phosphokinase (CPK) levels are often elevated in patients with malignant catatonia, but they can also be high in simple catatonias.

When a patient is in a catatonic stupor, the slow IV administration of amobarbital may relieve the syndrome long enough for a skillful clinician to perform an interview,[18,23] which may lead to a diagnosis. Anecdotally, patients with neuromedical etiologies may become more confused on amobarbital than those with psychiatric etiologies.

As noted later, lorazepam and other benzodiazepines are now the first-line treatment for any catatonia, as they often lyse the catatonic episode completely. Benzodiazepines, which also relieve secondary neuromedical catatonias, are not useful in distinguishing between primary and secondary etiologies.

The specific number and nature of signs and symptoms required to make a diagnosis of catatonia remains controversial. Lohr and Wisniewski[21] proposed that one or more cardinal features (including catalepsy, positivism [such as is seen in automatic obedience], and negativism), and two of the other features should be present to diagnose catatonia. Rosebush and colleagues[25] suggested that catatonia was present when three cardinal features (e.g., immobility, mutism, and withdrawal [with refusal to eat or drink]), or when two cardinal features and two secondary characteristics, were present.

Taylor[1] contended that even one cardinal characteristic has as much clinical significance (for diagnosis and treatment) as the presence of seven or eight characteristics. The evidence does not support a relationship among the number of catatonic features, the diagnosis, and response to treatment. Fink and Taylor[7] later argued that a minimum of two classic symptoms was sufficient to diagnose the syndrome, and, more recently, Bush and co-workers[48] developed a rating scale and guidelines for the diagnosis of catatonia. They found that two or more signs identified all of their patients with catatonia (Table 21–3; see also Table 21–1). Their method is consistent with the DSM-IV criteria for catatonia.

TABLE 21–3 Standardized Examination for Catatonia

The method described here is used to complete the 23-item Bush–Francis Catatonia Rating Scale (BFCRS) and the 14-item Bush–Francis Catatonia Screening Instrument (BFSCI). Item definitions on the two scales are the same. The BFCSI measures only the presence or absence of the first 14 signs.

Ratings are based solely on observed behaviors during the examination, with the exception of completing the items for "withdrawal" and "autonomic abnormality," which may be based on directly observed behavior or chart documentation.

As a general rule, only items that are clearly present should be rated. If the examiner is uncertain as to the presence of an item, rate the item as "0."

Procedure

1. Observe the patient while trying to engage in a conversation.
2. The examiner should scratch his or her head in an exaggerated manner.
3. The arm should be examined for cogwheeling. Attempt to reposture and instruct the patient to "keep your arm loose." Move the arm with alternating lighter and heavier force.
4. Ask the patient to extend his or her arm. Place one finger beneath his or her hand and try to raise it slowly after stating, "Do *not* let me raise your arm."
5. Extend the hand stating, "Do *not* shake my hand."
6. Reach into your pocket and state, "Stick out your tongue. I want to stick a pin in it."
7. Check for grasp reflex.
8. Check the chart for reports from the previous 24-hour period. Check for oral intake, vital signs, and any incidents.
9. Observe the patient indirectly, at least for a brief period each day, regarding the following:
   - Activity level
   - Abnormal movements
   - Abnormal speech
   - Echopraxia
   - Rigidity
   - Negativism
   - Waxy flexibility
   - *Gegenhalten*
   - *Mitgehen*
   - Ambitendency
   - Automatic obedience
   - Grasp reflex

The catatonic syndrome may be divided into primary (psychiatric) and secondary (neuromedical) varieties as well as simple and malignant ones. A malignant catatonia is one accompanied by fever, hyperautonomia, and increased morbidity and mortality. There may be primary as well as secondary simple catatonias and primary and secondary malignant catatonias. An example of a secondary malignant catatonia is NMS.

NEUROLEPTIC MALIGNANT SYNDROME

CASE 2 Neuroleptic Malignant Syndrome

A 56-year-old woman with a history of bipolar disorder was admitted to the hospital after arguing with her husband. She became agitated and combative and required haloperidol (5 mg IM) on two occasions in the emergency room. Her psychiatric history was notable for depression, suicidal ideation, and auditory hallucinations as a teenager that required ECT and long-term treatment with perphenazine, lithium, and imipramine. Soon after her admission, she became psychomotorically withdrawn, hypokinetic, mute, and rigid. Her temperature reached 101.6° F and her CPK level was elevated (2260 U/L). An EEG revealed generalized slowing. A diagnosis of NMS was made, and her medications were discontinued. Her catatonic symptoms responded to lorazepam (2 mg IV, twice). Divalproex sodium and olanzapine were started 2 weeks after the resolution of her NMS.

Epidemiology and Risk Factors

Estimates of the risk for NMS have varied widely (from 0.02% to greater than 3%). Different diagnostic criteria, survey techniques, population susceptibilities, prescribing habits, and treatment settings all contribute to the variance. In one center with a large number of patients treated with antipsychotics, 1 out of every 500 to 1000 patients was thought to develop NMS.[49] Age and sex do not appear to be reliable risk factors, though young adult men may be more prone to extrapyramidal symptoms (EPS). The fact that NMS occurs around the world suggests that environmental factors are not significant predictors. Although it can occur in association with any disorder treated with a neuroleptic, certain conditions may elevate the risk. A history of catatonia is a major risk factor for progression to the malignant catatonia of NMS. Schizophrenia, mood disorders, neuromedical organic brain disorders, alcoholism, and substance abuse disorders have been associated with NMS. The period of withdrawal from alcohol or sedative–hypnotics may increase the risk because of aberrant thermoregulation and autonomic dysfunction. Agitation, dehydration, and exhaustion may also increase the risk. Basal ganglia disorders (e.g., Parkinson's disease, Wilson's disease, Huntington's disease, tardive dystonia) are thought to place patients at increased risk. Low serum iron appears to be a state-specific finding in patients with NMS, and patients with low serum iron in the context of catatonia may be at increased risk for NMS if placed on neuroleptic medications. A history of NMS conveys the risk of recurrence, with up to a third of patients having a subsequent episode when rechallenged. High-potency neuroleptics have been thought to produce an elevated risk and more intense cases of NMS. Clozapine, for example, may cause NMS with significantly less rigidity. Nevertheless, use of atypical antipsychotics can cause NMS. Studies have not supported any particular genetic predisposition, although case reports have implicated an association with cytochrome CYP 2D6.[49]

Clinical Features and Diagnosis

Philbrick and Rummans[20] suggested using the term *malignant catatonia* rather than *lethal catatonia* (because not all cases are lethal) to describe critically ill patients whose disease is marked by autonomic instability or hyperthermia, in contradistinction to patients with simple, nonmalignant catatonia. The causes of malignant catatonia are the same as those of simple catatonia. *Pernicious catatonia* is another term that has been used to describe this catatonic variant.[50]

Consideration of neuroleptics as potential causative agents is important because NMS is currently considered to be a severe form of neuroleptic-induced catatonia. NMS is a syndrome of autonomic dysfunction with tachycardia and elevated blood pressure, fever, rigidity, mutism, and stupor, associated with the use of neuroleptics. Hyperthermia, sometimes in excess of 42° C (108° F), is reported in 98% of the cases.[49] "Leadpipe" rigidity can occur. Parkinsonian features, including cogwheeling, may be present. NMS, most often in the setting of atypical antipsychotic use, can occur without rigidity or CPK elevation. Mental status changes occur in 97% of the cases.[49] Most often, the NMS patient will be in a catatonic state akin to akinetic mutism; such patients may be alert, delirious, stuporous, or comatose. Diagnostic criteria for NMS are found in Table 21–4.[51]

In 1985, Fricchione[52] suggested that NMS is to lethal catatonia what neuroleptic-induced catatonia is to simple catatonia. Moreover, if neuroleptic-induced catatonia is a form of catatonia, then NMS is a form of malignant catatonia with a similar pathophysiology.[52] Goforth and Carroll[53] also noted the overlap of catatonia and NMS. All 27 of their cases of NMS met the DSM-IV diagnostic criteria for catatonia; 24 met stricter research criteria. The authors concluded that the two syndromes were identical, with NMS presenting as a more severe and iatrogenic variant of malignant catatonia. Fink[54] also arrived at this conclusion. Table 21–5 shows the symptoms of catatonia and NMS that overlap.

TABLE 21–4 Diagnostic Criteria for Neuroleptic Malignant Syndrome

Treatment with neuroleptics within 7 days of onset (2 to 4 weeks for depot neuroleptics)
Hyperthermia (≥38° C)
Muscle rigidity
Five of the following:
1. Change in mental status
2. Tachycardia
3. Hypertension or hypotension
4. Tachypnea or hypoxia
5. Diaphoresis or sialorrhea
6. Tremor
7. Incontinence
8. Creatine phosphokinase elevation, or myoglobinuria
9. Leukocytosis
10. Metabolic acidosis

Exclusion of other drug-induced, systemic, or neuropsychiatric illness

Adapted from Caroff SN, Mann SC, Lazarus A et al: Neuroleptic malignant syndrome: diagnostic issues, *Psychiatr Ann* 21:130–147, 1991.

TABLE 21–5 Catatonia and Neuroleptic Malignant Syndrome (NMS): Shared Features

	NMS	CATATONIA
Clinical Signs		
Hyperthermia	Yes	Often
Motor rigidity	Yes	Yes
Mutism	Yes	Yes
Negativism	Often	Yes
Altered consciousness	Yes	Yes
Stupor or coma	Yes	Yes
Autonomic Dysfunction	Yes	Often
Tachypnea	Yes	Often
Tachycardia	Yes	Often
Abnormal blood pressure	Yes	Yes
Diaphoresis	Yes	Yes
Laboratory Results		
Creatine phosphokinase (CPK) elevated	Yes	Often
Serum iron reduced	Yes	Probable
Leukocytosis	Yes	Often

NMS and lethal catatonia appear to be part of a single syndrome, with minor differences in their presentations (e.g., there is a behavioral prodrome and hyperthermia in the pre-stuporous stage of lethal catatonia, as opposed to its occurrence in the stage with stupor and rigidity in NMS). Indeed, although early reports suggested that the level of CPK is increased in NMS and not in primary lethal catatonia, a survey of 13 cases of primary malignant catatonia revealed that CPK levels were elevated in all nine of the cases in which they were tested.[20]

Encephalograms are abnormal in roughly half of cases, most often with generalized slowing that is consistent with encephalopathy.[49] In contrast, CT of the brain and cerebrospinal fluid (CSF) studies are normal in 95% of NMS cases.[49]

In 1991, Rosebush and Mazurek[55] found decreased levels of serum iron in patients with NMS and suggested a role for lowered iron stores in the reduction of DA receptor function. Supporting the hypothesis of NMS as a severe variant of catatonia, Carroll and Goforth[56] reported a similar decrease of serum iron in three of 12 cases of catatonia, with NMS developing in two of the three cases. The third was without neuroleptic exposure and did not progress to NMS.[56] Lee[57] prospectively studied 50 patients with catatonia; serum iron was measured in 39 of the episodes. The low serum iron level found in 14 cases (44%) was associated with lethal catatonia and with a poorer response to benzodiazepines. In seven episodes of lethal catatonia, a low level of serum iron was detected. Neuroleptics were used in five cases, and all five progressed to NMS.

Providing further support for the relationship between primary psychogenic catatonias and neuroleptic-induced catatonias, White and Robins[58] reported five consecutive cases of NMS that were each preceded by a catatonic state; none of the patients had received prior neuroleptics and none had a prior psychiatric history. White[59] concluded that NMS and lethal catatonia are not separate disorders. Mann and colleagues[60] also viewed NMS as a neuroleptic-induced iatrogenic form of organic lethal catatonia.

Most commonly, NMS develops over a few days, often beginning with rigidity and mental status changes followed by signs of hypermetabolism. The course is usually self-limited, lasting 2 days to 1 month (once neuroleptics are stopped and supportive measures are begun).[49] Persistent cases are usually secondary to the use of depot neuroleptics, and ECT is highly effective in these cases. Although the mortality rate has been reduced through better recognition and management, there is still an approximately 10% risk of death.[49] Myoglobinuric renal failure and rhabdomyolysis may have long-term consequences.

Neuropathophysiology

Catatonia is thought to reflect a disruption in basal ganglia thalamocortical tracts (including the motor circuit [rigidity], the anterior cingulate–medial orbitofrontal circuit [akinetic mutism and, perhaps through lateral hypothalamic connections, hyperthermia and dysautonomia], and the lateral orbitofrontal circuit [imitative and repetitive behaviors]) (Figure 21–1).[60] Such disruption may lead to a relative state of hypodopaminergia in these circuits through reduced flow in the medial forebrain bundle, the nigrostriatal tract, and the tuberoinfundibular tract. DA activity in the dorsal striatum and in the ventral striatum and paralimbic cortex is thus reduced, perhaps secondary to reduced $GABA_A$ inhibition of $GABA_B$, substantia nigra, and ventral tegmental area interneurons. This would lead to a dampened DA outflow, whereas activation at $GABA_A$, through use of agonists such as lorazepam, would indirectly disinhibit DA cell activity.[3,52] Another possible site of pathophysiology involves reduced $GABA_A$ inhibition of frontal corticostriatal tracts, leading to *N*-methyl-D-aspartate (NMDA) changes in the dorsal striatum, and indirectly in the substantia nigra and ventral tegmental area.[3] Multiple etiologies, if they affect the basal ganglia, thalamus, or paralimbic or frontal cortices, will have the potential to cause those neurotransmitter alterations that will disrupt basal ganglia thalamocortical circuits, leading to the phenomenology of catatonia.

In the mesostriatal and mesocorticolimbic systems, the long feedback loops from DA neurons are regulated by GABA pathways. Given its extensive projections on both limbic and motor structures, the nucleus accumbens may be a hub for the linkage between motivation and movement.[61] By extrapolating from animal evidence (i.e., $GABA_A$ antagonists lead to catalepsy, and $GABA_A$ agonists protect against catalepsy), and from the hypothesis that neuroleptic-induced catatonia may result from reduced DA and $GABA_A$ activity in the mesostriatum, it has been proposed that primary psychogenic catatonia results from a similar destabilization.[52] $GABA_A$ agonists could be restorative by inhibiting the pars reticulata's inhibitory $GABA_B$ neurons, resulting in disinhibition of the neighboring pars compacta's DA cells with a resultant striatal DA agonism.[52]

Electroconvulsive therapy may be effective for catatonia on the basis of this GABA-DA interaction. Sackeim and associates[62] proposed that the neural state following ECT is produced by increased GABA transmission. They cited animal studies in which the concentration of GABA in the striatum became elevated after ECT. Some investigators have believed that ECT may increase the sensitivity

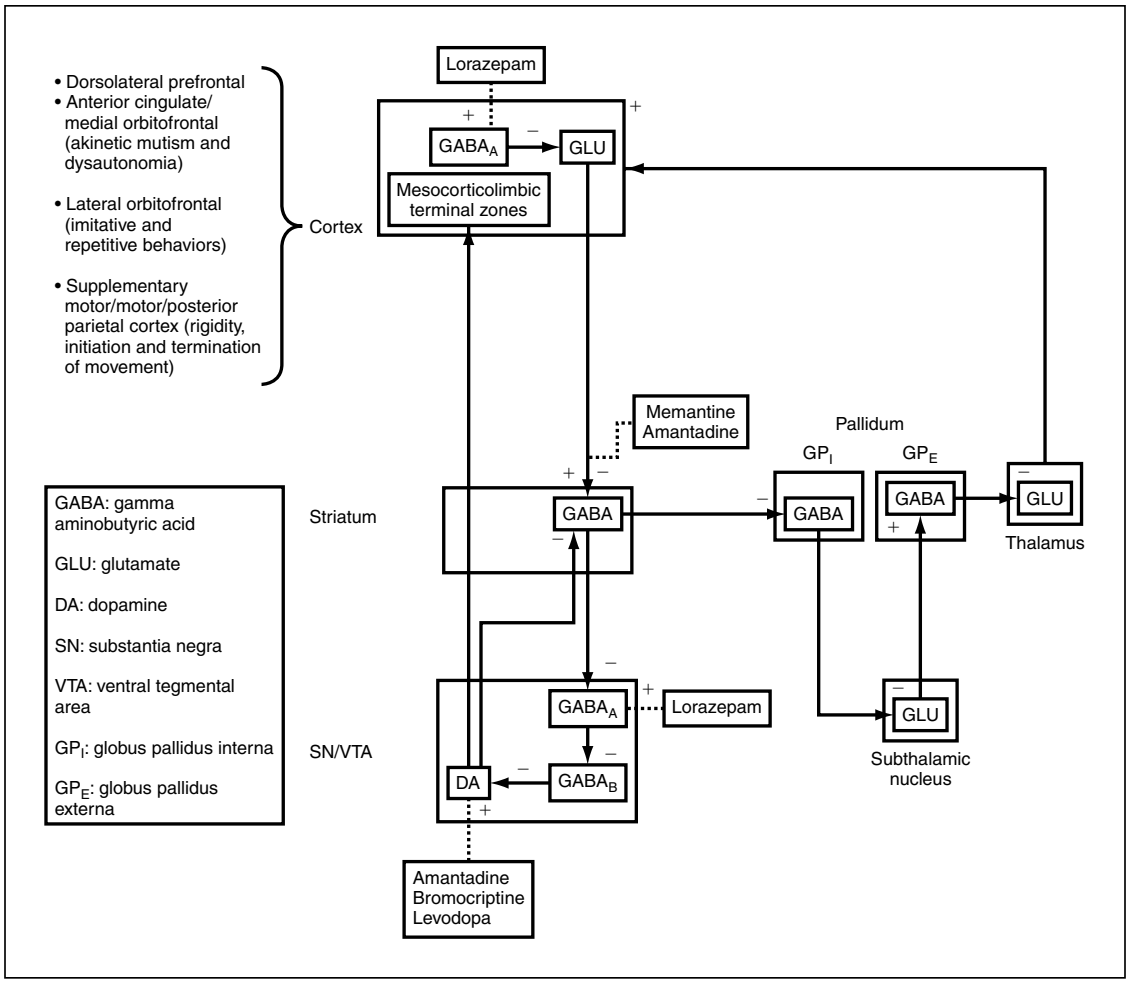

Figure 21–1. Basal ganglia thalamocortical circuits and catatonia: a candidate loop. (*From Fricchione GL, Huffman JC, Bush G et al*: Catatonia, neuroleptic malignant syndrome, and serotonin syndrome. *In Stern TA, Rosenbaum JF, Fava M et al, editors*: *Massachusetts General Hospital comprehensive clinical psychiatry*, *Philadelphia, 2008, Mosby, pp 761–771*.)

of postsynaptic DA receptors to available DA. An animal model of catatonia supports this hypothesis. Stevens and colleagues[63] instilled bicuculline, a $GABA_A$ antagonist, into the ventral tegmentum of cats; slinking, hiding, looking fearful, staring, sniffing, and taking a catatonic stance were noted. Waxy flexibility of the limbs developed and animals stood still and stared for extended periods.[63] When bicuculline was given in the ventral tegmentum after systemic haloperidol, marked dystonic postures were produced. Picrotoxin, an antagonist at the chloride channel of the benzodiazepine-$GABA_A$ recognition site, was administered in the ventral tegmental area as well. Smaller doses induced fear and staring, whereas larger doses produced prolonged severe dystonia, especially following haloperidol. Microinjection of the $GABA_A$ agonist muscimol into the ventral tegmental area of the rat caused a dose-dependent motor activation. This response was antagonized by administration of bicuculline or by haloperidol administration.[64] Neuroleptics reduce the conditioned avoidance response, which is thought to be secondary to decreased DA activity in the nucleus accumbens and the striatum. Stress has been shown to increase medial prefrontal cortical DA release, which in turn is thought to reduce DA activity in subcortical DA terminal fields in the mesolimbic and mesostriatal systems.[65,66] Friedhoff and coworkers[67] were able to show that rats undergoing twice-daily tail-shock stress for 8 days displayed conditioned avoidance response inhibition, along with a reduction in nucleus accumbens DA use. The findings provided support for a restitutive hypothesis involving an endogenous DA-dependent system that mimicked the effects of neuroleptics in the context of repeated stress–induced medial prefrontal cortical hyperdopaminergia. When such a system down-regulates too much because of neurologic or medical insult, primary psychiatric dysfunction, or neuroleptic medication, or a combination of all three, catatonic stupor may occur. These state changes may be tied to a genetic trait vulnerability for acute NMS, perhaps having to do with defective calcium regulation that leads to a dysregulated hyperactive sympathetic nervous system response in the presence of severe psychic stress and neuroleptic-induced hypodopaminergia.[68] NMS has been postulated to be secondary to DA blockade in the mesostriatum (which is responsible for the motor disorder), the mesolimbic

system (which is responsible for the mutism), and the preoptic anterior hypothalamus (which is responsible for the hyperthermia).[69]

A "universal field hypothesis" of catatonia and NMS has been proposed.[70] It speculates that some type of neurochemical predisposition, be it low activity at the D_2 or $GABA_A$ receptor for which most evidence exists, NMDA receptor dysregulation, or even high $5\text{-}HT_{1A}$ receptor activity, can modulate the circuits involved in catatonia and NMS and lower the threshold for the syndrome. In any event, the DA and $GABA_A$ disturbances in the basal ganglia thalamocortical circuits appear to be the primary physiologic derangements.

By examining the nature of basal ganglia thalamolimbic-cortical loops, we can hypothesize why such a wide array of neuromedical and psychiatric etiologies can present with the catatonic syndrome and why the treatments discussed later may be therapeutic (see Figure 21–1).

Management and Treatment

Whatever its etiology, catatonia is accompanied by significant morbidity and mortality from systemic complications. In addition, many of the physical illnesses responsible for catatonia can be hazardous (Table 21–6). Thus, timely diagnosis and treatment are essential. If a neurologic or medical condition is found, then treatment for that specific illness is indicated. Agents thought to exacerbate catatonia, including antipsychotic medications and dopamine-blocking drugs (e.g., metoclopramide), should be discontinued, and if dopamine agonists were recently stopped, they should be restarted. Occasionally psychiatric therapies are used to treat catatonia as a secondary behavioral manifestation of a medical illness. For example, lorazepam has been found to be effective in certain cases of catatonia secondary to medical illness, and it has become the first-line treatment for catatonia regardless of etiology.[25] In addition, ECT has been used to treat lupus patients with catatonia,[55] and other secondary catatonias, and remains the most effective treatment for catatonia.[28] Response to treatment is usually good for individuals with acute primary catatonia; 67% are improved by time of discharge.[71] Patients with manic features respond particularly well. Rates of long-term recovery range from 33% to 75%.[1] Fatality rates of 50% or more were the rule before the introduction of ECT.[72] Two or three ECT treatments are usually sufficient to lyse the catatonic state, although a course of four to six treatments is usually given to prevent relapse, and 10 to 20 treatments are sometimes needed in difficult cases. Nevertheless, patients' families are often reluctant to agree to ECT because of the stigma associated with it and the fear of side effects.

Intravenous amobarbital can be rapidly successful in some patients with catatonic stupor.[73] However, these effects tend to be short-lived, and there is a narrow therapeutic window. One approach is to administer 50 to 75 mg/mL IV at 1 mL/min for first 2 minutes; each additional 1 mL is given over 1 minute, with a 1-minute wait period to assess effect. Throughout the intervention, efforts should be made to keep the patient talking. When yawning, speech slurring, or nystagmus begins, stop the drug and check for orientation, memory, and a history of illness. Many centers now require practitioners to have certification in conscious sedation before performing an amobarbital interview. Furthermore, in one study, only 50% of psychiatric patients with catatonic mutism responded to an amobarbital interview.[74] Repeated IV doses lead to oversedation; amobarbital administered orally does not appear to prolong its benefits.

In the past, neuroleptics were frequently used to treat catatonia. In addition to the variable response of catatonia to these drugs, neuroleptics may complicate matters; their use also has precipitated catatonic reactions and NMS.[19] At times, higher doses of antipsychotics are used to treat psychosis and agitation, but it may worsen catatonia. Moreover, among the 292 patients with malignant catatonia reviewed by Mann and associates,[18] 78% of those treated with a neuroleptic alone died, compared with an overall mortality rate of 60%. In 18 cases reviewed by Philbrick and Rummans,[20] only one patient received a neuroleptic alone—this patient also died. Therefore, neuroleptics may be contraindicated during an acute episode of malignant catatonic stupor.[18,20]

In 1983, Lew and Tollefson[75] reported on the usefulness of IV diazepam, and, at the same time, Fricchione and colleagues[76] reported on the benefit of IV lorazepam given to patients in neuroleptic-induced catatonic states (including NMS) and suggested its use in primary psychiatric catatonia. In 1984, McEvoy and Lohr[77] successfully administered IV diazepam to two catatonic patients whose conditions

had not improved with haloperidol regimens (that had been initiated after the onset of catatonia). Rosebush and co-workers[25] reported that 80% of 15 catatonic episodes showed a complete and dramatic response within 2 hours of lorazepam treatment (1 to 2 mg oral, IM, or IV); one showed a partial response, and two showed no response. Side effects were uncommon. Catatonia related to a CNS abnormality was evident in 8 of 12 responders, which suggested that a beneficial response to lorazepam was not limited to patients with psychogenic catatonia.

Bush and co-workers[78] studied the use of lorazepam and ECT in the treatment of catatonia. Twenty-eight prospectively identified patients entered their open-trial protocol (which included parenteral lorazepam, oral lorazepam [1 to 2 mg orally two to three times a day], or both for 3 to 5 days, with referral for ECT if lorazepam failed). Of 21 patients (76%) who received a complete trial of lorazepam (11 received an initial 2-mg IV challenge), 16 had resolution of catatonic signs. All four patients referred for ECT (after failing lorazepam therapy) responded promptly. Bush and co-workers[78] specifically suggested a trial of lorazepam 2 mg IM or IV, with monitoring of respiratory status. Sometimes higher doses were required. With a drug distribution that is less rapid and less extensive, a relatively high plasma level can be maintained, thus prolonging the clinical benefit of IV lorazepam.[2] Given intramuscularly in the deltoids, lorazepam is more reliably absorbed than other IM benzodiazepines.[2] A switch to regular doses of lorazepam or diazepam maintains the therapeutic effect. Lorazepam given orally or via nasogastric tube in a daily dose of 6 to 20 mg also has been used effectively. Diazepam 10 to 50 mg/day or clonazepam 1 to 5 mg/day also has been used successfully, as has midazolam.[2] If lorazepam is unsuccessful within 5 days, ECT should be considered.[2]

Alternatives to ECT in simple catatonias include zolpidem 5 to 10 mg orally, which has been used as a test for catatonia, [79] amantadine 100 mg twice a day orally, memantine 5 to 10 mg twice a day orally,[80,81] and topiramate 100 mg twice a day orally.[82] Carbamazepine, valproate, calcium channel blockers, anticholinergics, lithium, thyroid medication, and corticosteroids have each had anecdotal success in catatonia.[20] In 1985, when it was suggested that psychogenic catatonia and neuroleptic-induced catatonia (including NMS) shared a common pathophysiology, use of specific dopaminergic or GABA-ergic drugs in psychogenic catatonia untreated by neuroleptic medication also was suggested.[52] Accordingly, it is of interest that 2.5 mg of oral bromocriptine twice a day was used successfully in a 16-year-old girl with catatonia that preceded neuroleptic exposure,[83] and that Rogers[84] used L-dopa to treat a patient with a 50-year history of severe catatonic schizophrenia (off neuroleptics for 5 years) with improvement in catatonic akinesia and without worsening of positive symptoms. Neppe[85] also has successfully used L-dopa to treat catatonic stupor.

In a study of lorazepam treatment for NMS, rigidity and fever abated in 24 to 48 hours, whereas secondary features of NMS dissipated within 64 hours (without adverse effects).[86] If lorazepam does not briskly reverse the lethal catatonia, the clinician should not wait for 5 days to begin ECT. Mann and associates[87] found that in one series of cases of lethal catatonia where ECT was used, 40 of 41 patients survived. In another series,[62] although 16 out of 19 patients who had received ECT within 5 days of symptom onset survived, none of the 14 patients who had received ECT after 5 days after symptom did.

Philbrick and Rummans[20] reviewed 18 cases of lethal catatonia and found that 11 out of 13 patients treated with ECT survived, whereas only one out of five not treated with ECT died. In terms of NMS, 39 reported cases of ECT treatment have been reported; 34 of them improved. The message is clear: When a patient presents with malignant catatonia of any type, ECT should be used expeditiously. Although an initial trial of lorazepam, a dopaminergic agent, or both, is reasonable for malignant catatonia, ECT should be instituted early (i.e., within 5 days) if a medication trial is unsuccessful. Adrenocorticotropic hormone and corticosteroids also have been reported to work in cases of lethal catatonia.[18] Dopaminergic agents, bromocriptine, and amantadine anecdotally have been used successfully in NMS.[88] In a retrospective review of 734 cases, Sakkas and associates[89] concluded that these agents and the muscle relaxant dantrolene led to improvement; bromocriptine and dantrolene also were associated with a significant reduction in the mortality rate. However, in a prospective study of 20 patients, Rosebush and colleagues[90] found that bromocriptine and dantrolene were not efficacious. Another DA agonist, lisuride, has been used intravenously with success in four patients with NMS, three of whom had failed to respond to other dopaminergic agents.[91]

Table 21–7 outlines recommendations for the treatment of simple and malignant (including NMS) catatonias, and Table 21–8 reviews management principles.

The treatment strategy for patients who have catatonia secondary to schizophrenia may be challenging, because the catatonia found in those with schizophrenia can at times be less responsive to lorazepam. In these patients, amantadine and more recently memantine have shown some effectiveness in isolated cases, suggesting that NMDA antagonists may add some benefit.[92,93]

Even if lorazepam has been helpful in lysing the catatonic state, the patient is often left with psychotic symptoms and may eventually need antipsychotic medications. A reasonable approach is to try an atypical neuroleptic while maintaining the patient on lorazepam as a buffer against reemergence of catatonia. Although atypical antipsychotics may be less likely to worsen catatonia than typical antipsychotics, all atypical neuroleptics have the potential to worsen catatonic symptoms, and there are no clear recommendations in the literature about which atypical is superior to use in the treatment of a patient with psychosis and catatonia. Aripiprazole, a unique atypical antipsychotic given its partial dopamine agonism, may be preferred in the setting of catatonia, and it has been used successfully, along with IV lorazepam, in the treatment of psychosis and catatonia.[94] However, there have also been case reports of aripiprazole causing NMS. Limitations for the treatment of concurrent schizophrenia with catatonic features include the lack of randomized clinic trials, as most recommendations stem from case reports. Long-term dosing and optimal duration of treatment have yet to be established, and the psychiatrist must rely on clinical judgment.

Rechallenging a patient who has had NMS with an antipsychotic is controversial. Most investigators suggest

TABLE 21–7 Treatment of Simple and Malignant Catatonia

A. Test for catatonia. Lorazepam 1 to 2 mg IV or zolpidem 5 to 10 PO mg may result in temporary relief.
B. *Simple catatonia* (including neuroleptic-induced catatonia): lorazepam* 1 to 4 mg IV/IM/PO trial followed by 3 to 20 mg/day in divided doses, or diazepam 5 to 20 mg followed by 10 to 40 mg/day. Monitor for respiratory depression.
   → If still catatonic, consider adding dopamine (DA) agonist.
   → If still catatonic, electroconvulsive therapy (ECT).†
C. *Malignant catatonia* (including neuroleptic malignant syndrome [NMS]):
   1. Lorazepam IV trial expeditiously (effective in 75% of NMS cases). May add dantrolene ± DA agonist, but less evidence for these.
   2. If still catatonic and especially if temperature is higher than 102° F, or if there is severe encephalopathy, ECT should be instituted before day 5 of syndrome, if possible.

Modified from Fricchione G, Bush G, Fozdur M et al: The recognition and treatment of the catatonic syndrome, *J Intensive Care Med* 12:135–147, 1997.
*Lorazepam effectiveness, 80% in one study,[25] 76% in another.[78]
†ECT effectiveness: 82% to 96% in 5 studies.

that antipsychotics should not be given until at least 2 weeks after an episode of NMS has resolved, and that rechallenge should be with an atypical or with a typical of a lower potency.

Prognosis and Complications

Catatonia is a fascinating condition that graphically links emotion and behavior, motivation, and movement. For patients with catatonia, the long-term prognosis is fairly good in almost half the cases.[95] Those with an acute onset, depression, or a family history of depression have a better prognosis.[96] Periodic catatonias can have good short- and long-term prognoses. However, given the potential morbidity and mortality, concerted efforts at supportive care are essential to avoid the myriad complications that are associated with simple catatonia and more so with malignant catatonia (see Table 21–6).

When catatonia is of the malignant variety, treatment should take place in the intensive care unit (ICU). All potential offending agents, especially neuroleptics and DA blockers (e.g., metoclopramide), should be discontinued. If antiparkinsonian dopaminergic agents have recently been discontinued or tapered, they should be reinstituted. Lorazepam (or another benzodiazepine) should be used in an effort to lyse catatonia, be it simple or malignant. ECT should be considered early because it is the definitive treatment for catatonia in the acute setting, and it can be lifesaving, especially in malignant instances of the syndrome. When any patient with malignant catatonia is first seen, the surrogate decision-maker should be approached in anticipation of the need for ECT should a lorazepam trial fail. Maintenance ECT may improve long-term prognosis.

If the condition is not life-threatening and if ECT is not available and lorazepam has not resolved the catatonia, DA agonists or dantrolene or other medications mentioned earlier may be tried in addition to supportive measures. If the condition is life-threatening, as is the case with malignant catatonia, and if lorazepam has not worked and ECT is not available, expeditious transfer to a facility where ECT is performed is appropriate.

