A major goal of social skills training is teaching persons who may or may not have emotional problems about the verbal as well as nonverbal behaviors involved in social interactions. There are many people who have never been taught such interpersonal skills as making “small talk” in social settings, or the importance of good eye contact during a conversation. In addition, many people have not learned to “read” the many subtle cues contained in social interactions, such as how to tell when someone wants to change the topic of conversation or shift to another activity. Social skills training helps patients to learn to interpret these and other social signals, so that they can determine how to act appropriately in the company of other people in a variety of different situations. SST proceeds on the assumption that when people improve their social skills or change selected behaviors, they will raise their self-esteem and increase the likelihood that others will respond favorably to them. Trainees learn to change their social behavior patterns by practicing selected behaviors in individual or **group therapy** sessions. Another goal of social skills training is improving a patient’s ability to function in everyday social situations. Social skills training can help patients to work on specific issues—for example, improving one’s telephone manners—that interfere with their jobs or daily lives.

Treatment of specific disorders

A person who lacks certain social skills may have great difficulty building a network of supportive friends and acquaintances as he or she grows older, and may become socially isolated. Moreover, one of the consequences of loneliness is an increased risk of developing emotional problems or mental disorders. Social skills training has been shown to be effective in treating patients with a broad range of emotional problems and diagnoses. Some of the disorders treated by social skills trainers include shyness; adjustment disorders; marital and family conflicts, anxiety disorders, **attention-deficit/hyperactivity disorder**, **social phobia**, alcohol dependence; depression; **bipolar disorder**; **schizophrenia**; developmental disabilities; **avoidant personality disorder**;

KEY TERMS

Cue—Any behavior or event in a person’s environment that serves to stimulate a particular response. For example, the smell of liquor may be a cue for some people to pour themselves a drink. In social skills training, the term is usually used to refer to social signals, whether spoken or unspoken.

Feedback—A reaction or response from others to a particular behavior or activity.

Generalization—A person’s ongoing use of new behaviors that were previously modeled for him or her. Generalization is also called transfer of training or maintenance.

Modeling—A type of teaching method used in social skills training. Therapists who use this method may offer positive and negative examples of the behaviors that make up a social skill.

Psychoeducation—An approach to treatment that combines instruction with various therapeutic techniques.

Reinforcement—In social skills training, responding to a client’s changed behavior in ways that will make the client want to perform the behavior again.

Role-playing—A technique used in social skills training and therapy in which participants act out roles relevant to real-life situations in order to change their attitudes and behaviors.

Shaping—A technique used in teaching social skills by prompting and reinforcing behaviors that come close to the desired behavior.

Social perspective-taking—A skill that involves a person’s capacity to perceive or recognize other people’s thoughts and feelings.

paranoid personality disorder; obsessive-compulsive disorder; and schizotypal personality disorder.

A specific example of the ways in which social skills training can be helpful includes its application to alcohol dependence. In treating patients with alcohol dependence, a therapist who is using social skills training focuses on teaching the patients ways to avoid drinking when they go to parties where alcohol is served, or when they find themselves in other situations in which others may pressure them to drink.

Another example is the application of social skills training to social phobia or shyness. People who suffer from social phobia or shyness are not ignorant of social cues, but they tend to avoid specific situations in which their limitations might cause them embarrassment. Social skills training can help these patients to improve their communication and social skills so that they will be able to mingle with others or go to job interviews with greater ease and self-confidence. Some studies indicate that the social skills training given to patients with shyness and social phobia can be applied to those with avoidant personality disorder, but more research is needed to differentiate among the particular types of social skills that benefit specific groups of patients, rather than treating social skills as a single entity. When trainers apply social skills training to the treatment of other **personality disorders**, they focus on the specific skills required to handle the issues that emerge with each disorder. For example, in the treatment of **obsessive-compulsive personality disorder** (OCD), social skills trainers focus on helping patients with OCD to deal with heavy responsibilities and **stress**.

People with disabilities in any age group can benefit from social skills training. Several studies demonstrate that children with developmental disabilities can acquire positive social skills with training. Extensive research on the effects of social skills training on children with attention-deficit/hyperactivity disorder shows that SST programs are effective in reducing these children's experiences of school failure or rejection as well as the aggressiveness and isolation that often develop in them because they have problems relating to others.

SST can be adapted to the treatment of depression with a focus on **assertiveness training**. Depressed patients often benefit from learning to set limits to others, to obtain satisfaction for their own needs, and to feel more self-confident in social interactions. Research suggests that patients who are depressed because they tend to withdraw from others can benefit from social skills training by learning to increase positive social interactions with others instead of pulling back.

There has been extensive research on the effective use of social skills training for the treatment of schizophrenia, in outpatient clinics as well as inpatient units. SST can be used to help patients with schizophrenia make better eye contact with other people, increase assertiveness, and improve their general conversational skills.

Social skills training in combination with other therapies

Social skills training is often used in combination with other therapies in the treatment of mental disorders.

For example, in the treatment of individuals with alcohol dependence, social skills training has been used together with cognitive restructuring and coping skills training. Social skills training has also been integrated with exposure therapy, cognitive restructuring, and medication in the treatment of social phobia. Social skills training has been used within **family therapy** itself in the treatment of marital and family conflicts. Moreover, SST works well together with medication for the treatment of depression. For the treatment of schizophrenia, social skills training has often been combined with pharmacotherapy, family therapy, and assertive **case management**.

Precautions

Social skills training should rest on an objective assessment of the patient's actual problems in relating to other people.

It is important for therapists who are using SST to move slowly so that the patient is not overwhelmed by trying to change too many behaviors at one time. In addition, social skill trainers should be careful not to intensify the patient's feelings of social incompetence. This caution is particularly important in treating patients with social phobia, who are already worried about others' opinions of them.

An additional precaution is related to the transfer of social skills from the therapy setting to real-life situations. This transfer is called generalization or maintenance. Generalization takes place more readily when the social skills training has a clear focus and the patient is highly motivated to reach a realistic goal. In addition, social skills trainers should be sure that the new skills being taught are suitable for the specific patients involved.

Description

Techniques in social skills training

Therapists who use social skills training begin by breaking down complex social behaviors into smaller portions. Next, they arrange these smaller parts in order of difficulty, and gradually introduce them to the patients. For example, a therapist who is helping a patient learn to feel more comfortable at parties might make a list of specific behaviors that belong to the complex behavior called "acting appropriately at a party," such as introducing oneself to others; making conversation with several people at the party rather than just one other guest; keeping one's conversation pleasant and interesting; thanking the host or hostess before leaving; and so on. The patient would then work on one specific behavior at a time rather than trying to learn them all at once.

Such specific techniques as instruction, **modeling**, role-playing, shaping, feedback, and **reinforcement** of positive interactions may be used in SST. For example, instruction may be used to convey the differences among assertive, passive, and aggressive styles of communication. The technique of monitoring may be used to ask patients to increase their eye contact during a conversation. In role-playing exercises, group members have the opportunity to offer feedback to one another about their performances in simulated situations. For example, two members of the group may role-play a situation in which a customer is trying to return a defective purchase to a store. The others can then give feedback about the “customer’s” assertiveness or the “clerk’s” responses.

Content of social skills training

SST may be used to teach people specific sets of social competencies. A common focus of SST programs is communication skills. A program designed to improve people’s skills in this area might include helping them with nonverbal and assertive communication and with making conversation. It might also include conversational skills that are needed in different specific situations, for example job interviews, informal parties, and dating. The skills might be divided further into such subjects as beginning, holding, and ending conversations, or expressing feelings in appropriate ways.

Another common focus of SST programs involves improving a patient’s ability to perceive and act on social cues. Many people have problems communicating with others because they fail to notice or do not understand other people’s cues, whether verbal or nonverbal. For example, some children become unpopular with their peers because they force their way into small play groups, when a child who has learned to read social signals would know that the children in the small group do not want someone else to join them, at least not at that moment. Learning to understand another person’s spoken or unspoken messages is as important as learning conversational skills. A social skills program may include skills related to the perceptual processing of the conversation of other individuals.

Scheduling

Social skills training may be given as an individual or as a group treatment once or twice a week, or more often depending upon the severity of a patient’s disorder and the level of his or her social skills. Generally speaking, children appear to gain more from SST in a peer group setting than in individual therapy. Social skill training groups usually consist of approximately 10 patients, a therapist, and a co-therapist.

Culture and gender issues

Social skills training programs may be modified somewhat to allow for cultural and gender differences. For example, eye contact is a frequently targeted behavior to be taught during social skills training. In some cultures, however, downcast eyes are a sign of respect rather than an indication of social anxiety or shyness. In addition, girls or women in some cultures may be considered immodest if they look at others, particularly adult males, too directly. These modifications can usually be made without changing the basic format of the SST program.

Generalization or transfer of skills

Current trends in social skills training are aimed at developing training programs that meet the demands of specific roles or situations. This need developed from studies that found that social skills acquired in one setting or situation are not easily generalized or transferred to another setting or situation. To assist patients in using their new skills in real-life situations, trainers use role-playing, teaching, modeling, and practice.

Preparation

Preparation for social skills training requires tact on the therapist’s part, as patients with such disorders as social phobia or paranoid personality disorder may be discouraged or upset by being told that they need help with their social skills. One possible approach is through reading. The social skills therapist may recommend some self-help books on social skills in preparation for the treatment. Second, the therapist can ease the patient’s self-consciousness or embarrassment by explaining that no one has perfect social skills. An additional consideration before starting treatment is the possibility of interference from medication side effects. The therapist will usually ask the patient for a list of all medications that he or she takes regularly.

One of the most critical tasks in preparation for social skills training is the selection of suitable target behaviors. It is often more helpful for the therapist to ask the patient to identify behaviors that he or she would like to change, rather than pointing to problem areas that the therapist has identified. The treatment should consider the patient’s particular needs and interests. Whereas social skills training for some patients may include learning assertiveness on the job, training for others may include learning strategies for dating. Therapists can prepare patients for homework by explaining that the homework is the practice of new skills in other settings; and that it is as relevant as the therapy session itself.

Aftercare

Some studies strongly suggest the need for follow-up support after an initial course of social skills training. One study showed that follow-up support doubled the rate of employment for a group of patients with schizophrenia, compared to a group that had no follow-up.

Normal results

Outcome studies indicate that social skills training has moderate short-term effects, but limited long-term effects. SST programs that include social perspective-taking may have greater long-term effects than traditional SST programs based on cognitive-behavioral models. In general, social skills training tends to generalize or transfer to similar contexts rather than to contexts that are not similar to the training. SST programs for patients with developmental disabilities should include programming for generalization, so that the patients can transfer their newly acquired skills more effectively to real-life settings. One approach to improving generalization is to situate the training exercises within the patient's work, living, or social environment.

The benefits of social skills training programs include flexibility. The treatment can take place either as individual or group therapy, and new trainers can learn the techniques of SST fairly quickly. An additional advantage of SST is that it focuses on teaching skills that can be learned rather than emphasizing the internal or biological determinants of social adequacy. Future research should explore the integration of social skills training with the needs of families from different cultural backgrounds; the relationship between social skills training and different categories of mental disorders; the transfer of skills from therapeutic contexts to daily life; and improving patients' long-term gains from SST.

Social workers

Definition

A social worker is a helping professional who is distinguished from other human service professionals by a focus on both the individual and his or her environment. Generally, social workers have at least a bachelor's degree from an accredited education program and in most states they must be licensed, certified, or registered. A Master's in Social Work is required for those who provide **psychotherapy** or work in specific settings such as hospitals or nursing homes.

Description

Social workers comprise a profession that had its beginnings in 1889 when Jane Addams founded Hull House and the American settlement house movement in Chicago's West Side. The ethics and values that informed her work became the basis for the social work profession. They include respect for the dignity of human beings, especially those who are vulnerable, an understanding that people are influenced by their environment, and a desire to work for social change that rectifies gross or unjust differences.