TABLE 21–8 Principles of Management of Catatonia

1. Early recognition is important. Once catatonia has been diagnosed, the patient must be closely observed and vital signs taken frequently.
2. Supportive care is essential. Such care involves hydration, nutrition, mobilization, anticoagulation (to prevent thrombophlebitis), and precautions against aspiration.
3. Discontinue antipsychotics or other drugs, such as metoclopramide, which can cause or worsen catatonia.
4. Restart recently withdrawn dopamine agonists, especially in patients with parkinsonism.
5. Institute supportive measures (e.g., a cooling blanket if hyperthermia is present, or parenteral fluids and antihypertensives or pressors if autonomic instability emerges and if malignant catatonia is suspected).
6. Maintain a high index of suspicion for the development of medical complications and for new medical problems.

Modified from Philbrick KL, Rummans TA: Malignant catatonia, *J Neuropsychiatry Clin Neurosci* 6:1–13, 1994.

SEROTONIN SYNDROME

CASE 3 Serotonin Syndrome

A 69-year-old woman with a history of depression partially responsive to paroxetine 40 mg/day had her dose increased to 60 mg/day; 2 weeks later, buspirone 5 mg tid was added, along with trazodone 100 mg for sleep. She became confused, diaphoretic, febrile (to 101.2° F), hyperreflexic, and mildly rigid and was admitted to the hospital. Paroxetine, prazodone, and buspirone were discontinued. Over the next 2 days, her condition improved (with acetaminophen and supportive care).

Definition

Serotonin is a neurotransmitter involved in many psychiatric disorders, and many pharmacologic agents have been designed that affect central serotonergic tone. As the serotonin level increases, it is likely to have certain nervous system effects, including toxicity when available in excess. Heightened clinical awareness is necessary to prevent, recognize, and intervene when a toxic syndrome secondary to serotonin excess emerges. Serotonin syndrome, as it is called, most commonly occurs as a result of an interaction between serotonergic agents and monoamine oxidase inhibitors (MAOIs). Signs of SS include mental status changes (e.g., confusion, anxiety, irritability, euphoria, dysphoria), gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea, incontinence), behavioral manifestations (e.g.,

restlessness and agitation), neurologic findings (e.g., ataxia or incoordination, tremor, myoclonus, hyperreflexia, ankle clonus, muscle rigidity), and autonomic nervous system abnormalities (e.g., hypertension, hypotension, tachycardia, diaphoresis, shivering, sialorrhea, mydriasis, tachypnea, hyperthermia).[97,98]

Epidemiology

The incidence of SS is unknown. There are no data to suggest that gender differences confer any particular vulnerability to the syndrome. Given the overlap of symptoms with NMS, SS is often mistaken for it and thus may be underreported. The existence of the syndrome in varying degrees also may confound its recognition, as can unawareness on the part of the majority of physicians.[99] SS most often occurs in individuals being treated with psychotropics for a psychiatric disorder. It occurs in about 14% to 16% of SSRI-overdosed patients.[100]

Most often, SS involves some combination of an SSRI, an MAOI, an antiparkinsonian agent, and lithium. At the outset, patients develop a peripheral tremor, confusion, and ataxia; these features are followed by systemic signs (e.g., hyperreflexia, diaphoresis, shivering, agitation). If the condition becomes more severe, fever, myoclonic jerking, and diarrhea may develop. The syndrome can last from hours to days after the offending agents have been stopped and supportive treatment has been initiated.

Clinical Features and Diagnosis

As with NMS, taking a detailed history is crucial. Use of two or more serotonergic agents confers a greater risk of developing SS. Obtaining a history of neuroleptic use can be especially important, because NMS shares many clinical features with SS, as do other toxic syndromes (Table 21–9).

Based on his review of 38 cases, Sternbach[101] proposed the first operational definition of the syndrome in humans. Diagnosis requires the following three criteria:

1. A serotonergic agent is added to an established medication regimen, or its dosage level is increased, in addition to at least three of the following features: mental status changes, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhea, and incoordination.
2. Other etiologies need to be ruled out.
3. A neuroleptic must not have been started or increased in dosage prior to the onset of the signs and symptoms listed previously.

Based on a review of other diagnostic criteria, Keck and Arnold[97] modified Sternbach's criteria to include mental status changes, agitation, restlessness, myoclonus, hyperreflexia, diaphoresis, tremor, shivering, incoordination, autonomic nervous system dysfunction, hyperthermia, and muscle rigidity. Most recently, the Hunter Serotonin Toxicity Criteria were proposed.[102] If a patient has been exposed to a serotonergic drug within the past 5 weeks and spontaneous clonus emerges, the patient has SS. If there is inducible clonus or ocular clonus plus either agitation or diaphoresis, SS is present. If there are tremor and hyperreflexia, SS can be diagnosed. If there are hypertonicity, temperature greater than 38° C (100.4° F), and either ocular or inducible clonus, SS is present. This approach to SS diagnosis may be more sensitive to serotonin toxicity and less prone to produce false-positive cases.

There is a temporal relationship between the start of pharmacotherapy and the development of the syndrome. The syndrome ranges from mild to severe, with a mildly affected patient showing restlessness, tremor, tachycardia, shivering, diaphoresis, and the start of hyperreflexia. Moderately severe cases show tachycardia, hypertension, and fever, sometimes as high as 40° C (104° F). There are also mydriasis, strong bowel sounds, hyperreflexia, and clonus (greater in the lower extremities than the upper ones).

TABLE 21–9 Comparison of Serotonin Syndrome with Neuroleptic Malignant Syndrome

FEATURE	SEROTONIN SYNDROME	NEUROLEPTIC MALIGNANT SYNDROME
Temperature	Hyperthermia variable	Hyperthermia
Mental status	Anxiety	Coma
	Coma	Confusion
	Confusion	Delirium
	Delirium	Stupor
	Euphoria	
	Irritability	
	Stupor	
Neurologic	Ankle clonus	Hyperreflexia (uncommon)
	Hyperreflexia, Incoordination	Muscle rigidity
	Muscle rigidity variable	Tremor

	Mydriasis	Mydriasis
	Shivering	Sialorrhea
	Sialorrhea	Tachycardia
	Tachycardia	Tachypnea
	Tachypnea	
Gastrointestinal	Diarrhea	
	Nausea	
	Vomiting	
Laboratory	Elevated (uncommon)	Elevated (common)
	Creatine phosphokinase (CPK)	CPK
	White blood cell count (WBC)	WBC
	Liver function tests (LFTs)	LFTs

Modified from Keck PE, Arnold LM: The serotonin syndrome, *Psychiat Ann* 30:333–343, 2000, p 339.

Horizontal ocular clonus is also seen in moderately severe cases, as well as mental status changes of agitation, pressured speech, and autonomic hyperactivity. Head rotation movement with neck extension has also been reported. In severe cases, there are severe autonomic hyperactivity and severe hyperthermia with temperatures sometimes over 41.1° C (106° F). There is an agitated delirium accompanied by severe muscular rigidity, again greater in the lower extremities. This severe hypertonicity may obscure the appearance of clonus and hyperreflexia and thereby confound the diagnosis.

Laboratory abnormalities are mostly nonspecific or are secondary to the medical complications of the syndrome. A complete laboratory evaluation is nevertheless essential to rule out other causes for the signs and symptoms that are shared with SS. Leukocytosis, rhabdomyolysis, and liver function test abnormalities have all been reported in patients with SS, along with hyponatremia, hypomagnesemia, and hypocalcemia. These latter disturbances are thought to be related to fluid and electrolyte abnormalities. Disseminated intravascular coagulation (DIC) also has been reported in SS. Acute renal failure secondary to myoglobinuria can occur and has been associated with fatalities, as has DIC.

It is interesting to note that certain secreting tumors like carcinoid and oat cell carcinoma have been associated with SS. X-ray examinations and imaging of the abdomen and lung may sometimes be helpful in working up SS. An EEG and neuroimaging are often useful in uncovering a seizure disorder or another neurologic condition as well.

The most common drug interactions associated with SS include combinations of MAOI and SSRI, MAOI and tricyclic antidepressants, and MAOI and venlafaxine. In general, when an SSRI is used in combination with an MAOI, an SS is more likely to occur. Drugs associated with SS are included in Table 21–10.

Overdoses of MAOIs have also caused SS. Because of the potential problems of using an MAOI and any medicine with serotonergic properties, caution on the part of the prescribing physician is required. A 2-week washout interval after discontinuation of an MAOI is required before starting any serotonergic medications. In the case of fluoxetine discontinuation, there should be a washout period of at least 5 weeks before an MAOI is initiated.

TABLE 21–10 Central Nervous System Serotonergic Agents

Enhanced Serotonin Synthesis
L-Tryptophan
Increased Serotonin Release
Amphetamines
Cocaine
Dextromethorphan
Fenfluramine
Meperidine
Methylenedioxymethamphetamine
Sibutramine
Serotonin Agonists
Buspirone
Dihydroergotamine (DHE)
Lithium
Meta-chlorophenylpiperazine (mCPP)
Sumatriptan
Trazodone
Inhibited Serotonin Catabolism
Isocarboxazid
Moclobemide
Phenelzine
Selegiline
Tranylcypromine
Inhibited Serotonin Reuptake
Amitriptyline
Bromocriptine
Clomipramine
Desipramine
Dextromethorphan
Fenfluramine
Fluoxetine
Fluvoxamine
Imipramine
Meperidine
Mirtazapine
Nefazodone
Nortriptyline
Paroxetine
Pethidine
Sertraline
Tramadol
Trazodone
Venlafaxine

Modified with permission from Keck PE, Arnold LM: The serotonin syndrome, *Psychiat Ann* 30:333–343, 2000, p 336.

Pathophysiology

In both animal and human studies, the role of 5-HT has been implicated in the pathogenesis of SS. Nucleus raphe serotonin nuclei (located in the midbrain and arrayed in the midline down to the medulla) are involved in mediating thermoregulation, appetite, nausea, vomiting, wakefulness, migraine, sexual activity, and affective behavior. The animal model of SS seems to be associated with receptors in the lower brainstem and spinal cord. Ascending serotonergic projections are likely to play a role, particularly in hyperthermia, mental status, and autonomic changes. The 5-HT_{2A} and 5-HT_{1A} receptors appear to be overactive in this condition,[100] which has led some to use 5-HT_{1A} antagonists in the management of SS. There also appears to be CNS norepinephrine overactivity. This is clinically significant because clinical outcomes may be associated with hypersympathetic tone.[99] The roles of catecholamines and 5-HT_2 and 5-HT_3 receptor interactions are unclear, as are the contributions of glutamate, GABA, and DA.

Management and Treatment

No prospective studies have looked at treatment of SS. Recommendations for treatment are based solely on anecdotes. SS is often self-limited, and removal of the offending agents frequently results in resolution of symptoms within 24 hours. Therefore, the initial step in managing

SS is to discontinue the suspected offending agent or agents. The next step is to provide supportive measures to prevent potential medical complications. These supportive measures include the use of antipyretics and cooling blankets to reduce hyperthermia, monitoring and support of the respiratory and cardiovascular systems, IV hydration to prevent renal failure, use of clonazepam for myoclonic jerking, use of anticonvulsants if seizures arise, and use of hypertensive agents (such as nifedipine) for significantly elevated blood pressures. The syndrome rarely leads to respiratory failure. When it does, it usually is because of aspiration, and artificial ventilation may be required.

Benzodiazepine management of agitation, even when mild, is essential for patients with SS. This is because benzodiazepines, such as diazepam and lorazepam, can reduce autonomic tone and temperature and thus may have positive effects on survival.[99] Physical restraints should be avoided if at all possible because muscular stress can lead to lactic acidosis and elevated temperature.

Specific 5-HT receptor antagonism has occasionally been advocated for the treatment or prevention of the symptoms associated with SS. Cyproheptadine (4 to 24 mg/day) has been used.[99] Ketanserin a 5-HT_2 antagonist and propranolol, which has 5-HT_{1A} receptor-blocking properties, have been used in a small number of cases. For the management of hypertension, nitroprusside and nifedipine, and for tachycardia, esmolol, have been advocated.[99] Because the rise in temperature is muscular in origin, antipyretics are of no use in SS, and paralytics are required when fevers are high.

Prognosis and Complications

The SS occurs as a toxic state secondary to serotonin excess produced by high doses or combinations of serotonergic medications. It usually begins soon after the addition of a serotonin agent or an increase in the dose of one. This syndrome is often mild and goes unrecognized, so it may not be as rare as portrayed; it also is self-limiting. Symptoms often disappear soon after the offending agents are discontinued. When severe, SS can lead to death from medical complications, and supportive measures are required. Nonspecific serotonin receptor antagonists may be helpful in the treatment of the SS. Prevention, early recognition, and intervention benefit from a heightened clinical awareness of medications that can cause serotonin excess.

In SS, rhabdomyolysis is the most common and serious complication; it occurs in roughly 25% of the cases.[49] Generalized seizures occur in approximately 1%, with 39% of these patients dying. Myoglobinuric renal failure accounted for roughly 5% of medical complications, as did DIC. Nearly two thirds of those with DIC died.

Patients with Disordered Sleep

22

Patrick Smallwood, M.D.
Davin K. Quinn, M.D.
Theodore A. Stern, M.D.

Scholars have long sought the cause and nature of sleep and sleep disorders, yet theories have far exceeded clear facts. Plato, for example, believed that sleep was caused by vapors arising from the stomach and condensing in the head, and Hippocrates believed that sleep was the result of blood and its warmth retreating into the body. Sixteenth- and 17th-century scholars debated whether sleep was induced by oxygen deprivation, accumulated toxins, or the daily thickening of blood that impaired spirits from entering the nerves.[1] Despite these age-old theories, only in recent years have the mysteries of sleep been slowly unraveled. Indeed, we now know that sleep is an active biochemical process complete with various physiologic markers, stages, and patterns that, like vital signs, provide a basic indication of overall well-being. This chapter examines the biological and psychiatric aspects of normal and disordered sleep, followed by a brief discussion of the diagnosis and treatment of common sleep disorders.

SLEEP STAGES AND NORMAL SLEEP

Aserinsky and Kleitman (1953) were the first to investigate eye movements during sleep. Kleitman postulated that depth of sleep could be assessed through eye motility, and he and Aserinsky began testing this hypothesis through direct observation of eye movements of infants during sleep.[2] They noted slow rolling eye movements during the early stages of sleep that disappeared as sleep progressed, and they saw periods of rapid eye movements associated with irregular breathing and increased heart rate.[2,3] They coined the terms *non–rapid eye movement* (NREM) to indicate the slow rolling rhythmic eye movements and *rapid eye movement* (REM) to indicate the fast erratic eye movements. In 1957 Kleitman and Dement discovered that REM and NREM sleep occurred cyclically throughout the night and named this overall NREM–REM pattern *sleep architecture*.[2,3]

Polysomnography

Polysomnography is the gold standard method for evaluating disordered sleep. It involves simultaneously recording multiple physiologic variables in a standardized fashion known as the *polysomnogram* (PSG).[4] The parameters recorded by the PSG include, but are not limited to, the following:

- Electroencephalogram (EEG): A recording of the electrical activity of cortical neurons via scalp electrodes that are placed in standardized positions according to the International 10–20 System.
- Electro-oculogram (EOG): A recording of eye movements.
- Electrocardiogram (ECG): A recording of heart rhythm.
- Electromyogram (EMG): A recording of the activity of the left and right tibialis anterior muscles and the submental (chin) muscles.
- Respiratory efforts: A recording of nasal and oral airflow by means of nasal thermistors and recording of thoracoabdominal movements by means of strain gauges.
- Pulse oximetry: A recording of oxygen saturation in the blood.
- Snore monitor: A detection and recording of snoring by means of a microphone placed on the lateral aspect of the neck.

Through the use of the PSG, wakefulness, sleep onset, NREM sleep, and REM sleep can be identified and studied.

The *waking state* is defined by polysomnography in the following manner: the EEG reveals an 8 to 14 Hz wave pattern known as *alpha waves*, the EMG reveals muscle tone and activity, and the EOG demonstrates variable eye movements, including blinking.[2] In the normal subject, *sleep onset* follows the transition from awake to NREM stage 1 sleep.[2,5–8] Being a state of altered consciousness, sleep onset is not reliably determined by asking the subject; it must be determined by specific polysomnographic criteria, which include a decrease in alpha activity, emergence of relatively low-voltage mixed-frequency (RLVMF) activity, and slow rolling eye movements on the EOG.[5] The EMG usually, but not always, registers a modest decrease in muscle activity. Some patients do not perceive themselves as asleep and can engage in *automatic behavior*, a phenomenon in which very complex cognitive and behavioral tasks are performed outside awareness.[5,9]

Sleep is normally entered through NREM sleep. NREM is divided into four stages; each one is identified by specific criteria on the PSG.[2,5]

- Stage 1: Alpha waves, present during the waking state, account for less than 50% of an epoch (a 30-second interval on the PSG). RLVMF waves emerge, with the most prominent ones being theta waves (4 to 7 Hz).
- Stage 2: Theta activity continues. During this stage, two new wave types emerge: sleep spindles (rhythmic 12 to 14 Hz waves lasting 0.5 seconds or more) and K-complexes (high amplitude negative waves followed by a positive deflection, lasting 0.5 seconds or more).

- Stage 3: Delta waves (high-amplitude, slow-frequency 0.5 to 2.0 Hz waves) occur. Delta waves occupy at least 20%, but not more than 50%, of an epoch. The EMG begins to show less muscle activity.
- Stage 4: Almost identical to stage 3, except delta waves now occupy greater than 50% of an epoch.

Stage 3 and 4 NREM sleep is also known as *delta* or *slow wave sleep*. The distinction between stage 3 and stage 4 NREM sleep, while scientifically intriguing, has no known clinical significance at this time.

REM sleep, also known as *paradoxical sleep* owing to its similarity to wakefulness and NREM sleep, is defined by three principal features. First, the EEG demonstrates RLVMF wave patterns that are virtually indistinguishable from those of NREM stage 1. Second, the EMG reveals an absence of, or a marked decrease in, muscle activity. Finally, conjugate rapid eye movements become evident on the EOG.[4]

Sleep Cycle and Architecture

NREM and REM sleep do not occur randomly throughout the night; instead, they alternate in a rhythmic fashion known as the *NREM–REM cycle*.[2,5,6] In healthy persons, this cycle begins with NREM stage 1 and it progresses to NREM stages 2, 3, 4, 3, 2, and then REM. This pattern generally repeats itself every 90 to 120 minutes throughout the night. NREM stages 3 and 4 are most prominent in the first half of the night; they diminish during the latter half of the night. REM sleep, however, is less prominent in the first half of the night, and it increases as the night progresses. *Sleep latency* is the time from "lights out" to the first NREM stage 1; it typically lasts 10 to 20 minutes. The time from sleep onset to the first REM is known as *REM latency*, which is usually 90 to 100 minutes. *Sleep efficiency* is the actual amount of sleep per total time in bed multiplied by 100. The average amount of sleep per night for adults is between 6 and 9 hours. The time spent awake after sleep onset is less than 5%.

The distributions of sleep stages across an average night are as follows: NREM stage 1, 2% to 5%; NREM stage 2, 45% to 55%; NREM stages 3 and 4, 13% to 23%; and REM sleep, 20% to 25%.

Sleep Across the Life Span

Sleep and sleep quality change across the lifespan.[10] Infants spend about two thirds of the day sleeping, whereas in adulthood this amount decreases to less than one third. As a result of degenerative changes in the central nervous system (CNS), sleep architecture becomes altered as people age. These changes include increases in sleep latency, nocturnal awakenings, time spent in NREM stage 1 sleep, and decreases in delta sleep, REM sleep, REM latency, and overall sleep efficiency.[11–13]

NEUROANATOMIC BASIS FOR SLEEP

The actual neuroanatomic basis for the sleep–wake cycle remains uncertain, but current research reveals that specific regions of the brain are critical for wakefulness and for sleep. These neuronal systems are located in the brainstem, hypothalamus, and basal forebrain, and they project diffusely throughout the neocortex.[14–16] Any disruption of these regions invariably leads to alterations in the sleep–wake cycle and gives rise to sleep disorders.

Although sleep architecture is influenced by a host of variables, the amount of wakefulness is largely determined by an internal biological cycle known as the *circadian rhythm*.[1,10] This biological clock is an endogenous rhythm of bodily functions that is influenced by environmental cues, or *zeitgebers*, of which the main one is daylight. The cycle is unique to each individual, averaging 25 hours for most people, but possibly 50 hours for others. Sleep disorders related to the circadian rhythm emerge when a person's circadian rhythm clashes with environmental and societal expectations.

The suprachiasmatic nuclei (SCN), a collection of approximately 50,000 cells in the anterior hypothalamus, is the brain region that moderates sleep–wake demand and environmental demands. The SCN receives input from the eyes via the retinohypothalamic tract, and it sends output to the thalamus and hypothalamus. Melatonin, a neuropeptide secreted by the pineal gland, is associated with suppression of the SCN and it induces sleep in mammals, but does not yet have a clear role in sleep homeostasis.[17]

Wakefulness is also maintained by tonic activity in the ascending reticular activating system (RAS) and is strongly influenced by sensory stimuli, the most powerful of which are sound and pain. Sleep develops when there is decreased activity in the ascending reticular activating system and activation of a hypnagogic sleep system located predominantly in the dorsal raphe nucleus. This homeostatic sleep–wake system interacts with the circadian rhythm system of the SCN and is either mitigated or amplified by it.[18] Although no specific neural generator for REM sleep has been identified, REM sleep is known to be an active process involving both the nucleus ceruleus and the gigantocellular tegmental field.

SLEEP DISORDERS

Although several classification systems for sleep disorders exist, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)[19] and the *International Classification of Sleep Disorders*, second edition (ICSD-2)[20] are the most widely used (see Table 22–1 for the classification schema). The ICSD-2 system offers a comprehensive nosology of sleep disorders and is the official classification recognized by the American Sleep Disorders Association (ASDA); it classifies the 70 sleep disorders into eight categories based on symptoms and etiology. The DSM-IV-TR classification is complaint-based (as such, it is perhaps the simplest and easiest to understand); it divides sleep disorders into primary and secondary sleep disorders based on presumed etiology.

Insomnia

Insomnia is a repeated difficulty with sleep initiation, duration, consolidation, or quality, despite adequate opportunity for sleep, that produces daytime impairment. Patients complain of deficient, inadequate, or unrefreshing sleep; malaise; and fatigue. Sufferers often experience hyperarousal and anxiety at bedtime and have decreased daytime function with mild to moderate impairment in concentration and psychomotor function.[21]

TABLE 22–1 Outline of Sleep Disorders in DSM-IV and ICSD-2

DSM-IV SLEEP DISORDERS

Primary Sleep Disorders

Dyssomnias
Primary insomnia
Primary hypersomnia
Narcolepsy
Breathing-related sleep disorder
Circadian rhythm sleep disorder
Dyssomnia not otherwise specified (NOS)

Parasomnias
Nightmare disorder
Sleep terror disorder
Sleepwalking disorder
Parasomnia not otherwise specified

Sleep Disorders Related to Another Mental Condition
Insomnia related to an Axis I or II condition.
Hypersomnia related to an Axis I or II condition

Other Sleep Disorders
Sleep disorder due to a general medical condition
Substance-induced sleep disorder

ICSD-2 SLEEP DISORDERS

Insomnia
Insomnia (acute insomnia)
Psychophysiologic insomnia
Paradoxical insomnia
Idiopathic insomnia
Insomnia due to a mental disorder
Inadequate sleep hygiene
Behavioral insomnia of childhood
Insomnia due to a drug or substance
Insomnia due to a medical condition
Insomnia not due to a substance or known physiologic condition, unspecified (nonorganic insomnia NOS)
Physiologic (organic) insomnia, unspecified

Sleep-Related Breathing Disorders

Central sleep apnea syndromes
Primary central sleep apnea
Central sleep apnea due to high-altitude periodic breathing
Central sleep apnea due to a medical condition (not Cheyne–Stokes)
Central sleep apnea due to a drug or substance
Primary sleep apnea of infancy (formerly primary sleep apnea of newborn)

Obstructive sleep apnea syndromes
Obstructive sleep apnea, adult
Obstructive sleep apnea, pediatric

Sleep-Related Hypoventilation and Hypoxemic Syndromes
Sleep-related nonobstructive alveolar hypoventilation, idiopathic
Congenital central alveolar hypoventilation syndrome

Sleep-related hypoventilation/hypoxemia due to a medical condition
Sleep-related hypoventilation/hypoxemia due to pulmonary parenchymal or vascular pathology
Sleep-related hypoventilation/hypoxemia due to lower airway obstruction
Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders

Other sleep-related breathing disorders
Sleep apnea or sleep-related breathing disorder, unspecified

Hypersomnias of Central Origin Not due to a Circadian Rhythm Sleep Disorder, Sleep-Related Breathing Disorder, or Other Cause of Disturbed Nocturnal Sleep
Narcolepsy with cataplexy
Narcolepsy without cataplexy
Narcolepsy due to a medical condition
Narcolepsy, unspecified
Recurrent hypersomnia
Kleine-Levin syndrome
Menstrual-related hypersomnia
Idiopathic hypersomnia with long sleep time
Idiopathic hypersomnia without long sleep time
Behaviorally induced insufficient sleep syndrome
Hypersomnia due to a medical condition
Hypersomnia due to a drug or substance
Hypersomnia not due to a substance or known physiologic condition (nonorganic hypersomnia NOS)
Physiologic (organic) hypersomnia, unspecified (organic hypersomnia NOS)

Circadian Rhythm Sleep Disorders
Circadian rhythm sleep disorder, delayed sleep phase type (delayed sleep phase disorder)
Circadian rhythm sleep disorder, advanced sleep phase type (advanced sleep phase disorder)
Circadian rhythm sleep disorder, irregular sleep–wake type (irregular sleep–wake rhythm)
Circadian rhythm sleep disorder, free-running type (nonentrained type)
Circadian rhythm sleep disorder, jet lag type (jet lag disorder)
Circadian rhythm sleep disorder, shift-work type (shift work disorder)
Circadian rhythm sleep disorder due to a medical condition
Other circadian rhythm sleep disorder (circadian rhythm disorder NOS)
Other circadian rhythm sleep disorder due to a drug or substance

Parasomnias

Disorders of arousal (from NREM sleep)
Confusional arousals
Sleepwalking
Sleep terrors

Parasomnias usually associated with REM sleep
REM sleep behavior disorder (including parasomnia overlap disorder and status dissociatus)
Recurrent isolated sleep paralysis
Nightmare disorder

Other parasomnias
Sleep-related dissociative disorders
Sleep-related groaning (catathrenia)
Exploding head syndrome
Sleep-related hallucinations
Sleep-related eating disorder
Parasomnia, unspecified
Parasomnia due to a drug or substance
Parasomnia due to a medical condition

Sleep-Related Movement Disorders
Restless legs syndrome
Periodic limb movement disorder
Sleep-related leg cramps
Sleep-related bruxism
Sleep-related rhythm movement disorder

Continued

TABLE 22–1 Outline of Sleep Disorders in DSM-IV and ICSD-2—*cont'd*

Sleep-related movement disorder, unspecified
Sleep-related movement disorder due to a drug or substance
Sleep-related movement disorder due to a medical condition

Other Sleep Disorders
Other physiologic (organic) sleep disorder
Other sleep disorder not due to a substance or known physiologic condition
Environmental sleep disorder

Sleep Disorders Associated with Conditions Classifiable Elsewhere
Fatal familial insomnia
Fibromyalgia
Sleep-related epilepsy
Sleep-related headaches
Sleep-related gastroesophageal reflux disease
Sleep-related coronary artery ischemia
Sleep-related abnormal swallowing, choking, and laryngospasm

DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition; ICSD-2, *International Classification of Sleep Disorders,* 2nd edition.

Diagnosis

To diagnose this disorder, there must be objective daytime sleepiness or subjective feelings of not being well rested; the presence of psychiatric or medical conditions that better account for the symptoms is called *insomnia due to a medical condition or mental disorder*. Objective findings include prolonged sleep latency (an inability to fall asleep in less than 30 minutes) and shallow or fragmented sleep as evidenced by multiple arousals on a PSG. The etiology of insomnia is multifactorial but the final common pathway is a state of increased arousal; there is evidence of increased arousal during sleep as well as during waking in neuroimaging studies in insomniac patients.[22] The subtypes of insomnia correspond to different presumed pathophysiologic processes that result in increased arousal.

Psychophysiologic insomnia is caused by somatized tension and by learned sleep-preventing associations. Sufferers react to stress with increased physiologic arousal, such as increased muscle tension and vasoconstriction. Learned associations consist mainly of an overconcern with an inability to sleep, which results in a vicious cycle of overconcern, increased arousal, insomnia, and reinforcement of concern. Environmental cues also become associated with an inability to sleep, and sufferers often report sleeping better in unfamiliar surroundings.

Paradoxical insomnia, also known as sleep-state misperception, is a primary insomnia in which sufferers complain of inadequate sleep or poor sleep, or both, but objective findings on the PSG are lacking. Invariably, patients with sleep-state misperception underestimate their total sleep time and their efficiency and overestimate sleep latency. Theories to explain this discrepancy include excessive mentation during sleep and obsessiveness about sleep.[23]

Idiopathic insomnia is a chronic primary insomnia that develops in childhood and is most likely the result of an innate abnormality in the sleep–wake cycle. Prolonged sleep latency, poor sleep efficiency, and REM sleep without eye movements are seen on PSG.[24]

Treatment

Insomnias are perhaps the hardest sleep disorders to treat; treatment involves selecting a specific modality based on the cause. Nonpharmacologic techniques, such as application of good sleep hygiene, use of the relaxation response, or meditation, should be attempted before any pharmacologic interventions. Table 22–2 provides a guideline for proper sleep hygiene. Sleep-restriction therapy, a specific method of graded matching of time spent in bed to actual sleep, is useful for more persistent and severe cases, but it often requires consultation with a sleep-disorders specialist. Other behavioral techniques can be learned through self-help audio/visual programs or manuals or from consultation with a mental health clinician.

TABLE 22–2 Basic Sleep Hygiene

Limit time in bed to the amount present before the sleep disturbance
Lie down only when sleepy, and sleep only as much as necessary to feel refreshed
Use the bed for sleep only
Maintain comfortable sleeping conditions and avoid excessive warmth and cold
Wake up at a regular time each day
Avoid daytime naps
Exercise regularly, but early in the day
Limit sedatives
Avoid alcohol, tobacco, and caffeine near bedtime
Eat at regular times daily and avoid large meals near bedtime
Eat a light snack, if hungry, near bedtime
Practice evening relaxation routines, such as progressive muscle relaxation, meditation, or taking a very hot, 20-minute, body temperature–raising bath near bedtime

If behavioral techniques are unsuccessful, brief intermittent use of a sedative–hypnotic may be appropriate. Useful sedative–hypnotic agents include trazodone, tricyclic antidepressants (TCAs), atypical antipsychotics, benzodiazepines, benzodiazepine receptor agonists, melatonin receptor agonists, antihistamines, and barbiturates.

Trazodone is the most commonly used agent and is commonly used in patients with a history of substance abuse or hypnotic abuse.[25] Doses from 25 mg to 200 mg are often used. TCAs are also often used for insomnia, but they can be lethal in overdose, and they induce anticholinergic-mediated side effects.

Second-generation antipsychotic agents, such as quetiapine and olanzapine, may also be helpful in resistant insomnia, but they can cause a metabolic syndrome, weight gain, orthostasis, extrapyramidal symptoms, and anticholinergic side effects.

The long-term use of benzodiazepines, although controversial, is a common practice, and it may be appropriate for patients who have insomnia secondary to an anxiety disorder.

Benzodiazepines should either be used cautiously or avoided in patients with a history of alcohol or substance abuse, with a personality disorder, or with a sleep-related breathing disorder. To avoid dose escalation with these agents, prescriptions should be carefully monitored, when used for more than 4 weeks. Newer benzodiazepine receptor agonists (such as zolpidem, eszopiclone, and zaleplon) are often preferred, owing to their lower abuse potential, shorter half-lives, and approval for long-term use (up to 6 months).[26,27]

Ramelteon, a melatonin receptor agonist, improves sleep latency alone and is effective for patients with poor sleep initiation. Melatonin itself remains incompletely studied, but it produces mixed results[28]; some authors suggest that 2 mg at bedtime may be effective.

Sedating antihistamines can be used as alternatives to benzodiazepines; however, they can cause delirium in the elderly or in those with a compromised CNS. Chloral hydrate, short-acting barbiturates, and ethchlorvynol are less effective and more toxic than other agents; they should be used rarely, if ever, and then only under closely monitored conditions.

Sleep-Related Breathing Disorders

Sleep related breathing disorders, and especially sleep apnea syndromes, are the most commonly encountered hypersomnias. The essential feature of these disorders is disrupted sleep due to repeated apnea and oxygen desaturation.

Diagnosis

Apnea is defined as the cessation of nasobuccal airflow longer than 10 seconds. The type of apnea that a person experiences during sleep is based on its proposed cause and the presence or absence of respiratory effort during the event.

Central apneas are identified by the cessation of airflow with no attempt to initiate thoracoabdominal respiratory effort. The ICSD-2 distinguishes between several different central sleep apnea syndromes, according to etiology; primary central apnea, although debated, is thought to lie in abnormal CNS processes. ICSD-2 also identifies a separate category of sleep-related hypoventilation and hypoxemia syndromes that do not feature apneic episodes with arousals but that are characterized by low tidal volumes during sleep that lead to decreased oxygen saturation.

Obstructive apneas, on the other hand, are identified by the cessation of airflow as a result of a collapse in the upper airway. Unlike central apneas, obstructive apneas demonstrate continued or even increased respiratory effort. These obstructions can be so complete and the effort so powerful that the chest and abdomen can move in opposite directions, a phenomenon known as *paradoxical breathing*.

Mixed apneas, the most common type of apneas encountered, are events in which a central apnea is followed by an obstructive apnea.

A *hypopnea* is simply a reduction, rather than cessation, of nasobuccal airflow or thoracoabdominal movements during sleep. To be clinically significant, a hypopnea must result in a 50% reduction in air flow, at least a 4% decrease in the oxygen saturation, or be associated with an arousal pattern on the EEG.