The social work profession is broader than most disciplines with regard to the range and types of problems addressed, the settings in which the work takes place, the levels of practice, interventions used, and populations served. It has been observed that social work is defined in its own place in the larger social environment, continuously evolving to respond to and address a changing world. Although several definitions of social work have been provided throughout its history, common to all definitions is the focus on both the individual and the environment, distinguishing it from other helping professions.

Social workers may be engaged in a variety of occupations ranging from hospitals, schools, clinics, police departments, public agencies, court systems to private practices or businesses. They provide the majority of mental health care to persons of all ages in this country, and in rural areas they are often the sole providers of services. In general, they assist people to obtain tangible services, help communities or groups provide or improve social and health services, provide counseling and psychotherapy with individuals, families, and groups, and participate in policy change through legislative processes. The practice of social work requires knowledge of human development and behavior, of social, economic and cultural institutions, and of the interaction of all these factors.

Somatization and somatoform disorders

Definition

Somatization is a term that describes the expression of psychological or mental difficulties through physical symptoms. Somatization takes a number of forms, ranging from preoccupation with potential or genuine but mild physical problems to the development of actual physical pain, discomfort, or dysfunction. The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, the professional handbook clinicians use to diagnose mental disorders, describes seven disorders under the category of somatoform disorders. These disorders are **somatization disorder**, **undifferentiated somatoform disorder**, **conversion disorder**, **pain disorder**, **hypochondriasis**, **body dysmorphic disorder**, and somatoform disorder not otherwise specified. Somatization appears to be fairly common, and a somatoform disorder **diagnosis** is not warranted unless symptoms cause significant distress or disability.

Description

Somatization disorder is characterized by a history of multiple unexplained medical problems or physical

complaints beginning prior to age 30. In the nineteenth and early twentieth centuries, somatization disorder was known as Briquet's syndrome or hysteria—a more generic term for such a condition. People with somatization disorder report symptoms affecting multiple organ systems or physical functions, including pain, gastrointestinal distress, sexual problems, and symptoms that mimic neurological disorders. Although medical explanations for their symptoms cannot be identified, individuals with somatization disorder experience genuine physical discomfort and distress. Review of their medical histories will usually reveal visits to a number of medical specialists, and many patients take numerous medications prescribed by different doctors, running the risk of dangerous drug interactions.

Undifferentiated somatoform disorder is similar to somatization disorder, but may involve fewer symptoms, have a shorter duration or begin after the age of 30. Common symptoms include chronic **fatigue**, loss of appetite, gastrointestinal distress or problems involving the genitals or urinary tract. This diagnosis is appropriate for patients with symptoms of somatization disorder who do not meet all diagnostic criteria.

Conversion disorder is marked by unexplained sensory or motor symptoms that resemble those of a neurological or medical illness or injury. Common symptoms include paralysis, loss of sensation, double vision, **seizures**, inability to speak or swallow and problems with coordination and balance. Symptoms often reflect a naive understanding of the nervous system, and physicians often detect conversion disorder when symptoms do not make sense anatomically. For instance, a patient may report loss of both touch and pain sensation on one side of the body, when, in fact, a genuine lesion would result in loss of touch and pain sense on opposite sides of the body. The name conversion disorder reflects a theoretical understanding of the disorder as a symbolic conversion of a psychological conflict into a concrete physical representation. Interestingly, patients with conversion disorder may not express the level of distress one would expect from someone with a disabling neurological con-

dition. This phenomenon is traditionally called *la belle indifférence*.

The primary feature of pain disorder is physical pain that causes significant distress or disability or leads an individual to seek medical attention. Pain may be medically unexplained, or it may be associated with an identifiable medical condition but far more severe than the condition would warrant. Common symptoms include headache, backache and generalized pain in muscles and joints. Pain disorder can be severely disabling, causing immobility that prevents patients from working, fulfilling family responsibilities or engaging in social activities. Like patients with somatization disorder, people with pain disorder often have a history of consultations with numerous physicians.

Hypochondriasis is diagnosed when a person is excessively concerned by fears of having a physical disease or injury. Individuals with hypochondriasis usually do not complain of disabling or painful symptoms. Instead, they tend to overreact to minor physical symptoms or sensations, like rapid heartbeat, sweating, small sores or fatigue. Many people with hypochondriasis develop fears in response to the illness or death of a friend or family member or after reading about a condition or seeing a feature on television. Hypochondriacal fears can be confined to a single disease or may involve a number of different physical concerns. Individuals with hypochondriasis seek frequent reassurance by consulting physicians or talking about their fears, yet these efforts provide only temporary relief from their fears. Although hypochondriasis is usually not as disabling as somatoform disorders involving the development of actual physical symptoms, it can put **stress** on relationships or reduce work productivity through time lost to frequent medical appointments and tests.

Body dysmorphic disorder is characterized by preoccupation with a defect in physical appearance. Often the defect of concern is not apparent to other observers, or if there is a genuine defect it is far less disfiguring than the patient imagines. Common preoccupations include concerns about the size or shape of the nose, skin blemishes, body or facial hair, hair loss, or “ugly” hands or feet. Individuals with body dysmorphic disorder may be extremely self-conscious, avoiding social situations because they fear others will notice their physical defects or even make fun of them. They may spend hours examining the imagined defect or avoid mirrors altogether. Time-consuming efforts to hide the defect, such as application of cosmetics or adjustments of clothing or hair, are common. Many people with body dysmorphic disorder undergo procedures like plastic surgery or cosmetic dentistry, but are seldom satisfied with the results.

Somatiform disorder, not otherwise specified, is diagnosed when somatoform symptoms are present but criteria for another somatoform disorder are not met. *DSM-IV-TR* includes several examples of symptoms that could merit this diagnosis, including false pregnancy, and hypochondriacal fears or unexplained physical symptoms of recent onset or short duration.

There is some disagreement among researchers about the *DSM-IV-TR* somatoform disorders category. Some have argued that hypochondriasis and body dysmorphic disorder are more similar to **obsessive-compulsive disorder** than to other somatoform disorders, while others think hypochondriasis may be more appropriately classified with the anxiety disorders.

Somatization disorder

Definition

Somatization disorder is a psychiatric condition marked by multiple medically unexplained physical, or somatic, symptoms. In order to qualify for the **diagnosis** of somatization disorder, somatic complaints must be serious enough to interfere significantly with a person's ability to perform important activities, such as work, school or family and social responsibilities, or lead the person experiencing the symptoms to seek medical treatment.

Somatization disorder has long been recognized by psychiatrists and psychologists, and was originally called Briquet's syndrome in honor of Paul Briquet, a French physician who first described the disorder in the nine-

teenth century. It is included in the category of somatoform disorders in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, the professional handbook that aids clinicians in diagnosing patients' mental disorders. The term "somatoform" means that the physical symptoms have a psychological origin.

Description

Individuals with somatization disorder suffer from a number of vague physical symptoms, involving at least four different physical functions or parts of the body. The physical symptoms that characterize somatization disorder cannot be attributed to medical conditions or to the use of drugs, and individuals with somatization disorder often undergo numerous medical tests (with negative results) before the psychological cause of their distress is identified. They often use impressionistic and colorful language to describe their symptoms, describing burning sensations, pains that move from place to place, strange tastes on the tongue, tingling, or tremors. While many symptoms resemble those associated with genuine diseases, some of the symptoms reported by people with somatization disorder are not. The individual usually visits many different physicians, but the information they provide about the patient's symptoms can be inconsistent. It is important to note that while the physical symptoms of somatization disorder frequently lack medical explanations, they are not intentionally fabricated. The typical person with somatization disorder has suffered from physical pain, discomfort, and dysfunction for an extended period of time and consulted several doctors; they are hopeful that they one can be found who can identify the cause of their illness and provide relief.

Somatization disorder can be dangerous, since patients may end up taking several different medications, thereby risking harmful drug interactions.

Causes and symptoms

Causes

DEFENSE AGAINST PSYCHOLOGICAL DISTRESS. One of the oldest theories about the cause of somatization disorder suggests that it is a way of avoiding psychological distress. Rather than experiencing depression or anxiety, some individuals will develop physical symptoms.

According to this model, somatization disorder is a defense against psychological pain that allows some people to avoid the **stigma** of a psychiatric diagnosis. While getting the care and nurturing they need from doctors and others who are responsive to their apparent medical illnesses, many patients are encouraged to continue their manipulative behavior.

Many patients described by Sigmund Freud would be diagnosed today with somatization disorder. His patients were usually young women who complained of numerous physical symptoms. In the process of speaking with Freud, they would often recall a number of distressing memories; discussing these memories frequently led to the relief of physical symptoms. These cases formed the foundation of Freud's psychoanalytic treatment. Although this theory offers a plausible explanation for somatization disorder, research indicates that people with multiple physical symptoms are actually more likely to report psychiatric symptoms than those with few physical problems. These findings appear to support a connection between psychological and physical distress, but are inconsistent with the idea that physical symptoms offer a defense against overt psychiatric symptoms.

HEIGHTENED SENSITIVITY TO PHYSICAL SENSATIONS. An alternative theory suggests that somatization disorder arises from a heightened sensitivity to internal sensations. People with somatization disorder may be keenly aware of the minor pains and discomforts that most people simply ignore. A similar theory has been offered to account for **panic disorder**. Studies have shown that people with panic disorder are particularly sensitive to internal sensations like breathing rate and heartbeats, which may lead them to react with intense fear to minor internal changes. The physiological or psychological origins of this hypersensitivity to internal sensations and their relevance to somatization disorder are still not well understood.

CATASTROPHIC THINKING ABOUT PHYSICAL SENSATIONS. According to these thoughts, somatization disorder results from negative beliefs and exaggerated fears about the significance of physical sensations. Individuals with somatization disorder are thus more likely to believe that vague physical symptoms are indicators of serious disease and to seek treatment for them. For instance, someone with somatization disorder may fear that a headache signals a **brain** tumor, or that shortness of breath indicates the onset of asthma. When their doctors can find no medical explanation for the symptoms, the patients may fear that they have a rare disease; they frantically look for specialists who can provide a diagnosis. Anxiety causes them to focus even more intensely on their symptoms, which in turn become more disabling. Many people with somatization disorder reduce or elim-

inate many activities out of fear that exertion will worsen their symptoms. With fewer activities to distract them from their symptoms, they spend more time worrying about physical problems, resulting in greater distress and disability.

Symptoms

Gastrointestinal (GI) complaints, such as nausea, bloating, diarrhea, and sensitivities to certain foods are common, and at least two different GI symptoms are required for the diagnosis. Sexual or reproductive symptoms, including pain during intercourse, menstrual problems, and **erectile dysfunction** are also necessary features for a diagnosis for somatization disorder. Other frequent symptoms are headaches, pain in the back or joints, difficulty swallowing or speaking, and urinary retention. To qualify for the diagnosis, at least one symptom must resemble a neurological disorder, such as **seizures**, problems with coordination or balance, or paralysis.

Demographics

According to the *DSM-IV-TR*, somatization disorder is rare in males in the United States, although higher rates are seen among males from some cultural and ethnic groups. The *DSM-IV-TR* estimates that between 0.2% and 2% of women, and less than 0.2% of men, suffer from somatization disorder in the U.S. Sex ratios may arise from different rates of seeking treatment. However, studies of unexplained somatic symptoms in the general population find less striking differences in rates between men and women. Specific symptoms may vary across cultures. For example, the *DSM-IV-TR* notes that the sensation of worms in the head or ants crawling under the skin are sometimes reported in African and South Asian countries, but rarely seen in North American patients.

Diagnosis

To receive a diagnosis of somatization disorder, the individual must have a history of multiple physical complaints that began before age 30 and that continued for several years (*DSM-IV-TR*). These symptoms must cause significant impairment to social, occupational or other areas of functioning—or lead the patient to seek medical treatment.

Each of the following four criteria must be met.

- The individual must report a history of pain affecting at least four different parts or functions of the body. Examples include headaches, back, joint, chest or abdominal pain, or pain during menstruation or sexual intercourse.