The *apnea index* is the number of clinically significant apneas per hour of sleep, and the *hypopnea index* is the number of clinically significant hypopneas per hour of sleep. The *respiratory disturbance index* (RDI),[29] also known as the *apnea–hypopnea* index (AHI), is the sum of the apnea index and the hypopnea index. An apnea index of greater than 5, a hypopnea index of greater than 5, or a respiratory disturbance index of greater than 10 is considered pathologic and warrants treatment.[29]

Of all the sleep apnea spectrum disorders and disorders of excessive daytime sleepiness (EDS), obstructive sleep apnea (OSA) syndrome is the most common, accounting for 40% to 50% of all patients seen in sleep disorders centers.[2,30,31] The estimated prevalence of OSA is 1% to 4% of the adult male population, and the prevalence increases to 8.5% of men between the ages of 40 and 65 years.[3,10,32,33] Women account for 12% to 35% of OSA patients, with the majority of them being postmenopausal, suggesting that female hormones may be somewhat protective against OSA.[19]

The most significant risk factors for OSA are being: male, 40 to 65 years old, obese, a smoker, a user or abuser of alcohol, in poor physical health, and having a neck circumference greater than 17 inches.[30,31,33,34] The principal defect is repetitive occlusion of the upper airway at the level of the pharynx (which results from an abnormal decrease in oropharyngeal muscle tone), excessive tissue mass in the pharynx and tongue, malposition of the jaw or tongue, or a narrow airway.

Nocturnal signs and symptoms include snoring, choking, enuresis, reflux, hypoxemia, hypercapnia, and cardiac dysrhythmias. Daytime signs and symptoms include headaches, hypersomnolence, automatic behavior, neuropsychiatric abnormalities, and hypertension.[35–37]

Treatment

The treatment of OSA involves identifying and correcting the underlying etiology. Patients should be encouraged to lose weight and to avoid alcohol and use of sedatives that prolong apneas by increasing vagal tone, relaxing muscles, and preventing arousal for breathing.

Because apneas are affected by gravity, positional therapy can be used in mild to moderate OSA. No medication has been shown to be of clear benefit in the treatment of OSA, although pharmacologic agents (e.g., protriptyline, fluoxetine, and medroxyprogesterone) have been used.[10,11,19,38] Stimulants, such as modafinil, can ameliorate EDS. Oral appliances aimed at altering the position of structures of the upper airway to create a larger airway or to prevent further collapse are indicated for patients who have primary snoring, mild OSA, or moderate to severe OSA and who are intolerant of, or refuse, continuous positive airway pressure (CPAP) or surgical interventions.[10,39,40]

Uvulopalatopharyngoplasty (UPPP), mainly used to prevent snoring, is an option selected by some patients; it aims to increase the volume of the oropharynx by removing the tonsils, adenoids, posterior soft palate, and redundant tissue on the sides of the pharynx by means of primary or laser-assisted surgery.[5,19] The overall success rate for uvulopalatopharyngoplasty, as measured by at least a 50% reduction in apnea index, is only 40% to 50%; moreover, there is often a gradual return of apneas to pretreatment levels.[3,5,19]

Until recently, tracheostomy was considered the treatment of choice for severe OSA. First-line therapy now includes nasal CPAP and bi-level positive airway pressure

(BiPAP), both of which work by providing an air pressure splint to the upper airway.

For patients who receive no treatment and who have an apnea index of greater than 20, the probability of a cumulative 8-year survival is reported at 63% ± 17%. With the use of nasal CPAP, regardless of the initial apnea index, the probability of a cumulative 8-year survival rises to 100%.[41]

Narcolepsy and Hypersomnias of Central Origin

Narcolepsy

Narcolepsy is a primary hypersomnia associated with a tetrad of symptoms:

- *Sleep attacks*: Irresistible and brief sleep episodes with sleep-onset REM periods (SOREMPs) that occur several times a day, often at inappropriate times;
- *Cataplexy*: Sudden and brief bilateral loss of motor tone without impairment of consciousness, triggered by strong emotions (such as laughter, anger, or surprise);
- *Sleep paralysis*: Brief episodes of muscular paralysis associated with the transitions of sleep onset or awakening; and
- *Hypnagogic* or *hypnopompic hallucinations*: Vivid visual and auditory phenomena that are associated with the transitions to sleep onset or awakening.

Narcolepsy occurs in approximately 0.07% of the general population; it typically arises in the second decade of life. Symptoms usually begin with sleep and are associated with excessive sleepiness. Current research suggests that genetics plays a role in this disorder because a strong association exists between narcolepsy and the human leukocyte antigen *HLA-DR2* and *DQ1* phenotypes. The most specific antigen associated with narcolepsy in all ethnicities is *HLA-DQB1*0602*,[20] and sufferers of narcolepsy without this antigen are extremely rare. The probability of developing narcolepsy is 40 times greater if an immediate family member suffers from it.[21,42,43]

Although the exact abnormality of narcolepsy is unknown, leading theories implicate a mutation in the gene that codes for the production of the neurotransmitter *hypocretin*.[44] Also known as orexin, this neurotransmitter is produced in the posterior hypothalamus, and it inhibits activity in the ventrolateral preoptic area (VLPO). Hypocretin deficiency destabilizes sleep–wake partitioning, and in narcolepsy with cataplexy there is a loss of hypocretin-secreting cells.[45]

The diagnosis of narcolepsy is made on the multiple sleep latency test (MLST), a series of five scheduled naps 2 hours apart each. Short sleep latency (less than 8 minutes per nap), and two episodes of sleep-onset REM are diagnostic for narcolepsy.

Treatment is aimed at reducing both daytime sleepiness and cataplexy. Daytime sleepiness is effectively treated with psychostimulants, particularly methylphenidate (Ritalin), dextroamphetamine (Dexedrine), and to a lesser extent, pemoline (Cylert).[46,47] Modafinil (Provigil), a central adrenergic stimulant, can promote wakefulness, has minimal side effects, and has a low potential for abuse.[48–51] Due to their ability to suppress REM sleep, antidepressants, particularly the TCAs, are the treatment of choice for cataplexy, sleep paralysis, and hypnagogic hallucinations. Gamma hydroxybutyrate (GHB; Xyrem) is a gamma-aminobutyric acid (GABA) metabolite that can improve nocturnal sleep and EDS, but it has high abuse potential. Prophylactic naps, when feasible, can reduce the total daily dose of stimulants.

Hypersomnias of Central Origin

Other hypersomnias of central origin include idiopathic hypersomnia, or *Kleine-Levin syndrome*, a rare, often self-limiting condition that primarily affects male adolescents. Symptoms include hypersomnia, hyperphagia, and hypersexuality. Although the exact cause is unknown, it often follows an acute viral infection. Treatment includes the use of psychostimulants, selective serotonin reuptake inhibitors (SSRIs), and monamine oxidase inhibitors (MAOIs).

Idiopathic hypersomnia is characterized by constant or recurrent EDS, typically with sleep episodes lasting 1 hour or longer, despite normal nocturnal sleep patterns. *HLA-Cw2* is associated with this disorder.[20]

Behaviorally induced insufficient sleep syndrome results from voluntary but unintentional chronic sleep deprivation. Patients do not appreciate the difference between the need for sleep and the amount they actually obtain. Prescribing longer periods of sleep reverses its symptoms.

Circadian Rhythm Sleep Disorders

Circadian rhythm sleep disorders emerge when societal expectations conflict with a person's endogenous sleep–wake cycle. Although patients who have these disorders might complain of insomnia, hypersomnia, sleepiness, and fatigue, the timing of sleep—not its quality and architecture—is adversely affected. The most commonly encountered circadian rhythm disorders include jet lag syndrome, shift-work sleep disorder, delayed sleep phase disorder, advanced sleep phase disorder, and non–24-hour day (or hypernyctohemeral) syndrome.

Jet lag occurs when a person rapidly crosses several time zones, often from western to eastern time zones. This results in an advancement in the sleep–wake cycle, leaving the person feeling tired earlier in the evening.[52]

Shift-work sleep disorder occurs when the circadian rhythm conflicts with a work schedule that does not coincide with a conventional day–night cycle.[53]

Delayed sleep phase disorder occurs in persons whose circadian rhythm is set for a later time than the conventional sleep–wake cycle.[54] Considered "night owls," these persons are most alert in the evening and at night and become sleepy several hours after the conventional bedtime. If left undisturbed, they can sleep 7 to 8 hours, with problems arising when they are required to adhere to conventional daytime schedules.

Advanced sleep phase disorder occurs in persons whose circadian rhythm is set for an earlier time than the conventional sleep–wake cycle.[55] Considered "larks," these persons (who are often elderly) are most alert in the earlier morning, and they become sleepy several hours earlier than the conventional bedtime. Although they sleep for 7 to 8 hours, they might awaken at 2 to 3 AM complaining of an inability to stay asleep all night.

The *non–24-hour day* (or *hypernyctohemeral*) *syndrome* is a phenomenon seen most commonly in persons who are totally blind and who are unable to perceive visual *zeitgebers*. These patients, who function on a natural circadian rhythm of 24.5 to 25.0 hours, go to sleep and wake up about 45 minutes later each day.[56] As opposed to persons who follow a conventional sleep–wake schedule, their sleep–wake cycle will literally go "around the clock" in approximately 3 weeks.

The diagnosis of circadian rhythm disorders is based primarily on the history that can be obtained through a detailed sleep–wake diary maintained for several weeks. Because most circadian rhythm disorders are self-limited and resolve as the person adjusts to the new sleep–wake schedule, aggressive treatment is not necessary. Common treatment options include gradually delaying sleep until the patient achieves a new schedule, receiving light therapy, or taking melatonin.

Parasomnias

Parasomnias are a group of primary sleep disorders in which abnormal behaviors or physiologic events arise during specific sleep stages or during the transitions between wakefulness and sleep. These events are often bizarre; however, they rarely are a cause for great concern for the patient or the physician. Unlike with dyssomnias (insomnia and hypersomnia), children are more commonly affected by parasomnias than are adults. The parasomnias are subdivided into arousal disorders, REM sleep disorders, and other parasomnias.

Arousal Disorders

In s*leepwalking disorder* or somnambulism, the patient experiences episodic motor behaviors while emerging from delta sleep, most often during the first third of the night. Some behaviors are simple (e.g., walking, sitting up in bed, or picking at bed sheets), but more complex and serious behaviors can occur (e.g., running, eating, driving, or committing violent attacks).[57] Patients are often unresponsive to efforts to wake them, confused and disoriented when actually awakened, and amnestic to the sleep-related event the next day. Sleepwalking is not uncommon in childhood; it is rare in adulthood, a fact that should prompt a search for a possible underlying medical, neurologic, or pharmacologic etiology. No definitive treatment for sleepwalking exists, but some patients respond to low-dose benzodiazepines or to sedating antidepressants. Adjunctive therapies include reassurance, hypnosis, and provision of a safe sleep environment, because patients have been known to trip or to fall out of open windows.

Like sleepwalking disorder, *sleep terror disorder*, also known as *night terrors*, *pavor nocturnus*, or *incubus*, occurs during partial arousal from delta sleep, usually during the first third of the night. As in sleepwalking disorder, patients are difficult to awaken, they lack dream recall, and they are amnestic for the episodes. Caretakers are often bothered more by this disorder than are patients. Symptoms include repeated awakenings followed by intense fear, screaming, flailing, and autonomic hyperarousal (e.g., tachycardia, tachypnea, and mydriasis).[58] In adults, this disorder is associated with posttraumatic stress disorder (PTSD), generalized anxiety disorder, and borderline personality disorder. Treatment includes use of low-dose benzodiazepines, which suppress delta sleep. Adjunctive therapies include psychotherapy and stress reduction techniques.

Confusional arousals, also known as sleep drunkenness, occur when persons are awakened from delta sleep, from a nap, or induced to wake in the morning. They are characterized by disorientation, by amnesia, and occasionally by violent or sexual behavior. Allowing enough time for disorientation to wear off is usually sufficient treatment.[20]

REM Sleep Disorders

The hallmarks of this group of parasomnias are the occurrence in REM sleep, dreaming, and awareness of the specific events. The most commonly encountered REM sleep disorders are nightmare disorder and REM sleep behavior disorder. The essential feature of *nightmare disorder* is repeated episodes of terrifying dreams that awaken the patient. In contrast to patients with sleep terror disorder, patients with nightmare disorder often have vivid recall of the events, are atonic during the experience, lack autonomic arousal, and experience the events in the latter half of the night when REM sleep is longest and most dense. The specific etiology for nightmares is often underlying emotional stress; treatment targets stress reduction, but it can include psychotherapy, rehearsal instructions, and reassurance.

REM sleep behavior disorder (RBD) is perhaps the most dramatic of all the parasomnias. As in sleepwalking disorder, patients with RBD can exhibit simple to quite complex behaviors while asleep, including jumping out of bed, walking, running, or singing.[59] In contrast to sleepwalking disorder, RBD, like all REM sleep disorders, occurs later in the night when REM is longest, and it is accompanied by vivid dream recall. Unlike other REM sleep disorders, however, patients with RBD lack the muscle atonia that normally accompanies REM sleep; this results in the literal acting out of dream content.[60] The disorder is idiopathic in more than half of the cases, but it can result from underlying organic processes such as Parkinson's disease, vascular and Alzheimer's dementia, multiple system atrophy, focal brain stem lesions, and alcoholism. It is more common in the elderly, and it affects men nine times more frequently than women. Low-dose clonazepam, which suppresses REM density and length, has an 80% to 90% success rate. Other treatment options, if clonazepam is ineffective, include levodopa–carbidopa, clonidine, or carbamazepine.

Other REM sleep disorders include *recurrent isolated sleep paralysis*, which involves the inability to move voluntarily at sleep onset or awakening. It can last up to several minutes, and it disappears spontaneously or with external stimulation.

Sleep-Related Movement Disorders

Periodic limb movement disorder (PLMD), sometimes called *nocturnal myoclonus*, is a common parasomnia that affects up to 40% of people older than 65 years of age and 11% of sleep disorder clinic patients who complain of insomnia.[61–63] PLMD manifests as brief (0.5 to 5.0 seconds), stereotypic, and involuntary contractions of the lower limbs (often the dorsiflexors of the foot and flexors of the lower legs), at intervals of 20 to 40 seconds. Contractions appear more commonly during NREM stages 1 and 2. Although patients

are unaware of them, the EEG demonstrates nocturnal arousals and actual awakenings. Sleep is often unrefreshing, with hypersomnia being the most common complaint.

Diagnosis is made by overnight PSG and is confirmed when the *myoclonus index* (the number of leg jerks per hour of sleep that are accompanied by arousals) reaches five or more. Although the pathogenesis of PLMD is unknown, it is associated with a variety of medical conditions such as renal failure, diabetes, chronic anemia, peripheral nerve injuries, and even uncomplicated pregnancy. Medications including antidepressants, neuroleptics, lithium, diuretics, and narcotics, especially with narcotic withdrawal, are also associated with it. Treatment is symptomatic and includes use of dopaminergic facilitating agents (e.g., selegiline), and benzodiazepines (particularly clonazepam).[64]

A disorder closely related to PLMD is the *restless legs syndrome*. Restless legs syndrome is characterized by intense aching or crawling sensations inside the legs and calves that occur while sitting or lying; it causes an irresistible urge to move or rub the legs. Symptoms arise mainly at bedtime and are partially relieved by movement, which unfortunately interrupts sleep initiation because the patient often paces. Like PLMD, restless legs syndrome is associated with various medical problems, especially kidney failure, diabetes, iron-deficiency anemia, and peripheral nerve injury, as well as with use of medications, particularly SSRIs. Symptomatic relief may be provided by iron supplementation, avoidance of alcohol, exercise, and tapering offending medications. Medications such as pramipexole and ropinirole are effective dopamine agonists. Other agents that might provide relief include gabapentin and clonazepam.[65,66]

Nocturnal leg cramps can occur multiple times a night, several times per week, and are often seen in the elderly. *Rhythmic movement disorder* involves stereotyped repetitive movements of large muscles, often of the head and neck, occurring before sleep and sustained into light sleep. A normal aspect of infancy, rhythmic movement disorder beyond childhood may be associated with mental retardation, developmental delay, or psychopathology.

Sleep Disorders Resulting from a Medical Condition

Sleep disturbance is extremely common as a secondary symptom of other medical, psychiatric, or neurologic conditions. The ICSD-2 categorizes sleep disturbances resulting from medical conditions according to the subtype of sleep disorder; what follows is a general discussion of psychiatric, medical, neurologic, and substance-induced conditions and their associated sleep disturbances. Secondary sleep disorders often masquerade as primary sleep disorders; they require skill and vigilance on the part of psychiatrists and primary care physicians to ensure proper treatment for the principal disorder.

Sleep Disorders Related to Another Mental Disorder

Sleep disturbance is such a common feature of psychiatric illness that it is often the first neurovegetative symptom about which psychiatrists inquire. In patients with known psychiatric illness, however, care must be taken to avoid attribution of a sleep disturbance solely to the mental disorder because psychiatric patients also have primary sleep disorders and co-morbid medical problems with associated disturbances of sleep. If a primary sleep disorder is not present and the complaint of sleep disturbance is not the predominant complaint but is temporally related to a mental disorder, then a sleep disorder related to another mental illness may be diagnosed. Although a patient might complain of either hypersomnia or insomnia, insomnia is the most common sleep-related complaint that results from psychiatric disorders. Because the mental disorder is the cause of the sleep disturbance, treatment consists of treating the primary psychiatric condition.

Mood Disorders

Sleep abnormalities occur in up to 60% of outpatients and 90% of inpatients with depression. Consequently, more is known about sleep disturbances in depressed patients than in any other psychiatric illness. Most patients who have depression complain of initial, middle, and terminal insomnia and early morning awakening; in addition, they experience restlessness and fatigue. Hypersomnia and neurovegetative reversal, however, tends to occur in atypical depression.

Objective findings on the PSG include prolonged sleep latency, decreased delta sleep, decreased REM latency, increased duration and density of the first REM period, and early morning awakening. Evidence suggests that these abnormalities can persist after remission and that they precede the onset of another episode. In addition, some studies suggest that decreased REM latency or decreased delta sleep can predict relapse in depressed patients.[67]

Sleep disturbance in bipolar illness depends on which phase of the illness the patient is experiencing. During a depressed phase, for example, bipolar patients tend to experience hypersomnia and have an increased percentage of REM sleep, whereas during a manic episode they experience insomnia and have a lower percentage of REM sleep. Unlike other patients with insomnia, however, patients with mania rarely complain of their inability to sleep.

Psychotic Disorders

The most common sleep abnormalities in patients with psychotic disorders are difficulties with sleep initiation and sleep maintenance, which become apparent during the acute phase of these illnesses. Patients with psychosis, like those with depression, also have decreases in REM latency, total sleep time, sleep efficiency, and delta sleep. Because many of the medications used for treating psychosis can cause similar disruptions in sleep architecture, medication side effects must be ruled out. Current evidence suggests, however, that many of these sleep abnormalities, particularly delta sleep deficits, are the function of a psychotic disorder rather than the result of medication use.[68]

Anxiety Disorders

Although anxiety disorders are perhaps the most common cause of insomnia, their exact effect on sleep architecture is tenuous. As a general rule, patients with anxiety disorders often complain of disturbed sleep and have poor sleep efficiency.[69] Patients suffering from panic disorder can experience attacks during sleep, usually during the transition from NREM stage 2 sleep and early delta sleep.[70,71] Patients with obsessive–compulsive disorder (OCD) report difficulties with initiating and maintaining sleep, which

is often a result of pre-sleep anxiety and bedtime rituals before sleep onset. Of all the anxiety disorders, PTSD is the best studied. Sleep findings in patients with PTSD include easy arousability, nightmares, night terrors, and increased sleep-related movements.[72] In addition, total sleep time is often reduced owing to recurrent awakenings and impaired sleep maintenance.[69,72] Patients suffering from generalized anxiety have difficulty falling asleep and can awaken with anxious ruminations throughout the night.

Sleep Disorders Related to a General Medical Condition

Because pain, discomfort, and unremitting symptoms can interfere with sleep continuity, sleep complaints are common in a host of medical conditions. To diagnose a sleep disorder related to a general medical condition, the history and physical examination must demonstrate a solid connection between the sleep disorder and the underlying medical problem; in addition, the sleep disturbance must be severe enough to warrant independent clinical attention.

The most common sleep complaint is insomnia, but general medical conditions can produce sleep disturbances that mimic any sleep disorder. The list of medical conditions that result in a sleep disorder is quite lengthy, and this section highlights the more common ones. As with all secondary sleep disorders, the definitive treatment rests on treatment of the underlying medical condition.

Patients who have pain syndromes often complain of symptoms that worsen at bedtime. Consequently, these patients often have disrupted sleep patterns, insomnia, early morning awakening, and daytime fatigue.[73–75] Polysomnographic features include increased NREM stage 1 sleep, decreased delta sleep, an increased number of arousals, and an alpha pattern known as *alpha–delta sleep anomaly*. This anomaly can also be seen in sleep-deprived persons and in persons in whom deep pain has been induced.[74,76,77] Adequate pain control can substantially improve sleep for these patients. Sedating antidepressants or benzodiazepines, although they do not directly treat the pain, can help with sleep initiation and maintenance.

Patients who have respiratory conditions, such as asthma and chronic obstructive pulmonary disease, often complain of frequent nocturnal awakening, light sleep, terminal insomnia, and daytime hypersomnia. Many of these symptoms are attributable to an inability to enter or to maintain REM sleep owing to decreases in ventilatory drive, which cause hypoxia and hypoxemia that signals the patient to awaken. In such cases, supplemental oxygen can improve the quality of sleep. Other polysomnographic features are identical to those found in patients with OSA, because many patients with primary respiratory disorders also suffer from co-morbid breathing-related sleep disorders.

Several neurologic disorders are commonly associated with sleep disturbance, including cerebral degeneration, dementia, Parkinson's disease, and epilepsy. In cerebral degenerative disorders (e.g., Huntington's disease, spinocerebellar degeneration, and Rett syndrome) sleep fragmentation is common, as are periodic leg movements, reduced REM and delta sleep, and apneas. Patients with dementia often experience sleep disturbance with delirium, agitation, wandering, and vocalizations. Their PSGs show sleep fragmentation and decreases in sleep efficiency, delta sleep, and REM sleep. Those with Parkinson's disease have similar PSG findings, including prolonged sleep latency, increased number of awakenings, and decreased REM sleep. They also demonstrate REM periods outside of REM sleep, as well as periodic leg movements, tremors at sleep-stage transitions, and brief EMG bursts without movement.[20]

Epilepsy is classified as sleep-related if more than 75% of seizures occur during sleep. Suspicion for this condition is raised if a person experiences abrupt nocturnal awakenings, unexplained urinary incontinence, or abnormal movements during sleep. Epileptic discharges are typically activated by NREM sleep and suppressed by REM sleep. Sleep-related seizures are quite rare and are often confused with parasomnias, such as sleep terror disorder, REM sleep behavior disorder, sleepwalking disorder, enuresis, or nocturnal panic attacks.[78] Seizures occur predominantly during the first 2 hours of sleep and most often during light NREM sleep or in transitional states to and from REM sleep. Seizure type may be either generalized or partial, with temporal and frontal lobe seizures being the most commonly encountered variety of partial seizures.[79] The chief complaint is often nonspecific and can include disturbed sleep, tousled bed linens, confusion, or muscle soreness. Some patients may be unaware that they have sleep-related seizures until someone observes a convulsion. The treatment for sleep-related seizures, as with most forms of seizures, involves use of anticonvulsants.

Sleep complaints are common in other chronic medical problems, but they are less well investigated. Patients with angina and cardiac arrhythmias can experience exacerbations of their symptoms during sleep, most often during REM sleep. Patients in congestive heart failure often suffer orthopnea, paroxysmal nocturnal dyspnea, and nocturia, which may be confused with a primary sleep disorder, such as breathing-related sleep disorder, sleep terror disorder, nocturnal panic disorder, and sleep-related seizures.[80]

A discussion of sleep disorders associated with medical conditions would be incomplete without mention of paroxysmal nocturnal hemoglobinuria, even though it is not a true sleep disorder. A rare condition, paroxysmal nocturnal hemoglobinuria is an acquired hemolytic anemia exacerbated by sleep. Patients complain of rust-colored morning urine that is the result of hemolysis.[81] Paroxysmal nocturnal hemoglobinuria rarely affects the life span. Death most often results from thrombosis or various cytopenias. Treatment includes blood transfusions, immunosuppressive therapies, or a bone marrow transplant.

Substance-Induced Sleep Disorder

Substances, whether prescribed or illicit, can have profound effects on sleep. These effects can arise during regular use, acute ingestion, or withdrawal and can masquerade as any primary sleep disorder. As a general rule, if the substance is a CNS depressant, intoxication results in sedation and withdrawal results in insomnia. Similarly, if the substance is a CNS stimulant, intoxication results in insomnia and withdrawal results in sedation. Diagnosis of these disorders can only be made if the sleep disturbance is severe enough to warrant independent clinical attention, it is caused by the direct physiologic effects of a substance, if it developed during or within a month of intoxication or withdrawal from the substance, and if it is not the result of a mental disorder or delirium. Once a substance-related sleep disorder

is suspected, a thorough substance-abuse history must be obtained to recognize the offending substance. Treatment consists of judicious discontinuation of the substance, management of any acute withdrawal, and treatment of any underlying co-morbid psychiatric problems that initiated or contributed to the substance abuse in the first place.

Alcohol is perhaps the most commonly used sleep aid, but its soporific value is limited by significant side effects, including dependence, addiction, and withdrawal. Its effects on sleep are well documented and depend on the pattern of use and the state of intoxication or withdrawal. During acute intoxication, alcohol alters sleep architecture by decreasing sleep latency, increasing delta sleep, and decreasing REM sleep for the first 3 to 4 hours of sleep. In the last 2 to 3 hours of sleep, wakefulness and REM are increased. During acute withdrawal, however, its effects on sleep architecture are reversed; initial insomnia, decreased delta sleep, short REM latency, an increased percentage of REM sleep, decreased total sleep time, and decreased sleep efficiency all develop. Each of these features may be a contributing factor for alcohol relapse in dependent patients.[82–84] For recovering alcoholics, insomnia, poor sleep continuity, and decreased delta sleep can persist for several years after detoxification.[82,83] The definitive treatment for alcohol-related sleep complaints is detoxification and abstinence, in addition to treatment of co-morbid psychiatric conditions. Benzodiazepines, hypnotics, and sedating antidepressants should, in general, be avoided due to cross-tolerance, risk of alcohol relapse, and synergistic sedative effects that can lead to CNS depression should the patient relapse.

The effects of nonalcoholic substances on sleep are not as well established as are the effects of alcohol. In general, intoxication with either amphetamine or cocaine prolongs sleep latency, decreases the amount of REM sleep, disrupts sleep continuity, and shortens total sleep time. During the first week of withdrawal from these substances, patients often experience hypersomnia (a "crash") and excessive REM sleep, followed perhaps by several days of insomnia.[85]

Sedative–hypnotics, particularly benzodiazepines, shorten sleep latency, increase delta sleep, and decrease REM sleep. Caution must be taken when prescribing benzodiazepines, particularly those with a short half-life, because 1 or 2 days of withdrawal-based insomnia can occur after just a few days of benzodiazepine use.[86] Opiates are also known to increase sleep and to reduce REM sleep, with rebound insomnia occurring upon their discontinuation.

SSRIs can produce arousal and insomnia in some patients and sedation in others. The effects of SSRIs on sleep architecture include decreased REM sleep and decreased delta sleep. They can also aggravate sleepwalking and REM sleep behavior disorder, and they can induce REM during NREM sleep.[87]

APPROACH TO THE PATIENT WITH DISORDERED SLEEP

Once a sleep complaint has reached clinical attention, it is important to conduct a careful evaluation to correctly assess, diagnose, and treat any potential sleep disorder. Because this process can be complex and time consuming, the skills of a board-certified sleep specialist might be required. The following discussion is based on the general approach that many sleep specialists recommend for proper diagnosis and management of sleep complaints and disorders.

The initial step in the diagnostic process is to obtain a detailed sleep history, either through direct inquiry of the patient and his or her bed partner or by means of a sleep questionnaire. Table 22–3 provides a list of specific areas that should be addressed.[88] In addition to a detailed sleep history, patients are encouraged to keep a 2-week sleep diary that details the time and amount of sleep, the number and length of any naps, the number of awakenings, wake-up times, any medications taken, and subjective mood during the day. For patients in whom hypersomnia is the major complaint, an Epworth Sleepiness Scale—a simple, self-administered questionnaire that requires patients to rate their degree of sleepiness in a variety of routine situations)—is often given. A score of 10 or more on the Epworth Sleepiness Scale distinguishes normal patients from patients with various hypersomnias, including OSA, narcolepsy, and idiopathic hypersomnia (Table 22–4).[89] In addition to the sleep history and screening examinations, a medical history including past medical history, current medications, alcohol and drug history, family history, and psychiatric history is completed.

After a comprehensive history, and if clinically indicated, the patient receives a detailed physical examination. For patients who have hypersomnia, this examination focuses on the distribution of obesity, the respiratory system, the cardiovascular system, and the oronasomaxillofacial region, with careful attention to the tongue, tonsils,

TABLE 22–3 Sleep History

What are the times of retiring and arising? Note any variations between weekdays and weekends.
Note changes in sleep–wake schedule.
What is the subjective quality of sleep?
How much sleep is needed to feel ideally alert and energetic during daily function? Note any drugs needed.
How frequently is the ideal amount of sleep achieved compared to the average amount of sleep obtained? Note any disagreement between the patient and the bed partner about time spent asleep.
What are the sleep habits and requirement in childhood and other major periods of life? Note the subjective quality of sleep and attitudes toward sleep during those periods.
Have there been difficulties with initiation, maintenance, or early termination of sleep? Note daytime symptoms and effect on daily functioning.
Have there been problems with daytime sleepiness? Note if the problem is worsening. Note any snoring, intermittent snoring with gagging, episodes of muscle weakness with laughter, leg jerking in sleep, or other troublesome events during sleep.
Are drugs and alcohol used before 6 PM or after 6 PM?
Are there general emotional and physical problems? Note treatment modalities.
What is the sleep hygiene?

Modified from Roffward H, Erman M: Evaluation and diagnosis of the sleep disorders: implications for psychiatry and other clinical specialties. In Hales RE, Frances AJ, editors: Psychiatry update: American Psychiatric Association annual review, vol 4, Washington, DC, 1985, American Psychiatric Press, pp 204–328.

TABLE 22–4 Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation:

0 = no chance of dozing
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

SITUATION	SCORE
Sitting and reading	_____
Watching TV	_____
Sitting inactive in a public place (e.g., a theater or a meeting)	_____
As a passenger in a car for an hour without a break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after a lunch without alcohol	_____
In a car, while stopped for a few minutes in traffic	_____
TOTAL	_____

uvula, and pharynx.[12,13,90,91] If indicated, laboratory examinations including a complete blood cell count, blood gas analysis, pulmonary function tests, an electrocardiogram, thyroid function tests, serum iron analysis, and electrolyte count are ordered. Cephalometric x-rays of the skull and neck may be obtained to evaluate for skeletal discrepancies if craniofacial malformations are suspected as a possible etiology for any breathing-related sleep disorder.[10,12,13,90,91] Polysomnography completes the evaluation and often confirms the diagnosis.

Once a diagnosis has been confirmed, patients are offered appropriate treatment. Table 22–5 summarizes nonpharmacologic and pharmacologic treatments for the most commonly encountered primary sleep disorders.

TABLE 22–5 Treatment Options for Commonly Encountered Primary Sleep Disorders

PRIMARY SLEEP DISORDER	NONPHARMACOLOGIC TREATMENT	PHARMACOLOGIC TREATMENT

The Psychiatric Management of Patients with Cardiac Disease

23

Guy Maytal, M.D.
Jeff C. Huffman, M.D.
James L. Januzzi, Jr., M.D.
Theodore A. Stern, M.D.

Caring for cardiac patients can present a host of dilemmas for the general hospital psychiatrist. Patients with psychiatric conditions may exhibit cardiac symptoms, psychotropic agents can result in electrocardiographic abnormalities, and psychiatric manifestations may result from cardiac conditions. Moreover, patients with cardiac conditions can exhibit psychiatric symptoms, and cardiac drugs can result in psychiatric and neuropsychiatric symptoms. Because the overlap between psychiatry and cardiology is so great, knowledge of ways to manage specific problems can be of tremendous benefit. For instance, knowing how to deal with chest pain in the face of a psychiatric syndrome, an electrocardiographic complication from a psychotropic agent, or delirium due to invasive technology or cerebral hypoperfusion can facilitate comprehensive and compassionate care.

This chapter focuses on three main psychiatric syndromes related to the cardiac patient: anxiety, depression, and delirium. For each of these syndromes, we will consider epidemiology, clinical manifestations, differential diagnosis, psychopharmacologic approaches, and practical management strategies for patients with cardiac disease in the general hospital. Additional information on the interface between psychiatric and cardiac care will also be provided in other chapters.

ANXIETY IN THE CARDIAC PATIENT

Anxiety and the heart have long been linked. In 1836 Williams[1] published a text called *Practical Observations on Nervous and Sympathetic Palpitations of the Heart*. In 1871 Da Costa[2] described *irritable heart*, a condition in which chest discomfort was caused by emotional upset. In 1882 Osler[3] discussed the difficulty of differentiating cardiac and noncardiac etiologies of chest pain and described a subset of patients with atypical chest pain and nervousness. Since then, numerous authors have linked anxiety and chest pain and have described such symptoms using terms that have included Da Costa syndrome, soldier's heart, neurocirculatory asthenia, and effort syndrome. For years it has been suggested that anxiety and worry might cause heart conditions; more recent work has shown that both acute and chronic anxiety (as measured, for example, on the Cornell Medical Index[4]) are associated with sudden cardiac death (SCD) and coronary artery disease (CAD).[5,6]

The assessment of anxiety in the cardiac patient in the general hospital is often complex. First, it may be difficult to ascertain whether the patient is experiencing distress as a result of a myocardial event, an acute confusional state, a primary anxiety condition, or a complex interaction among these factors. Furthermore, there are many potential causes of anxiety for the cardiac patient, from an adjustment reaction to a serious cardiac event to the anxiogenic effects of cardiac medications administered to treat such events. Among hospitalized inpatients, the threshold for treatment of anxiety tends to be lower than it is in the outpatient setting, insofar as the elevations in catecholamine levels and vital signs associated with mild to moderate anxiety may have profound cardiovascular effects in the patient who has recently experienced a myocardial infarction (MI), coronary artery bypass grafting (CABG), or congestive heart failure (CHF).

Epidemiology

Anxiety Among Cardiac Patients

Patients who have an acute coronary syndrome or who undergo CABG are commonly anxious. Cardiac patients who are more critically ill (e.g., those on intraaortic balloon pumps [IABPs]) also experience significant anxiety; the presence of technology (e.g., automatic implanted cardiac defibrillators [AICDs]) can exacerbate such symptoms. Furthermore, patients who are initially identified as "cardiac" patients—including those who are admitted with chest pain but who have no known cardiac cause for their symptoms—may also have severe anxiety. Such anxiety may be both the cause of their chest pain and the result of being told that the cause for their symptoms is unknown.

Approximately 50% of patients with an acute coronary syndrome experience abnormal anxiety,[7] and 25% are at least as anxious as the average inpatient on a psychiatric unit.[8] These symptoms peak in the first 2 hospital days, then slowly drop over the next few days[8,9]; however, those with elevated levels of anxiety while in the hospital continue to be anxious 1 year later.[10] In addition, up to 40% of patients who have undergone CABG have clinically significant anxiety[11]; such symptoms are generally greatest before CABG,[12] but they can persist throughout the hospitalization.

Cardiac patients with invasive technology may also experience panic and fear associated with these devices. Approximately 10% to 15% of outpatients with pacemakers and AICDs have elevated levels of anxiety.[13,14] Not

surprisingly, patients whose AICDs discharged frequently (10 or more shocks received) are significantly more anxious; more than half of such patients had abnormal anxiety in one study.[14] Over the past several years, there has been a sharp increase in the number of studies examining psychopathology after AICD implantation. During the past 2 years, the number of studies examining psychopathology and quality of life after AICD implantation has increased dramatically. Multiple variables have been studied (including recipient age, gender, and social support network; the development of new depression and anxiety disorder diagnoses; and premorbid personality structure). A great deal of contradictory data have emerged. However, it is clear that in a significant minority of AICD recipients, the device worsens anxiety, probably more so if it fires.[15–18] In addition to high levels of free-floating anxiety, cardiac patients also experience elevated rates of formal anxiety disorders. Approximately 20% of all patients who arrive at emergency departments with chest pain meet criteria for panic disorder (PD).[19] Patients who visit outpatient cardiology clinics for evaluation of their chest pain have rates of PD that are even higher. A study of patients presenting to primary care clinics with chest pain found that although half of the patients met criteria for PD or infrequent panic attacks, few of the patients received the appropriate diagnosis of panic, and the presence of panic was associated with more testing and higher costs.[20] However, not all patients with PD are free of cardiac disease; in fact, patients with CAD appear to have PD at approximately four times the rate of the general population.[19] Furthermore, panic attacks may initiate or exacerbate cardiac events. Patients with co-morbid CAD and PD are among the most difficult for the general hospital psychiatrist because the cause of chest pain, palpitations, and other symptoms is often unclear. Therefore once PD is diagnosed, the clinician must remain open to the possibility of co-morbid cardiac illness as well.[21]

Cardiac patients who experience events as traumatic during their hospitalization may exhibit symptoms of post-traumatic stress disorder (PTSD). Recent studies have found that 8% to 16% of patients who have an MI develop symptoms of PTSD[22–24]; such PTSD symptoms also arise at a similar rate among patients who undergo CABG.[24,25] Studies of patients receiving intensive care for burn injuries and acute respiratory distress syndrome[26,27] suggest that PTSD may be even more prevalent among cardiac patients in intensive care units (ICUs). Finally, generalized anxiety disorder (GAD), though not formally studied in cardiac patients, appears to be common among patients with CAD. As noted previously, anxiety is prevalent 1 year after MI, and this may correlate with elevated rates of GAD. Furthermore, a study of chest pain in patients with GAD, but without cardiac disease, found that 48% of patients reported chest pain and 24% of patients had sought out medical evaluation for their pain.[28]

Association Between Anxiety and Cardiac Illness

Epidemiologic studies suggest that cardiac illness may lead to increased anxiety and that anxiety may also exacerbate cardiac illness. Acute and chronic emotional stress has been linked to the development of ventricular arrhythmias[29] and to the exacerbation of silent myocardial ischemia.[30]

A number of studies have also found a correlation between anxiety and sudden cardiac death (SCD). The Normative Aging Study,[31] an epidemiologic study of 2280 men, found that those with two or more anxiety symptoms on the Cornell Medical Index[4] had a fourfold greater risk of SCD than those without anxiety symptoms. Furthermore, prospective epidemiologic studies[32,33] of phobic anxiety have found a significantly increased rate of SCD. However, a few studies have not found a relationship between anxiety and cardiac mortality.[18]

Several specific anxiety disorders have been associated with adverse cardiac outcomes.[34] GAD predicted major cardiac events in a 2-year follow-up study of patients with CAD.[35] GAD has also been associated with increased rates of cardiovascular disorder risk factors (e.g., smoking, diabetes, hypercholesterolemia).[36] Furthermore, recent research has begun to explore physiologic markers common to both CAD and anxiety disorder. For example, a recent study by Bankier and co-workers evaluated 120 consecutive, stable CAD outpatients for the association between anxiety and inflammatory biomarkers. Even after adjusting for relevant demographic, medical, and psychiatric co-variables, the data demonstrated an association between C-reactive protein and GAD.[37]

One anxiety disorder in particular, PD, has been associated with a number of cardiovascular illnesses, (e.g., episodic and baseline hypertension,[38,39] small-vessel cardiac ischemia,[40] and the development of idiopathic cardiomyopathy[41,42]); idiopathic cardiomyopathy has been hypothesized to result from elevated catecholamine levels that cause a dilated cardiomyopathy.[43] Furthermore, a large community survey of more than 5000 patients found that, controlling for demographic factors, patients with PD had more than four times the risk of MI than those without PD.[44,45] Small longitudinal studies have suggested that PD may be associated with a greater overall cardiovascular mortality than those without PD; this effect appears to be greatest in men.[46] However, a recent study by Bringager and associates[47] evaluated the link between PD and cardiac morbidity and mortality in 199 patients referred for chest pain. After a 9-year review, the researchers found that PD was associated with increased chest pain intensity scores and poorer health-related quality of life measures but that it had no significant associations between baseline PD and mortality from cardiac illness at follow-up.[47] It is important to note that these links are at the level of association; it is not yet clear that PD *causes* these cardiovascular conditions; rather, patients with PD have them more frequently.

In the post-MI setting, anxiety may be associated with worse in-hospital and longitudinal outcome. Moser and Dracup[48] found that patients with post-MI anxiety were nearly five times more likely to have in-hospital ischemic or arrhythmic complications than those who did not. Frasure-Smith, Lespérance, and Talajic[49] found that patients with elevated levels of anxiety immediately after MI were more than twice as likely to have recurrent cardiac events over the next year. Furthermore, in a study of 129 post-MI patients, Huffman and co-workers found that post-MI anxiety was an independent factor associated with in-hospital cardiac complications (e.g., recurrent ischemia, re-infarction, CHF, and ventricular arrhythmias).[50] However, three other studies[51–53] found that post-MI anxiety did not

predict cardiac morbidity over the following year. One of these studies[51] did find that anxiety predicted poor quality of life, greater recurrent chest pain, more use of primary care services, and reduced adherence with medical recommendations. Despite these different findings, the studies were largely similar, using similar inclusion and exclusion criteria, standard instruments, and comparable numbers of patients.

Anxiety among patients undergoing CABG appears to have a similar effect. Two studies found that pre-CABG anxiety predicted poor psychosocial adjustment and quality of life both before and after surgery.[54,55] These studies are consistent with the literature on psychiatric outpatients with PD and GAD; investigators have found that these anxiety disorders were associated with a lower quality of life as well as increases in functional morbidity and the use of primary care services.[56–58]

Anxiety has also been shown to negatively affect patients with CHF. Friedmann and colleagues recently studied the prevalence of depression and anxiety in CHF as well as the relationship of psychosocial factors to mortality in outpatients with CHF. They found that anxiety was prevalent at a rate of 45% in their sample. However, they did not find an association between increased anxiety and increased mortality (though depression and social isolation were associated with it).[59] Furthermore, the tachycardia associated with anxiety can worsen CHF symptoms and lead to even worse cardiac output. This can become a spiraling process wherein patients' anxious concerns about their physical capacity can lead them to resist physical activity and hamper attempts at cardiac rehabilitation.[60]

In sum, cardiac patients have high rates of situational anxiety and formal anxiety disorders (e.g., PD, GAD, and PTSD). Such anxiety has been associated with elevated rates of myocardial ischemia, SCD, and other cardiac diseases, and in the post-MI setting may be associated with worse in-hospital and longitudinal cardiac outcomes. Furthermore, in addition to suboptimal medical outcomes, anxiety among cardiac patients in the general hospital is also associated with poor psychosocial outcomes.

Differential Diagnosis of Anxiety in the Cardiac Patient

Anxiety in the general hospital is often a primary psychiatric problem caused by stressful medical events. However, anxiety in the cardiac patient can also be caused by a number of general medical conditions and medications commonly associated with cardiac care (Table 23–1).

Not uncommonly, cardiac events cause anxiety. Myocardial ischemia, arrhythmias, and CHF can each cause anxiety owing to the sympathetic discharge associated with these conditions *and* because of what they may represent to the patient (e.g., the fear of dying, the worsening of medical illness, the loss of role identity). Other general medical conditions may cause or exacerbate anxiety in the cardiac patient; important among these is pulmonary embolism in the sedentary cardiac patient. Anxiety may also be a side effect of medications administered to cardiac patients, and it can result from substance intoxication or withdrawal (e.g., cocaine intoxication, alcohol withdrawal). Finally, impaired sleep in the coronary care unit (as the result of an unfamiliar setting, frequent nursing interventions, and significant noise) can lead to or exacerbate anxiety.

TABLE 23–1 Selected General Medical Causes of Anxiety Among Cardiac Patients in the General Hospital

Cardiac Events
Myocardial ischemia
Atrial and ventricular arrhythmias
Congestive heart failure
Other Medical Conditions
Pulmonary embolism
Asthma/chronic obstructive pulmonary disease (COPD) exacerbation
Hyperthyroidism
Hypoglycemia
Medications
Sympathomimetics
Thyroid hormone
Bronchodilators
Stimulants
Corticosteroids
Illicit Substances
Cocaine or amphetamine intoxication
D-Lysergic acid diethylamide (LSD) or phencyclidine (PCP) intoxication
Alcohol or benzodiazepine withdrawal

The general hospital psychiatrist should consider general medical causes of anxiety when evaluating cardiac patients; this is especially true when the anxiety has developed during an uneventful hospitalization, when the patient has no history of anxiety, or when anxiety persists despite appropriate treatment.

Psychopharmacologic Issues in the Anxious Cardiac Patient

Agents used to treat anxiety in the general hospital patient include benzodiazepines, antidepressants, and antipsychotics. Benzodiazepines are the medications most frequently used in the treatment of anxiety in cardiac patients. These medications rapidly relieve anxiety and appear to have a number of beneficial cardiovascular effects.

Benzodiazepines: Among patients with myocardial ischemia or infarction, benzodiazepines reduce catecholamine levels[61,62] and decrease coronary vascular resistance.[63] Although β-blockers, now commonly prescribed to cardiac patients, have similar effects, anxious patients tend to have elevations in vital signs, catecholamines, and coronary pressures as the result of their anxiety, despite the use of β-blockers; benzodiazepines can effectively treat these abnormalities. In addition, there is some evidence that benzodiazepines may inhibit platelet aggregation[64] and raise the ventricular fibrillation (VF) threshold.[65,66] Furthermore, benzodiazepines are generally well tolerated by the general hospital population; low rates of hypotension, virtually no anticholinergic effects, and very low rates of respiratory compromise develop when standard doses of benzodiazepines are used.[67] Benzodiazepines also appear to be safe even in seriously ill patients. A naturalistic study of 173 seriously ill medical inpatients (25% of whom died while in the hospital) who received IV diazepam for a variety of indications found that rates of any adverse effect from the benzodiazepine were low (3.5%).[68] Although clinicians

may be concerned about the development of benzodiazepine dependence, when these agents are used in the acute care setting, at adequate doses and for appropriate indications, the risk of dependence is minimal.[69]

Studies of benzodiazepines in cardiac patients have found that these agents effectively reduce anxiety and may have beneficial effects on cardiovascular outcome in selected cardiac populations. For example, patients with cocaine-induced chest pain are effectively treated with benzodiazepines; a recent study of patients who presented to an emergency department with chest pain after cocaine use found that the use of IV lorazepam in combination with nitroglycerin was safe and more efficacious in relieving cocaine-associated chest pain than was the use of nitroglycerin alone.[70] In addition, benzodiazepines may have beneficial effects in patients with more conventional causes of acute myocardial ischemia. A report by Wheatley[71] combined the results of three studies using benzodiazepines in post-MI patients; Wheatley found that the addition of benzodiazepines to standard cardiac medications led to significantly lower rates of reinfarction over the study period. It should be noted that the patients in these studies, however, were not taking β-blockers.

In short, benzodiazepines are rapidly effective in the treatment of anxiety in the cardiac patient. They are well tolerated and are associated with low rates of adverse effects and minimal risk of dependence when used in acute care settings. Benzodiazepines have favorable effects on catecholamines and coronary pressures and may have favorable effects on cardiac outcome when administered in the post-MI period. One important caveat for the use of benzodiazepines is that they can exacerbate confusion and paradoxically worsen agitation in patients with delirium or dementia; therefore other agents (e.g., antipsychotics) may be more appropriate for the treatment of anxiety, fear, and distress in the delirious or demented cardiac patient.

Antidepressants: Antidepressants can also be used in the treatment of anxiety in the general hospital. However, these agents often take several weeks to work and are best used to treat Axis I anxiety disorders, such as PD, GAD, or PTSD. For acutely anxious cardiac patients in the general hospital, when antidepressants are prescribed, it is often wise to co-administer benzodiazepines to acutely reduce anxiety during a vulnerable cardiovascular state.[72] Among the antidepressants, selective serotonin reuptake inhibitors (SSRIs) are generally the agents of choice for cardiac patients, given that tricyclic antidepressants (TCAs) can cause orthostasis, tachycardia (resulting from anticholinergic effects), and arrhythmias. The SADHART trial by Glassman and colleagues[73] established that the SSRI sertraline appears to be safe when administered 1 month after MI, with no adverse effects on cardiac function; smaller studies[74,75] and our own clinical experience have found that sertraline and other SSRIs may be used safely in the days and weeks after MI. Antidepressants will be discussed more extensively in the section on depression.

Antipsychotics: Antipsychotics can also be used for the treatment of heightened anxiety in the general hospital. Although the use of antipsychotics for anxiolysis has not been widely studied, the Massachusetts General Hospital (MGH) Consultation–Liaison (C-L) Service has long used antipsychotics when fear impairs reason in general hospital patients; both typical and atypical antipsychotics appear effective for this indication. Atypical antipsychotics, especially quetiapine[75] but also olanzapine and risperidone, are also being used more frequently in the treatment of acute anxiety. A recent review of the use of antipsychotics for anxiety noted that although there is ample clinical experience to support the efficacy of antipsychotic use to treat anxiety disorders, there is no large, well-designed study of antipsychotics in the treatment of primary or co-morbid anxiety symptoms or disorders.[76] These agents have the additional beneficial effects of symptomatically treating co-morbid delirium, and they do not cause the paradoxical disinhibition that is sometimes associated with benzodiazepines. Antipsychotics, however, can cause orthostasis and anticholinergic effects (associated with low-potency typical agents and, to a lesser degree, some atypical agents) and may be associated with prolongation of the corrected QT (QTc) interval. Antipsychotics will be discussed more extensively in the section on delirium.

Other Agents: Anticonvulsants, such as valproate and gabapentin, have been used in the acute treatment of anxiety. These agents are associated with essentially no risk of physiologic dependence, and they do not cause orthostasis or anticholinergic effects. Like antipsychotics, their efficacy in the treatment of acute anxiety in hospitalized cardiac patients has not been examined. They may be especially effective in patients with anxiety and co-morbid neuropathic pain.[77]

Approach to the Anxious Cardiac Patient

The psychiatric consultant is frequently called to cardiac floors to assess and treat anxiety. A careful, stepwise approach to these consultations can ensure an accurate diagnosis and appropriate treatment.

Consider a broad differential diagnosis for the patient's distress. A primary role of the general hospital psychiatrist is to accurately characterize a patient's distress as anxiety, denial, depression, delirium, or another psychiatric phenomenon. When the psychiatrist is consulted for so-called anxiety, it is easy to be biased toward making a diagnosis of anxiety. However, patients who appear anxious and tremulous may in fact be disoriented, paranoid, and frightened—that is, delirious. Therefore the consultant should be careful in the interview to assess affect, behavior, and cognition.

If the patient's primary psychiatric symptom appears to be anxiety, the consultant should then consider the potential contribution of medications or medical symptoms to this anxiety. As noted earlier, there is a long list of conditions that can cause or exacerbate anxiety, and the consultant should carefully consider these and recommend appropriate diagnostic studies, if appropriate. It may be especially useful to note correlations between anxiety levels and the initiation or discontinuation of potentially offending medications or substances. For example, the development of anxiety, tremulousness, insomnia, and fluctuations in vital signs 24 to 48 hours after admission might suggest alcohol withdrawal, even in a patient who denies alcohol use.

Evaluate sources of anxiety and assess how the patient has dealt with difficult situations in the past. A careful psychiatric interview of the anxious patient will help determine what factors are causing his or her anxiety. Is the preoperative CABG patient anxious because a relative died during

cardiac surgery years ago? Is the post-MI mother of three worried because she is afraid that no one will be able to care for her children if she dies as a result of cardiac disease? Is the patient with an AICD fearful that his defibrillator will painfully discharge again? By determining the sources of anxiety, the consultant will be able to address these anxieties through education, reassurance, medication, or brief psychotherapy. Often, many of these worries (e.g., worries about being able to sleep in the hospital and worries that family members have not been contacted) can be directly addressed. Furthermore, knowledge of the factors that contribute to anxiety may allow the consultant to estimate the duration of such symptoms; for example, a patient who reports that he will be "just so relieved" once the surgery to place his AICD is performed is likely to have a relatively short course of anxiety, whereas the patient with chronic, uncontrollable worries is likely to have anxiety throughout the hospitalization.

A related task is to determine the patient's coping style and coping strengths. How does he or she manage anxiety outside of the hospital? How has he or she managed difficult situations in the past? The consultant can use this information to identify the patient's strengths and determine the best approach to the patient's anxieties. Patients who identify themselves as survivors or as people who persevere and succeed despite difficult obstacles often take quite well to a consultant who also identifies this quality in them.

Another question for patients involves stimulation and control. Some cardiac patients crave control and wish to know every detail of their care; they feel anxious when they do not feel that they have comprehensive information about their illness and when they are not part of all treatment decisions. In contrast, other patients find such information and the pressure to make decisions overstimulating and feel less anxious when told only the general details of their condition.

Recommend appropriate behavioral and therapeutic interventions. Having learned about the patient's sources of anxiety, coping strengths, and preferences regarding control, the consultant is in an excellent position to design a treatment plan that reduces a patient's anxiety. For example, if a patient reports that the hospitalization is overwhelming, members of the treatment team can be encouraged to limit detailed information and reassure the patient that they see this condition frequently (if true) and that they plan to provide excellent care to the patient. On the other hand, for the patient whose anxiety increases with the perceived lack of control, the treatment team can be encouraged to provide the patient with detailed information and written materials. The patient should also be included in treatment decisions; inclusion in even small decisions (e.g., the best time for dressing changes) can allay anxiety and allow the patient to feel in control.

In other cases, worried cardiac patients simply need to express their anxieties to someone. If the consultant, treating physician, and nursing staff can set aside short periods to reflectively listen to the patient's fears, this investment of time often results in significantly less anxiety, greater compliance with treatment, and less chaos for patient and staff alike. If the patient seems to have an insatiable desire to discuss his or her fears, staff can be taught to consistently set aside time to listen to the patient while setting limits on his or her time; for example, a nurse may tell the patient that she will sit with him or her for 5 minutes at the beginning, middle, and end of the shift to talk about his or her worries. If the patient attempts to engage the nurse in further conversation about this topic, the nurse can calmly tell the patient that they can discuss it at their next appointment.

Intelligently use psychiatric medications for specific target symptoms. Benzodiazepines are often the agents of choice for the anxious cardiac patient. If the anxiety appears to be short-term or situation-specific (e.g., whenever a procedure is performed), a short-acting benzodiazepine can be used on an as-needed basis, (e.g., lorazepam 0.5 to 1.0 mg as needed for acute anxiety). However, for most patients, longer-acting benzodiazepines given on a standing basis provide the smoothest and most consistent reduction of anxiety. Most anxious cardiac patients can be started on clonazepam 0.5 mg at night or twice per day; doses can be adjusted upward if this dose is well tolerated and anxiety persists. In general, these agents can be discontinued on discharge from the hospital if they were only used on a short-term basis.

Benzodiazepines may not be the agents of choice for patients with acute or chronic organic brain syndromes (e.g., delirium, dementia, traumatic brain injury), tenuous respiratory function (including obstructive sleep apnea), or a history of substance dependence. For these patients antipsychotics are often useful, alleviating agitation and confusion in delirious patients while also reducing anxiety. We often start with doses of quetiapine at 12.5 to 25.0 mg at night or twice per day or olanzapine at 2.5 to 5.0 mg at night or twice per day.

Anticonvulsants may be useful when a patient has anxiety that is co-morbid with neuropathic pain or with a chronic brain disturbance, such as a dementia or head injury. Antidepressants may be useful in the treatment of Axis I anxiety disorders and when depression is co-morbid with anxiety; we generally co-administer a benzodiazepine to reduce initial anxiety associated with initiation of antidepressants.

Return frequently to see the patient. Anxious patients generally are relieved to see a familiar face, especially one that has attempted to understand and address their anxiety. Such frequent follow-up, therapeutic in itself, allows for careful monitoring of behavioral and pharmacologic interventions.

CASE 1

Mr. A, a 53-year-old executive without a psychiatric history, was admitted for CABG after cardiac catheterization revealed three-vessel cardiac disease. He initially had an uneventful perioperative course. However, on the day after his operation, psychiatry was consulted to assess his capacity to leave the hospital against medical advice.

On interview, Mr. A was alert, oriented, lucid, and initially quite angry. He reported, "I have no assurance that I'm getting the right care; the doctors and nurses come in and out of my room and bark orders to one another but they don't include me at all. They haven't even listened to the fact that I always take my sleeping pill at 9 PM every night instead of 11 PM like they give it to me. I'm fed up." By the end of his tirade, Mr. A's anger had changed to fear and anxiety.

The consultant told Mr. A that he would bring his concerns to the team. The consultant met with members of the treatment team and encouraged them to provide as much information as possible about his care and to allow him to mandate his treatment when possible (e.g., getting his sleeping pill at 9 PM). The consultant, nurse, and Mr. A then met together so that Mr. A could express his concerns and the nurse and consultant could outline the ways their procedures would change so that he could have more information and more control. Mr. A agreed to this plan and also agreed to clonazepam 0.5 mg twice per day to reduce his anxiety.

The consultant checked back frequently with Mr. A to assess his response to this treatment plan. Small changes in the plan were instituted at his request, and his anxiety steadily decreased. He was discharged to cardiac rehabilitation and thanked the nursing staff for their "compassionate care."

DEPRESSION IN THE CARDIAC PATIENT

Over the past 2 decades, substantive research has firmly established a bidirectional link between depression and cardiac disease: Patients with depression are more likely to develop cardiac disease, and patients with cardiac disease are more likely to suffer from depression.[78] Initial studies by Frasure-Smith and colleagues[79,80] suggested that depressive symptoms immediately after MI are associated with greater cardiac mortality 6 and 18 months later. Such findings renewed interest in the treatment of post-MI depression and led to further studies of the safety and efficacy of antidepressants in the post-MI period. In addition, patients undergoing cardiac surgery are more likely to have adverse medical outcomes if they are depressed before surgery.[81] These findings have underscored the importance of the general hospital psychiatrist's role in identifying depressed cardiac patients and considering appropriate treatments.

Depression in Patients with Established Cardiac Illness

Depression is common among patients with CAD, with prevalence rates of major depression hovering around 20%.[82–85] This rate of depression is greater than the prevalence of depression in the general population (approximately 15%).[86] Such elevated rates of depression are also present among cardiac patients in the general hospital: 15% to 30% of post-MI patients have major depression, and 65% manifest at least minor depression.[87,88] Moreover, a study by Baker and associates[89] found that more than 30% of pre-CABG patients were depressed. Adequate treatment of depression is essential given that it is a serious and debilitating illness. Furthermore, as will be discussed later, optimal treatment of depression may reduce cardiac morbidity and mortality.

With regard to depression, post-MI patients have been the most extensively studied cardiac population. As mentioned previously, Frasure-Smith and colleagues demonstrated that patients diagnosed with major depression disorder (MDD) after MI had higher mortality rates than patients without MDD.[79] The Stockholm Female Coronary Risk Study[90] followed 292 women for 5 years and found that women with two or more depressive symptoms had an increased risk (hazard ratio 1.9) of future cardiac events (acute MI, cardiovascular mortality, and revascularization procedures) compared with women who had one or no depressive symptoms. In a more recent study, Frasure-Smith and Lespérance examined the cardiac prognostic importance of MDD and GAD in 804 patients with stable CAD.[35] They found that compared with patients without psychiatric diagnoses, those with MDD or GAD had a significantly higher risk of major adverse cardiac events (cardiac death, MI, cardiac arrest, or nonelective revascularization). Furthermore, a meta-analysis of 22 studies of post-MI subjects found that post-MI depression was associated with a 2- to 2.5-fold increased risk of negative cardiovascular outcomes.[91]

Despite the high prevalence of depression and the risks it carries for cardiac patients, only 10% of post-MI depressed patients are recognized as such.[92] Several factors likely account for these low rates of recognition. The pattern of depression (with hostility, listlessness, and withdrawal being more common than sad mood) is often somewhat atypical[93]; furthermore, depression is often seen as a normal consequence of a serious medical event, such as MI. Finally, most patients with uncomplicated MI have brief inpatient stays, and it may be difficult to assess a patient's mood or to obtain psychiatric consultation during this limited time frame.

In a review of post-MI depression, Strik, Honig, and Maes[87] delineated a number of putative risk factors for the development of post-MI depression. These risk factors included smoking, hypertension, female gender, social isolation, medical complications during acute hospitalization, a history of depression, and first-time prescription of benzodiazepines (suggesting potential co-morbidity between anxiety and depression).

The course of post-MI depression may be relevant in its relationship to ischemic heart disease and cardiac morbidity. When a depressive episode occurs immediately after an MI, it is considered an incident episode. The causes and effects of such episodes may be distinct from those of depressive episodes that occur long before or after the MI (i.e., ongoing or recurrent depression). The Depression after Myocardial Infarction Study followed 468 MI patients for 2.5 years after an index MI. The authors found that 25.4% of patients experienced a depressive episode in the year after the MI, and 44.6% of these were incident MIs. Patients with incident depression were more likely to have new cardiovascular events (hazard ratio 1.65), whereas patients with nonincident depression were not.[94,95] In an 8-year study of 588 individuals following MI, Dickens and co-workers found that new-onset depression after MI was associated with increased cardiac mortality (hazard ratio 2.33), whereas pre-MI depression did not add any additional risk of cardiac mortality.[96] Post-MI depression is frequently persistent; Travella and associates[97] reported that the average length of a depressive episode after MI is 4 to 5 months. Frasure-Smith and colleagues[98] found that more than half of patients with post-MI depression remained depressed after 1 year. Even more strikingly, Lespérance and colleagues[99] found that only 26% of the patients who were depressed immediately after MI were alive and known to be depression-free at follow-up.

Other cardiac patients may also have elevated rates of depression. Shapiro and colleagues[100] followed 30 recipients of left ventricular assist devices and found that 17% became depressed in the postoperative period. Candidates for cardiac transplantation have elevated rates of anxiety and depression[101]; depressive symptoms can persist for years after transplantation.[102] Dew and co-workers[103] found that one quarter of transplant recipients developed MDD in the 3 years after transplantation. Furthermore, rates of MDD have also been found to be elevated in longitudinal studies of patients with CHF.[60] In a study of 152 patients with New York Heart Association (NYHA) Class III heart failure, Majani and colleagues found a significantly higher incidence of MDD compared with controls.[104]

In short, depression is common among cardiac patients, and it has been best studied in those with recent MI. Post-MI depression is highly prevalent, poorly recognized, and frequently persistent.

Depression as a Risk Factor for Cardiac Disease

Evidence from many community studies over the past 20 years indicates that depression is an independent risk factor for cardiovascular disease.[105] Several studies have found that patients with depressive symptoms are 1.5 to 3.5 times more likely to have an MI than are those without such symptoms.[78,106–111] Patients with full-blown MDD appear to have an even greater risk (4.5 times greater than nondepressed patients) of suffering an MI.[109] Another study of patients with asymptomatic CAD (noted on coronary angiography) found that 18% were depressed, a rate of depression that is more than 3 times greater than in the general population.[110] In addition, the Johns Hopkins Precursor Study[106] found that, in a 40-year follow-up of male physicians, depression was associated with a strongly significant twofold risk of developing heart disease.

Although much of the research on the association between MDD and cardiac disease has been done in men, recent data indicate that this association also holds true for women. The Women's Ischemia Syndrome Evaluation (WISE) study followed 505 women referred for coronary angiography for an average of 4.9 years. The study found that even adjusting for other factors related to cardiac disease (e.g., age, smoking, diabetes, hypertension, body mass index, stenosis score on angiography), women with elevated Beck Depression Inventory scores or prior treatment for depression (or both) had significantly increased rates of mortality and cardiovascular events (e.g., CHF, stroke, unstable angina, MI, revascularization).[112]

Recent studies have also examined the relationship between depression and cardiac disease in the elderly. Several large longitudinal studies have demonstrated that for individuals over the age of 65, a new diagnosis of depression is associated with a significantly higher risk of new cardiovascular events or death resulting from cardiovascular causes.[113,114]

Critics of all of these studies have raised two important arguments. First, relative to the human life span, the follow-up periods of these studies are too short. Second, depression measured only by way of elevated depressive symptom scales may reflect generalized distress and may not be specific enough to capture true depressive disorder. In response to these concerns, the Stockholm Heart Epidemiology Program (SHEEP) study examined the risk of MI among individuals hospitalized for depressive disorder over a 26-year period.[115] This case-control study examined 1799 cases and 2339 controls and demonstrated a significantly increased risk (relative risk 2.3) for acute MI among patients hospitalized for depression—even after controlling for cardiac risk factors.

A recent meta-analysis examined these and other studies to determine the role of depression as a predictor of CAD.[116] Van der Kooy and colleagues identified 28 relevant studies that comprise more than 80,000 subjects. Despite differences in study design and quality, the meta-analysis demonstrated that depression was associated with an increased risk of cardiovascular disease (RR 1.46). This analysis also found that the strongest association was made when patients were diagnosed by clinical interview. Also, studies using depression scales demonstrated a dose–response relationship between depressed mood and the development of cardiovascular disease. The authors concluded that depression predicts the development of CAD among initially healthy persons. In addition to predicting the development of CAD in healthy people, depression has also been associated with significantly higher rates of cardiac death and overall mortality among patients with established CAD. In the specific population of post-MI patients, numerous studies have examined the relationship between post-MI depressive symptoms and cardiac mortality; the majority of these studies,[53,79,80,117,118] though not all,[51,52] have found that depressive symptoms after MI predict cardiac mortality 6 to 18 months later. These effects on mortality appear to be largely independent of the severity of cardiac disease, demographic variables, medications, or other confounding factors. The best known of these studies (by Frasure-Smith and co-workers[79,80]) found that depressive symptoms immediately after MI were associated with a fourfold to sixfold augmentation of risk of cardiac mortality 6 and 18 months after MI. Bush and colleagues[117] found that even minimal depressive symptoms were associated with an elevated risk of cardiac mortality, though more severe depressive symptoms more strongly predicted cardiac mortality.

Depressive symptoms also appear to predict cardiac morbidity and mortality in other cardiac populations as well. At least three studies have found that pre-CABG depressive symptoms have been associated with an increase in cardiac morbidity at 6 or 12 month follow-up.[81,89,119] Among patients undergoing cardiac transplantation, persistent depression was associated with increased rates of incident CAD.[103] Furthermore, a study by Zipfel and associates[120] found that preoperative depressive symptoms predicted mortality in cardiac transplant recipients. Finally, Friedmann and colleagues found that in patients with CHF, depression and social isolation predicted higher mortality independent of demographic factors or clinical status.[59]

Numerous mechanisms have been offered to explain the link between depression and cardiovascular disease.[121] Some are behavioral and include continued poor health habits (e.g., smoking, lack of exercise) and noncompliance with medical care. Depressed patients appear to have decreased adherence to medication regimens,[122] and depressed cardiac patients attend cardiac rehabilitation

programs less frequently than their nondepressed peers.[123] Furthermore, patients who are depressed after MI are less likely to follow recommendations about diet, exercise, and smoking cessation.[124,125]

The possible physiologic mechanisms by which depression may contribute to increased cardiac morbidity and mortality rates are several, though none has been clearly outlined. The increased morbidity rate may be attributable to increased catecholamine levels. Depressed patients have increases in baseline levels of circulating catecholamines and exaggerated rises in catecholamine levels during stress[126]; elevated catecholamine levels can result in increased myocardial oxygen demand and elevations in blood pressure and heart rate. Furthermore, elevated catecholamine levels have been associated with infarct initiation, infarct extension, and the development of VF in patients with myocardial ischemia.[127,128]

The association between depression and cardiac morbidity may be mediated by changes in autonomic nervous system tone, which may be manifested as decreased heart rate variability (HRV) or as abnormalities in baroreflex sensitivity. HRV is a measure of autonomic regulation of cardiac activity, and decreased HRV has been established as an independent risk factor for the development of SCD. Both depressed psychiatric outpatients and patients with post-MI depression have been found to have decreased HRV,[129,130] and depressed patients with CAD have been shown to have elevated rates of ventricular arrhthymias.[131] Therefore depressed patients with CAD may have decreased HRV, leading to increased susceptibility to ventricular arrhythmias and SCD; this may explain increases in cardiac morbidity and mortality.