- A history of at least two gastrointestinal symptoms, such as nausea, bloating, vomiting, diarrhea, or food intolerance must be reported.
- There must be a history of at least one sexual or reproductive symptom, such as lack of interest in sex, problems achieving erection or ejaculation, irregular menstrual periods, excessive menstrual bleeding, or vomiting throughout pregnancy.
- One symptom must mimic a neurological condition. Examples include weakness, paralysis, problems with balance or coordination, seizures, **hallucinations**, loss of sensations such as touch, seeing, hearing, tasting, smelling—or difficulty swallowing or speaking, or **amnesia** and loss of consciousness. Pseudo-neurologic symptoms like these are the primary characteristics of another somatoform disorder known as “conversion disorder.”

If a thorough medical evaluation reveals no evidence of an underlying medical- or drug- or medication-induced condition, the diagnosis of somatization disorder is likely. People with genuine medical conditions can qualify for the diagnosis if the level of functional impairment reported is more than would be expected based on medical findings. The symptoms must not be intentionally produced. If the patient is feigning symptoms, a diagnosis of **factitious disorder** or **malingering** would most likely be considered.

Treatments

Cognitive behavior therapy

Cognitive-behavioral therapy (CBT) for somatization disorder focuses on changing negative patterns of thoughts, feelings, and behavior that contribute to somatic symptoms. The cognitive component of the treatment focuses on helping patients identify dysfunctional thinking about physical sensations. With practice, patients learn to recognize catastrophic thinking and develop more rational explanations for their feelings. The behavioral component aims to increase activity. Patients with somatization disorder have usually reduced their activity levels as a result of discomfort or out of fear that activity will worsen symptoms. CBT patients are instructed to increase activity gradually while avoiding overexertion that could reinforce fears. Other important types of treatment include relaxation training, sleep hygiene, and communication skills training. Preliminary findings suggest that CBT may help reduce distress and discomfort associated with somatic symptoms; however, it has not yet been systematically compared with other forms of therapy.

Medications

Antidepressant medications may help to alleviate symptoms of somatization disorder. According to one study, patients with somatization disorder who took the antidepressant **nefazodone** (Serzone) showed reductions in physical symptoms, increased activity levels, and lower levels of anxiety and depression at the end of treatment.

Prognosis

Untreated somatization disorder is usually a chronic condition, though specific symptoms can come and go and overall severity may fluctuate over time. Somatization disorder poses a serious problem for society, since many who suffer from it become functionally disabled and unable to work. In addition, patients with unexplained physical symptoms strain already overburdened health care resources. Unexplained physical symptoms are extremely common among patients visiting general practitioners, with some estimates suggesting that over two-thirds of general medical patients have symptoms that cannot be explained by medical tests. Fortunately, there is preliminary evidence that **psychotherapy** and medication can effectively reduce symptoms and disability.

Prevention

Greater awareness of somatization disorder, particularly among physicians, can help them identify individuals with somatization disorder, and help these patients get appropriate psychological or psychiatric treatment.

Specific phobias

Definition

Specific phobia is a type of disorder in which the affected individual displays a marked and enduring fear of specific situations or objects. Individuals with specific phobias experience extreme fear as soon as they encounter a defined situation or object, a phobic stimulus. For example, an individual with a specific phobia of dogs will become anxious when coerced to confront a dog. The specific phobia triggers a lot of distress or significantly impairs an affected individual.

Mental health professionals use the ***Diagnostic and Statistical Manual of Mental Disorders*** (the *DSM*) to diagnose mental disorders. The 2000 edition of this manual (the Fourth Edition Text Revision, also called the *DSM-IV-TR*) classifies specific phobia as a type of anxiety disorder. Formerly, specific phobia was known as simple phobia. In the last few years, mental health professionals have paid more attention to specific phobias.

Description

Specific phobia has a unique position among the anxiety disorders in that individuals with this disorder do not experience pervasive anxiety nor do they seek treatment as readily as individuals with other anxiety disorders. Unlike individuals with other anxiety disorders, the fear of individuals with specific phobias is limited to defined situations or objects. Individuals with specific phobias experience impairment or a significant amount of anguish. They may lead restricted lifestyles depending upon the phobia type. Adults and adolescents with specific phobias recognize that their fear is unreasonable. Children, on the other hand, may not recognize that their fear of the phobic stimulus is unreasonable or extreme.

The types of specific phobias include situational, object, and other. The situational type is diagnosed if an individual's fear is cued by a defined situation. Examples include situations such as flying, enclosed places, tunnels, driving, bridges, elevators, or public transportation. Object types include animal, natural environment, and blood-injection-injury types. Animal type is diagnosed if an individual's fear is cued by animals or insects. Natural environment type is diagnosed if an individual's fear is cued by storms, water, or heights. Blood-injection-injury type is diagnosed if an individual's fear is cued by seeing an injury or blood or by an injection or other invasive medical treatment. Other type is diagnosed if an individual's fear is cued by other stimuli such as fears of vomiting, choking, becoming ill, and falling down if far from a means of physical support, and a child's fears of loud noises or characters in costumes.

Researchers have found that the frequency of type for adults in clinical settings, from least to most frequent, is: animal, blood-injection-injury, natural environment, and situational. The most common phobias for community samples, however, include phobias of heights, mice, spiders, and insects.

Causes and symptoms

Causes

The development of a specific phobia may be determined by a variety of factors. Behavioral, cognitive, and social theories of learning and conditioning, psychodynamic models such as the psychoanalytic theory of Freud, physiological studies of the **brain**, family background and genetic predisposition, variations in sociocultural themes, and theories on trauma can influence the development of specific phobia disorder. Some theorists propose that biological researchers have ignored specific phobias because pharmacological treatment is not the treatment of choice for this disorder.

LEARNING AND CONDITIONING CAUSES. As of 2002, research on phobias focuses on information-processing, learning, and conditioning themes. Learning to experience fear is the core of a conditioning perspective. Informational and instructional factors can result in the formation of fears. For example, an individual who frequently hears of plane crashes in the news may develop a specific phobia of flying. Research shows that individuals with specific phobias pay more attention to information about danger than do individuals who do not have specific phobias. Vicarious acquisition occurs when an individual witnesses a traumatic event or sees another individual behave with fear when confronting a phobic stimulus. Direct conditioning occurs when an individual is frightened by a phobic stimulus.

A major determinant of specific phobias is conditioning. Association and avoidance are types of conditioning. In association conditioning, a stimulus that was initially neutral begins to trigger an anxiety response. For example, if an individual was driving one day and experienced a strong anxiety response, an association may form between driving and anxiety. Individuals do not learn to become phobic until they begin to avoid. In avoidance conditioning, individuals learn to avoid a stimulus that triggers anxiety. Every time individuals avoid the phobic stimulus—driving, for example—they are rewarded by the relief from anxiety.

TRAUMATIC CAUSES. A determinant of specific phobias includes traumas. For example, individuals who have been attacked by a dog may develop a specific phobia disorder and become conditioned to fear dogs. Individuals who observe others experiencing a trauma (the others are “modeling” behavior for the individual who will be affected) may become predisposed to developing specific phobia disorder. For example, individuals who witness people falling from a building may develop a specific phobia disorder. Phobias with a traumatic origin may develop acutely, or, in other words, have a more sudden onset than other phobias that develop more gradually.

PSYCHODYNAMIC CAUSES. Psychodynamic theorists explain that phobias emerge because individuals have impulses that are unacceptable, and they repress these impulses. More specifically, Freud proposed that phobias emerge because of an unresolved oedipal conflict. According to Freud’s theory, an oedipal conflict is a developmental conflict that emerges during the third (or oedipal) stage of Freud’s psychosexual development stages. During this stage, a conflict emerges with regard to the triad of father, mother, and child. The conflict concerns the sexual impulses that the child has toward the parent of the opposite gender and the hostile impulses that the child has towards the parent of the same gender. During this stage, the developmental conflict concerns a

Oedipal conflict—A developmental conflict that emerges during the third or oedipal stage of Freud’s psychosexual development stages. During this stage, a conflict emerges with regard to the triad of father, mother, and child. The conflict concerns the sexual impulses that the child has toward the parent of the opposite gender and the hostile impulses that the child has towards the parent of the same gender. During this stage, the developmental conflict concerns a resolution of oedipal issues.

resolution of oedipal issues. Psychoanalysts propose that when repression does not work, individuals with phobias displace their anxiety connected to the unresolved oedipal conflict upon a situation or object that is less relevant. The feared situation or object symbolizes the source of the conflict. For example, a specific phobia may be connected to an individual’s conflict about aggressive or sexual thoughts and feelings. In one sense, a phobia protects individuals from realizing their emotional issues.

The case of Hans, a boy with a horse phobia, is Freud’s paradigm example of a phobia. Freud attributed Hans’ fear of horses to an oedipal conflict that was not resolved, and he explained that Hans repressed his sexual feelings for his mother and his wish that his father would die. Freud proposed that Hans feared that his father would discover his wish, repressed his wish to attack his father, and displaced his fear of his father’s aggression onto horses. The young boy resolved the conflict of loving and hating his father by hating horses rather than admitting that he had aggressive feelings towards his father. Hans was better able to avoid the feared horses than his father. Thus, the phobia in the case of Hans represents a compromise of intrapsychic movement.

PHYSIOLOGICAL CAUSES. Some research has suggested that the high activation of brain pathways that correspond to the cognitive and emotional constituents of anxiety biologically predispose individuals to specific phobias.

GENETIC AND FAMILY CAUSES. Although specific phobia is frequently attributed to environmental issues such as **modeling**, learning by association, and negative **reinforcement**, genetic predisposition can influence this

disorder. An individual who has a family member with a specific phobia is at an increased risk for developing this disorder. Some research indicates that the pattern of types are similar within families. For example, a first-degree biological relative of individuals with a situational type is likely to have phobias of situations. Studies indicate that the blood and injury phobias have strong familial patterns.

SOCIOCULTURAL CAUSES. There is a paucity of information about cultural differences in specific phobias. Phobia content may vary by culture. Fear of a phobic stimulus such as magic or spirits, present in several cultures, is diagnosed as a specific phobia only if the fear is excessive for a particular culture and if the fear triggers major distress or interferes with functioning. Some research indicates that African Americans are more likely than whites to report specific phobias. Some studies show that specific phobias are less common among whites born in the U.S. or immigrant Mexican-Americans than among Mexican-Americans born in the U.S. Research suggests mixed data with regard to socioeconomic level, with some data associating specific phobia disorder with a lower socioeconomic level.

PERSONAL VARIABLES. Studies suggest a relationship between age and specific phobia. Research indicates some connections between the age of individuals with specific phobias and insight into the extreme quality of their fears. Insight increases with age. Children, unlike adults and adolescents, often do not report feelings of distress about having phobias. Insight into the unreasonable nature of the fear is not required for a **diagnosis** of specific phobia in children. The animal and natural environment types of specific phobia are common and generally transitory in children. Some studies indicate a connection between gender and specific phobia. Research shows that specific phobias from the animal type are more common among women. Some studies suggest that women are more likely to report specific phobias and to seek treatment than men.

Symptoms

DSM-IV-TR delineates seven diagnostic criteria for specific phobia:

- Significant and enduring fear of phobic stimulus: Patients with specific phobia display marked and enduring fear when they encounter a defined situation or object, the phobic stimulus.
- Anxiety response to phobic stimulus: Patients with specific phobia display anxiety as soon as they confront the phobic stimulus. When they confront the phobic stimulus, a defined situation or object, patients with specific phobia may experience a **panic attack** related to the specific situation. Children may cry, cling, freeze, or display tantrums when they express their anxiety in the face of the phobic stimulus.
- Recognition: Although adolescents and adults realize that their fear is unreasonable and disproportionate to the situation, children may not recognize that their fear is excessive.
- Avoidance: Individuals with specific phobia avoid the phobic stimulus or endure it with deep distress and anxiety.
- Impairment and distress: Individuals with specific phobia display avoidance, distress, and anxious anticipation when they encounter the phobic stimulus. Their avoidance reactions interfere with their daily functioning, or they express significant distress about having a phobia.
- Duration: To diagnose specific phobia in a patient who is under 18 years of age, the duration of the disorder needs to be at least six months.
- Not accounted for by another disorder: A diagnosis of specific phobia is assigned if the phobic avoidance, panic attacks, or anxiety related to the defined situation or object are not better accounted for by other disorders.

Demographics

General United States population

Specific phobias are common. The prevalence rates of specific phobia in community samples range from 4% to 8%. Over the course of a lifetime, the prevalence estimates in community samples range from 7.2% to 11.3%.

High-risk populations

Individuals whose family members have specific phobia are at a higher risk for developing this disorder.

Cross-cultural issues

Prior to assigning a diagnosis of specific phobia, clinicians need to consider whether a patient's fear is extreme in the context of a particular culture and whether the phobia causes difficulties in daily functioning or triggers a lot of distress. Further research is needed on the effects of culture upon the symptoms of specific phobia.

Gender issues

There are twice as many women with specific phobia than there are men with this disorder. The gender ratio variable varies depending upon the type of specific phobia. Approximately 75%–90% of people with the animal, situational, and natural environment types are female.

Approximately 55%–70% of people with the blood-injection-injury subtype are female. For height phobias, there are fewer women than men than for other specific phobia types; however, illness phobias are more common in men.

Diagnosis

The diagnosis of specific phobia is complicated by factors such as degree of impairment and differential diagnosis. Although fears of specified situations or objects are common, a diagnosis of specific phobia relies on the degree of sufficient impairment.

With regard to differentiating specific phobia types, factors such as the focus of fear and the predictability and timing of the reaction to the phobic stimulus across the specific phobia types can assist clinicians to differentiate. With regard to differentiating specific phobia from other disorders, there are several disorders with similar symptoms. They include **panic disorder with agoraphobia, social phobia, post-traumatic stress disorder, obsessive-compulsive disorder, hypochondriasis, schizophrenia**, delusional, and other psychotic disorders. Generally, a diagnosis of specific phobia rather than panic disorder is made when there are no spontaneous panic attacks and no fear of panic attacks. It is often difficult to differentiate specific phobia, situational type, from panic disorder with agoraphobia. Specific phobia, situational type, is commonly diagnosed when an individual displays situational avoidance without unexpected and recurrent panic attacks. On the other hand, panic disorder with agoraphobia is diagnosed if an individual experiences an initial onset of panic attacks that are not anticipated and subsequently experiences avoidance of several situations considered triggers of panic attacks. Although individuals with specific phobia, unlike individuals with panic disorder with agoraphobia, do not display enduring anxiety, anxious anticipation may occur when confrontation with a phobic stimulus is more likely to occur. *DSM-IV-TR* outlines differentiating factors as the type and number of panic attacks, the number of avoided contexts, and the focus of the fear. At times, both diagnoses, specific phobia and panic disorder with agoraphobia, need to be assigned.

Psychological measures

Measures used to diagnose specific phobia include behavioral observation, clinical interviews, physiological evaluation, and self-report measures. The Behavioral Avoidance Task (BAT) is a common behavioral observation method used to assess specific phobia. Often, the diagnosis of specific phobia is made on the basis of an individual's responses to semistructured interviews such

as the Anxiety Disorders Interview Schedule for *DSM-IV* (ADIS-IV) and the Structured Clinical Interview for *DSM-IV* Axis I Disorders (SCID-IV). To assist in differential diagnosis between specific phobias and other disorders with similar characteristics, clinicians use the Anxiety Disorders Interview Schedule for *DSM-IV* (ADIS-IV). Physiological evaluations usually include heart rate monitors. Self-report questionnaires include measures such as the SUDS (subjective units of discomfort/distress scale), the most frequently used self-report measure, the Fear Survey Schedule (FSS-III), and the Mutilation Questionnaire, specifically for measuring fear of the blood type of specific phobia.

Time of onset/symptom duration

Generally, the initial symptoms of specific phobia occur when an individual is a child or a young adolescent. The type of phobia determines the age of onset. The blood, animal, and natural environment types begin when an individual is a child; however, many new cases of the natural environment type occur when an individual is a young adult. The onset for the height type begins in adolescence. The onset age for the situational type occurs in childhood, but peaks again in the mid-twenties. There is no specific onset age for phobias with a traumatic origin.

Individual variations in specific phobia

Classification systems distinguish between individuals with different types of specific phobias. The types of specific phobia, situation, object, and other, relate to particular features such as the age, gender, and culture of an individual. Some researchers propose that to distinguish individual differences in treatment planning, it is more

helpful to simply name the specific phobia rather than to use the type classification system. For example, researchers have found that for the animal type, some animals such as a tiger or a bear did not trigger disgust for tiger-phobic or bear-phobic individuals, but other animals such as a spider triggered disgust for some spider phobic individuals, but did not trigger disgust for other spider phobic individuals.

Dual diagnoses

Specific phobia often occurs with other disorders of mood and anxiety, and with substance-related disorders. When specific phobias occur with other disorders in clinical contexts, the primary diagnosis is associated with greater distress than is the specific phobia. The blood-injury-injection type of specific phobia may occur with physical symptoms such as vasovagal fainting. The vasovagal fainting response is characterized by a short heart rate acceleration and blood pressure elevation. Then, the heart rate decelerates and the blood pressure drops. Research shows that individuals who have one specific phobia type are more likely to have other phobias of the same type.

Treatments

Specific phobias are highly treatable. They are most effectively treated by psychological rather than biological treatments. The primary goal of most treatments of specific phobias is to reduce fear, phobic avoidance, impairment, and distress. Approximately 12%–30% seek treatment for specific phobias.

Cognitive-behavioral therapy

Cognitive-behavioral therapy has been effective in treating specific phobias. There has not been much research on the effects of cognitive therapy alone on specific phobias. Cognitive therapists challenge fearful thoughts and replace them with more positive thoughts. Although some studies show benefits in that cognitive therapy may assist patients to decrease anxiety related to their exposure exercises, research indicates that cognitive therapy alone is probably not an effective treatment for specific phobia. Researchers suggest adding panic management strategies such as cognitive restructuring to assist with behavioral treatments.

Several studies indicate that real-life (in vivo) desensitization or exposure is the most effective and long-lasting treatment for a broad range of specific phobias. **Systematic desensitization** includes a process by which individuals unlearn the association between the phobic stimulus and anxiety. Incremental exposure involves the

patient's gradual facing of the phobic stimulus through a series of graded steps. Wolpe's imagery desensitization is suggested so that patients with specific phobias can face the fear in imagery prior to attempting in vivo exposure. Unlike many of the other treatments, the treatment gains of in vivo exposure are maintained upon follow-up. Some desensitization treatments employ flooding as a useful strategy. When flooding is used, patients maintain a high anxiety level without retreating. Similar to desensitization, flooding can be used both in imagination and in vivo. Flooding is not suggested for most individuals because it can trigger a higher level of sensitization and fear reinforcement. For in vivo treatment, a patient needs to be highly motivated because the treatment may lead to temporary discomfort. The primary reasons for poor **compliance** with cognitive-behavioral treatment include lack of time, anxiety, and low motivation.

Psychodynamic therapy

Psychodynamic psychotherapy, or insight-oriented therapy assists patients to become more aware of the symbolic nature of their anxiety and to explore traumatic past events. Insight-oriented therapy is a psychodynamic therapy that aims to expose and reduce patients' unconscious conflicts, increase patients' understanding of their underlying thoughts, and assist patients to gain conscious control over their psychological conflicts. In psychodynamic therapy, for example, patients may discover that their anxiety may be connected to aggressive or sexual feelings and thoughts.

Group therapy

There is little research on **group therapy** for specific phobia disorder. Some studies suggest that group treatment has been effective for dental and spider phobias.

Medications

There has been a paucity of research on the relationship between medication and specific phobia. Generally, pharmacotherapy has not been considered to be a treatment of choice for individuals with specific phobias. Benzodiazepines, however, (medications that slow the central nervous system to ease nervousness and tension) may decrease anticipatory anxiety prior to an individual's entrance into a phobic situation. A low dose of a benzodiazepine such as **clonazepam** (Klonopin) or **alprazolam** (Xanax) is indicated to decrease some fear arousal prior to in vivo exposure. The reduction of symptoms, however, may interfere with the treatment. Prior to beginning in vivo exposure, an antidepressant such as **sertraline** (Zoloft) or **paroxetine** (Paxil) is suggested to increase motivation for undertaking an uncomfortable

treatment. **Beta blockers** can assist individuals to confront the specific phobia.

Alternative therapies

Research shows some benefits for specific phobias with applied relaxation. Relaxation training includes abdominal breathing and muscle relaxation on a regular basis. Studies have indicated that applied muscle tension has been highly effective for individuals with blood type phobias who faint in that the treatment triggers an early response. When using applied tension, therapists request that patients tense their muscles several times. The repeated muscle tensing results in a temporary increase in blood pressure and prevents fainting when patients see blood. Similar to in vivo exposure, the gains from applied tension are maintained upon follow-up. Some alternative therapies include immersive virtual reality, **hypnotherapy**, eye-movement desensitization and reprocessing (EMDR), and energy balance approaches such as massage and **acupuncture**.

Prognosis

If specific phobias exist in adolescence, they have a greater chance of persisting in early adulthood. Specific phobias that continue into adulthood generally become chronic if they are not treated. Furthermore, there is a greater chance for an individual diagnosed with specific phobia to develop new phobias as a young adult. Phobias contracted during childhood or adolescence that continue when individuals become young adults remit approximately 20% of the time. Individuals with specific phobias do not often seek treatment. For those who seek treatment, research suggests that compared to individuals with specific phobias whose fear diminishes slowly during exposure, individuals with specific phobias whose fear diminishes more rapidly have a better prognosis for recovery.

A consideration of prognosis takes into account the distinction between fear onset and phobia onset. Studies indicate that individuals with specific phobias of animal, blood, heights, and driving had a fear onset nine years earlier than their phobia onset. Some studies have shown that generalized anxiety level, severity of symptoms, and prior experience with the phobic stimulus are factors that have been associated with treatment outcome.

Although most mental health professionals consider specific phobia that begins in childhood to be a benign disorder, it can last for years if left untreated. Some studies indicate, however, that specific phobia does not become worse and usually diminishes as an individual ages. Without treatment, the prognosis is poor for an individual who has several phobias.

Prevention

Early detection is a key to assisting individuals with mild cases of specific phobia to seek treatment to prevent the development of full-blown cases of the disorder. Individuals who are at risk for developing specific phobia as well as individuals who already have been diagnosed with specific phobia need to avoid caffeine because caffeine can increase arousal. Further research is needed to discover variables that predict the reason that only certain individuals will develop specific phobias after conditioning or acquiring information that leads to fear.

Speech-language pathology

Definition

Speech-language pathology is the treatment for the improvement or cure of communication disorders, including speech, language, and swallowing disorders. The term used to describe professionals in this discipline is speech and language pathologist (SLP).

Description

The discipline of speech-language pathology includes professionals that are trained in the techniques, strategies, and interventions designed to improve or correct communication disorders. Communication disorders include disorders of speech, language, and swallowing.

In 2000, there were nearly 88,000 speech-language pathologists in the United States certified by the American Speech-Language-Hearing Association (ASHA), and an additional 13,000 audiologists, who often work with speech pathologists to diagnose disorders. Speech disorders treated by speech-language pathologists include voice disorders (abnormalities in pitch, volume, vocal quality, or resonance or duration of sounds), articulation disorders (problems producing speech sounds), and fluency disorders (impairment in speech fluency, such as **stuttering**). Language disorders include developmental or acquired conditions that lead to difficulties in understanding or producing language. Speech-language pathologists participate in the screening, assessment, and treatment of patients who experience one or a combination of these disorders.