Several other mechanisms have been proposed to explain the link between depression and heart disease. Recently, an association has been demonstrated between MDD and elevated levels of the inflammatory biomarker C-reactive protein.[132] Another mechanism involves platelet aggregation; depressed patients with CAD appear to have increased platelet aggregation,[82,133] and this could increase vulnerability to myocardial ischemia. Another involves the inflammatory changes and endothelial dysfunction seen in depression that may worsen risk of acute cardiac events.[134,135] Another explanation rests on the observation that sleep and circadian rhythm dysfunction are associated with both increased risk of cardiac disease and depressive disorder.[136]

The link between depression in cardiac patients and increased cardiac morbidity is likely mediated by multiple factors. One crucial question that remains unanswered is whether treatment of depression among cardiac patients improves cardiac prognosis.

Differential Diagnosis of Depression in the Cardiac Patient

As with anxiety in the cardiac patient, there are a number of medical conditions and medications that can cause or exacerbate depressive symptoms. Table 23–2 lists a number of these medical influences on mood. Conditions associated with depressed mood that are common in the cardiac patient include hypothyroidism (both idiopathic and secondary to amiodarone, which is increasingly prescribed to cardiac patients), Cushing's disease (idiopathic or cushingoid symptoms secondary to steroid administration), neoplasm (especially pancreatic), vitamin B_{12} and folate deficiency, and depression associated with vascular dementia.

TABLE 23–2 Selected General Medical Causes of Depression Among Cardiac Patients in the General Hospital

Medical Conditions
Hypothyroidism (idiopathic or amiodarone-induced)
Cushing's disease
Vitamin B_{12} or folate deficiency
Neoplasm (especially pancreatic, lung, or central nervous system tumors)
Vascular dementia
Movement disorders (e.g., Parkinson's disease or Huntington's disease)
Medications
Angiotensin-Converting Enzyme (ACE) inhibitors
Methyldopa
Reserpine
Corticosteroids
Interferon
Illicit Substances
Chronic alcohol or benzodiazepine abuse
Cocaine or amphetamine withdrawal

A number of medications sometimes used in cardiac populations have been associated with depression. Steroids, methyldopa, and reserpine have each been linked with increased rates of depression. Substances can also influence mood; chronic alcohol use and withdrawal from cocaine or amphetamines commonly lead to depression. β-blockers have long been associated with depression; however, a recent reexamination of the literature suggests a minimal association between β-blockers and depression.[137]

Because depression can have significant effects on cardiac and psychosocial outcome in cardiac patients and because the causes of depression are often reversible or treatable, the general hospital psychiatrist should consider these in all depressed cardiac patients.

Psychopharmacologic Issues in the Depressed Cardiac Patient

Antidepressants are effective in the treatment of depression. However, older antidepressants (i.e., TCAs and monoamine oxidase inhibitors [MAOIs]) have effects that make their use in cardiac patients difficult. TCAs have anticholinergic effects (including tachycardia) and can cause orthostasis; these effects make their use questionable in patients with significant cardiac disease. Even more concerning is the propensity of TCAs to prolong cardiac conduction and to have a pro-arrhythmic effect in some patients as a result of their guanidine-like properties.[138,139] A recent study, controlling for medical and demographic factors, found that depressed patients on TCAs had more than a twofold risk of MI, whereas SSRIs did not enhance risk of MI.[140] For these reasons, the use of TCAs is generally not recommended for patients with cardiac conduction disease[141] and in the 2- to 3-month period after MI;[139,142] unfortunately, this peri-MI period appears to be the time when post-MI depression is both most prevalent and most dangerous.

Newer antidepressants (e.g., SSRIs, bupropion, and mirtazapine) do not appear to have the negative cardiovascular effects of TCAs. They are generally not associated with significant anticholinergic effects or orthostasis, and they do not appear to result in adverse effects on cardiac conduction. These properties make SSRIs and other new agents a more logical choice for most patients with cardiac disease. This recommendation is supported by a study (by Roose and associates[143]) that compared paroxetine and nortriptyline in depressed patients with ischemic heart disease. The two agents were equally efficacious, but the TCA was associated with a significantly higher rate of serious adverse cardiac events.

One cardiac population in whom the cardiac safety of SSRIs has been scrutinized is the post-MI population. Though a small study of fluoxetine found this agent to be safe in a post-MI population,[144] the most extensive study has been on the SSRI sertraline. The preliminary SADHAT trial by Shapiro and co-workers[75] found that the open-label administration of sertraline to 26 post-MI patients was associated with clinical improvement of depression and resulted in no significant changes in heart rate, blood pressure, cardiac conduction, left ventricular ejection fraction, or coagulation measures. This study paved the way for the more extensive multicenter SADHART trial by Glassman and colleagues.[73] This study used a double-blind, placebo-controlled design to administer sertraline or placebo to 369 post-MI patients. The investigators found that compared with placebo, sertraline significantly improved depressive symptoms and was not associated with changes in ejection fraction, cardiac conduction, or adverse cardiac events. Two important limitations of this study were that patients did not begin treatment until an average of 34 days after their MI and that the patients were followed for only 24 weeks. Most intriguing was the finding that the incidence of severe cardiac events was numerically lower in patients receiving sertraline, but this result did not reach statistical significance. The SADHART trial was not designed to detect a difference in morbidity and mortality, but it did achieve its principal aim of proving the safety of sertraline for use in depressed post-MI patients when administered to patients approximately 1 month after MI.

More recently, the Canadian Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial studied the safety and efficacy of citalopram and interpersonal therapy (IPT) in 284 depressed patients with CAD in a double-randomized, placebo-controlled design.[145] They found citalopram safe and effective in treating depression in this patient population. Interestingly, there was no discernible added value to IPT over clinical management as usual.

Therefore it appears that citalopram and sertraline (and likely other SSRIs) are safe to use in patients with cardiac disease. Our clinical experience with SSRI administration in cardiac patients has also found SSRIs to be safe, and we have safely prescribed SSRIs in post-MI patients earlier than 1 month after the MI when indicated by the severity of depression or the follow-up circumstances.

Though other new non-SSRI antidepressants appear to have properties that would render them safe in cardiac populations, these agents have been less extensively studied. Bupropion, at therapeutic doses, does not have adverse effects on blood pressure, heart rate, or other cardiovascular parameters.[146] Furthermore, a study of bupropion in depressed patients with CAD found that this agent had a favorable cardiovascular side effect profile in this specific population.[147] Although bupropion overdose can cause hypertension and tachycardia,[148] it generally does not lead to adverse cardiovascular events[149,150]; however, some studies of bupropion overdose have noted cardiovascular effects, including tachycardia, hypertension, wide-complex tachycardia, and cardiac arrest.[151] Therefore bupropion should be used cautiously in depressed cardiac patients with a history of overdose or significant impulsivity. The use of bupropion in the cardiac patient is made more appealing by its ability to aid smoking cessation.[152,153] Bupropion (at 300 mg per day) has been found to be effective for this indication, and therefore cardiac patients who are depressed and who continue to smoke might be excellent candidates for bupropion therapy.

Mirtazapine is another new antidepressant that has a favorable cardiovascular side effect profile. It has few effects on cardiac conduction or vital signs, even in overdose,[154] and is otherwise well tolerated. Recently, the Myocardial Infarction Depression Intervention Trial (MIND-IT), a 24-week randomized, placebo-controlled study, evaluated the safety and efficacy of mirtazapine in 209 post-MI patients diagnosed with depression within the first year of their cardiac event.[155] The study found mirtazapine to be safe in post-MI patients. It also found a dose-dependent relationship between depressive symptom severity and left ventricular ejection fraction. Finally, the MIND-IT investigators did not find statistically significant changes in the Hamilton-Depression (Ham-D) scores at 8 and 24 weeks of treatment (primary outcome measure). However, there were statistically significant improvements on self-report rating scales and, in their statistical analysis, the authors concluded that they found a significant difference favoring mirtazapine over placebo.[156] One potential drawback of the use of mirtazapine in cardiac patients is its propensity to cause weight gain in some patients as a result of its interaction with histamine receptors.

Psychostimulants have also been shown to be rapidly acting, efficacious antidepressants in medically hospitalized patients.[157,158] Though they may elevate blood pressure or heart rate, stimulants may be indicated in cardiac patients whose depression requires rapid treatment (e.g., depression that is severe, is negatively affecting rehabilitation owing to anergia or minimal oral intake, or is affecting the patient's capacity to make medical decisions). Stimulants are relatively contraindicated in patients with a history of ventricular tachycardia, recent MI, CHF, uncontrolled hypertension or tachycardia, or those who are concurrently taking MAOIs. However, in many cardiac patients, psychostimulants can be safely used with slow dosage titration, beginning with 2.5 to 5.0 mg in the morning and increasing up to 20 mg per day.

Several studies have also examined the efficacy of psychotherapy to treat depression in cardiac patients. Interestingly, there is no convincing evidence for using manualized psychotherapy techniques (e.g., cognitive behavior therapy [CBT] or IPT) in cardiac patients. The Enhancing Recovery in Coronary Heart Disease (ENRICHD) trial enrolled 2481 patients after an MI with depression or low

social support in either CBT or usual care. Antidepressant therapy was allowed (in a nonrandomized manner) as a supplement in patients with persistent depressive symptoms. The study found no impact of CBT on the end point of death or nonfatal MI. However, the investigators found a 40% lower risk of either death or nonfatal MI in patients treated with antidepressant medications.[159] Likewise, the CREATE trial discussed previously[145] found no impact of IPT on depressive symptoms in post-MI patients with depression. These data suggest that psychotherapy interventions that are effective in depressed patients in the general population may not be effective in those with ischemic heart disease.

Approach to the Management of the Depressed Cardiac Patient

The approach to the depressed cardiac patient is in many ways similar to the approach to the anxious cardiac patient. The consultant must first confirm that depression is the primary psychiatric symptom and evaluate for co-morbid psychiatric conditions. Furthermore, the psychiatrist must consider the presence of medical conditions or medications that can cause or exacerbate mood symptoms. Once these steps have been completed, an approach to treatment involves an identification of the patient's coping strengths and support network; it may also involve the weighing of the risks and benefits of antidepressant treatment. In the subsequent paragraphs, we outline the approach to the depressed cardiac patient.

Consider appropriate psychiatric and medical differential diagnoses. As with consultations on cardiac floors for apparent anxiety, we also find that consultations for apparent depression often reveal that a patient's distress is caused by another psychiatric syndrome. Commonly, disordered sleep, inability to engage with caregivers, and social withdrawal may result from a hypoactive delirium rather than from depression, and therefore cognitive status must be addressed. Furthermore, anxiety is often prominent in cardiac patients, and the patient's distress may be more accurately assessed and treated as anxiety.

The consultant should also note the course of depressive symptoms to see if the onset or worsening of such symptoms correlated with the administration of a new medication or new physical symptoms or if there are other indications that a physical disorder might be implicated in the evolution of the depressive symptoms. The general hospital psychiatrist should also order laboratory tests and other studies as indicated (e.g., vitamin B_{12} and folate in an elderly patient with poor nutrition; thyroid function tests in a patient with recent cold intolerance, weight gain, loss of appetite, and thinning of hair; or toxicologic screening tests when clinical suspicion of substance use arises).

Attempt to identify the patient's coping style and the triggers for depressive symptoms. Determining the external factors that exacerbate depressive symptoms may help the consultant reduce the patient's stressors. Is the patient feeling more depressed because he must face his mortality? Does he feel that his children will not respect him? Is he stuck in the hospital and unable to attend an important family function? The consultant can use this information to implement solutions that are psychotherapeutic in nature (e.g., discussing mortality and life goals) or more concrete (e.g., having family members call the patient to let him know he is missed and important to them). Identification of the patient's coping strengths—especially, how the patient has previously managed difficult situations—will inform the treatment team's approach to the patient.

Of particular interest to the psychiatric consultant is recent data indicating that patients with CAD who use a repressive coping style are at particular risk of adverse cardiac events and death.[160,161] Perhaps because these individuals report low levels of anxiety and depression, they were once thought to be at low psychological risk for clinical events. However, it is now thought that these individuals often fail to detect or report significant emotional distress, which could contribute to their increased risk of MI and death. The consultant should be particularly mindful of patients whose emotional cool seems at variance with the severity of their clinical circumstances.

Make use of existing social supports or help develop a network. Social support has been associated with superior medical outcomes in depressed patients after MI[162]; therefore if such social support does not exist, the consultant can work with the treatment team to consider options to improve the patient's support system. Such options could include participation in cardiac rehabilitation, having visiting nurses, joining a support group, or beginning psychotherapeutic treatment for depressive symptoms (CBT has been found to be effective in the treatment of post-MI depression,[163] and it carries no concern of drug–drug interactions). Such interventions should not be limited to post-MI patients; all cardiac patients can benefit from increased social support, and creating a more coherent system of support for a cardiac patient improves the chances of recovery.

Carefully consider the use of antidepressant medication. SSRIs, bupropion, and mirtazapine appear to be both safe and effective for patients with CAD, with few cardiovascular side effects. Therefore in most cardiac patients who meet criteria for MDD, these antidepressants can be administered at standard doses. The SSRIs sertraline, citalopram, and escitalopram have the additional advantage of having few drug–drug interactions and little interaction with the cytochrome P450 system; therefore we use these agents more frequently in cardiac patients on multiple medications. Bupropion also has few drug–drug interactions and may be the agent of choice in patients with co-morbid MDD and a desire to stop smoking.

The risks and benefits of antidepressant medications should be more carefully considered in patients with recent MI and probably by extension all patients with severe cardiac disease, a history of ventricular arrhythmia, or recent cardiac surgery. For most patients who have just had an MI or a CABG, we typically do not prescribe antidepressants for the onset of depressive symptoms within days after MI, both because such patients have not yet met criteria for MDD and because extensive data establishing the safety of these agents in the post-MI or postcardiac surgery period do not exist. For most patients who become depressed after an MI, a reasonable and conservative approach is to have the patient follow up with a psychiatrist (or primary care physician) within 2 to 3 weeks; then, if the patient remains depressed, he or she can start sertraline or another antidepressant.

Certain factors may cause a clinician to lean toward the earlier prescription of antidepressants. These include the following:

- Depression with suicidal ideation
- Severe depression that inhibits participation in rehabilitation or self-care
- The development of depressive symptoms during hospitalization in a patient with a history of severe depression
- An inability or unwillingness to follow up in the next 2 to 3 weeks (We often see patients who wish to see only their primary care physicians, and then only every 2 to 3 months. These patients are quite compliant with their medication regimen and would therefore take an antidepressant if prescribed on discharge, but they would be unlikely to return to see their physician in the next 6 weeks.)

When one or more of these factors is present, we frequently initiate antidepressant therapy in the hospital in coordination with cardiology. As noted previously, when anxiety is present co-morbidly, it is best to use benzodiazepines when beginning an antidepressant, given that most antidepressants can cause initial anxiety or insomnia in the first few days of use.

CASE 2

Mr. B, a 52-year-old gentleman with a history of MDD, was admitted to the hospital with chest pain. His electrocardiogram showed ST-segment depression in the anterolateral leads, his cardiac enzymes were elevated, and he ruled in for an MI. Though he had not been depressed in the year before admission, he developed depressive symptoms in the days after his MI; psychiatric consultation was obtained.

On interview, Mr. B was dysphoric but alert, oriented, and able to actively engage in conversation with the interviewer. He reported depressed mood, anhedonia, and low energy, along with disturbed concentration and appetite; he denied significant anxiety. He denied feeling suicidal or being unable to care for himself. Mr. B reported one episode of relatively mild MDD 3 years ago that responded well to citalopram (20 mg per day, for 1 year); he had also had several episodes of "feeling low" for 3 to 5 days that spontaneously resolved. He appeared to be invested in getting better, he had a strong social support network, and he planned to follow up with his cardiologist shortly after his hospitalization.

Given Mr. B's relatively mild current depressive symptoms, his history of having only one mild episode of MDD, and his ability and willingness to follow up with his cardiologist, the consultant decided to defer antidepressant treatment while Mr. B was in the hospital. The consultant contacted Mr. B's cardiologist and they agreed that citalopram should be started (given Mr. B's history of good response to this medication) if he continued to be depressed at his follow-up appointment in 2 weeks.

Mr. B had an uneventful medical course and was discharged 3 days after his MI. He followed up in 2 weeks with his cardiologist; he remained depressed and was started on citalopram. He tolerated the citalopram (20 mg per day) well, and his depressive symptoms subsided over the next 8 weeks.

DELIRIUM IN CARDIAC PATIENTS

Patients with cardiac disease have long been found to have a propensity for delirium. In an era when open-heart surgery was common, the incidence of postcardiotomy delirium (PCD) was found to be 32%.[164] Despite advances in the treatment of cardiac illness and the use of noninvasive procedures to open coronary arteries and replace abnormal valves, general hospital patients with cardiac disease continue to suffer delirium at high rates (ranging from 3% to 72% depending on the specific illness and type of procedure).[165] High rates of co-morbid medical illness, complex medication regimens, and central nervous system (CNS) hypoperfusion due to poor cardiac output all contribute to elevated rates of delirium among cardiac patients. The general hospital psychiatrist should be aware of the special issues in the diagnosis and management of delirium in cardiac patients.

Epidemiology

Delirium and Cardiac Disease

Delirium is more generally reviewed elsewhere in this handbook; this section focuses more specifically on delirium in patients with cardiac illness.

Among cardiac patients in the general hospital, rates of delirium are high. A study of patients suffering acute MI found that approximately 20% suffered delirium during the hospitalization.[166] Though estimates vary widely, postoperative delirium affects about 20% to 25% of the patients undergoing cardiac surgery.[167–169] Furthermore, two studies of patients receiving IABP therapy found that 34% of such patients were delirious.[170,171]

Reports of risk factors for the development of delirium in cardiac patients have varied, but it is universally agreed that the etiology of delirium in cardiac patients is multifactorial, with different factors varying in importance from patient to patient. The risk factors for delirium in cardiac patients can be divided into three categories: patient demographic factors, biological and iatrogenic factors, and psychological factors.[165] Among patient demographic factors, increased age is associated with increased risk of delirium. There appears to be no difference in the rate of PCD between men and women.[172,173]

Among biological and iatrogenic factors, there are multiple preoperative risk factors for PCD (including a history of MI or stroke, diabetes, aortic insufficiency, decreased cardiac output, dehydration, electrolyte imbalance, and the use of anticholinergic drugs).[167,174,175] Intraoperatively, the use of on-pump CABG surgery is associated with an increased rate of intracerebral microemboli and dysfunction of several neurotransmitter systems (serotonergic, noradrenergic, dopaminergic, and anticholinergic). Cerebral microemboli and widespread neurotransmitter dysfunction are both associated with neurocognitive dysfunction and delirium.[176,177]

Postoperatively, factors related to the hospital setting may also increase the risk of delirium.[178] Sleep deprivation as the result of light, noise, and an unfamiliar setting can predispose patients to delirium. Furthermore, discomfort (resulting from a prolonged need to remain supine, IV catheters, or multiple painful procedures) may

be treated with narcotics or benzodiazepines, which can then induce delirium. Also, several cardiac medications (including β-blockers, angiotensin-converting enzyme [ACE] inhibitors, and digoxin) have been associated with delirium, particularly in the days before and after the surgery.[165]

Several psychological factors have been implicated as risk factors for PCD. In particular, preoperative depression, dementia, and executive dysfunction have all been associated with increased risk of postoperative dementia.[179] In one study of 998 successive preoperative patients, Smith and associates found that the more severe the executive dysfunction, the greater the risk of postoperative delirium.[180]

In short, rates of delirium are high among patients with cardiovascular disease. Acute MI, cardiac surgery, and cardiac failure requiring IABP support are each associated with high rates of delirium, and a number of risk factors for delirium have been established in the cardiac population.

Delirium and Medical Outcome

To our knowledge, there have been no studies investigating the outcome of delirium specifically in cardiac patients. However, a number of studies have examined the effects of delirium on the medical outcome of general hospital patients. Studies of ICU patients have found that delirium significantly increases length of stay (LOS) in the ICU,[182–185] overall length of hospitalization,[181,183,185] and amount of time on a ventilator[184]; one such study found that when other factors (e.g., severity of illness, age, gender, race, and days of benzodiazepine and narcotic drug administration) were controlled, delirium was the strongest independent determinant of hospital LOS.[181]

In addition to increased LOS in the ICU and hospital, delirium can significantly affect other important outcome measures. Delirium has been associated (independent of disease severity, age, and other medical and demographic factors) with significantly greater rates of functional decline during hospitalization, increased rates of admission to long-term care after admission, and reduced ability to perform activities of daily living compared with patients without delirium.[185–188]

Finally, and perhaps most important, delirium appears to be independently associated with increased mortality. Delirium is associated with high rates of in-hospital mortality.[185,188,189] Furthermore, prospective studies have found that delirium predicts mortality at 1,[190] 2,[191] and 3[192] years after discharge in elderly patients. In one study, each additional day the patient spent in delirium was associated with a 20% increased risk of prolonged hospitalization and a 10% increased risk of death.[193] These effects of delirium on life span are independent of medical co-morbidity, functional status, and baseline cognitive status.

In short, delirium is common among cardiac patients in the general hospital, including post-MI patients, patients undergoing cardiac surgery, and severely ill patients on IABP therapy. Multiple risk factors are associated with delirium in cardiac patients, and the causes for any particular patient's delirium are often multiple. Although the effects of delirium on outcome have not been studied specifically in cardiac patients, in the general medical population, delirium has been associated with increased LOS, worsened functional outcome, and increased mortality. Still needed are studies that examine the effects of delirium treatment on long-term outcome of cardiac patients in particular.

Differential Diagnosis of Delirium in the Cardiac Patient

A wide variety of medical conditions and medications can cause or exacerbate delirium, and it is helpful for the psychiatrist to use mnemonics (such as VINDICTIVE MAD,[148] cited in Chapter 10) to allow for a systematic approach to delirium. In the delirious cardiac patient, a number of specific causes should be carefully considered (Table 23–3). CNS hypoperfusion is a common mechanism of delirium in the cardiac population; this can result from poor cardiac output caused by CHF or myocardial ischemia, from co-morbid carotid disease, from CNS bleeding (in the setting of anticoagulation), or from relative hypotension.

The phenomenon of relative hypotension deserves special mention. Patients with baseline uncontrolled hypertension who are admitted with myocardial ischemia or another cardiac event are often placed on one or more antihypertensives, and blood pressure is run "low," with systolic blood pressure typically between 100 and 120 mm Hg. Such patients are likely to have significant baseline hypertension, which may lead to stiffening of cerebral vessels with impaired ability to autoregulate. When these patients' blood pressure is lowered to "normal" (significantly below their baseline blood pressure), cerebral hypoperfusion and ischemia may result, leading to delirium.

Other common causes of delirium in the cardiac patient include hypoxia during CHF, hypertensive encephalopathy, electrolyte abnormalities (e.g., hyponatremia in the

TABLE 23–3 Selected Causes of Delirium Among Cardiac Patients in the General Hospital

Central Nervous System Hypoperfusion
Myocardial infarction/ischemia
Cerebrovascular accident (ischemic or hemorrhagic)
Hypovolemia (due to dehydration or bleeding)
Relative hypotension
Other Central Nervous System Disorders
Dementia (of any type)
Major depressive disorder
Other General Medical Conditions
Electrolyte abnormalities (especially sodium with diuretic administration)
Thyroid abnormalities
Hypertensive encephalopathy
Hypoxia (during pulmonary edema)
Infections (e.g., pneumonia, urinary tract infections)
Alcohol withdrawal
Cardiopulmonary bypass
Medication-Related Causes
Digoxin toxicity
Narcotic analgesics
Benzodiazepines
Anticholinergic medications
H_2-blockers

context of diuretic therapy), and medication effects (e.g., digoxin toxicity). The general hospital psychiatrist should rule out each of these potential etiologies of delirium in the cardiac patient.

Psychopharmacologic Issues in the Delirious Cardiac Patient

As noted in the American Psychiatric Association's *Practice Guideline for the Treatment of Patients with Delirium*,[194,195] the use of medications is an important component of a multipronged approach to the psychiatric management and treatment of delirium; such an approach also includes monitoring and ensuring safety, educating the patient and family regarding the illness, and implementing environmental and supportive interventions (e.g., placing the patient near the nursing station and frequently reorienting the patient). This chapter will not discuss the treatment of delirium in depth (see Chapter 10), but it will touch on the topics relevant to the delirious cardiac patient.

In general, psychotropic agents are used for the supportive treatment of delirium. They can reduce agitation and psychotic symptoms and may help normalize the sleep–wake cycle. They usually are not the primary treatment or antidote for delirium (i.e., determining and specifically treating the etiology of the delirium), but they can reduce the risk of patient harm and alleviate patient distress until the etiology is identified and effectively treated.

Antipsychotics are the symptomatic treatment of choice for most delirious patients. These agents effectively reduce agitation and provide sedation for the delirious patient; moreover, they are generally quite safe. The greatest experience has been with haloperidol. This agent can be given orally or intramuscularly, but the IV form is both more rapidly acting and much less associated with the development of extrapyramidal symptoms (EPS); prospective study[196] and clinical experience have found the rate of EPS with IV haloperidol to be minimal. Haloperidol generally has no significant effects on heart rate, blood pressure, or respiratory status, and it has essentially no anticholinergic effects.

Haloperidol has, however, been associated with the development of torsades de pointes (TDP), a malignant polymorphic ventricular arrhythmia that can occur with medications that lengthen the cardiac QTc interval. More than two dozen cases of TDP have been reported with haloperidol,[197–199] and rates of TDP from haloperidol in the treatment of delirious patients have ranged from 0.36% to 3.5%.[197,200] TDP appears more common at high doses (> 35 mg per day) of haloperidol, though it has also occurred at low doses.[197] Because hypokalemia and hypomagnesemia have been associated with the development of TDP, it is recommended that patients receiving IV haloperidol have these electrolytes monitored and repleted as needed. IV droperidol has also been used effectively in the treatment of delirium, though concerns about its propensity to cause TDP have significantly reduced its availability and use.

More recently, atypical antipsychotics, especially risperidone[201,202] and olanzapine,[203] have been used in the treatment of delirium. These agents are also well tolerated; risperidone and quetiapine can cause orthostatic hypotension, and olanzapine has mild anticholinergic effects, but in general, these agents have little effect on heart rate, blood pressure, or respiratory status and can be safely used in cardiac patients.

Several studies have evaluated the use of atypical antipsychotics in delirious patients. In a small prospective study, Mittal and co-workers found that cognitive and behavioral symptoms of delirium improved with risperidone.[204] A double-blind study of haloperidol and risperidone found no difference in the response rates of delirious patients.[205] Another observational study of 64 patients found risperidone to be clinically effective in 90% of delirium cases.[206]

Comparative studies of olanzapine and haloperidol have shown similar improvements in symptoms of delirium with some increased sedation in patients treated with olanzapine.[207,208] Furthermore, quetiapine has been reported to be a safe and effective treatment of delirium in multiple studies (retrospective, case series, and open prospective).[209,210] Finally, aripiprazole has also been reported to be of benefit in treating delirium in a case series.[211]

Studies comparing haloperidol and atypical antipsychotics have not identified any clinical advantages to use of an atypical agent over use of haloperidol.[211,212] However, EPS have been seen less often after use of atypical agents than with haloperidol—although studies evaluating adverse effects are limited in scope and size.[213] No study has examined the efficacy or tolerability of atypical antipsychotics in the specific population of cardiac patients.

There have been concerns about the potential for atypical antipsychotics to cause QTc prolongation (potentially predisposing to TDP), especially in patients with cardiac disease. To address this, a study of the effects of a number of antipsychotics on the QTc of 154 subjects was undertaken.[214] In the study six antipsychotics (thioridazine, haloperidol, ziprasidone, risperidone, quetiapine, and olanzapine) were orally administered to the highest dose tolerated. Thioridazine (the antipsychotic most associated with TDP with oral admistration[215]) and ziprasidone were associated with the greatest QT prolongation, whereas olanzapine and haloperidol had the least. It is difficult to extrapolate the results of this study to delirious cardiac patients, however, because the subjects were largely healthy young men without co-morbid medical illness.

Furthermore, the Food and Drug Administration recently issued a black box warning about the increased risk of sudden death associated with the use of all antipsychotic medications in demented elderly patients. Psychiatrists treating delirium in such patients must be thoughtful in balancing the risks of a persistent delirium with the risk highlighted by the black box warning.[216]

Recently, several studies have evaluated the efficacy of antipsychotic medications preoperatively to reduce the risk of patients developing delirium. A small, randomized, placebo-controlled trial found that haloperidol prophylaxis in patients undergoing gastrointestinal surgery reduced the postoperative incidence of delirium.[217] Delirium prophylaxis with atypical antipsychotics has also been studied. In a study by Prakanrattana and associates, 126 patients receiving cardiac surgery on bypass were randomized to receive risperidone or placebo after awakening postoperatively.[218] The delirium incidence (but not other postoperative outcomes) was significantly lower in the risperidone group

as compared with the placebo group. Lastly, a randomized, placebo-controlled study of olanzapine in orthopedic surgery found that patients treated with olanzapine had a lower incidence of postoperative delirium.[219] Treatment of cardiac patients with delirium with benzodiazepine monotherapy is generally contraindicated because these agents can worsen confusion or cause paradoxical disinhibition, especially in elderly, demented, or brain-injured patients. However, benzodiazepines are the treatment of choice in delirium secondary to alcohol or benzodiazepine withdrawal and in delirious patients unable to tolerate high doses of antipsychotics (or who have significant cardiovascular side effects such as hypotension). Benzodiazepines may be used in combination with antipsychotics in the symptomatic treatment of delirium.

Other agents may be used to treat certain delirious states in cardiac patients. For example, physostigmine can be used to treat delirium resulting from anticholinergic toxicity,[220] naloxone can be used to treat delirium caused by opioid intoxication, and IV thiamine can be administered to those with Wernicke's encephalopathy.

The Practical Management of the Delirious Cardiac Patient

As with other conditions involving cardiac patients, the management of delirium involves careful diagnosis and the consideration of co-morbid conditions. Once diagnosis and etiology have been established, the general hospital psychiatrist can then implement optimal behavioral and nonpharmacologic strategies and intelligently use psychotropic agents that reduce medical risk while effectively decreasing symptoms:

Make an informed diagnosis of delirium, and carefully consider potential etiologies. Delirium is characterized by an acute onset, disorientation, poor attention, fluctuation of levels of consciousness, and alterations in sleep–wake cycle. Psychotic symptoms, anxiety, worry, and reports of depressed mood may or may not be present. A careful review of the chart and cognitive evaluation (that considers orientation, attention, and executive function) can allow the consultant to use these factors to distinguish delirium from other psychiatric illnesses. Once a diagnosis has been made, the psychiatrist should work to consider all possible causes of delirium. The cause of delirium is frequently multifactorial; therefore the identification of one potential contributing factor of delirium should not preclude the search for further potential abnormalities leading to an acute confusional state. The consultant should pay special attention to the initiation and termination of medications and their relationship to the onset of delirium; a careful review of nursing medication sheets often reveals a wealth of information that can provide important answers regarding a delirium of unknown etiology.

Aggressively treat all potential etiologies of delirium. Treating the core etiology of delirium is the only way to definitively reverse delirium; all other behavioral and pharmacologic remedies are symptomatic treatments that reduce risk and increase comfort until the primary etiologies of the delirium resolve. Therefore treatment of urinary tract infections, vitamin B_{12} deficiency, mild metabolic abnormalities, and other seemingly minor contributing factors to delirium is absolutely crucial.

Use nonpharmacologic strategies to minimize confusion and ensure safety. Having the patient situated near the nursing station or in other areas where the patient can be frequently monitored can reduce the risk of falls, wandering, or other dangerous actions. Placing the patient in a room with a window and a clock—to help orient patients to day–night cycles—can also be useful. The use of Posey vests, sitters, or locked restraints may be required when a delirious patient's inability to safely navigate places him or her at risk; in almost all cases, medication should be given in combination with physical restraint to reduce discomfort and risk of harm while in restraints. The presence of reassuring family members or friends at the bedside can mitigate paranoia and agitation, whereas visitors that overstimulate the patient may worsen symptoms. The consultant may recommend that the team either encourage or dissuade interaction with certain visitors depending on the response of the patient's symptoms to the visitors.