Persons with isolated speech sound disorders are often helped by articulation therapy, in which they practice repeating specific sounds, words, phrases, and sentences. For individuals experiencing voice disorders, a combination of medical and behavioral treatments are often helpful. For stuttering and other fluency disorders, treatment approaches usually help individuals develop techniques to both reduce the severity of stuttering and allow the individual to produce more fluent speech. For all of these therapies, individuals are taught to cope more effectively with their speech in progressively difficult situations, starting with speaking alone to the pathologist and ending with speaking to a group of people. In treating children with developmental language disorders, treatment often focusses on **modeling** and stimulation of correct productions of language. This type of approach may also be useful for adults with language disorders, secondary to a **stroke** or degenerative neurological disorder. For people with severe communication disorders, those due to either a speech or language problem, speech pathologists can assist with alternate means of communication, such as manual signing and computer-synthesized speech. Finally, speech-language pathologists have become increasingly involved with the assessment and treatment of individuals with swallowing disorders, or dysphagia.

The majority of speech-language pathologists work in public schools. They are also found at both residential health care facilities and outpatient clinics that specialize in communication disorders. Finally, speech-language pathologists are often employed at hospitals and universities. Professional training programs in speech-language pathology are offered at both the undergraduate and graduate levels. Undergraduate training may include classes in

biology, anatomy, psychology, linguistics, education, and special education. Graduate training, at both the masters and doctoral level, provides much deeper opportunities to study communication disorders and their treatment. To receive the Certificate of Clinical Competence (CCC) in speech-language pathology, individuals must hold a master's degree in communications sciences and disorders from a program accredited by the ASHA and complete their Clinical Fellowship Year (CFY).

St. John's wort

Definition

St. John's wort is a perennial, yellow-flowering plant that grows in the wild throughout Europe and is now found also in North America. The plant tends to be in blossom in the month of June, around the day considered to be the birthday of John the Baptist; hence its popular name. The plant's Latin name is *Hypericum perforatum*.

St. John's wort has been used as a popular herbal folk remedy for centuries. More recently, practitioners of conventional Western medicine have been exploring its utility for treating depression and anxiety.

Purpose

Writings since the Middle Ages have described using St. John's wort as treatment for inflammation, injuries, burns, muscle pain, anxiety, high blood pressure, stomach problems, fluid retention, **insomnia**, hemorrhoids, cancer, and depression. Research conducted over the 1990s in Europe studied the efficacy of St. John's wort for the treatment of depression and anxiety. Research protocols have been developed in the United States to study the same issues, to determine appropriate dosages,

Monoamine oxidase inhibitors—A group of antidepressant drugs that decrease the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Reserpine—Medication to treat high blood pressure. Brand names include Serpalan, Novoreserpine, and Reserfia.

Theophylline—A medication used to treat asthma. Sold under many brand names, including Aerolate Sr, Respbid, and Theolair.

Warfarin—A medication that helps to prevent the formation of clots in the blood vessels. Sold as Coumadin in the U.S.

to develop standard formulations, and to define whether it can be used for all forms of depression or only for more mild forms of the condition.

Description

Research has yet to completely explain how St. John's wort affects the **brain** in depression. It is, however, thought to change the balance of chemicals in the brain in much the same way as selective serotonin reuptake inhibitors (SSRIs) such as **fluoxetine** (Prozac), and monoamine oxidase inhibitors (MAOIs). The active ingredients are thought to be compounds called hypericin and pseudohypericin, although researchers are attempting to identify other chemicals that may be involved in the herb's effectiveness.

The leaves and flowers of St. John's wort are both used. St. John's wort is available as pills, capsules, extracts, dried herbs for tea, and oil infusions for skin applications.

Recommended dosage

Because dosages of herbal preparations are not always standardized, it is important to discuss with a knowledgeable practitioner the most reliable form of St. John's wort. Recommendations call for 300–500 mg (of a standardized 0.3% hypericin extract) three times daily. It can take four to six weeks to notice the antidepressant effects of this preparation.

Alternatively, one to two teaspoons of dried St. John's wort can be put into a cup of boiling water and

steeped for 10 minutes to make tea. The recommended dosage of tea is one to two cups daily. Again, four to six weeks may be necessary in order to notice improvement in symptoms of depression.

Precautions

The following precautions should be considered and discussed with a knowledgeable practitioner before St. John's wort is taken:

- Some people may become more sensitive to the sun.
- Patients taking MAOIs must carefully avoid taking St. John's wort due to serious adverse effects of combining the two.
- Because the effects of St. John's wort are still being studied, pregnant and breast-feeding women should avoid its use.
- Depression can be a serious, even life-threatening, condition; therefore, it is imperative that depressed patients using St. John's wort are carefully monitored.

Side effects

People taking St. John's wort may develop one or all of the following side effects:

- skin rash due to sun sensitivity—the most common side effect
- headache, dizziness, dry mouth, constipation
- abdominal pain, confusion, sleep problems, and high blood pressure are less frequently experienced

Interactions

Again, a knowledgeable professional should be consulted before St. John's wort is taken to determine the appropriateness of its use and avoid serious interactions. Interactions include:

- Possible decrease in effectiveness of reserpine, warfarin, theophylline, immunosuppressant medications such as cyclosporine, and antiviral drugs such as indinavir.
- Dangerous interactions when used with other antidepressant medicines (especially MAOIs), digoxin, and loperamide.
- Interactions with oral birth control pills. St. John's wort may interfere with the effectiveness of birth control pills, increasing the risk of pregnancy; an alternative form of birth control should be considered while taking St. John's wort. In addition, women taking both birth control pills and St. John's wort may notice bleeding between menstrual periods.

Stanford-Binet Intelligence Scale

Definition

The Stanford-Binet Intelligence Scale: Fourth Edition (SB: FE) is a standardized test that measures intelligence and cognitive abilities in children and adults, from age two through mature adulthood.

Purpose

The Stanford-Binet Intelligence Scale was originally developed to help place children in appropriate educational settings. It can help determine the level of intellectual and cognitive functioning in preschoolers, children, adolescents and adults, and assist in the **diagnosis** of a learning disability, developmental delay, **mental retardation**, or giftedness. It is used to provide educational planning and placement, neuropsychological assessment, and research. The Stanford-Binet Intelligence Scale is generally administered in a school or clinical setting.

Precautions

The Stanford-Binet Intelligence Scale is considered to be one of the best and most widely used **intelligence tests** available. It is especially useful in providing intellectual assessment in young children, adolescents, and young adults. The test has been criticized for not being comparable for all age ranges. This is because different age ranges are administered different subtests. Additionally, for very young preschoolers, it is not uncommon to receive a score of zero due to test difficulty or the child's unwillingness to cooperate. Consequently, it is difficult to discriminate abilities in this age group among the lower scorers.

Administration and interpretation of results of the Stanford-Binet Intelligence Scale requires a competent examiner who is trained in psychology and individual intellectual assessment, preferably a **psychologist**.

Description

The Stanford-Binet Intelligence Scale has a rich history. It is a descendant of the Binet-Simon scale which was developed in 1905 and became the first intelligence test. The Stanford-Binet Intelligence Scale was developed in 1916 and was revised in 1937, 1960, and 1986. The present edition was published in 1986. The Stanford Binet Intelligence Scale is currently being revised and the Fifth Edition is expected to be available in the spring of 2003.

Administration of the Stanford-Binet Intelligence Scale typically takes between 45 to 90 minutes, but can take as long as two hours, 30 minutes. The older the child and the more subtests administered, the longer the test generally takes to complete. The Stanford-Binet Intelligence Scale is comprised of four cognitive area scores which together determine the composite score and factor scores. These area scores include: Verbal Reasoning, Abstract/Visual Reasoning, Quantitative Reasoning, and Short-Term Memory. The composite

Abstract and visual reasoning are analyzed in Stanford-Binet intelligence tests. This blindfolded subject is matching shapes by touch. (Richard Nowitz. Photo Researchers, Inc. Reproduced by permission.)

score is considered to be what the authors call the best estimate of “g” or “general reasoning ability” and is the sum of all of subtest scores. General reasoning ability or “g” is considered to represent a person's ability to solve novel problems. The composite score is a global estimate of a person's intellectual functioning.

The test consists of 15 subtests, which are grouped into the four area scores. Not all subtests are administered to each age group; but six subtests are administered to all age levels. These subtests are: Vocabulary, Comprehension, Pattern Analysis, Quantitative, Bead Memory, and Memory for Sentences. The number of tests administered and general test difficulty is adjusted based on the test taker's age and performance on the subtest that measures word knowledge. The subtest measuring word knowledge is given to all test takers and is the first subtest administered.

The following is a review of the specific cognitive abilities that the four area scores measure. The Verbal Reasoning area score measures verbal knowledge and understanding obtained from the school and home learning environment and reflects the ability to apply verbal skills to new situations. Examples of subtests comprising this factor measure skills which include: word knowledge, social judgment and awareness, ability to isolate the inappropriate feature in visual material and social intelligence, and the ability to differentiate essential from non-essential detail.

The Abstract/Visual Reasoning area score examines the ability to interpret and perform mathematic operations, the ability to visualize patterns, visual/motor skills, and problem-solving skills through the use of reasoning.

An example of a subtest which determines the Abstract/Visual Reasoning score is a timed test that involves tasks such as completing a basic puzzle and replicating black and white cube designs.

The Quantitative Reasoning area score measures: numerical reasoning, concentration, and knowledge and application of numerical concepts. The Quantitative Reasoning area is combined with the Abstract/Visual Reasoning area score to create an Abstract/Visual Reasoning Factor Score.

The Short-Term Memory score measures concentration skills, short-term memory, and sequencing skills. Subtests comprising this area score measure visual short-term memory and auditory short term memory involving both sentences and number sequences. In one subtest that measures visual short-term memory, the participant is presented with pictures of a bead design, and asked to replicate it from memory.

Results

The Stanford-Binet Intelligence Scale is a standardized test, which means that a large sample of children and adults were administered the exam as a means of developing test norms. The population in the sample was representative of the population of the United States based on age, gender, race or ethnic group, geographic region, community size, parental education, educational placement (normal versus special classes), etc. From this sample, norms were established. Norms are the performance of a comparison group of subjects—that nature of the group should be specified, and this usually constitutes a normal group so that the performance of the tested individual can be compared to this group and thus evaluated.

The numbers of correct responses on the given subtests are converted to a SAS score or Standard Age Score which is based on the chronological age of the test subject. This score is similar to an I.Q. score. Based on these norms, the Area Scores and Test Composite on the Stanford-Binet Intelligence Scale each have a mean or average score of 100 and a standard deviation of 16. For this test, as with most measures of intelligence, a score of 100 is in the normal or average range. The standard deviation indicates how above or below the norm a child's score is. For example, a score of 84 is one standard deviation below the norm score of 100. Based on the number of correct responses on a given subtest, an age-equivalent is available to help interpret the person's level of functioning.

Test scores provide an estimate of the level at which a child is functioning based on a combination of many different subtests or measures of skills. A trained psychologist is needed to evaluate and interpret the results,

determine strengths and weaknesses, and make overall recommendations based on the findings and observed behavioral observations.

Stereotypic movement disorder

Definition

Stereotypic movement disorder is a disorder characterized by repeated, rhythmic, purposeless movements or activities such as head banging, nail biting, or body rocking. These movements either cause self-injury or severely interfere with normal activities. Until 1994, the American Psychiatric Association referred to stereotypic movement disorder as stereotypy/habit disorder.

Description

Stereotypic movements were first described as a psychiatric symptom in the early 1900s. Since then, they have been recognized as a symptom of both psychotic and neurological disorders. They may also arise from unexplained causes. These movements may include:

- head banging
- nail biting

- playing with hair (but not hair pulling, which is considered the separate disorder of **trichotillomania**)
- thumb sucking
- hand flapping
- nose picking
- whirling
- body rocking
- picking at the body
- self-biting
- object biting
- self-hitting
- compulsive scratching
- eye gouging
- teeth grinding (bruxism)
- breath holding
- stereotyped sound production

The precise definition of stereotypic movement disorder has changed over the past 20 years. Today, it limits the disorder to repetitive movements that cause physical harm or severely interfere with normal activities. These movements cannot be better described by another psychiatric condition such as anxiety disorder, a general medical condition such as Huntington's disease, or as the side effect of a medication or illicit drug (for example, cocaine use).