Use antipsychotic medications to reduce agitation and psychotic symptoms and regulate the sleep–wake cycle. IV haloperidol is often the drug of choice for agitated, paranoid, or hyperactive patients with delirium. As noted previously, this agent is associated with low rates of EPS, and it has little effect on heart rate or blood pressure. It is rapidly effective in the IV form. Cardiac patients may be at increased risk for TDP, and therefore risk factors for this arrhythmia (e.g., prolonged QTc interval and electrolyte abnormalities) must be considered before its use. The protocol used at the MGH (Table 23–4) for the use of IV haloperidol

TABLE 23–4 Massachusetts General Hospital Protocol for IV Haloperidol in Agitated Delirious Patients

Check pre-haloperidol QTc interval.
If QTc > 450 ms, proceed with care.
If QTc > 500 ms, consider other options.
Check potassium and magnesium, and correct abnormalities.
Aim for potassium > 4 mEq/L, magnesium > 2 mEq/L.
Give dose of haloperidol (0.5–10 mg) based on level of agitation and patient's age and size.
Goal is to have patient calm and awake.
Haloperidol precipitates with phenytoin and heparin; flush line before giving haloperidol if these agents have been used in the same intravenous tubing.
Wait 20-30 minutes. If patient remains agitated, double dose.
Continue to double dose every 30 minutes until patient is calm.
Follow QTc interval to ensure that QTc is not prolonging.
If QTc increases by 25% or becomes >500, consider alternative treatments.
Once effective dose has been determined, use that dose for future episodes of agitation.
Depending on likely course of delirium, may schedule haloperidol or give on as-needed basis.
For example, may divide previous effective dose over next 24 hours, giving every 6 hours.
Or may simply give effective dose as needed for agitation.
Consider small dose at night to regulate sleep–wake cycle in all delirious patients.

considers these risk factors for TDP and uses a progressive dosing schedule. An initial dose (from 0.5 to 10 mg based on the age and size of patient and the extent of agitation) is selected and administered to the patient. If the patient is not calm within 20 to 30 minutes, the dose is doubled and continues to be doubled every 20 to 30 minutes until the patient is calm. This effective dose is then used when and if the patient again becomes agitated. Though most patients require standard doses of haloperidol (2 to 10 mg), some patients have required (and safely received) thousands of milligrams for agitation.[221]

If an agitated, delirious patient is or becomes unable to receive IV haloperidol (e.g., because of QTc prolongation), there are a number of other options. Sublingual olanzapine wafers are also fast-acting and effective in the treatment of delirium. Mildly agitated patients willing to take oral medications can be given oral atypical antipsychotics, such as risperidone, olanzapine, or quetiapine. Finally, patients whose agitation requires rapidly acting IV medication and who cannot receive IV antipsychotics may be given narcotics (e.g., morphine) or benzodiazepines (e.g., lorazepam) parenterally when immediate sedation is required; though these agents may worsen confusion, they are effective in the short term, when sedation is urgently needed. IV benzodiazepines are also the agents of choice in delirium tremens caused by benzodiazepine or alcohol withdrawal.

Once the agitated delirious patient has been safely and adequately sedated, there is often a question of whether to schedule antipsychotic medication or to use it on an as-needed basis for agitation. Such a decision may depend on the likely duration of the delirium, if this can be determined. For example, if the delirium is secondary to CNS hypoperfusion in a patient with low cardiac output on an IABP, such delirium may well be prolonged, and scheduling of an antipsychotic would be reasonable. In contrast, delirium in an elderly cardiac patient resulting from narcotic administration may be short-lived once the narcotic has been eliminated, and standing antipsychotics may not be needed. In most cases of delirium, we have found that it is often reasonable to schedule a low dose of IV haloperidol or an oral atypical antipsychotic at bedtime to help regulate the sleep–wake cycle, which is often seriously perturbed in delirious patients. We have found that by ensuring adequate sleep at appropriate hours, delirious cardiac patients have the best possible chance to recover.

CASE 3

Mr. C, a 64-year-old man with three-vessel CAD and no significant psychiatric history, was admitted for CABG. Though he was alert, oriented, pleasant, and cooperative before his surgery, he became angry and threatening 2 days later, reporting that the nurses were the "minions of the devil" and that he needed to leave the hospital immediately; notes revealed that he had not slept for 24 hours. Psychiatry was urgently consulted for "psychosis and capacity to leave against medical advice."

The psychiatrist found Mr. C sitting on his bed, wearing only his pajama top. He angrily reported that the nurses were stealing money from him and had injected "poisons" into him. He was disoriented to time and place, and he was unable to attend to conversation for more than a few seconds. He had pulled off his telemetry leads and not allowed the nurses to check his vital signs. The psychiatrist was able to get Mr. C to agree to stay for the moment, and after confirming a normal postoperative QTc interval and normal electrolyte levels, he persuaded Mr. C to accept an injection of 3 mg IV haloperidol. After 20 minutes Mr. C became sedated, and he fell asleep after 45 minutes.

When Mr. C's leads were reattached and vital signs checked, he was noted to have new-onset atrial fibrillation with a rate of 119. His heart rate was slowed with the use of β-blockers, and he returned to normal sinus rhythm within 12 hours. He received two further doses of IV haloperidol, and 25 mg of quetiapine each night. His delirium slowly resolved over the next 6 days, coinciding with resolution of his atrial fibrillation and with treatment of a urinary tract infection, and the quetiapine was discontinued on his discharge to a cardiac rehabilitation facility.

Sexual Disorders and Sexual Dysfunction

24

Linda C. Shafer, M.D.

A comprehensive psychiatric evaluation of any patient in the general hospital setting should include close attention to complaints, impairments, and deviations of sexual function. Although on occasion, sexual problems are the primary reason for consultation (particularly among patients admitted to urologic or gynecologic services), more often they may provide important clues about an underlying medical or psychologic condition. Consider the "difficult" patient on obstetrics who repeatedly refuses gynecologic exams, the formerly mild-mannered elderly gentleman who now shouts obscenities and gropes at nurses, or the sexually-provocative patient who evokes strong reactions from the medical team. Could the patient on obstetrics have a history of sexual trauma, the elderly man a frontal lobe tumor, or the provocative patient a personality disorder? These are a few of many examples that serve to highlight the role that understanding sexuality plays in caring for patients both compassionately and effectively.

The consulting psychiatrist should also be reminded of the importance that being able to maintain a healthy sexual life holds for many patients, regardless of the reason for hospitalization. Sexuality may take on even greater significance for patients suffering from illness that directly impairs sexual function, because of the difficulties both real and perceived. Psychiatric consultants should be alerted to high rates of sexual problems in patients with chronic diseases (especially cardiovascular disease, cancer, diabetes, neurologic problems, end-stage renal disease, and pain). Many chronic diseases result in depression, which in turn contributes to decreased sexual desire. Moreover, psychological reactions to existing illnesses run the gamut, from fear that sex can kill (post–myocardial infarction) to distress over low sexual self-image (post–disfiguring surgery), to avoidance of sex, to fear of pain during sex, to fear that sexual advances will be rejected, all leading to decreased sexual intimacy.[1]

When offering suggestions for patient management, such as prescribing a new psychotropic medication, care should be taken to minimize or treat sexual side effects as much as is possible. This may also help to improve patient rapport and compliance. In cases where sexual dysfunction appears to have a psychological component, or where longer-term behavioral, psychotherapeutic, or pharmacologic therapy may be warranted, referral for outpatient psychiatric care can be arranged.

The purpose of this chapter is two fold. The first aim is to assist the consulting psychiatrist in developing an approach to assessing sexual issues (including creation of a differential diagnosis and a management plan) as they may appear in the inpatient setting. The second aim is to educate the consulting psychiatrist on sexual disorders of primary psychological and mixed psychological and organic origins, so that appropriate outpatient care can be arranged, if necessary. In this way, the transition from inpatient care to outpatient follow-up can be optimized.

EPIDEMIOLOGY AND RISK FACTORS

Sexual disorders are extremely common. It has been estimated that 43% of women and 31% of men in the United States suffer from sexual dysfunction.[2] In addition, lack of sexual satisfaction is associated with significant emotional (including depression and marital conflict) and physical (e.g., cardiovascular disease and diabetes mellitus) problems.[2,3]

Sexual disorders affect individuals across the epidemiologic spectrum, and risk factors for them have been identified. Overall, the prevalence of sexual dysfunction is greater in women than it is in men. Sexual dysfunction increases with age, regardless of gender. Men and women with higher levels of education have fewer sexual problems and less anxiety about sexual issues.[2,3] Co-existing psychiatric or medical conditions (including diabetes mellitus, cardiovascular disease, other genitourinary disease) are associated with a decline in sexual function in both men and women, as is diminished general health status.[2–4] It has been estimated, for example, that 10% to 54% of patients do not resume sexual activity after myocardial infarction (MI); 45% to 100% of patients with uremia or who are undergoing hemodialysis experience low sexual desire; and 26% to 50% of patients with untreated depression experience erectile dysfunction (ED).[5]

Among those with obesity and a sedentary lifestyle, weight loss and increased physical activity are associated with improved sexual function.[6–8] The association between race and sexual dysfunction is more variable.[2,9] There is a strong association between ED and vascular diseases.[10] In fact, ED may be the initial complaint in patients with underlying cardiovascular disease.[11] Recent evidence suggests an increased risk of ED among individuals who possess specific genetic mutations (e.g., polymorphisms in genes for nitric oxide synthase and Rho kinase) in molecular pathways responsible for resisting endothelial dysfunction.[12] Sexual trauma for both sexes is associated with long-term negative changes in sexual function.[13] A strong association exists between paraphilias and childhood attention-deficit/hyperactivity disorder (ADHD), substance abuse, major depression or dysthymia, and phobic disorder.[14,15] The prototypical paraphiliac is young, white, and male.

PATHOPHYSIOLOGY

The ability to maintain adequate sexual function depends on complex interactions among the brain, peripheral nerves, hormones, and the vascular system. Disease states in these systems are associated with sexual dysfunction. However, no single comprehensive view has been established.

Brain regions involved in sexual arousal include the anterior cingulate gyrus, prefrontal cortex, thalamus, temporo-occipital lobes, hypothalamus, and amygdala.[16] The neurotransmitters dopamine and norepinephrine appear to stimulate sexual function, whereas serotonin may inhibit orgasm. Testosterone, estrogen, progesterone, oxytocin, and melanocortin hormones have a positive effect on sex, but prolactin is an inhibitor.[17,18]

Recent data suggest a central role for nitric oxide (NO) at the vascular level. In women, NO is thought to control vaginal smooth muscle tone; higher levels of NO are associated with increased vaginal lubrication. In men, NO allows for increased intrapenile blood flow, which facilitates erection. NO acts via the generation of cyclic guanosine monophosphate (cGMP), which has vasodilatory properties. Phosphodiesterase type-5 (PDE-5) inhibitors (the prototype of which is sildenafil) act to inhibit the degradation of cGMP, which prolongs the effects of NO.[19] Cholinergic fibers, prostaglandin E, vasoactive intestinal peptide (VIP), and possibly neuropeptide Y (NPY) and substance P may also improve vasocongestion.[20]

Sexual dysfunction may be best understood by having knowledge of the stages of the normal sexual response; these vary with age and physical status. Medications, diseases, injuries, and psychological conditions can affect the sexual response in any of its component phases, and can lead to different dysfunctional syndromes (Table 24–1).[21] Three major models of the human sexual response have been proposed.

Masters and Johnson[22,23] developed the first model of the human sexual response, consisting of a linear progression through four distinct phases: (1) excitement (arousal), (2) plateau (maximal arousal before orgasm), (3) orgasm (rhythmic muscular contractions), and (4) resolution (return to baseline). Following resolution a refractory period exists in men.

Kaplan[24] modified the Masters and Johnson model by introducing a desire stage; this model emphasized the importance of neuropsychological input in the human sexual response. The Kaplan model consisted of three stages: (1) desire; (2) excitement/arousal (including an increase in peripheral blood flow); and (3) orgasm (muscular contraction).

Basson,[25] who recognized the complexity of the female sexual response, more recently proposed a biopsychosocial model of female sexuality that consisted of four overlapping components: (1) biology, (2) psychology, (3) sociocultural factors, and (4) interpersonal relationships. Notably, this conceptualization suggested that women may be receptive to, and satisfied with, sex even in the absence of intrinsic sexual desire if other conditions were met (such as emotional closeness). These other factors could then potentially stimulate direct sexual desire. The fact that physical measurements of female arousal (such as increased vaginal secretions) are poorly correlated with sexual satisfaction lends support for Basson's view.

Aging is associated with changes in the normal human sexual response. Men are slower to achieve erections and require more direct stimulation of the penis to achieve erections. Women have decreased levels of estrogen, which leads to decreased vaginal lubrication and narrowing of the vagina. Testosterone levels in both sexes decline with age, which may result in decreased libido.[26]

TABLE 24–1 Classification of Sexual Dysfunctions

IMPAIRED SEXUAL RESPONSE PHASE	FEMALE	MALE
Desire	Hypoactive sexual desire Sexual aversion	Hypoactive sexual desire Sexual aversion
Excitement (arousal, vascular)	Sexual arousal disorder	Erectile disorder
Orgasm (muscular)	Orgasmic disorder	Orgasmic disorder Premature ejaculation
Sexual pain	Dyspareunia Vaginismus	Dyspareunia

CLINICAL FEATURES AND DIAGNOSIS

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)[27] classifies sexual disorders into four major categories. *Sexual dysfunction* is characterized by disturbances in sexual desire and/or psychophysiologic changes in the sexual response cycle. *Paraphilias* are characterized by recurrent, intense sexual urges that involve unusual objects or activities. *Gender identity disorders* involve persistent cross-gender identification and discomfort with one's assigned sex. *Sexual disorders not otherwise specified* are used to code disorders that are not classifiable into any of the other categories. All sexual disorders must cause clinically significant distress or an impairment of social function before a diagnosis can be made. Disorders are classified as *primary*, when there has never been a period of satisfactory function, or *secondary*, when the difficulty occurs after adequate function had been obtained.[27]

The diagnosis of a sexual problem relies upon a thorough medical and sexual history. Physical examination and laboratory investigations may be crucial to identification of organic causes of sexual dysfunction. Primary psychiatric illness may present with sexual complaints (Table 24–2).[27] However, most sexual disorders have both an organic and a psychological component. Physical disorders, surgical conditions (Table 24–3),[21,28] medications, and use or abuse of drugs (Table 24–4)[29] can affect sexual function directly or cause secondary psychological reactions that lead to a sexual problem. Psychological factors may predispose, precipitate, or maintain a sexual disorder (Table 24–5).[30,31]

APPROACH TO SEXUAL HISTORY-TAKING

The sexual history provides an invaluable opportunity to uncover sexual problems. Because patients are often embarrassed to discuss their sexuality with physicians or view sex

TABLE 24–2 Psychiatric Differential Diagnosis of Sexual Dysfunction

PSYCHIATRIC DISORDER	SEXUAL COMPLAINT
Depression (major depression or dysthymic disorder)	Low libido, erectile dysfunction
Bipolar disorder (manic phase)	Increased libido
Generalized anxiety disorder, panic disorder, posttraumatic stress disorder	Low libido, erectile dysfunction, lack of vaginal lubrication, anorgasmia
Obsessive–compulsive disorder	Low libido, erectile dysfunction, lack of vaginal lubrication, anorgasmia, "anti-fantasies" focusing on the negative aspects of a partner
Schizophrenia	Low desire, bizarre sexual desires
Paraphilias	Deviant sexual arousal
Gender identity disorder	Dissatisfaction with one's own sexual preference or phenotype
Personality disorder (passive–aggressive, obsessive–compulsive, histrionic)	Low libido, erectile dysfunction, premature ejaculation, anorgasmia
Marital dysfunction/ interpersonal problems	Varied
Fears of intimacy/ commitment	Varied, deep intrapsychic issues

as outside the realm of medicine, and because physicians are often reluctant to broach the topic of sex for fear of offending their patients, the need to make sexual history-taking a routine part of practice is paramount. Physicians should always attempt to be sensitive and nonjudgmental in their interviewing technique, moving from general topics to more specific ones. Questions about sexual function may follow naturally from aspects of the medical history (such as introduction of a new medication, or investigation of a chief complaint that involves a gynecologic or urologic problem).

Screening questions include: Are you sexually active? If so, with men, women, or both? Is there anything you would like to change about your sex life? Have there been any changes in your sex life? Are you satisfied with your present sex life? To maximize its effectiveness the sexual history may be tailored to the patient's needs and goals.[32] Physicians should recognize that paraphiliacs are often secretive about their activities, in part because of legal and societal implications. Patients should be reassured about the confidentiality of their interaction (except in cases where their behavior requires mandatory legal reporting, e.g., as with child abuse).

In taking a sexual history, the consulting psychiatrist should recognize that chronic illness often contributes to sexual dysfunction, whether by direct physical damage or associated psychological effects. Patients with cancer, end-stage renal disease, coronary artery disease, multiple sclerosis, and diabetes are all at increased risk of sexual problems. To explore the role physiologic illness may play in sexual dysfunction, consultants should ask questions about diseases, procedures, and medications that might affect hormone balance, disrupt normal anatomic genitalia, cause CNS dysfunction, damage vascular or peripheral nerve supply to sexual organs, or contribute to pain during sexual activity.[1]

Physical Examination and Laboratory Investigation

Though history-taking is often the most important tool in the diagnosis of sexual disorders, the physical examination may reveal a clear medical or surgical basis for sexual dysfunction. Special attention should be paid to the endocrine, neurologic, vascular, urologic, and gynecologic systems. Similarly, laboratory studies may be indicated, depending on the degree to which an organic cause is suspected.[5,16,18] There is no "routine sexual panel."

Screening tests can be guided by the history and physical examination. Tests for systemic illness include: complete blood count (CBC), urinalysis, creatinine, lipid profile, thyroid function studies, and fasting blood sugar (FBS). Endocrine studies (including testosterone, prolactin, luteinizing hormone [LH], and follicular stimulating hormone [FSH]), can be performed to assess low libido and ED. An estrogen level and microscopic examination of a vaginal smear can be used to assess vaginal dryness. Cervical culture and pap smear can be performed to investigate a diagnosis of dyspareunia. The nocturnal penile tumescence (NPT) test is valuable in the assessment of ED. If NPT occurs regularly (as measured by a RigiScan monitor), problems with erection are unlikely to be organic. Penile plethysmography is used to assess paraphilias by measurement of an individual's sexual arousal in response to visual and auditory stimuli.[33]

DIAGNOSTIC CRITERIA OF SPECIFIC SEXUAL DISORDERS

Male Disorders of Sexual Function

Male Erectile Disorder. Erectile dysfunction ("impotence") is defined as the inability of a male to maintain an erection sufficient to engage in intercourse; it is considered a problem if it occurs in more than 25% of attempts. Roughly 20 to 30 million American men suffer from ED; this symptom accounts for more than 500,000 ambulatory care visits to health care professionals annually. A number of risk factors for ED have been identified (Table 24–6). Between 50% and 85% of cases of ED have an organic basis. Primary (life-long) ED occurs in 1% of men under the age of 35 years. Secondary (acquired) ED occurs in 40% of men over the age of 60 years; this figure increases to 73% in men who are 80 years old. ED may be generalized (i.e., it occurs in all circumstances) or situational (i.e., it is limited to certain types of stimulation, situations, and partners). ED may be a symptom of a generalized vascular disease and should prompt further investigation.[2,10,34,35] Bicycle

TABLE 24–3 Medical and Surgical Conditions Causing Sexual Dysfunctions

ORGANIC DISORDERS	SEXUAL IMPAIRMENT
Endocrine	
Hypothyroidism, adrenal dysfunction, hypogonadism, diabetes mellitus	Low libido, impotence, decreased vaginal lubrication, early impotence
Vascular	
Hypertension, atherosclerosis, stroke, venous insufficiency, sickle cell disorder	Impotence, ejaculation and libido intact
Neurologic	
Spinal cord damage, diabetic neuropathy, herniated lumbar disc, alcoholic neuropathy, multiple sclerosis, temporal lobe epilepsy	Sexual disorder – early sign, low libido (or high libido), impotence, impaired orgasm
Local genital disease	
Male: Priapism, Peyronie's disease, urethritis, prostatitis, hydrocele	Low libido, impotence
Female: Imperforate hymen, vaginitis, pelvic inflammatory disease, endometriosis	Vaginismus, dyspareunia, low libido, decreased arousal
Systemic debilitating disease	
Renal, pulmonary, or hepatic diseases, advanced malignancies, infections	Low libido, impotence, decreased arousal
Surgical postoperative states	
Male: Prostatectomy (radical perineal), abdominal-perineal bowel resection	Impotence, no loss of libido, ejaculatory impairment
Female: Episiotomy, vaginal repair of prolapse, oophorectomy	Dyspareunia, vaginismus, decreased lubrication
Male and Female: Amputation (leg), colostomy, and ileostomy	Mechanical difficulties in sex, low self-image, fear of odor

riding has also been linked to penile numbness (associated with perineal nerve damage) and to ED (due to decreased oxygen pressure in the pudendal arteries).[36] Depression is a common comorbidity in patients with ED.

Male Orgasmic Disorder. This disorder ("retarded ejaculation") is defined as a persistent delay or absence of orgasm following normal sexual excitement. It is infrequent, with a lifetime prevalence of 2%; it occurs in men who are usually under the age of 35 years and who are sexually inexperienced. Retarded ejaculation is usually restricted to failure to reach orgasm in the vagina during intercourse. Orgasm can usually occur with masturbation or from a partner's manual or oral stimulation. The condition must be differentiated from retrograde ejaculation, where the bladder neck does not close off properly during orgasm, causing semen to spurt backward into the bladder. One must rule out retarded ejaculation in a couple who presents with infertility of unknown cause. The male may not have admitted his lack of ejaculation to his partner. Compared to men with other sexual dysfunctions, men with male orgasmic disorder have lower levels of relationship satisfaction, greater levels of distress, higher levels of health-related problems, and lower levels of self-reported sexual arousal despite strong penile response during psychophysiologic testing.[37,38]

Premature Ejaculation. This disorder is defined as recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it (most often less than 2 minutes after penetration or on fewer than 10 thrusts). The lifetime prevalence of premature ejaculation is 15%. Premature ejaculation is the most common male sexual disorder, affecting 30% of men. Prolonged periods of no sexual activity make premature ejaculation worse. If the problem is chronic and untreated, secondary impotence often occurs.[39]

Female Disorders of Sexual Function

Female Sexual Arousal Disorder. This disorder is defined as a persistent inability to attain or maintain an adequate lubrication–swelling response of sexual excitement. The lifetime prevalence is 60%. This condition is linked to problems with sexual desire. A lack of vaginal lubrication may lead to dyspareunia.[40–45]

Female Orgasmic Disorder. This disorder is defined as a recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Some women who can have orgasm with direct clitoral stimulation find it impossible to reach orgasm during intercourse. This is a normal variant of sensitivity that requires the pairing of direct clitoral contact with intercourse. Female orgasmic disorder has a lifetime prevalence of 35%. Approximately 5% to 8% of afflicted individuals are totally anorgasmic. Moreover, 30% to 40% of afflicted individuals are unable to achieve orgasm without clitoral stimulation during intercourse. The ability to reach orgasm increases with sexual experience. Claims that stimulation of the Grafenberg spot, or G-spot, in a region in the anterior wall of the vagina will cause orgasm and female ejaculation have never been substantiated. Premature ejaculation in the male may contribute to female orgasmic dysfunction.[41–45]

TABLE 24–4 Drugs and Medicines that Cause Sexual Dysfunction

DRUG	SEXUAL SIDE EFFECT
Cardiovascular	
Methyldopa	Low libido, impotence, anorgasmia
Thiazide diuretics	Low libido, impotence, decreased lubrication
Clonidine	Impotence, anorgasmia
Propranolol, metoprolol	Low libido, impotence
Digoxin	Gynecomastia, low libido, impotence
Clofibrate	Low libido, impotence
Psychotropics	
Sedatives	
Alcohol	Higher doses cause sexual problems
Barbiturates	Impotence
Anxiolytics	
Alprazolam, diazepam	Low libido, delayed ejaculation
Antipsychotics	
Thioridazine	Retarded or retrograde ejaculation
Haloperidol	Low libido, impotence, anorgasmia
Risperidone	Impotence
Antidepressants	
MAOIs (phenelzine)	Impotence, retarded ejaculation, anorgasmia
TCAs (imipramine)	Low libido, impotence, retarded ejaculation
SSRIs	
Fluoxetine, sertraline	Low libido, impotence, retarded ejaculation
Atypical (trazodone)	Priapism, retarded or retrograde ejaculation
Lithium	Low libido, impotence
Hormones	
Estrogen	Low libido in men
Progesterone	Low libido, impotence
Gastrointestinal	
Cimetidine	Low libido, impotence
Methantheline bromide	Impotence
Opiates	Orgasmic dysfunction
Anticonvulsants	Low libido, impotence, priapism

MAOI, Monoamine oxidase inhibitor; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant.

Vaginismus. This disorder is defined as recurrent involuntary spasm of the musculature of the outer third of the vagina, interfering with sexual intercourse. The frequency of this disorder is unknown, but it probably accounts for less than 10% of female sexual disorders. The diagnosis is often made on routine gynecologic examination when contraction of the vaginal outlet occurs as either the examining finger or the speculum is introduced. There is a high incidence of associated pelvic pathology. Life-long vaginismus has an abrupt onset, at the first attempt at penetration, and has a chronic course. Acquired vaginismus may occur suddenly, following a sexual trauma or a medical condition.[46]

TABLE 24–5 Psychological Causes of Sexual Dysfunction

Predisposing factors
Lack of information/experience
Unrealistic expectations
Negative family attitudes to sex
Sexual trauma: rape, incest
Precipitating factors
Childbirth
Infidelity
Dysfunction in the partner
Maintaining factors
Interpersonal issues
Family stress
Work stress
Financial problems
Depression
Performance anxiety
Gender identity conflicts

TABLE 24–6 Risk Factors Associated with Erectile Dysfunction

Hypertension
Diabetes mellitus
Smoking
Coronary artery disease
Peripheral vascular disorders
Blood lipid abnormalities
Peyronie's disease
Priapism
Pelvic trauma or surgery
Renal failure and dialysis
Hypogonadism
Alcoholism
Depression
Lack of sexual knowledge
Poor sexual technique
Interpersonal problems

Sexual Dysfunction Disorders Affecting Both Genders

Hypoactive Sexual Desire Disorder. This disorder is defined as a recurrent deficit or absence of sexual fantasies or a desire for sexual activity (taking into account factors affecting sexual function). The incidence of this disorder has increased from 37% in the early 1970s to 55% in the early 1980s. The lifetime prevalence of this condition is 40% in women and 30% in men.[47,48]

Dyspareunia. This disorder is defined as persistent genital pain associated with sexual intercourse. The prevalence of dyspareunia is 15% in females and 5% in males. Patients with dyspareunia often seek out medical treatment, but the physical examination is generally unremarkable, without genital abnormalities. If pain is caused solely by vaginismus or by a lack of lubrication, the diagnosis of dyspareunia is not made.[49]

Sexual Aversion Disorder. This disorder is defined as a persistent extreme aversion to genital sexual contact with a sexual partner. The exact incidence is unknown, but the condition is common. Primary sexual aversion is higher in men, but secondary aversion is higher in women. The syndrome is associated with phobic avoidance of sexual activity and/or the thought of sexual activity. One fourth of those with this condition also meet criteria for panic disorder. Affected individuals engage in intercourse once or twice a year. Patients tend to respond naturally to sexual relations if they can get past their high anxiety and initial dread.[50]

Paraphilias

Paraphilias. Most paraphilias are thought to have a psychological basis. Individuals with paraphilias have difficulty forming more socialized sexual relationships. Paraphilias may involve a conditioned response in which nonsexual objects become sexually arousing when paired with a pleasurable activity (masturbation). The diagnostic criteria and clinical features of the major paraphilias are summarized in Table 24–7.[27]

Gender Identity Disorder

Gender Identity Disorder. The onset of this disorder may be as early as 4 years of age, but the diagnosis cannot be made until adolescence or adulthood. In adolescents and adults, the disturbance is manifested by a variety of symptoms, such as preoccupation with getting rid of primary and secondary sex characteristics (e.g., requests for hormones or surgery), or a belief in being born the wrong sex. By late adolescence or adulthood, 75% of boys with a history of gender identity disorder as a child will have a homosexual or bisexual orientation. Children with gender identity disorder may have co-existing separation anxiety, generalized anxiety, and depression, whereas adolescents are at risk for depression, suicidal ideation, and suicide attempts. Adults with the condition often have co-existing anxiety and depression. Adult males may have a history of transvestic fetishism as well as other paraphilias. Associated personality disorders are common in male patients. One in 30,000 males and 1 in 100,000 females have sex-reassignment surgery.[51]

DIFFERENTIAL DIAGNOSIS OF SEXUAL DISORDERS

The differential diagnosis of sexual disorders includes medical and surgical conditions (see Table 24–3),[21,28] adverse effects of medications (see Table 24–4),[29] and other psychiatric disorders (see Table 24–2).[27] Before a primary sexual disorder is diagnosed, it is important to identify potentially treatable conditions (both organic and psychiatric) that manifest as problems with sexual function. For example, treatment of depression may improve erectile function. Although paraphilias often have a psychological basis, an organic cause should be considered if the behavior begins in middle age or later; there is regression from previously normal sexuality; there is excessive aggression; there are reports of auras or seizure-like symptoms before or during the sexual behavior; there is an abnormal body habitus; or there is an abnormal neurologic examination. See Table 24–8 for the psychiatric differential diagnosis of paraphilias.[27] Patients who present with gender identity disorder generally have normal physical findings and normal laboratory studies. The differential diagnosis includes nonconformity

TABLE 24–7 Diagnostic Criteria of Specific Paraphilias

DISORDER	DEFINITION	FEATURES
Exhibitionism	Exposure of genitals to unsuspecting strangers in public.	Primary intent is to evoke shock or fear in victims. Offenders are usually male.
Fetishism	Sexual arousal using nonliving objects (e.g., female lingerie).	Masturbation occurs while holding the fetish object. The sexual partner may wear the object.
Frotteurism	Sexual arousal by touching and rubbing against a nonconsenting person.	The behavior occurs in a crowded public place from which the offender can escape arrest.
Pedophilia	Sexual activity with a prepubescent child. The patient must be at least 16 years of age and be 5 years older than the victim.	Pedophilia is the most common paraphilia. Most of the victims are girls. Victims are often relatives. Most pedophiles are heterosexual.
Sexual masochism	Sexual pleasure comes from physical or mental abuse or humiliation.	A dangerous form of hypoxyphilia, where oxygen deprivation enhances arousal, and accidental deaths can occur.
Sexual sadism	Sexual arousal is derived from causing mental or physical suffering to another person.	Sexual sadism is mostly seen in men. It can progress to rape. 50% of those afflicted are alcoholic.
Transvestic fetishism	Cross-dressing in heterosexual males for sexual arousal.	The wife (partner) may be aware of the activity and help in the selection of clothes or insist on treatment.
Voyeurism	Sexual arousal by watching an unsuspecting person who is naked, disrobing, or engaging in sexual activity.	Most commonly occurs in men, but it can occur in women. Masturbation commonly occurs. A variant is telephone sex.
Paraphilia not otherwise specified	Paraphilias that do not meet criteria for any of the previous categories.	Categories include necrophilia (corpses), zoophilia (animals), urophilia (urine), and coprophilia (feces).

TABLE 24–8 Psychiatric Differential Diagnosis of Paraphilias

Mental retardation
Dementia
Substance intoxication
Manic episode (bipolar disorder)
Schizophrenia
Obsessive–compulsive disorder
Gender identity disorder
Personality disorder
Sexual dysfunction
Nonparaphiliac compulsive sexual behaviors
Compulsive use of erotic videos, magazines, or cybersex
Uncontrolled masturbation
Unrestrained use of prostitutes
Numerous brief, superficial sexual affairs
Hypersexuality/sexual addiction

to stereotypical sex role behaviors, transvestic fetishism (cross-dressing), and schizophrenia (e.g., with the delusion that one belongs to the other sex).

TREATMENT

Organically-Based Treatment

The essence of treatment for sexual disorders involves the treatment of preexisting illnesses (e.g., diabetes); discontinuation or substitution of offending medications; reduction of alcohol, smoking, or both; increase in exercise; improvement in diet; and addition of medications for psychiatric conditions (e.g., depression). Although many medications for the treatment of hypertension inhibit sexual function, the angiotensin II–receptor blockers (e.g., losartan), are not associated with sexual side effects and may actually help prevent or correct sexual problems (such as sexual dissatisfaction, low frequency of sex, ED).[52] Any hormone deficiency should be corrected (e.g., addition of testosterone for hypogonadism, thyroid hormone for hypothyroidism, estrogen/testosterone for postmenopausal females, or bromocriptine for elevated prolactin after neuroimaging of the pituitary). Many medical illnesses are associated with physiologic and psychological impairments that when treated improve sexual function; selected examples are shown in Table 24–9.[5]

Psychotropic Medication–Induced Sexual Dysfunction

Antidepressants

Sexual dysfunction is a commonly reported side effect of selective serotonin reuptake inhibitors (SSRIs). According to some estimates, as many as 30% to 40% of SSRI users experience anorgasmia, 10% to 20% of patients experience decreased libido or ED, and 30% to 50% experience low desire.[5,53] Strategies to treat SSRI-induced sexual dysfunction are presented in Table 24–10.[53–62] Monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs) also cause sexual problems. Because of their sexual side effects, the SSRIs have been used with success to treat premature ejaculation and reduce compulsive sexual acts associated with Alzheimer's disease,[63] paraphiliac behavior,[64] and sexual obsessions in obsessive–compulsive disorder (OCD) spectrum patients.[65]

Antipsychotics

Typical antipsychotics (e.g., haloperidol and thioridazine) as well as atypical agents (e.g., risperidone and clozapine) are all associated with sexual dysfunction. Hyperprolactinemia may play a causal role. Most second-generation antipsychotics (e.g., olanzapine, quetiapine, aripiprazole, and ziprasidone) are associated with fewer sexual side effects.[66] Antipsychotics have also been used to dampen sexually inappropriate behaviors and paraphilias.[67]

Premature Ejaculation

There is no Food and Drug Administration (FDA)-approved treatment for premature ejaculation. However, the SSRIs (e.g., fluoxetine, sertraline, and paroxetine), used continuously or intermittently (2 to 12 hours before sex), can cause delayed or retarded ejaculation, which can treat premature ejaculation. Low doses may be effective. Clomipramine (a TCA) may be more effective in delaying

TABLE 24–9 Specific Treatments for Sexual Dysfunction Attributable to Medical Illness

DISEASE	ASSOCIATED IMPAIRMENT CAUSING SEXUAL DYSFUNCTION	TREATMENT
Coronary artery disease	Fear of recurrent MI	Reassure, exercise
	Fear of nitrate-PDE-5 interaction	Switch from nitrate to trimetazidine (not FDA-approved)
	Concurrent depression	Treat depression
Renal failure	Low testosterone (men)	Consider testosterone
	Hyperprolactinemia	Try bromocriptine, 25(OH)D
	Low zinc levels	Consider zinc replacement
	Anemia	Erythropoietin
	Uremic menorrhagia	Consider cyclic or daily progesterone
	Concurrent depression	Treat depression
	Estrogen deficiency	Local estrogen therapy
Urinary incontinence	Urinary leakage during sex	Consider surgery
Diabetes	Hyperglycemia	Improve glycemic control
Elevated prolactin	Hyperprolactinemia	Treat underlying cause
Adrenal disease	Diminished adrenal hormones	Consider DHEA

TABLE 24–10 Treatment Strategies for SSRI-Induced Sexual Dysfunction

STRATEGY	COMMENTS
Decrease the dose	May diminish antidepressant effect Consider in patients on high doses
Switch SSRIs	Paroxetine linked to highest rates of sexual dysfunction Fluvoxamine may have fewer sexual side effects No clear evidence to support this strategy
Switch to a non-SSRI agent	Data support bupropion, mirtazapine, duloxetine, nefazodone Consider transdermal selegiline Not FDA-approved: tianeptine, reboxetine, moclobemide Venlafaxine and desvenlafaxine *not* superior to SSRIs
Add "antidote" drug	Best evidence to support PDE-5 inhibitors (sildenafil, tadalafil, vardenafil), next bupropion, then buspirone (high dose) PDE-5 inhibitors not only improve erectile dysfunction but also arousal and orgasm even in some women on SSRIs Small studies support maca root (herbal agent) Consider amantadine, dextroamphetamine, methylphenidate, ginkgo biloba, granisetron, cyproheptadine, yohimbine, atomoxetine (data mixed)
Take a drug holiday	Limited studies show no clear benefit to this approach May precipitate withdrawal and encourage noncompliance
Await spontaneous remission	Rarely occurs

ejaculation than the SSRIs.[68] Dapoxetine, an SSRI in phase III clinical trials with a rapid onset and short half-life, is being studied as an on-demand treatment for premature ejaculation.[69] Topical anesthetic creams (such as lidocaine derivatives) appear to be successful in slowing ejaculation without inducing the systemic side effects of antidepressants; however, they can cause local skin irritation and penile numbing that sometimes leads to erectile problems. The most popular of these agents is EMLA cream, a combination of lidocaine and prilocaine.[70] When the premature ejaculation is secondary to ED, PDE-5 inhibitors should be used to treat ED first.

Erectile Dysfunction

The mainstay of treatment for ED is the use of oral PDE-5 inhibitors (e.g., sildenafil, vardenafil, and tadalafil), which can help men with a wide range of conditions; they are easy to use, and have few adverse effects (Table 24–11).[19,61,71,72] The PDE-5 inhibitors are effective in the treatment of antidepressant-induced ED and retarded ejaculation. Of note, the PDE-5 inhibitors are metabolized by P450 3A4 and 2C9 isoenzyme systems. Patients who take potent inhibitors (including grapefruit juice, cimetidine, ketoconazole, erythromycin, and ritonavir) of these P450 isoenzyme systems, should have a lower starting dose of a PDE-5 inhibitor. Statins may also help improve the efficacy of PDE-5 inhibitors.

Other oral agents are used to treat ED. Yohimbine (Yocon), an α_2-adrenergic inhibitor, has been available for many years and it may be useful in the treatment of psychogenic ED; however, its efficacy is uncertain. Phentolamine (Vasomax) is an α-blocker (not yet FDA-approved), that may produce erections by dilation of blood vessels. Apomorphine (Uprima) is a centrally acting D_1/D_2 dopamine receptor agonist administered sublingually (not yet FDA-approved). Although efficacious in the stimulation of erections, the drug is limited by its side effects, especially nausea and vomiting.[19] Centrally acting melanocortin receptor agonists (in development as an intranasal preparation) appear to be effective, but side effects (flushing, nausea) may limit their utility.[73] The amino acid L-arginine (an NO precursor) appears promising in men.

Second-line treatments for ED include use of intrapenile injection therapy, intraurethral suppository therapy, and vacuum-assisted devices (Table 24–12). The third-line treatment for ED is surgical implantation of an inflatable or malleable rod or penile prosthesis. Endarterectomy may correct ED in certain patients with underlying vascular disease.[74]

Female Sexual Dysfunction

The only approved medical–surgical intervention for the treatment of female sexual dysfunction is EROS-CTD, a clitoral suction device, which is used to increase vasocongestion and engorge the clitoris for better sexual arousal and orgasm. Numerous drug trials are being done using medications approved for male sexual dysfunction (PDE-5 inhibitors), hormone-based therapies, and novel agents. In general, PDE-5 inhibitors are not effective in improving female sexual function, but they may benefit some women who exhibit greatly diminished genital vasocongestion.[75] PDE-5 inhibitors also appear to be effective for women with SSRI-induced sexual dysfunction.

Testosterone (in a variety of forms), in combination with estrogen (Estratest), has been shown to improve libido, sexual arousal, and the frequency of sexual fantasies in surgically and naturally postmenopausal women.[76] However, it requires a relatively high dose, and because long-term estrogen use (including combination with progestin) is associated with risks, it is not routinely recommended. Recently, transdermal testosterone was shown to improve sexual function in postmenopausal women *not* taking estrogen, but long-term safety data are not available.[77] Tibolone, a steroid hormone with estrogenic, androgenic,

TABLE 24–11 First-Line Treatment for Erectile Dysfunction: Comparison of PDE-5 Inhibitors

MEDICATION	DOSE	ONSET	DURATION	FOOD INTERACTION	ADVANTAGES	SIDE-EFFECTS	CONTRAINDICATIONS
Sildenafil (Viagra)	25-100 mg Max - one dose per day	30-60 min	4 hrs (up to 12 hrs)	Delayed absorption with high-fat foods	50%-85% efficacy	Headache, low BP, flushing, dyspepsia, vasodilation, diarrhea, visual changes (blue tinge to vision) Non-arteritic anterior ischemic optic neuropathy (NAION)	Active caronary artery disease, hypotension No nitrates for 24 hrs after dose Caution with α-blockers
Vardenafil (Levitra)	2.5-20 mg Max -one dose QD	15-30 min	4 hrs (up to 12 hrs)	Delayed absorption with high-fat foods	75% efficacy No visual side-effects	Headache, low BP, flushing, dyspepsia, vasodilation, diarrhea Non-arteritic anterior ischemic optic neuropathy (NAION)	Active CAD, hypotension May prolong QTc May increase liver function tests Avoid nitrates for 24 hrs after dose Avoid α-blockers (Hytrin and Cardura); use cautiously with Flomax or Uroxotra
Uroxatral	5-20 mg	30-45 min	24-36 hrs	None	75% efficacy No visual side-effects Can be taken with food	Headache, low BP, flushing, dyspepsia, vasodilation, diarrhea Non-arteritic anterior ischemic optic neuropathy (NAION)	Active CAD, hypotension Avoid nitrates for 48 hrs after dose Avoid α-blockers (Hytrin and Cardura); use cautiously with Flomax or Uroxatral

CAD, Coronary artery disease; *QTc*, corrected QT interval; *LFTs*, liver function tests.

TABLE 24–12 Second-Line Treatments for Erectile Dysfunction

TREATMENT	EFFECTS	ADVANTAGES	DISADVANTAGES
Intraurethral suppository: MUSE (alprostadil)	Prostaglandin E_1 gel delivered by applicator into meatus of penis Induces vasodilation to cause erection	60% efficacy Less penile fibrosis and priapism than with penile injections Can be used twice daily	Not recommended with pregnant partners Mild penile/urethral pain
Penile self-injection: alprostadil (Caverject and Edex)	Prostaglandin E_1 injected into base of penis Induces vasodilation to cause erection	50%-87% efficacy Few systemic side effects	Can cause penile pain, priapism, fibrosis Not recommended for daily use
Vacuum constriction device (pump)	Creates vacuum to draw blood into penile cavernosa Elastic band holds blood in penis	67% efficacy No systemic side effects Safe if erection not maintained more than 1 hour	May not be acceptable to partner Erection hinged at base; does not allow for external ejaculation

and progestogenic metabolites, has been shown to increase vaginal lubrication, arousability, and sexual desire, but not the frequency of sexual intercourse or orgasm. It is also associated with an increased risk of stroke in women with osteoporosis over age 60 years.[78,79]

Bupropion (a dopamine and noradrenergic agonist) may increase arousability and sexual response in women. As in men, trials of yohimbine, apomorphine, and melanocortin agonists are ongoing. L-Arginine may also enhance female sexual function.[44]

Paraphilias

Pharmacologic therapy for paraphilias is aimed at suppression of compulsive sexual behavior. The antiandrogen drugs, cyproterone (CPA) and medroxyprogesterone acetate (MPA, Depo-Provera), which act by competitive inhibition of androgen receptors, are used to reduce aberrant sexual tendencies by decreasing androgen levels (not yet FDA-approved). Treatment with leuprolide (approved for prostate cancer) and triptorelin (not yet FDA-approved), synthetic gonadotropin-releasing hormone analogues, decrease testosterone to chemically castrating levels (after an initial transient increase) and may completely abolish deviant sexual tendencies. The SSRIs and clomipramine may lower aberrant sexual urges by decreasing the compulsivity/impulsivity of the act and by decreasing aggressive behaviors. Antipsychotics have also been used to treat paraphilias.[80,81]

Gender Identity Disorder

The major treatment for gender identity disorder is sex-reassignment surgery. Hormone therapy may be necessary to suppress original sex characteristics (i.e., with luteinizing hormone–releasing hormone (LHRH) agonists, CPA, estrogens, and testosterone).

Psychologically-Based Treatments

Sexual Dysfunction

General principles of treatment include improving communication (verbally and physically) between partners, encouraging experimentation, decreasing the pressure of performance by changing the goal of sexual activity away from erection or orgasm to feeling good about oneself, and relieving the pressure of the moment (by suggesting there is always another day to try). The PLISSIT model provides a useful framework for approaching treatment of sexual problems and can be tailored to the desired level of intervention. The stages are (1) P: permission; (2) LI: limited information; (3) SS: specific suggestions; and (4) IT: intensive therapy. Permission-giving involves reassuring the patient about sexual activity, alleviating guilt about activities the patient feels are "bad" or "dirty," and reinforcing the normal range of sexual activities. Limited information includes providing basic knowledge about anatomy and physiology and correcting myths and misconceptions. Specific suggestions include techniques of behavioral sex therapy (Table 24–13). Intensive therapy may be useful for patients with chronic sexual problems, complex psychologic issues, or both. Whereas the first three stages (P, LI, SS) may be implemented by any health care provider, the last stage (IT) usual requires an expert with special training in sex therapy.[21,28,82]

Paraphilias

Paraphilias are often refractory to treatment, and recidivism is high, but several nonpharmacologic modalities have been used with varying success. Insight-oriented or supportive psychotherapy is relatively ineffective. Cognitive-behavioral therapy (CBT) can be used to help patients identify aberrant sexual tendencies, alter their behavior, and avoid sexual triggers to prevent relapse. Aversive therapy, via conditioning with ammonia, is used to reduce paraphiliac behavior. Orgasmic reconditioning is used to teach the paraphiliac how to become aroused by more acceptable mental images. Social skills training (individual or group) is used to help the paraphiliac form better interpersonal relationships. Surveillance systems (using family members to help monitor patient behavior) may be helpful. Lifelong maintenance is required.[83]

Gender Identity Disorder

Individual psychotherapy is useful both in helping patients understand their gender dysphoria and in addressing other psychiatric issues. A thorough psychologic evaluation is generally required before sex reassignment surgery can be performed. Marital and family therapy can help with adjustment to a new gender.[84]

TABLE 24–13 Specific Behavioral Techniques of Sex Therapy

SEXUAL DISORDER	SUGGESTIONS
Hypoactive sexual disorder	Sensate focus exercises (nondemand pleasuring techniques) to enhance enjoyment without pressure
	Erotic material, masturbation training
Sexual aversion disorder	Same as for hypoactive sexual disorder For phobic/panic symptoms, use antianxiety/antidepressant medications
Female sexual arousal disorder	Lubrication—saliva, KY jelly for vaginal dryness
Male erectile disorder	Sensate focus exercises (nondemand pleasuring techniques)
	Use female superior position (heterosexual couple) for nondemanding intercourse
	Female manually stimulates penis and if erection is obtained she inserts the penis into the vagina and begins movement
	Learn ways to satisfy partner without penile/vaginal intercourse
Female orgasmic disorder	Self-stimulation
	Use of fantasy materials
	Kegel vaginal exercises (contraction of pubococcygeus muscles)
	Use of controlled intercourse in female superior position
	"Bridge technique"—male stimulates female's clitoris manually after insertion of the penis into the vagina
Male orgasmic disorder (during intercourse)	Female stimulates male manually until orgasm becomes inevitable Insert penis into vagina and begin thrusting
Premature ejaculation	Increased frequency of sex
	"Squeeze technique"—female manually stimulates penis until ejaculation is approaching, then the female squeezes the penis with her thumb on the frenulum; pressure is applied until the male no longer feels the urge to ejaculate (15-60 sec); use the female superior position with gradual thrusting and the "squeeze" technique as excitement intensifies
	"Stop–start technique"—female stimulates the male to the point of ejaculation then stops the stimulation; she resumes the stimulation for several stop–start procedures, until ejaculation is allowed to occur
Dyspareunia	Treat any underlying gynecological problem first
	Treat insufficient lubrication
Vaginismus	The female is encouraged to accept larger and larger objects into her vagina (e.g., her fingers, her partner's fingers, Hegar graduated vaginal dilators, syringe containers of different sizes)
	Recommend the use of the female superior position allowing the female to gradually insert the erect penis into the vagina
	Use extra lubricant (KY jelly)
	Practice Kegel vaginal exercises to develop a sense of control

CONCLUSION

Sexual problems are common in the general population, and in medically ill, hospitalized patients, the prevalence is even greater. Even when a sexual problem is not the primary reason for consultation, the consulting psychiatrist should feel comfortable and well-equipped to take a sexual history as a routine part of the evaluation. Although time and privacy are important limitations in the inpatient setting, the sexual history may reveal an unrecognized sexual concern; uncover an underlying medical or psychiatric illness; or at the very least help better understand the *patient* in a functional context, and in turn, improve the patient–doctor relationship.

With our population growing older, the potential for sexual problems is on the rise. Patients both in and out of the hospital are living with complex medical problems and taking multiple medications. At the same time, with the shifting focus of medicine from improving not only the length of life but also the *quality* of life, physician responsibility to recognize and treat sexual problems is ever greater. Consulting psychiatrists can be helpful in discerning the biological, psychological, and social factors that contribute to a sexual problem. Recognizing the sexual side effects of psychotropics and other medications is a key part of the evaluation. Fortunately, many effective treatment strategies now exist (e.g., use of PDE-5 inhibitors for SSRI-induced sexual dysfunction). With increasing understanding of the biological basis for sexual dysfunction, the opportunity to treat sexual problems should only continue to expand.

Some sexual problems may be the result of an acute illness or require only short-term treatment or medication adjustment. By seeing patients in the hospital setting and getting an appreciation of the psychological and physical

limitations that patients face, consultant psychiatrists may offer creative solutions to facilitate a sexual life. The inpatient setting also provides a unique opportunity to get multiple specialists involved as necessary (e.g., urologist, gynecologist, and endocrinologist) to provide comprehensive care. Ultimately, the consultant psychiatrist may play a pivotal role in triaging the patient to an outpatient provider for longer-term management.

Organ Failure and Transplantation

25

Owen S. Surman, M.D.
Laura M. Prager, M.D.

ADVANCES IN TRANSPLANTATION BIOLOGY

The past 4 decades have seen dramatic growth in organ transplantation. Kidney transplantation, an uncommon event in the mid 1960s, is now a routine operation. With the advent of cyclosporine, tacrolimus, and other immunosuppressive treatments for graft rejection, transplantation (of livers, hearts, and lungs) became practical in the 1980s; excellent survival statistics now accompany such procedures. Solid organ transplantation is the focus of this chapter. Bone marrow transplantation is beyond the scope of this chapter.[1]

PROCEDURAL LIMITATIONS

Although a variety of factors affect the efficacy of organ transplantation, the most pressing challenge remains the shortage of available deceased-donor and living-donor organs. Rejection and the complications of antirejection therapy continue to limit successful transplantation. Exciting developments are on the horizon. Steroid-sparing approaches using sirolimus show promise in pancreatic islet cell transplantation research. Work proceeds on animal models of xenotransplantation, even though the potential for interspecies spread of infection remains a major concern. Tissue engineering is at an early, but promising, stage of scientific discovery. Immunologic tolerance is essential to transplantation, and one new strategy is to irradiate the bone marrow of transplant recipients and to perform transplantation of donor marrow as a means of producing temporary immunologic chimerism. This protocol has had initial success in clinical trials with combined bone marrow and renal transplantation for patients with myeloma kidney.[2]

In some nations, societal limits have restricted access to deceased donor organs.[3] Japan, for one, will permit family consent for deceased organ availability beginning in July 2010. Asystolic cadaveric organ donation offers an alternative for renal allografts[4]; however, other organs are less able to withstand ischemic injury. Kidney donation from living donors is common in many countries, and participation of unrelated living donors is now a common and accepted practice in the United States. Unfortunately, the scarcity of kidneys has stimulated a burgeoning black market in illicit sale of organs from poor third-world donors, who risk their health as victims of organ trafficking.[5]

Living donors can be a source of transplanted organs under some circumstances. Parent-to-child liver transplantation is frequently performed using the left lateral lobe, and living-related or living-unrelated lobar-lung transplantation is another option, with a lung lobe donated by each of two living donors. Transplantation of the right hepatic lobe from a living adult donor to a recipient has proved lifesaving for liver transplant candidates, who face a 20% risk of dying before obtaining a liver from a cadaveric source. The greater morbidity of this type of surgery for liver donors has become a source of ethical deliberation.[6] Risk of mortality has decreased with operative experience and improvement in criteria for donor selection and perioperative care. Complications include biliary stricture, bile leaks, secondary biliary cirrhosis, pulmonary embolism, bleeding, pain, and prolonged recovery time. Posttraumatic stress disorder (PTSD) has been reported in one study of living partial-liver donors in Japan.[7] State regulations for partial-liver transplantation from living donors have been developed under the auspices of the New York State Department of Public Health,[8] and there are clear national guidelines from the Center for Medicare and Medicaid Services (CMS).[9] The National Organ Transplant Act endorses ethical practices related to organ donation and prohibits the sale of organs.

THE NEED FOR PSYCHIATRIC INTERVENTION

Patient selection and organ donor selection require psychiatric input. In some centers, a psychiatrist works with each specific transplantation team. However, many transplantation centers rely on general hospital psychiatric consultation services, and in some centers, psychologists and social workers are involved in the psychosocial screening of recipients and donors.

Perioperative psychiatric support of transplant candidates requires an appreciation of the special needs of patients with end-stage organ failure.[10] Psychiatrists are asked to predict the likelihood of patient compliance after transplantation and to treat preoperative and postoperative psychiatric syndromes. Postoperative sequelae unique to transplantation are a consequence of allograft rejection and the use of immunosuppressive agents. Many clinicians refer to the patient's rollercoaster-like experience of transplantation, replete with promise and uncertainty.

ORGAN FAILURE

Common Features

Functional decline and subsequent loss of previous social roles are inevitable sequelae of end-organ failure. Such conditions predispose to adjustment disorders, anxiety syndromes, and depression. Loss of mental acuity, which may progress to frank encephalopathy, may also accompany organ failure.

End-Stage Renal Disease

Renal failure may have a systemic or a local cause. Systemic diseases include diabetes mellitus (DM), hypertension, and collagen vascular diseases. Patients with DM often bear the added burden of retinopathy, sensory deficits, neuropathy, and gastrointestinal dysmotility. Chronic lithium therapy can cause renal failure. Hereditary causes of renal failure, such as polycystic kidney disease, can have the added complication of reducing family donor availability. Patients with familial syndromes are sometimes burdened with concern about the emergence of the disorder among younger family members. Their acceptance of treatment for renal failure may be affected by adverse experiences of other afflicted family members.

The availability of dialysis is the feature that most clearly distinguishes renal failure from other types of end-organ disease. Hemodialysis is performed at most acute care centers, typically three times weekly in approximately 4-hour sessions. Patients can also undergo hemodialysis at chronic care centers or even receive home-based treatments. The scheduling of treatments has a significant impact on work and family life. Continuous ambulatory peritoneal dialysis can be performed intermittently, typically four times daily or continuously throughout the night. To avoid peritonitis, patients must be capable of meticulous self-care. Mood disorders, cognitive impairment, environmental stress, and noncompliance, among other things, can impair adherence to a careful regimen. All of these may be indications for referral for psychiatric or social service assistance.

Depression, a common complication of dialysis treatment, emerges more frequently among those with a higher level of morbidity. Some researchers have attempted to standardize measures for medical impairment in this population. An example of this is the end-stage renal disease (ESRD) severity index.[11] Some studies suggest that depression increases the mortality rate among dialysands.[12] Alterations of endocrine function (especially from hyperparathyroidism), anemia, metabolic stress, and cognitive function contribute to the depression associated with renal failure.[13]

Encephalopathy is a common consequence of uremia and an indication for hemodialysis; it is often confused with depression by nonpsychiatric physicians. Neuropsychiatric syndromes have included dialysis disequilibrium and dialysis dementia, which is obviated by removal of aluminum hemodialysis.[13] Seizures are common in patients with uremia; complex partial seizures often result in behavioral changes (e.g., agitation and catatonia) that respond to anticonvulsant therapy.[14,15] Encephalopathy may also occur in response to activation of cytokines as part of the immunologic activation by synthetic dialysis membranes.[16]

Psychopharmacologic care of the patient with renal failure requires dosage adjustments of standard anxiolytics, antidepressants, and neuroleptics, as described by Bennett and associates.[17] Depression is best managed with selective serotonin-reuptake inhibitors (SSRIs), bupropion, and psychostimulants.[13,18] Short-acting anxiolytics are generally preferable to longer-acting ones to minimize the buildup of metabolites. Monitoring the blood levels of anticonvulsants can be complicated by low values that may result from changes in protein binding. Unbound or free levels of phenytoin and carbamazepine are more valuable measurements. Lithium carbonate is readily dialyzed; therefore, it should be administered after dialysis treatments. Some patients require continued administration on the days they do not receive dialysis. Frequent monitoring (especially at the outset of treatment) is essential to detect and avoid toxicity. Monthly levels, drawn before hemodialysis, are advisable once a satisfactory dosing schedule has been established. Deferoxamine, an iron-binding and aluminum-binding agent, should be administered when aluminum encephalopathy is suspected.[13]

Psychotherapy can be challenging with patients in renal failure. Insight-oriented psychotherapeutic strategies may be destabilizing for those who rely on denial and who lack a sense of control[19]; cognitive therapy and other active, ego-supportive approaches may be more helpful. Hypnotherapy can be beneficial for patients with needle phobias and other forms of anxiety.

Dialysis patients sometimes choose to terminate treatment, particularly in the face of what they feel is an unacceptable reduction in their quality of life.[20,21] In such instances, the psychiatrist may be called on to assess the patient's capacity to refuse treatment. As the following case example illustrates, careful psychiatric diagnostic evaluation and treatment can have a significant, sometimes life-changing, impact on the patient's course.

CASE 1

Mr. A, 40-year-old man with DM, was referred for psychiatric evaluation of depression because he wanted to discontinue hemodialysis. There was no personal or family history of depression. He reported a depressed mood in association with chronic pain from diabetic neuropathy and from the severe headaches that often followed hemodialysis sessions. Mr. A agreed to a trial of an antidepressant and an analgesic after hemodialysis. His pain remitted, his mood lifted, and he subsequently chose to undergo renal transplantation.

On occasion, a patient has the capacity to refuse treatment, wishes to withdraw from therapy, and demonstrates a full understanding of the impact of such a choice. In these cases, it may be necessary for the psychiatrist to support the team and the patient's family while dialysis is discontinued.

Quality of Life and Choice of Renal Failure Therapy

The choice between dialysis and transplantation for patients with ESRD varies with the medical circumstances. Patients with DM are less tolerant of hemodialysis

and are at risk for acceleration of retinopathy. Patients older than 60 years who are on chronic hemodialysis are also at increased risk for mortality and morbidity. Historically, some centers have had a bias toward either dialytic or transplantation-based treatment of patients with ESRD.[22]

Waiting time varies among organ procurement centers in the 11 designated regions functioning under the auspices of the United Network of Organ Sharing (UNOS), and it is not unusual for patients in New England, for example, to wait 4 or 5 years to obtain a deceased-donor kidney. Those with financial means can be listed at more than one center, but transplantation will not improve quality of life for those patients unable even to secure funding for the required, expensive immunosuppressant medication. Patients may have difficulty gaining access to an established transplantation center for perioperative and postoperative care. Likewise, for a patient with advanced atherosclerosis, a successful vascular anastomosis and transplantation may not be possible. For diabetic patients and those older than 60 years, "extended donor organs" derived from older deceased donors whose kidneys do not meet standard UNOS criteria can be another option. Combined pancreas and kidney transplantation, although associated with an increased risk for postoperative morbidity, offers an advantage because the need for insulin therapy is eliminated.

In 1985, Evans and associates[23] reported that 80% of 144 kidney transplant recipients and 48% to 60% of 715 dialysis patients were functioning at a near-normal level. Overall, transplant patients do better than patients receiving dialysis. Improvements in dialysis technique and the availability of erythropoietin to combat the anemia of renal failure have done much to improve the circumstances of those who have high levels of preformed antibody or who are otherwise unsuited for transplantation.

Organ Donation

Further discussion of organ donation and its psychiatric implications is provided later in this chapter. Criteria for unrelated organ donation have traditionally included documentation of a close bond between the donor and the recipient, altruistic intent on the part of the donor, and lack of coercion (as evidenced during medical evaluation and a standard psychiatric interview). Liberalization of organ donor criteria now allows for selective participation of Good Samaritan donors. A new challenge has arisen as some recipients turn toward one or another form of public solicitation. Some make their needs known in newsletters at places of worship. A website (MatchingDonors.com) offers Internet exposure for a fee; many centers choose not to accept such arrangements.

Organ donation depends on the willing participation of the donor, the recipient, and the surgical team. Transplantation surgeons must decide on their level of acceptance before operating on a healthy individual for purposes of organ donation, and centers vary regarding the inclusion of living-donor surgery of any type. Historically, UNOS has prohibited financial remuneration of a donor by a recipient.[24] The World Health Organization has also taken a strong stand against the sale of organs. But medical ethics evolve with changing social mores, and recently UNOS has allowed donors to receive reimbursement for specific expenses related to organ donation, such as travel costs. Psychiatric evaluation of donors often reveals new information about donors that may inform the selection process.

CASE 2

Ms. B, a 32-year-old woman, wanted to be a kidney donor for her divorced boyfriend's ex-wife, whose renal failure had been caused by systemic lupus erythematosus. Psychiatric evaluation revealed that the intended donor was guilt ridden about the recipient's circumstances. No established bond existed between the two women. The potential donor was "the other woman," a role in which she had been cast. Ms. B. gave a history of physical abuse by her mother and sexual abuse by her mother's three marital partners. She acknowledged a feeling of universal love and a wish to please others. She seemed accepting and possibly relieved when the psychiatrist rejected her candidacy as a donor. She also pointed out the parallels between her current situation and her past traumas.

At some centers, family members and close friends of the recipient are included in a pretransplantation family meeting attended by the recipient's nephrologists, nurse coordinator, social worker, a transplantation psychiatrist, a financial coordinator, and a representative from the tissue-typing laboratory. Current practice requires that transplant recipients and donors receive informed consent from the multidisciplinary care team. Donors who have completed a separate selection process can participate with the (intended) recipient in family meetings joined by a designated donor psychiatrist, social worker, and nurse coordinator. This attention to providing separate teams for evaluation of donor and recipient is a CMS-established protocol change.

Allograft survival statistics have improved substantially, granting a living-donor kidney transplant a half-life of 16 years. To deal with the critical shortage of kidneys, a donor-swap program is available in the New England region and through some other organ procurement organizations. In this program, two donors, each of whom is blood type–incompatible with an intended recipient, can exchange roles, thereby allowing the two recipients to obtain a kidney. In all instances of living-donor participation, it must be understood that the donor is a patient with rights to medical care independent of the recipient's need or institutional priorities.[24]

End-Stage Heart Disease

Among those who undergo heart transplantation, the leading preoperative diagnoses are coronary artery disease and cardiomyopathy. Before transplantation, prolonged intensive care unit (ICU) stays are the rule, because medical selection criteria are based on urgency. Many relatively high-functioning younger patients, who risk death from arrhythmia, have lengthier waits as outpatients.

Pretransplantation stress is similar to the stress associated with increased cardiac vulnerability in the general population. Major factors include the adverse impact of role loss and of separation from family.[25,26] Recently, attention has been paid to the favorable impact of positive affect on autonomic regulatory balance and heart rate variability.[27] Fear that transplantation may not be forthcoming or effective also causes anticipatory bereavement.

As with other types of organ failure for which there is no sustaining maintenance therapy, a patient approaching heart transplantation may express a willingness to proceed because there is no other choice. The anger and anxiety that frequently accompany this predicament are also associated with cardiovascular morbidity.[28] Encephalopathy may develop secondary to decreased cerebral blood flow, metabolic disorders, and medication effects (e.g., of lidocaine and β-blocking agents).[29]

Prolonged ICU stays and their attendant stress call for creative management strategies. Psychopharmacologic support may include use of anxiolytics and antidepressants (e.g., those with a low risk for cardiotoxicity). Tricyclic antidepressants (TCAs) are disadvantageous in this population before transplantation surgery because of their potential for causing arrhythmias and orthostatic hypotension. Constipation, a frequent side effect of TCAs, may also increase cardiovascular risk by creating the need for Valsalva maneuvers.[30] Use of bupropion or an SSRI is preferred, with appropriate regard for their potential drug–drug interactions related to their cytochrome P450 isoenzyme effects.

CASE 3

Mr. C, a middle-aged man with a highly counter-dependent style, became depressed after learning that his status on the transplant list had fallen because other patients were more acutely ill. Although he confided that he planned to forgo transplantation and leave the ICU, he agreed to a trial of bupropion. Within 3 days, his mood improved and he again elected to undergo transplantation. When pruritus developed, Mr. C agreed to add diphenhydramine to his regimen rather than discontinue bupropion. His transplantation proceeded uneventfully, and he required no postoperative antidepressant therapy.

Delirium is a common and demanding complication for those who require placement of an intraaortic balloon pump. Hypotension and microembolic events may be responsible, although cytokine activation might play a role. Use of IV haloperidol is a first-line approach to the management of agitated delirium. Adequate analgesia also is essential for patients with severe angina; additional support from a hospital-based pain management team may be required.

Hypnotherapy and other cognitively based strategies can enhance the patient's adaptive response. For example, one young mother used self-hypnosis to master lonely nights in the ICU; she imagined that the beeping of her monitor represented the sound of a spaceship on which she journeyed each night with her children. Another patient, a middle-aged policeman with intractable chest pain, found relief in frequent images of fishing with a brother who resided out of state. Another man who proved especially intolerant of medical dependency was able to use a hypnotic suggestion that he had a double. While engaged in a more active fantasy of managing his horse farm, he could imagine that it was his double that lay in the hospital as a passive recipient of life-saving care.

End-Stage Liver Disease

The most frequent causes of liver failure in the United States are alcoholic cirrhosis and alcoholic hepatitis; other causes include infectious and autoimmune hepatitis, primary biliary cirrhosis, and sclerosing cholangitis. Hepatocellular carcinoma is also an indication for transplantation when the disease is confined to the liver. Acuity is the deciding factor in the allocation of livers. The current Model for End-Stage Liver Disease (MELD) system gives priority to ICU-based patients and to medically stable outpatients with good-prognosis hepatocellular carcinoma.[31,32] There are strict criteria for deceased-donor liver transplantation in the setting of hepatocellular carcinoma, and the shortage of organs has virtually eliminated liver transplantation as a palliative approach.

At the time of evaluation and listing for transplantation, patients with liver failure have less than a year to live. Recurrent esophageal bleeding, tense ascites, recurrent encephalopathy, nutritional impairment, coagulopathy, and jaundice are common findings. Sleep apnea, another complication of end-stage liver disease, is presumably related to accumulation of abdominal ascites.[33]

The principal cause of hepatic encephalopathy is absorption of toxic metabolites from the intestine. The presence of false neurotransmitters may also result in central nervous system depression. Grading of hepatic encephalopathy has traditionally been accomplished with the Parsons-Smith criteria.[34] Some critically ill patients present in frank stupor and may not recall their preoperative course. Subtler cognitive dysfunction may be evident on a standard mental status examination or notation of odd behavior patterns. It is especially important for the consultant to learn about premorbid function because patients with so-called subclinical hepatic encephalopathy[35] are likely to improve after transplantation. Neurologic improvement after transplantation may be slow for some patients, but, in general, transplantation is associated with a significant improvement in the recipient's quality of life.[36]

Medical management is the primary approach to these patients. Control of bleeding and infection, reduction of protein intake, and administration of lactulose constitute the standard approach. Use of anxiolytics and sedatives must be used carefully because most are hepatically metabolized and may precipitate obtundation even when used in relatively modest doses.[36]

Patient Selection and End-Stage Alcoholic Liver Disease

There is considerable variation in both screening methods and acceptance criteria for transplant candidates between centers. Type of psychosocial assessment, degree of reliance on standardized testing, and level of training and experience of mental health professionals differ.[10,37–39]

Other factors that may influence a center's decision include the patient's age and body mass index. Delisting criteria for patients whose medical prognosis has deteriorated during the wait for a liver are not standardized.[10,40]

As in the case of heart and lung transplantation, many patients awaiting liver transplant die before an organ becomes available, so the principal consideration in patient selection is capacity to benefit.[41] The steady attrition of candidates for solid organs leads inevitably to utilitarian considerations.[42] In 1991, Moss and Siegler[43] argued that patients with end-stage alcoholic liver disease (ESALD) should be accountable for their histories of substance abuse, even if assignment of fault to such patients leads to second-class status. A risk of such logic is the possibility that patients will become hostages to their past and be excluded by third-party payers from reimbursement of transplantation.[44] Unequal access within a specific category, independent of prognosis, is a form of discrimination incompatible with federal guidelines for the disabled.[45] Predicting the risk for relapse has become the principal challenge in regard to patient selection. Absence of reliable biological markers for active alcohol abuse and difficulty in obtaining reliable historical data from patients and families intent on obtaining advanced medical care for a loved one complicate the picture.