Stereotypic movements occur in people of any age, including the very young, but they are most prevalent in adolescence. People may exhibit only one particular stereotyped movement or several. The movements may be slow and gentle, fast and frenetic, or varied in intensity. They seem to increase with boredom, tension, or frustration, and it appears that the movements are self-stimulatory and sometimes pleasurable. The root causes are unknown.

Stereotypic movements are common in infants and toddlers. Some estimates suggest that 15–20 percent of children under age three exhibit some kind of rhythmic, repetitive movements. Certainly thumb sucking and body rocking are common self-comforting mechanisms in the very young. This type of repeated movement is temporary, and usually ends by age three or four. It is not the same as stereotypic movement disorder.

Causes and symptoms

Causes

Stereotypic movements can be caused by:

- sensory deprivation (blindness or deafness)

- drug use (cocaine, amphetamines)
- brain disease (**seizures**, infection)
- major psychiatric disorders (anxiety disorder, **obsessive-compulsive disorder**, **autism**)
- **mental retardation**

It has also been suggested that inadequate caregiving may cause the disorder. Although many situations can give rise to stereotypic movements, the root cause of stereotypic movement disorder is unknown. Different theories propose that the causes are behavioral, neurological, and/or genetic. Although there are many theories to account for this disorder, no hard evidence clearly supports one line of reasoning or specific cause.

Symptoms

Symptoms of stereotypic movement disorder include all the activities listed above. It should be noted that many of these activities are normal in infants. They usually begin between five and 11 months, and disappear on their own by age three. In fact, about 55% of infants grind their teeth. These passing phases of repetitive movement in infants are not the same as stereotypic movement disorder. They do not cause harm, and often serve the purpose of self-comforting or helping the child learn a new motor skill.

People with stereotypic movement disorder often hurt themselves. They may pick their nail cuticles or skin until they bleed. They may repeatedly gouge their eyes, bite or hit themselves causing bleeding, bruising, and sometimes, as in the case of eye gouging or head banging, even more severe damage. Some people develop behaviors such as keeping their hands in their pockets, to prevent these movements. In other cases those who hurt themselves appear to welcome, rather than fight, physical restraints that keep them safe. However when these restraints are removed, they return to their harmful behaviors.

Demographics

Stereotypic movement disorder is most strongly associated with severe or profound mental retardation, especially among people who are institutionalized and perhaps deprived of adequate sensory stimulation. It is estimated that 2–3% of people with mental retardation living in the community have stereotypic movement disorder. About 25% of all people with mental retardation who are institutionalized have the disorder. Among those with severe or profound retardation, the rate is about 60%, with 15% showing behavior that causes self-injury.

Stereotypic movements are common among children with **pervasive developmental disorders** such as autism, childhood degenerative disorder, and **Asperger's disorder**. These movements can also be seen in people with Tourette's disorder or with tics. Head banging is estimated to affect about 5% of children, with boys outnumbering girls three to one, although other stereotypic behaviors appear to be distributed equally between males and females. Despite its association with psychiatric disorders, there are some people with normal intelligence and adequate caregiving who still develop stereotypic movement disorder.

Diagnosis

Stereotypic movements are diagnosed by the presence of the activities mentioned above. Young children rarely try to hide these movements, although older children may, and the first sign of them may be the physical harm they cause (bleeding skin, chewed nails). Often parents mention these repetitive movements when the physician takes a history of the child.

The difficulty in diagnosing stereotypic movement disorder comes from distinguishing it from other disorders where rhythmic, repetitive movements occur. To be diagnosed with stereotypic movement disorder, the following conditions must be met:

- The patient must show repeated, purposeless motor behavior.
- The patient must experience physical harm from this behavior or it must seriously interfere with activities.
- If the patient is mentally retarded, the behavior must be serious enough to need treatment.
- The behavior must not be a symptom of another psychiatric disorder.
- The behavior must not be a side effect of medicinal or illicit substance use.
- The behavior must not be caused by a diagnosed medical condition.
- The behavior must last at least four weeks. The disorder may be classified as either with self-injurious behavior or without self-harm.

This definition of stereotypic movement disorder rules out many people who show repetitive movement because of autism or other pervasive developmental disorders. It also rules out those with obsessive-compulsive disorder, where movements are apt to be ritualistic and follow rigid rules or patterns. In addition, specific disorders such as trichotillomania (hair pulling) do not fall under the **diagnosis** of stereotypic movement disorder, nor do developmentally appropriate self-stimulatory

behavior among young children, such as thumb sucking, rocking or transient pediatric head banging.

Treatments

There are few successful treatments for stereotypic movement disorder. When the patient harms himself, physical restraints may be required. In less severe situations, behavioral modifications using both rewards and punishments may help decrease the intensity of the behavior. Drugs that have been used with some success to treat stereotypic movement disorder include **clomipramine** (Anafranil), **desipramine** (Norpramin), **haloperidol** (Haldol) and **chlorpromazine** (Thorazine).

Prognosis

Stereotypic movements peak in adolescence, then decline, and sometimes disappear. Although **behavior modification** may reduce the intensity of the stereotypic movements, rarely does it completely eliminate them. **Stress** and physical pain may bring on these movements, (which may come and go for years), especially among those patients with severe mental retardation.

Prevention

Stereotypic movement disorder cannot be prevented. Interventions should be done to prevent self-injury.

Stigma

Definitions

The 1999 report on mental health by the Surgeon General of the United States was regarded as a landmark document in the United Kingdom, as well as the United States. This was because of its straightforward identifica-

tion of the stigma associated with mental illness as the chief obstacle to effective treatment of persons with mental disorders. *Stigma* (plural, *stigmata*) is a Greek word that in its origins referred to a kind of tattoo mark that was cut or burned into the skin of criminals, slaves, or traitors in order to visibly identify them as blemished or morally polluted persons. These individuals were to be avoided or shunned, particularly in public places. The word was later applied to other personal attributes that are considered shameful or discrediting.

Social psychologists have distinguished three large classes, or categories, of stigma:

- Physical deformities. These include extremes of height and weight and such conditions as albinism and facial disfigurements or missing limbs. In the developed countries, this category also includes such signs of aging as gray hair, wrinkles, and stooped posture.
- Weaknesses or defects of individual character. This category includes biographical data that are held to indicate personal moral defect, such as a criminal record, **addiction**, divorce, treatment for mental illness, unemployment, **suicide** attempts, etc.
- Tribal stigma. This type of stigma refers to a person's membership in a race, ethnic group, religion, or (for women) gender that is thought to disqualify all members of the group.

The nature of stigma

Origins

One explanation for the origin of *stigmata* is that its roots in the human being's concern for group survival at earlier times in their evolutionary journey. According to this theory, stigmatizing people who were perceived as unable to contribute to the group's survival, or who were seen as threats to its well-being, were stigmatized in order to justify being forced out or being isolated.

The group survival theory is also thought to explain why certain human attributes seem to be universally regarded as *stigmata*, while others are specific to certain cultures or periods of history. Mental illness appears to be a characteristic that has nearly always led to the stigmatization and exclusion of its victims. The primary influences on Western culture, the classical philosophical tradition of Greece and Rome, and the religious traditions of Judaism and Christianity indicate that mental illness was a feared affliction that carried a heavy stigma. The classical philosopher's definition of a human being as a "rational animal" excluded him or her who had lost the use of reason and was no longer regarded as fully human; most likely he or she was under a divine curse. This attitude was summarized in the well-known saying of

KEY TERMS

Stigma—A mark or characteristic trait of a disease or defect; by extension, a cause for reproach or a stain on one's reputation.

Lucretius, "Whom the gods wish to destroy, they first make mad."

In the Bible, both the Old and the New Testaments reflect the same fear of mental illness. In 1 Samuel 21, there is an account of David's pretending to be insane in order to get away from the king of a neighboring territory. "He changed his behavior before [the king's servants]; he pretended to be mad in their presence. He scratched marks on the doors of the gate, and let his spittle run down his beard." The king, who was taken in by an act that certainly fits the *Diagnostic and Statistical Manual of Mental Disorders* criteria for **malinger**ing, quickly sent David on his way. In the New Testament, one of Jesus' most famous miracles of healing (Mark 5:1-20) is the restoration of sanity to a man so stigmatized by his village that he was hunkered down in the graveyard (itself a stigmatized place) outside the village when Jesus met him. Mark's account also notes that the villagers had tried at different times to chain or handcuff the man because they were so afraid of him. One important positive contribution of Biblical heritage, however, is a sense of religious obligation toward the mentally ill. Among Christians, the New Testament's account of Jesus' openness to all kinds of stigmatized people—tax collectors, prostitutes, and physically deformed people, as well as the mentally ill—became the basis for the establishment of the first shelters and hospitals for the mentally ill.

Contemporary contexts

The core feature of stigma in the modern world is defined by social psychologists as the possession of an attribute "that conveys a devalued social identity within a particular context." Context is important in assessing the nature and severity of **stress** that a person suffers with regard to stigma. Certain attributes, such as race or sex, affect an individual's interactions with other people in so many different situations that they have been termed "master status" attributes. These have become the classic identifying characteristic of the person who possesses them. Dorothy Sayers' essay, "Are Women Human?" is not only a witty satire on the way men used to describe a woman's job or occupation (with constant reference to feminine qualities), but a keen social analysis of the problems created by master status attributes for persons who are stigmatized.

Other forms of devalued social identity are relative to specific cultures or subcultures. In one social context, a person who is stigmatized for an attribute devalued by a particular group may find acceptance in another group that values the particular attribute. A common example is that of an artistically or athletically talented child who grows up in a family that values only intellectual accomplishment. When the youngster is old enough to leave the family of origin, he or she can find a school or program for other students who share the same interest. A less marked contrast, but one that is relevant to the treatment of mental illness, is the cultural differences with regard to the degree of response to certain symptoms of mental illness. A study conducted in the early 21st century assessed the reaction of family members to elderly people who were diagnosed with **Alzheimer's disease** (AD). Findings pointed to considerable variation across racial and ethnic groups. Asian Americans were most affected by feelings of shame and social stigma relative to the memory loss of a family member, while African Americans were the least affected.

One additional complicating feature of stigma is the issue of overlapping stigmata. Many people belong to several stigmatized groups or categories, and it is not always easy to determine which category triggers the unkind or discriminatory treatment encountered. For example, one study of the inadequate medical treatment that is offered to most HIV-positive Native Americans noted that the stigma of Acquired Immune Deficiency Syndrome (AIDS) provides a strong motivation for not seeking treatment. The study protocol, however, did not seek to investigate whether young Native American men are afraid of being stigmatized for their sexual orientation, their race, their low socioeconomic status, or all three.

Stigma and mental illness

Stigma and specific disorders

The stigma that is still attached to mental illness in the developed countries does not represent a simple or straightforward problem. Public health experts who have studied the stigmatization of mental illness in recent years have noted that the general public's perception of mental illness varies, depending on the nature of the disorder. While in general the stigma of mental illness in contemporary society is primarily associated with the second of the three categories of stigma listed above,—supposed character failings—it also spills over into the first category. Mental disorders that affect a person's physical appearance—particularly weight gain—are more heavily stigmatized than those that do not.

The stigma related to certain types of mental disorders has declined since the 1950s, most notably in regard

to depression and the anxiety disorders. It is thought that the reason for this change is that people are more likely nowadays to attribute these disorders to stress, with which most people can identify. On the other hand, the stigma associated with psychotic disorders appears to be worse than it was in the 1950s. Changes in public attitude are also reflected in age-group patterns in seeking or dropping out of treatment for mental disorders. One study demonstrated that older adults being treated for depression were more likely than younger adults to drop out of treatment because they felt stigmatized. The difference in behavior is related to public attitudes toward mental illness that were widespread when the older adults were adolescents.

In 2002, the types of mental disorders that carry the heaviest stigma fall into the following categories:

- Disorders associated in the popular mind with violence and/or illegal activity. These include **schizophrenia**, mental problems associated with HIV infection, and substance abuse disorders.
- Disorders in which the patient's behavior in public may embarrass family members. These include **dementia** in the elderly, **borderline personality disorder** in adults, and the autistic spectrum disorders in children.
- Disorders treated with medications that cause weight gain or other visible side effects.

The role of the media

The role of the media in perpetuating the stigmatization of mental illness has received increasing attention from public health researchers, particularly in Great Britain. In 1998, the Royal College of Psychiatrists launched a five-year campaign intended to educate the general public about the nature and treatment of mental illness. Surveys conducted among present and former mental patients found that they considered media coverage of their disorders to be strongly biased toward the sensational and the negative. One-third of patients said that they felt more depressed or anxious as a result of news stories about the mentally ill, and 22% felt more withdrawn. The main complaint from mental health professionals, as well as patients, is that the media presented mentally ill people as “dangerous time bombs waiting to explode” when in fact 95% of murders in the United Kingdom are committed by people with no mental illness. The proportion of homicides committed by the mentally ill has decreased by 3% per year since 1957, but this statistic goes unreported. Much the same story of unfair stigmatization in the media could be told in the United States, as the Surgeon General's report indicates.

Physicians' attitudes toward mental illness

Physicians' attitudes toward the mentally ill are also increasingly recognized as part of the problem of stigmatization. The patronizing attitude of moral superiority toward the mentally ill in the early 1960s, specifically in mental hospitals, has not disappeared. This was reported by Erving Goffman in his classic study. A Canadian insurance executive told a conference of physicians in May 2000 that they should look in the mirror for a picture of the ongoing stigmatization of the mentally ill. The executive was quoted as saying, "Stigma among physicians deters the detection of mental disorders, defers or pre-empts correct **diagnosis** and proper treatment and, by definition, prolongs suffering." An American physician who specializes in the treatment of substance addicts cites three reasons for the persistence of stigmatizing attitudes among his colleagues: their tendency to see substance abuse as a social issue, rather than a health issue; their lack of training in detecting substance abuse; and their mistaken belief that no effective treatments exist. A similar lack of information about effective treatments characterizes many psychiatrists' attitudes toward borderline personality disorder.

Stigma as cause of mental illness

It is significant that researchers in the field of social psychology have moved in recent years to analyzing stigma in terms of stress. Newer studies in this field now refer to membership in a stigmatized group as a stressor that increases a person's risk of developing a mental illness. The physiological and psychological effects of stress caused by racist behavior, for example, have been documented in African Americans. Similar studies of obese people have found that the stigmatization of **obesity** is the single most important factor in the psychological problems of these patients. To give still another example, the high rates of depression among postmenopausal women have been attributed to the fact that aging is a much heavier stigma for women than for men in contemporary society.

Stigma has a secondary effect on rates of mental illness in that members of stigmatized groups have less access to educational opportunities, well-paying jobs, and adequate health care. They are therefore exposed to more environmental stressors in addition to the stigma itself.

Stigma as effect

Stigma resulting from mental illness has been shown to increase the likelihood of a patient's relapse. Since a mental disorder is not as immediately apparent as race, sex, or physical handicaps, many people with mental disorders undergo considerable strain trying to conceal their condi-

tion from strangers or casual acquaintances. More seriously, the stigma causes problems in the job market, leading to stress that is related to lying to a potential employer and fears of being found out. Erving Goffman reported in the 1960s that a common way around the dilemma involved taking a job for about six months after discharge from a mental institution, then quitting that job and applying for another with a recommendation from the first employer that did not mention the history of mental illness.

The stigmatization of the patient with mental illness extends to family members, partly because they are often seen as the source of the patient's disorder. A recent editorial in the *Journal of the American Medical Association* tells the story of two sets of parents coping with the stress caused by other people's reactions to their children's mental illness, and the different responses they received when the children's disorders were thought to be a physical problem. The writer also tells of the problems encountered by the parents of an autistic child. The writer stated that family excursions were difficult, and continued, "My friend's wife was reprimanded by strangers for not being able to control her son. The boy was stared at and ridiculed. The inventive parent, fed up with the situation, bought a wheelchair to take the child out. The family was now asked about their child's disability. They were praised for their tolerance of his physical hardship and for their courage; the son was commended for his bravery. Same parents, same child, different view."

The results of stigma

The stigmatization of mental disorders has a number of consequences for the larger society. Patients' refusal to seek treatment, noncompliance with treatment, and inability to find work has a high price tag. Disability related to mental illness accounts for fully 15% of the economic burden caused by *all* diseases in developed countries.

Seeking treatment

Stigmatization of mental illness is an important factor in preventing persons with mental disorders from asking for help. This factor affects even mental health services on university campuses; interviews with Harvard students following a 1995 murder in which a depressed student killed a classmate, found that students hesitated to consult mental health professionals because many of their concerns were treated as disciplinary infractions, rather than illnesses. The tendency to stigmatize mental disorders as character faults is as prevalent among educators as among medical professionals. In addition, studies of large corporations indicate that employees frequently hesitate to seek treatment for depression and

other stress-related disorders for fear of receiving negative evaluations of job performance and possible termination. These fears are especially acute during economic downturns and periods of corporate downsizing.

Compliance with treatment

Another connection between mental disorders and stigma is the low rates of treatment **compliance** among patients. To a large extent, patient compliance is a direct reflection of the quality of the doctor-patient relationship. One British study found that patients with mental disorders were likely to prefer the form of treatment recommended by psychiatrists with whom they had good relationships, even if the treatment itself was painful or difficult. Some patients preferred **electroconvulsive therapy** (ECT) to tranquilizers for depression because they had built up trusting relationships with the doctors who used ECT, and perceived the doctors who recommended medications as bullying and condescending. Other reasons for low compliance with treatment regimens are related to stigmatized side effects. Many patients, particularly women, discontinue medications that cause weight gain because of the social stigma attached to obesity in females.

Social and economic consequences

As already mentioned, persons with a history of treatment for mental disorders frequently encounter prejudice in the job market and the likelihood of long periods of unemployment; this can result in lower socioeconomic status, as well as loss of self-esteem. These problems are not limited to North America. A recent study of mental health patients in Norway, which is generally considered a progressive nation, found that the patients had difficulty finding housing as well as jobs, and were frequently harassed on the street as well as being socially isolated. In 1990, the Congress of the U.S. included mental disorders (with a few exceptions for disorders related to substance abuse and compulsive sexual behaviors) in the anti-discriminatory provisions of the Americans with Disabilities Act (ADA). As of 2002, mental disorders constitute the third-largest category of discrimination claims against employers.

Stigmatization of mental disorders also affects funding for research into the causes and treatment of mental disorders. Records of recent Congressional debates indicate that money for mental health research is still grudgingly apportioned as of 2002.

Future prospects

The stigma of mental illness will not disappear overnight. Slow changes in attitudes toward other social

issues have occurred in the past three decades, giving hope to the lessening of stigma toward people with mental illness. However, limitations on indefinite economic expansion are an reason for concern. As the economic "pie" has to be divided among a larger number of groups, causing competition for public funding, persons with mental disorders will need skilled and committed advocates if their many serious needs are to receive adequate attention and help.

Stress

Definitions

Stress is a term that refers to the sum of the physical, mental, and emotional strains or tensions on a person.

Feelings of stress in humans result from interactions between persons and their environment that are perceived as straining or exceeding their adaptive capacities and threatening their well-being. The element of perception indicates that human stress responses reflect differences in personality as well as differences in physical strength or health.

A stressor is defined as a stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism. The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* defines a psychosocial stressor as “any life event or life change that may be associated temporally (and perhaps causally) with the onset, occurrence, or exacerbation [worsening] of a mental disorder.”

Stress affects the lives of most adults in developed countries in many ways. It is a major factor in rising health care costs; one public health expert maintains that 90% of all diseases and disorders in the United States are stress-related. Stress plays a part in many social problems such as child and elder **abuse**, workplace violence, juvenile crime, **suicide**, substance **addiction**, “road rage,” and the general decline of courtesy and good manners. Stress also affects the productivity of businesses and industries. One nationwide survey found that 53% of American workers name their job as the single greatest source of stress in their lives. Furthermore, the overall cost of medical care, time lost from work, and workplace accidents in the United States comes to over \$150 million per year.

The neurobiology of stress

One way to understand stress as a contemporary health problem is to look at the human stress response as a biologically conditioned set of reactions that was a necessary adaptation at earlier points in human evolution, but is less adaptive under the circumstances of modern life. Hans Selye (1907-1982), a Canadian researcher, was a pioneer in studying stress. Selye defined stress, in essence, as the rate of wear and tear on the body. He observed that an increasing number of people, particularly in the developed countries, die of so-called diseases of civilization, or degenerative diseases, which are primarily caused by stress. Selye also observed that stress in humans depends partly on people’s evaluation of a situation and their emotional reaction to it; thus, an experience that one person finds stimulating and exciting—for example, bungee jumping—would produce harmful stress in another.

The stress response

In humans, the biochemical response to acute stress is known as the “fight-or-flight” reaction. It begins with

KEY TERMS

Adjustment disorder—A disorder defined by the development of significant emotional or behavioral symptoms in response to a stressful event or series of events. Symptoms may include depressed mood, anxiety, and impairment of social and occupational functioning.

Adrenaline—Another name for epinephrine, the hormone released by the adrenal glands in response to stress. It is the principal blood-pressure raising hormone and a bronchial and intestinal smooth muscles relaxant.

Allostasis—The process of an organism's adaptation to acute stress.

Amygdala—An almond-shaped brain structure in the limbic system that is activated in acute stress situations to trigger the emotion of fear.

Burnout—An emotional condition that interferes with job performance, marked by fatigue, loss of interest, or frustration; usually regarded as the result of prolonged stress.

Catecholamine—A group of neurotransmitters synthesized from the amino acid tyrosine and released by the hypothalamic-pituitary-adrenal system in the brain in response to acute stress. The catecholamines include dopamine, serotonin, norepinephrine, and epinephrine.

Coping—In psychology, a term that refers to a person's patterns of response to stress.

Cortisol—A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Eustress—A term that is sometimes used to refer to positive stress.

Flashback—The re-emergence of a traumatic memory as a vivid recollection of sounds, images, and sensations associated with the trauma. The person having the flashback typically feels as if he or she is reliving the event.

Hippocampus—A part of the brain that is involved in memory formation and learning. The hippocampus is shaped like a curved ridge and belongs to an organ system called the limbic system.

Homeostasis—The tendency of the physiological system in humans and other mammals to maintain its internal stability by means of a coordinated response to any stimulus that disturbs its normal condition.

Limbic system—A group of structures in the brain that includes the amygdala, hippocampus, olfactory bulbs, and hypothalamus. The limbic system is associated with homeostasis and the regulation and arousal of emotions.

Relaxation response—The body's inactivation of stress responses and return of stress hormone levels to normal after a threat has passed.

Stress management—A set of techniques and programs intended to help people deal more effectively with stress in their lives by analyzing the specific stressors and taking positive actions to minimize their effects. Most stress management programs deal with job stress and workplace issues.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

the activation of a section of the **brain** called the hypothalamic-pituitary-adrenal system, or HPA. This system first activates the release of steroid hormones, which are also known as glucocorticoids. These hormones include cortisol, the primary stress hormone in humans.

The HPA system then releases a set of **neurotransmitters** known as catecholamines, which include dopamine, norepinephrine, and epinephrine (also known as adrenaline). Catecholamines have three important effects:

- They activate the amygdala, an almond-shaped structure in the limbic system that triggers an emotional response of fear.
- They signal the hippocampus, another part of the limbic system, to store the emotional experience in long-term memory.
- They suppress activity in parts of the brain associated with short-term memory, concentration, and rational thinking. This suppression allows a human to react

quickly to a stressful situation, but it also lowers ability to deal with complex social or intellectual tasks that may be part of the situation.