CASE 4

Ms. D, a middle-aged woman who presented for liver transplantation, had generalized anxiety. Postoperatively, she was tremulous and encephalopathic. Alcohol withdrawal was considered, but her husband steadfastly swore that his wife did not drink. Her condition continued to deteriorate, and she developed hyperbilirubinemia. In a visit to the transplantation unit, her husband confided that at home he had unexpectedly discovered a medicine bottle filled with hard liquor, suggesting a history of surreptitious drinking. She went on to retransplantation and again developed malignant hyperbilirubinemia of unknown cause, which proved fatal.

Beresford and colleagues[46] advocated a system of inclusion based on Valliant's prognostic criteria. They assessed the extent to which patients and their families recognized alcohol dependence, the current degree of social stability, and the prospect and degree of lifestyle change conducive to long-term sobriety. Yates and co-workers[47] assessed prognosis with attention to the amount of alcohol consumed and the frequency and success of prior rehabilitation efforts.

Reported rates of recidivism have varied after transplantation for ESALD. For example, Knechtle and colleagues[48] proceeded with liver transplantation in those whose families advocated for transplantation despite failure of the patient to meet criteria for abstinence. This cohort of patients did as well as those with established sobriety, but long-term data from this study are not available. However, subsequent studies demonstrated that patient and graft survival for appropriately selected members of this patient population are comparable to those of other groups with liver failure.[49,50]

Candidates for liver transplantation for ESALD should acknowledge their history of substance abuse, agree to lifelong sobriety, and participate in an active treatment program before undergoing transplantation.[10] Important risk factors are shorter periods of sobriety, polysubstance abuse, history of multiple rehabilitation attempts, history of alcohol dependency, and family history of alcohol abuse.[10] Many centers provide written criteria and require that patients commit themselves to sobriety by signing a formal contract, with the understanding that alcoholism is a relapsing illness. Patients should be advised and encouraged to acknowledge relapse after transplantation, so that effective treatment can be initiated in a timely fashion. Some centers also include random testing.

Patients with opioid addictions have done well on methadone maintenance. Attempts to wean patients from methadone often prove destabilizing, although some centers persist in excluding patients on methadone mainenance.[51,52] Carefully screened patients with bipolar disorder or psychotic disorders can do well after transplantation. It is essential to determine that the condition is manageable before proceeding with transplantation and to arrange for reliable long-term psychiatric follow-up care in the community.[10]

Organ Donorship

The demand for cadaveric livers has led to a number of innovative procedures, including split-liver transplantation and reduced-size grafts for pediatric recipients. The ethics of partial hepatectomy from parent donors to critically ill offspring was initially explored by Singer and associates in 1989[53]; their approach is now widely accepted. Nonetheless, postoperative risks are greater for liver donors than for kidney donors. Right hepatic lobe adult-to-adult transplantation, which places the living donor at still greater risk, initially proceeded without the level of thoughtful deliberation that had marked the introduction of parent-to-child partial liver transplantation.[6] With increased experience, there has been a reduction in operative complications and recognition that donor safety comes first.[54]

Confounding the problem of selection and informed consent is the determination of donors who have made up their mind to proceed. Donor candidates sometimes engage in "impression management," and outright deception has been known to occur.[55] Communication psychologists have referred to the concept of *strategic trajectory*, wherein the intended donor filters new information through a preestablished set of expectations. This is a useful concept in regard to preoperative teaching and informed consent.[56] Current best practices provide the donor with opportunity to hear about the potential risks of organ donation, as well as about the benefits shared with the recipient, from the perspective of an independent donor advocate and from the designated donor surgeon, medical specialist, social worker, coordinator, and psychiatrist.

Psychopharmacologic care of the patient with end-stage liver disease has limitations imposed by the metabolism of psychoactive medications and by the role of hepatic enzymes. Preoperative anxiety and agitation can be treated with low doses of short-acting benzodiazepines. In the presence of hepatic encephalopathy, oxazepam is preferred because it does not require oxidative metabolism.

Lorazepam is a safe agent in low dosage for nocturnal sedation. Although insomnia is frequent in this patient population, it must be treated gently.

Antidepressants can be helpful in the management of liver transplant patients and in those awaiting transplant who contend with hepatitis C infection and who become depressed as a side effect of interferon therapy.[57,58] Bupropion is preferred because of its stimulating effect, but SSRIs are also effective. All antidepressants carry a small risk for hepatotoxicity. Duloxetine (Cymbalta) carries a black box warning against use in the setting of hepatic impairment.

End-Stage Lung Disease

Lung transplantation is a therapeutic option for many patients with end-stage pulmonary failure. Afflicted patients may suffer from obstructive lung disease (e.g., chronic obstructive pulmonary disease or α_1-antitrypsin deficiency), restrictive lung disease (e.g., idiopathic pulmonary fibrosis), septic lung disease (e.g., cystic fibrosis or bronchiectasis), or pulmonary vascular disease (that results in pulmonary hypertension). As lung transplantation is a therapy of last resort, all candidates must accept that they have a limited life expectancy without surgery, and deem that the benefits of transplantation outweigh the risks.

Unfortunately, the number of candidates for lung transplantation exceeds the number of available cadaveric donor organs. Therefore, the waiting list for lung transplantation can be several years long, even though ranking is now based on severity of illness as reflected in a calculated lung allocation score. When pulmonary failure develops, unlike in the case of other solid organs, there is no machine that can provide satisfactory support for patients who are awaiting transplantation. In fact, ventilator dependence can be a contraindication to transplantation. Most candidates, therefore, wait at home, often at some distance from the transplantation center.

A joint statement by the International Society of Heart and Lung Transplantation, the American Society of Transplant Physicians, the American Thoracic Society, the European Respiratory Society, and the Thoracic Society of Australia and New Zealand offers general guidelines for consideration of lung transplant candidates.[59] Shared guidelines for contraindications to transplantation include, in addition to active medical problems (such as malignancy and human immunodeficiency virus infection), many psychosocial parameters. Active cigarette smoking and alcohol or recreational drug abuse are absolute contraindications to lung transplantation. Other disabling psychological symptoms (e.g., ongoing suicidal or homicidal ideation, a history of suicide attempts or chronic self-injurious behaviors, poor compliance with medication regimens, acute psychosis, an eating disorder, and dementia) are relative contraindications to transplantation.

Because of the scarcity of cadaveric organs, many centers now offer the option of living-donor lobar-lung transplantation to suitable recipients. Such recipients are typically young people with cystic fibrosis who are usually small in stature, and, therefore, a single lobe from two individuals of average size will provide sufficient pulmonary capacity. Donors must have the same blood type as the recipient, but they do not have to be biologically related. Potential donors must undergo a comprehensive psychological evaluation as well as a medical work-up (both by evaluators who are not active members of the transplantation team) to determine motivation and to ensure autonomy, informed consent, and the absence of coercion.

Many psychiatric disorders occur in patients with pulmonary failure. Almost all candidates referred for lung transplantation suffer some degree of anxiety, as most people become anxious in the setting of increasing shortness of breath. Candidates for transplantation often describe both anticipatory anxiety (particularly in the setting of planned exertion) and panic attacks, despite oxygen supplementation. This is consistent with the study by Pollack and co-workers,[60] which showed a 17% incidence of panic disorder among 115 patients referred for pulmonary function testing. Adjustment disorder with depressive features is also common in this population, as patients struggle to cope with their progressive inability to perform even simple activities of daily living. In the setting of chronic, debilitating illness, pulmonary patients may develop major depression that requires aggressive psychopharmacologic intervention as well as supportive therapy. Those who are extremely ill may become delirious from hypoxia or hypercapnia. In addition, the medications used to treat the complications of pulmonary disease may precipitate psychiatric problems.

CASE 5

Ms. E, a 21-year-old married woman with pulmonary fibrosis, was referred by her pulmonologist for lung transplantation. She had no other medical problems and had no formal psychiatric history. A college graduate, she had worked full time for several years. During the year before her evaluation, she had to work fewer hours because of worsening pulmonary function. Although she described herself as "even-keeled," she had become increasingly anxious as her pulmonary function worsened. Even when her pulmonologist started her on continuous oxygen treatment, she remained anxious. At the time of her evaluation, she felt overwhelmed and was having panic attacks, particularly when she anticipated leaving her apartment to go to work. She also had trouble socializing with her husband and her friends. Her discomfort was such that she considered leaving her job. Panic disorder secondary to pulmonary decline was diagnosed, and an SSRI and a benzodiazepine (in a low dose) were prescribed. She did extremely well on this regimen, began a pulmonary rehabilitation program, kept her job, and resumed her social life with her friends.

As with other solid organ transplant patients, lung transplant patients are maintained on immunosuppressive drugs (including cyclosporine, FK-506 [tacrolimus], and prednisone) for the remainder of their lives; each can produce a variety of neuropsychiatric disorders (such as mood disorders, psychosis, and leukoencephalopathy).[10] Because of their immunosuppression, these patients are vulnerable to infections (such as by cytomegalovirus, *Aspergillus*, *Nocardia*, *Listeria*, *Cryptococcus*, and nontubercular *Mycobacterium*) that can also cause neuropsychiatric signs and symptoms.

CASE 6

Mr. F, a 60-year-old married man with no psychiatric history, became quite depressed and developed suicidal thoughts several months after single-lung transplantation for chronic obstructive pulmonary disease. He suffered from anhedonia and felt sleepy all the time (despite receiving adequate rest at night). His medications included cyclosporine and antihypertensives. His prednisone had been tapered slowly down to 15 mg/day. He took no pain medications or sedative–hypnotics. He denied any acute psychosocial stressors. Cyclosporine was discontinued, and tacrolimus was begun. His mood improved within several weeks and he felt more alert and awake; he began to participate once again in the activities of his household.

PREOPERATIVE CONSIDERATIONS

Psychiatric Concerns

Hope versus Loss

Typically, the first psychiatric encounter with the transplant patient occurs at the initial medical evaluation for transplantation candidacy. For many, transplantation represents hope for autonomy and prolongation of life; it also implies the terminal nature of their organ failure. While the patient tries to accept the need for transplantation, grief (which varies in intensity with the severity of organ failure and with styles of adaptive function) is manifest.

Preparation for Living versus Dying

Christopherson[61] described the challenge to families who simultaneously prepare for the alternative outcomes of survival and death for loved ones facing heart transplantation. Our group reported the case of a successful liver transplant candidate whose family was making funeral arrangements when he was placed on the list.[62]

False Starts

Patients awaiting transplantation experience considerable stress. For the cardiac patient waiting in the ICU, the wait for a heart is like the watched pot that never boils. For outpatients waiting years for lung transplantation, there is the feeling of having been forgotten. For some, the long preparation for transplantation is followed by a call to the hospital for an organ that never materializes. These false starts are expectedly unsettling.

Survivor Guilt and Its Variations

Transplantation candidates commonly express guilt about their need for an organ—a need that can only be filled by another person's death. Patients with familial disorders may also be sensitive to a loved one's inability to obtain a successful allograft. Patients who have experienced organ failure often have an opportunity to bond with other candidates undergoing similar evaluations and therapy. As transplantation becomes available, some patients feel sadness for those who continue to wait for a graft, guilt because they received the organ first, or unhappiness and disillusionment because their suffering continues as a result of postoperative complications. At the time of the transplantation evaluation, patients often feel guilty about the stress that their illness imposes on family members.

Depression

Premorbid depression has long been thought to predispose to postoperative morbidity.[63] Patients with a premorbid history of depressive disorder require a treatment plan to safeguard against the risk for postoperative depression that is associated with noncompliance with medication requirements and postoperative follow-up visits.[10]

Anxiety

Transplant recipients often experience some degree of preoperative anxiety, which rapidly resolves with postoperative return of end-organ function. For some solid-organ recipients, the hope for an organ may give way to anxiety when a graft finally becomes available. On rare occasions, such anxiety may lead a patient to refuse an organ. Emergency psychiatric consultation may prove helpful.

Some patients approach surgery with minimal apprehension. Frank denial can be a problem for the individual who mistakenly expects that transplantation will be immediately beneficial and uneventful. Psychiatric intervention is recommended for the patient with debilitating anxiety, with unrealistic expectations, or with premorbid anxiety disorders or phobias specific to the planned procedure.[10]

Personality Impairment

Trust is essential to successful organ transplantation because of the need for the patient to work closely with members of a treatment team around life and death issues. Patients with personality disorders present with a pattern of strained relationships and are at higher risk for transplantation complications. Fortunately, most transplantation procedures occur in a time frame that allows the team to establish a therapeutic alliance. Overall, the best predictor of postoperative compliance is preoperative compliance.[10]

Informed Consent

Teaching and informed consent are the cornerstones of preoperative care. In addition to a declaration of clinical goals and methods for their accomplishment, preoperative discussions between the patient and the transplant team form the basis of a bond that will ultimately allow continued communication during the difficult times that inevitably follow solid-organ transplantation. The opportunity to shape expectations is especially important. Transplant patients need to understand that hospital care may be prolonged and that recurrent admissions may be necessitated by rejection, infection, and other posttransplantation complications. The need for indwelling catheters, drains, and special diets must be addressed and an approach to postoperative pain established. Transplant recipients need to manage complicated medication regimens, frequent postoperative clinic visits, and the financial demands of transplantation. The process of selection, the contemplated waiting time for transplant, and the rules governing status on the list should be carefully explained. Young people especially must be made aware of the cosmetic impact associated with the use of high dosages of steroids after transplantation,

including the likelihood of weight gain and the potential for DM, cataract formation, mood swings, irritability, impaired concentration, and tremor. Potential complications must be presented with sensitivity. It may seem kind to withhold information, but patients who were uninformed and who then suffer adverse postoperative effects experience failed expectation and regret about undergoing transplantation. Observation by the team in the course of teaching and informed consent provide important information about mental status and coping styles.[10]

Teaching Venues

For most solid-organ transplantation evaluations, the patient undergoes a standard series of visits with surgery, nursing, psychiatry, social services, anesthesiology, and other medical and paramedical subspecialties as indicated. Some insurance plans allow inpatient admission to facilitate evaluation, and others require that this process occur on an outpatient basis. Our institution sometimes uses a family meeting format for interviewing kidney transplantation patients before placing their name on the cadaveric organ list or proceeding with living-donor evaluation.

The psychosocial interview complements the process of informed consent and provides an excellent opportunity to instruct patients in relaxation techniques, to counsel them about mobilizing an effective support network, and to inform them about the potential for postoperative mental status change and how it is best addressed. The psychiatrist, consulting psychologist, and social worker are in the optimal position to reinforce adaptive skills and to assist in cognitive reframing and use of behavioral techniques for the enhancement of perceived control and well-being. Several studies have demonstrated the favorable postoperative impact of preoperative psychological interventions.[64,65]

Patient–patient interactions provide a valuable adjunct to preoperative teaching. Many successful transplant recipients enjoy the opportunity to give something back by sharing their experience with new transplant candidates. Patient groups are similarly effective. They may rely on lay leadership or on a skilled group therapist. The format may include didactic teaching sessions to which members of the surgical team are invited. Some groups include patients and family members. Printed materials and audiovisual presentations are a useful educational supplement.

Psychotherapy

Indications

Patients with Axis I or Axis II disorders should be encouraged to receive psychiatric care in preparation for transplantation. Ongoing treatment is crucial, particularly when compliance is a concern or the patient is experiencing debilitating emotional symptoms. Patients who are psychologically asymptomatic or who have mild adjustment disorders are best advised to mobilize whatever resources they find most beneficial. This may include supportive counseling for the patient and family, religious involvement, or community-based support.

The pretransplantation psychiatric evaluation provides a format for brief therapy. It often is useful to tell patients that the purpose of the psychiatric interview is to teach, to form a basis for subsequent *ad hoc* psychiatric referrals, and to ascertain whether any special needs must be addressed for transplantation to be successful. Patients should be advised that the object is to see whether they can realistically benefit from a transplant, and whether there are specific circumstances that need to be addressed before transplantation can proceed. Even this one-time psychiatric interview may provide a unique opportunity for listening and debriefing. While underscoring the hope of transplantation, the therapeutic psychological encounter allows recognition of loss and expression of grief. Patients who express feelings of guilt about the need for a cadaveric organ are best reminded of the inevitability of death and of the relief many bereaved families experience when informed of the opportunity for organ donation. Some patients may require reassurance about body image after transplantation. Above all, the pretransplantation interview is an excellent opportunity to strengthen the therapeutic alliance.

The preoperative transplantation patient is like a cryptographer in search of clues that will aid him or her in mastering unforeseen events. In an early study, Schachter and Singer[66] found that experimental participants responded differentially to injected adrenaline depending on their exposure to waiting room "stooges" who were either irritable or elated. This is not to say that one should deny pain or tell patients how to feel, but that patients can be taught how to cope within the range of experiences typically encountered in the transplantation setting. Egbert and associates[67] demonstrated that patients undergoing abdominal surgery had greater postoperative comfort and required fewer narcotics when they were taught before their operation about the normalcy of postoperative pain and were encouraged to ask for pain medication as needed. Similarly, one can instruct patients about the risk for postoperative delirium, while emphasizing that some degree of confusion is frequent, that this is temporary, and that it will respond to appropriate adjustments in medication.

Phobic disorders relevant to the surgical setting should be identified and plans made to effect desensitization. Postnoxious desensitization, in which individuals are encouraged to fantasize acquisition of a desired goal and then to work backward in their imagination to gain mastery of the steps required for goal attainment, has been described.[68]

Psychotherapy is demanding for clinicians who serve these patients. The consultant visits the ICU each time with the realization that the patient's room may be empty and the bed neatly remade (or occupied by a new patient). The effort to diminish one's own sense of loss may deter even a seasoned consultant from making an emotional commitment. Such countertransference reactions, when acknowledged, add to the psychiatric consultant's appreciation of the level of stress encountered by a patient's relatives and friends and by other members of the transplantation team.

Psychopharmacologic Treatment

Psychopharmacologic care of the transplantation patient has been reviewed in depth by Trzepacz and associates.[57,69,70] Judicious use of antidepressants, anxiolytics, and antipsychotics can be lifesaving. The pretransplantation evaluation

provides an excellent chance to learn which agents have been helpful and which have not. Some patients give histories of intolerance to benzodiazepines or neuroleptics; this information may prove invaluable on subsequent admissions if the patient's ability to communicate effectively is compromised.

In general, it is essential to tailor psychopharmacologic management to the demands of organ failure and to maintain a close liaison with other medical subspecialists involved in the patient's care. Cassem's[71] dictum, "start low and go slow," is valuable and helps avoid the pitfalls of oversedation and iatrogenesis.

Special Services

Social Service Intervention

It is most helpful to work with a medical social worker who is familiar with the demands of transplantation and who is available to attend work rounds on a weekly basis. The social worker is an invaluable source of patient and family support and plays a pivotal role in ensuring that the patient will be able to access needed health care perioperatively.

Recreation Therapy and Audiovisual Material

Patients who wait for weeks in the hospital require support and distraction. Activities (such as card games, board games, and crafts) may prove useful. One heart transplant patient who enjoyed oil painting was able to overcome his depression by producing canvases that he offered for sale to the staff.

Relaxation videotapes may be made available through a closed-circuit teaching channel. Some hospitals use teaching films for patients and their potential donors when they come to family meetings before transplantation selection. Movies, music, and books on tape may reduce tension during prolonged hospital stays. Complementary medicine procedures, such as therapeutic touch, may also prove effective.

PATIENT SELECTION

Tragic Choices

Tragic Choices, Calabrese and Bobbit's[72] landmark work in medical ethics, is an apt phrase for the challenge posed by the limitation in resources for solid-organ transplantation. Ethical models applied to this task are inevitably in conflict if each is taken to its logical endpoint.[72] Assignment may be made on a basis that is relatively egalitarian or utilitarian. If the decision to transplant is primarily driven by patient demand, candidates with unacceptably high risk are included, and the pool of recipients is larger than if the decision were made on the basis of potential outcome and societal benefit.[42] If wait time is the predominant consideration in listing for transplant, patients in most acute need will not survive long enough to receive an organ, and patients who are relatively healthy will decline in health status before they reach the top of the list.

A rational approach to solid-organ transplantation is necessarily multicameral.[73] Current selection procedures are based on acuity of illness. However, special consideration among renal transplant recipients is given to patients who are sensitized with high levels of preformed antibody. Availability of a six-antigen match is considered a priority, independent of other factors. Transplantation is prioritized for patients willing to accept a kidney from older donors whose kidneys would customarily be discarded because of age.

Outcome data are important in patient selection, but some high-risk candidates are accepted. For example, the 1-year survival rate for early retransplantation of a failed hepatic allograft is comparable to the results with a primary liver transplant. In the setting of later retransplantation, results are 15% to 40% worse than with primary transplantation, especially in the setting of infection with hepatitis C virus. Many centers perform second transplantations.[74] Multiple organ recipients are another subgroup at high risk. Some centers offer transplantation to Jehovah's Witnesses, despite the religious prohibition of the use of blood products. Recipients who belong to this group may elect to accept blood or plasma, and church elders can sometimes participate to the advantage of the patient and the surgical team. Among lung transplant recipients, ventilator support can be a contraindication to transplantation, whereas heart and liver candidates are given priority listing when on a ventilator, unless the likelihood of a successful outcome is poor because of additional complications, such as active infection or renal failure.

Prioritization in solid-organ transplantation has varied over time, beginning with the more selective or para-judicial lifeboat ethics philosophy of the 1960s and continuing to our current, more egalitarian approach. It is principally, however, a societal consideration. Individual transplantation centers may vary in their assessment of a given candidate, but the decision to transplant is driven by a medical model.[41,75,76] The team must determine who will benefit in the context of currently accepted norms for selection.[10]

Psychiatrist's Role

The psychiatrist is charged with the task of determining whether the patient is sufficiently able, motivated, and possessed of sufficient social supports to follow through with the demands of transplantation. Unfortunately, we lack valid and reliable predictive data. Freeman and co-workers[77] used the determination "reservation about suitability for transplantation" for 19 of 70 patients who were psychiatrically screened for heart transplantation. Fourteen of their patients who met *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (DSM-III), criteria for a psychiatric disorder had postoperative surgical or psychiatric complications. Levenson and Olbrisch[37,38,78] showed that transplantation centers differ in their acceptance of patients who manifest psychiatric symptoms or syndromes. Some groups do not accept patients with active schizophrenia. Most centers deny patients with active substance abuse, dementia, current suicidality, multiple past suicide attempts, or severe mental retardation. Mild mental retardation, affective disorder, and commission of a felony are other considerations that may be exclusionary, especially in cardiac and lung transplantation programs, which tend to be more selective. In an attempt to standardize patient evaluation and selection, Olbrisch developed the psychosocial assessment of candidates for transplantation (PACT), which rates each of four categories along a five-point

semantic differential: social support, psychological health, lifestyle factors, and understanding of transplantation and follow-up.[79] Transplantation centers tolerate potentially high risk patients based on factors that include size of the center and total volume of cases, outcome statistics, and availability of psychiatric consultation. Experience dictates that solid-organ transplantation has proved successful in selected patients with schizophrenia, major depression, personality disorder, substance abuse, and moderate mental retardation.[42]

Through active participation with the transplantation unit, the psychiatrist learns about specific concerns that team members bring to the selection process. Patient compliance is an obvious concern; the social worth of the candidate is another.[80] Some patients who come to transplantation evaluation pose a measure of social risk, as in the case of an antisocial patient or the patient whose care will require extensive and expensive resources. Team members may also be overly invested when they have participated in the long-term care of a patient who has experienced multiple setbacks or rejection of a previous allograft. The psychiatrist plays an important role as educator, sharing current practice standards in psychiatric care and participating in ethical review of complex clinical events.

Nonadherence

Nonadherence is an important source of secondary graft failure.[81] Nonadherence may be evident in various forms, including missed appointments, failure to report important clinical changes in a timely fashion, dietary abuse, and missed medications. Unexpectedly low blood levels of cyclosporine or of other required medications might signal failure to take prescribed doses. Patients with recurrent rejection who stabilize with surprising rapidity after hospital admission and routine monitoring of medications are very likely nonadherers.

Other factors that predispose patients to nonadherence include depression, substance abuse, cognitive impairment, and personality disorder. Patients are at increased risk when they live at a distance from the transplantation center, and when there is insufficient social and financial support. Youth is another risk factor; young people may be more prone to denial and more reactive to the cosmetic complications of immunosuppressant medications.[82]

Although it is difficult to predict with certainty in individual cases, the patient's history of adherence is a valuable clue to future performance.[10] When possible, patients who are at risk by virtue of psychiatric history or social turmoil should have an extended period of follow-up, with the understanding that documentation of compliance must precede transplantation. All reasonable efforts should be undertaken to treat ongoing psychiatric impairment and to improve social support. Frequent posttransplantation clinic visits may reduce risk of nonadherence among high-risk patients.

ORGAN DONATION

Types of Donation

In the United States, the principal source of organs available for transplantation is cadaveric, brain-dead donors with a heartbeat. Hospitals have site-specific criteria for determination of brain death that usually include both diagnostic tests (such as an apnea test, electroencephalography, transcranial Doppler, and a cerebral blood-flow scan) and clinical signs (such as fixed and dilated pupils, absent reflexes, unresponsiveness to external stimuli, and apnea).

UNOS is the nonprofit agency endowed by the United States Congress that regulates the distribution of organs for transplantation. One of its branches, the Organ Procurement and Transplant Network, divides the country into 11 geographic regions in which the allocation of organs proceeds according to local need and priority. Each region has its own organ procurement organization. The radius of distribution for each type of organ depends on how vulnerable each type is to ischemic injury. Donor hearts are limited to a 500-mile radius. Kidneys can be transported across the continent because they can tolerate up to 48 hours of hypothermic perfusion. Lungs can tolerate only 6 hours outside the body.

The length of time candidates spend on the waiting list for transplantation differs between geographic regions. Furthermore, the waiting list for each organ type is arranged according to different models. For kidney transplantation, the time the candidate has spent waiting is the primary determining factor. However, full compatibility of human leukocyte antigens between donor and candidate confers priority for potential candidates for kidney transplantation. For heart, lung, and liver candidates, acuity of illness confers priority on the list. Pediatric candidates have priority on the waiting list for both kidneys and livers.

Many transplantation centers support a coordinator for organ donation who usually is a registered nurse. That person serves as a liaison between the transplantation team and the local organ procurement organization and also educates the hospital staff and the patients about organ donation and transplantation.

Mechanisms for Increased Organ Donation

The mismatch between the number of persons requiring organ transplantation and the number of available cadaveric organs has prompted investigation into other opportunities for organs, such as extending the age limit on donors, donors without a heartbeat, and living donors. Efforts have also been made to educate the public about the need for organs and to ask patients and relatives to consider the issue and to state their wishes prior to death. In the United States, the required consent law protects individuals; all potential organ donors must have provided clear consent for organ donation. In Spain, Belgium, and Singapore, the rule of presumed consent applies: all persons are presumed to be organ donors unless they have specifically refused to donate.

Deceased donors are identified by neurologic criteria of brain death. In contrast, the non–heart-beating donor has suffered irreversible cardiac or respiratory failure. Weber and co-workers[83] demonstrated no difference in outcome for 122 kidney transplants regardless of whether the transplanted organ was from a heart-beating or non–heart-beating donor. Notwithstanding initial controversy about the use of non–heart-beating donors, the current demand for organs

has led to increased use of this approach in kidney transplantation and frequently, albeit less frequently, in liver transplantation.

The participation of living organ donors was discussed earlier. The mortality rate for nephrectomy is 0.03%, and the risk for morbidity ranges from 1% to 10%.[84] The mortality rate for partial hepatectomy is approximately 0.2%.[8] Estimates of morbidity have varied but are currently considered to be in the range of 25% to 30%. To date, no deaths have been associated with living-donor lobar-lung donation, although the morbidity rate has been estimated to be as high as 61% at some centers.[85] A recent study of medical and psychological sequelae of living-donor lobar-lung donation suggests that these living donors feel positively about their donation despite experiencing a subjective decline in exercise tolerance.[86]

A qualitative study of kidney donors by Fellner and Marshall[87] reported on the psychological benefit experienced by a majority of participants. A sobering finding was the tendency of donor candidates to minimize risk, an observation that led the authors to question the meaningfulness of informed consent. Donors often want to get on with the process and put it behind them. One technique for dealing with this strategic trajectory (see Organ Donorship, earlier) is to enlist the donor in the evaluation process and share the challenge inherent in successful informed consent with the donor candidate. The intent is to tear down the barrier of formality and invite the donor metaphorically to the other side of the treatment setting. Development of rapport is often sufficient to counter resistance and allow the donor to be forthcoming about perceived coercion or ambivalence. Simmons demonstrated the potential benefits of donor participation as well as some of the caveats, such as the need to be mindful of the "black sheep" donor whose participation was probably an attempt to gain favor through an aura of altruism.[73]

A shortcoming in the history of living-donor organ donation in the United States has been the lack of a medical registry. We are now accumulating sufficient data to know that kidney donors experience good health relative to the general public.[88] Likewise, living-donor lobar-lung donors demonstrate pulmonary function tests within the normal range after lobectomy, despite volume loss of approximately 20% of the total.[86]

Evaluation of the potential donor must ensure autonomy, lack of coercion, absence of psychiatric contraindication or active substance abuse, sufficient social support, and medical coverage in the event of postoperative complication. There must be full disclosure about the details of perioperative procedures, required recovery time, postoperative physical limitations, and the required length of time before resumption of driving and a return to active employment or full-time childcare. Pain, potential length of disability, appearance of the operative incision, and potential risk of graft loss must be discussed. Families and patients can put considerable pressure on individual family members or friends to donate. In some instances, patients or family members have offered a financial incentive to donation or have threatened to withdraw financial support if the potential donor backs out. Sometimes the spouse or significant other of the potential donor objects to donation and withdraws emotional support or even leaves the relationship altogether. The potential donor should always be informed that, should he or she choose not to donate, the transplantation team will protect his confidences and not reveal the reason for refusing him as a candidate.

POSTOPERATIVE PSYCHIATRIC CONSIDERATIONS

Improvement in Psychological Function

Improved neuropsychiatric function after transplant surgery accompanies the reversal of end-organ failure; at times it is associated with a sense of rebirth. Improvement in anxiety, depression, and cognition typically occurs most rapidly after renal transplantation, and it is often evident within the first 2 days after transplantation because blood urea nitrogen and creatinine levels decrease. Riether and associates found marked improvement in depression and anxiety within the first 3 months after heart transplantation.[89] Liver recipients improve more slowly, but some patients have shown marked progress in well-being as early as 2 to 3 weeks after transplantation. Increased psychological adjustment and improved quality of life after liver transplantation have been well documented and are attributable in part to change in neuropsychiatric function.[35]

Organic Brain Syndromes

Intraoperative cerebral ischemia may occur among heart transplant patients because of decreased perfusion resulting from hemorrhagic or embolic phenomena. Psychotic reactions are most likely to occur within the first 48 hours after surgery. Hotson and Enzmann pointed out that when psychotic manifestations are delayed by 2 to 5 days with rapid response to neuroleptic treatment and environmental support, the cause is more likely to be multifactorial.[90]

Factors contributing to postoperative delirium include endocrinopathy, electrolyte abnormality, hypovitaminosis, infection, bleeding, drug or medication withdrawal, cerebrovascular abnormality, drug–drug interactions, and adverse medications effects.[10] For a complete discussion of the cause and treatment of delirium, see Fricchione and co-workers.[91] Sources of drug toxicity include anesthetic agents, analgesics (including normeperidine toxicity), and prednisone, which may cause sleep impairment, emotional lability, and perceptual abnormalities. Affective psychosis was a more frequent finding in the earlier years of transplantation, when rapid dosage reduction of prednisone was not yet standard. Both cyclosporine and tacrolimus may be associated with neurologic complications (including seizures, delirium, headache, coma, cortical blindness); another complication, central pontine myelinolysis, can occur as a locked-in syndrome.[10,92,93]

Development of leukoencephalopathy can be identified by fluid-attenuated inversion recovery (FLAIR).[94] Switching calcineurin agent (cyclosporine or tacrolimus) is often efficacious. Hypertension, renal dysfunction, and tremor may serve as clues to calcineurin toxicity. This may result from drug–drug interactions secondary to cytochrome

P450 enzyme inhibitors (such as erythromycin, ketoconazole, and diltiazem).[10] Calcineurin toxicity has also been described as a consequence of genetic polymorphism in P-glycoprotein.[95]

Herbal Toxicity

Herbal agents may be a cause of drug–drug interaction and allograft loss, or may be a cause of direct renal, hepatic, or cardiac toxicity.[10,96]

Anxiety

Anxiety in the early postoperative period can result from failed expectations or from repeated and disabling major complications. Decreasing amounts of medical supervision or change from one-to-one nursing in the ICU to shared nursing on the transplantation floor may also precipitate increased anxiety.

Patients who undergo IV pulses of corticosteroids may experience mood swings or anxiety that typically subsides within a day or two of completion of rescue therapy. Increasing tremor signals cyclosporine toxicity. OKT3, a monoclonal antibody used for acute rejection, may be associated with severe headache, joint pains, and other anxiety-generating systemic effects.

Posttransplantation biopsy procedures are another source of stress. Renal and hepatic biopsies are performed on an *ad hoc* basis. Routine endocardial biopsy and bronchoscopy, however, are ordered for heart and lung transplant recipients.