In reaction to stress, heart rate and blood pressure rise, and the person breathes more rapidly, which allows the lungs to take in more oxygen. Blood flow to the muscles, lungs, and brain may increase by 300–400%. The spleen releases more blood cells into the circulation, which increases the blood's ability to transport oxygen. The immune system redirects white blood cells to the skin, bone marrow, and lymph nodes; these are areas where injury or infection is most likely.

At the same time, nonessential body systems shut down. The skin becomes cool and sweaty as blood is drawn away from it toward the heart and muscles. The mouth becomes dry, and the digestive system slows down.

The relaxation response

After the crisis passes, the levels of stress hormones drop and the body's various organ systems return to normal. This return is called the relaxation response. Some people are more vulnerable to stress than others because their hormone levels do not return to normal after a stressful event. An absent or incomplete relaxation response is most likely to occur in professional athletes and in people with a history of depression.

Physical effects of chronic stress

In chronic stress, the organ systems of the body do not have the opportunity to return fully to normal levels. Different organs become under- or overactivated on a long-term basis. In time, these abnormal levels of activity can damage an organ or organ system.

Cardiovascular system

Stress has a number of negative effects on the heart and circulatory system. Sudden stress increases heart rate, but also causes the arteries to narrow, which may block the flow of blood to the heart. The emotional effects of stress can alter the rhythm of the heart. In addition, stress causes the release of extra clotting factors into the blood, which increases the risk of a clot forming and blocking an artery. Stress also triggers the release of fat into the bloodstream, which temporarily raises blood cholesterol levels. Lastly, it is thought that people who regularly have sudden increases in blood pressure due to mental stress may over time suffer injuries to the inner lining of their blood vessels.

Gastrointestinal system

The effects of chronic stress on the gastrointestinal system include diarrhea, constipation, bloating, and irritable bowel syndrome. Although stress is not the direct cause of either peptic ulcers or inflammatory bowel disease, it may predispose people to develop ulcers and worsen flareups of inflammatory bowel disease.

Stress is the cause of abnormal weight loss in some people and of weight gain in others, largely from stress-related eating. It is thought that stress related to the physical and emotional changes of puberty is a major factor in the development of eating disorders.

Reproductive system

Stress affects sexual desire in both men and women and can cause impotence in men. It appears to worsen the symptoms of premenstrual syndrome (PMS) in women. Stress affects fertility, in that high levels of cortisol in the blood can affect the hypothalamus, which produces hormones related to reproduction. Very high levels of cortisol can cause amenorrhea, or cessation of menstrual periods.

Stress during pregnancy is associated with a 50% higher risk of miscarriage. High stress levels on the mother during pregnancy are also related to higher rates of premature births and babies of lower than average birth weight; both are risk factors for infant mortality.

Musculoskeletal system

Stress intensifies the chronic pain of arthritis and other joint disorders. It also produces tension-type headaches, caused by the tightening of the muscles in the neck and scalp. Research indicates that people who have frequent tension headaches have a biological predisposition for converting emotional stress into muscle contraction.

Brain

The physical effects of stress hormones on the brain include interference with memory and learning. Acute stress interferes with short-term memory, although this effect goes away after the stress is resolved. People who are under severe stress become unable to concentrate; they may become physically inefficient, clumsy, and accident-prone. In children, however, the brain's biochemical responses to stress clearly hamper the ability to learn.

Chronic stress appears to be a more important factor than aging in the loss of memory in older adults. Older people with low levels of stress hormones perform as well as younger people in tests of cognitive (knowledge-related) skills, but those with high levels of stress hormones test between 20% and 50% lower than the younger test subjects.

Immune system

Chronic stress affects the human immune system and increases a person's risk of getting an infectious illness. Several research studies have shown that people under chronic stress have lower than normal white blood cell counts and are more vulnerable to colds and influenza. Men with HIV infection and high stress levels progress more rapidly to AIDS than infected men with lower stress levels.

Stress and mental disorders

DSM-IV-TR specifies two major categories of mental disorders directly related to stress—the post-traumatic syndromes and adjustment disorders. Stress is, however, also closely associated with depression, and can worsen the symptoms of most other disorders.

Post-traumatic disorders

Post-traumatic stress disorder (PTSD) and **acute stress disorder (ASD)** are defined by their temporal connection to a traumatic event in the individual's life. The post-traumatic disorders are characterized by a cluster of anxiety and dissociative symptoms, and by their interference with the patient's normal level of functioning. **Magnetic resonance imaging (MRI)** studies have shown that the high levels of sustained stress in some PTSD patients cause demonstrable damage to the hippocampus. Excessive amounts of stress hormones in brain tissue cause the nerve cells, or neurons, in parts of the hippocampus to wither and eventually die. One group of Vietnam veterans with PTSD had lost as much as 8% of the tissue in the hippocampus.

Substance abuse disorders

Stress is related to substance abuse disorders in that chronic stress frequently leads people to self-medicate with drugs of abuse or alcohol. Substance abuse disorders are associated with a specific type of strategy for dealing with stress called emotion-focused coping. Emotion-focused coping strategies concentrate on regulating painful emotions related to stress, as distinct from problem-focused coping strategies, which involve efforts to change or eliminate the impact of a stressful event. Persons who handle stress from a problem-oriented perspective are less likely to turn to mood-altering substances when they are under stress.

Adjustment disorders

DSM-IV-TR defines adjustment disorders as psychological responses to stressors that are excessive given the nature of the stressor; or result in impairment of the per-

son's academic, occupational, or social functioning. The most important difference between the post-traumatic disorders and adjustment disorders is that most people would not necessarily regard those stressors involved in the latter disorder as traumatic. **Adjustment disorder** appear to be most common following natural disasters, divorce, becoming a parent, and retirement from work.

Causes of stress

The causes of stress may include any event or situation that a person considers a threat to his or her resources or coping strategies. A certain amount of stress is a normal part of life; it represents a person's response to inevitable changes in his or her physical or social environment. Moreover, positive events can generate stress as well as negative events. Graduating from college, for example, is accompanied by stress related to employment or possible geographical relocation and the stress of saying good-bye to friends and family, as well as feelings of positive accomplishment. Some researchers refer to stress associated with positive events as eustress.

Acute stress is defined as a reaction to something perceived as an immediate threat. Acute stress reactions can occur to a falsely perceived danger as well as to a genuine threat; they can also occur in response to memories. For example, a war veteran who hears a car backfire may drop to the ground because the noise triggers vivid memories, called flashbacks, of combat experience. Common acute stressors include loud, sudden noises being in a crowded space such as an elevator, being cut off in heavy traffic; and dangerous weather. Chronic stress is a reaction to a situation that is stressful but ongoing, such as financial worries or caring for an elderly parent. Modern life is stressful because changes in various areas of life have increased the number of acute and chronic stressors in most people's lives at the same time that they have weakened certain buffers or protections against stress.

Social changes

Social changes that have increased the stress level of modern life include increased population mobility and the sprawling size of modern cities. It is not unusual for adults to live hundreds of miles away from parents and siblings; and it is hard to make and keep friendships when people move every few years. In most large cities, many people live in apartment buildings where they do not know their neighbors. Social isolation and loneliness can produce chronic stress. A study done in Norway between 1987 and 1993 found that social support networks made a significant difference in lowering the impact of both acute and chronic stress on mental health.

Social scientists have observed that the increased isolation of married couples from extended families and friendship networks increases strains on the marriage. The rising divorce rate in the United States has been attributed in part to the loss of social supports that once helped to keep married couples together. The experience of divorce then adds to the stress level on the former spouses and the children, if any. A long-term study at the University of Pittsburgh has found that divorce is associated with a higher rate of premature death in men.

Economic changes

The rapid pace of change in manufacturing and other businesses means that few people will work at the same job for their entire career. In addition, corporate mergers and downsizing have weakened job security, thus producing chronic anxiety about unemployment in the minds of many employees. Many people work two jobs in order to make ends meet; and even those who work only one job often have to commute by car or train to their workplace. In many large American cities, traffic jams, cost of gasoline, and other problems related to commuting are a major factor in job-related stress. Another stress factor is sleep deprivation. Many people get only six or less hours of sleep each night even though the National Sleep Foundation estimates that most adults need 8–8-1/2 hours per night for good health. **Fatigue** due to sleep deprivation causes additional stress.

Lastly, economic trends have produced a “winner-take-all” economy in which the gap between the well-off and the average family is constantly widening. Socioeconomic status (SES) affects health in a number of ways. Persons of higher SES can afford better health care, are less likely to suffer from exposure to environmental toxins, and generally lead healthier lifestyles. In addition, chronic stress associated with low SES appears to increase morbidity and mortality among persons in these income groups.

Technological changes

Technology has proved to be a source of stress as well as a solution to some kinds of stress. Machines that help workers to be more productive also make their jobs more complicated and raise the level of demands on them. An office clerk in 2002 can produce many more letters per day than one in 1952, but is often expected to produce more elaborate, professional-looking documents as well as a higher number of them.

One specific technological development that has been singled out as a major stressor in modern life is the evolution of news reporting. For most of human history, people had to wait several days or even weeks to hear

about the outcome of an election, a battle, or some other important event. Moreover, they usually heard only the news that affected their region or their country. Today, however, news is reported as soon as it happens, it is broadcast 24 hours a day, and it covers events around the world. This “communications overload,” as it has been termed, is a source of genuine stress to many people, particularly when the newscast emphasizes upsetting or frightening events. It is not surprising that a common recommendation for lowering one’s stress level is to cut down on watching television news programs. A team of physicians conducted telephone interviews following the events of September 11, 2001, in order to assess stress reactions in the general American population. The team found that the single most important factor was not geographical location relative to the attacks or educational level, but the amount of time spent watching televised reports of the attacks. The interviewers discovered that 49% of the adults had watched at least eight hours of television on September 11, and also that “extensive television viewing was associated with a substantial stress reaction.”

Environmental changes

One significant source of stress in modern life is the cumulative effect of various toxic waste products on the environment. Studies of the aftermath of such environmental disasters as Three Mile Island and Chernobyl found that not only evacuees and people living in the contaminated area had high levels of emotional distress, but also cleanup workers and people living in nearby noncontaminated areas. In the case of Chernobyl, Russian physicians have reported a psychoneurological syndrome with several unexplained symptoms, including fatigue, impaired memory, muscle or joint pain, and sleep disturbances. The syndrome appears to be due to chronic emotional stress rather than radiation exposure.

Changes in beliefs and attitudes

Changes in beliefs that influence stress levels include the contemporary emphasis on individualism and a corresponding change in attitudes toward trauma. A number of observers have remarked that Western culture has moved away from its traditional high valuation of the family and community toward an increased focus on the individual. Some have called this trend the “Me First!” society—it emphasizes personal rights and entitlements rather than duties and responsibilities to others. It has, in the view of some physicians, encouraged people to dwell on trauma and its effects on them as individuals rather than to live up to more traditional ideals of composure and resilience in the face of distress.

Risk factors

Research indicates that some categories of people have a higher risk of stress-related illnesses and disorders:

- Children have very little control over their environments. In addition, they are often unable to communicate their feelings accurately.
- In elderly adults, aging appears to affect the body's response to stress, so that the relaxation response following a stressful event is slower and less complete. In addition, the elderly are often affected by such major stressors as health problems, the death of a spouse or close friends, and financial worries.
- Caregivers of mentally or physically disabled family members.
- Women in general.
- People with less education.
- People who belong to racial or ethnic groups that suffer discrimination.
- People who live in cities.
- People who are anger-prone. Chronic anger is associated with narrowing of the arteries, a factor in heart disease.
- People who lack family or friends.
- People who are biologically predisposed to an inadequate relaxation response.

Coping with stress

Coping is defined as a person's patterns of response to stress. Many clinicians think that differences in attitudes toward and approaches to stressful events are the single most important factor in assessing a person's vulnerability to stress-related illnesses. A person's ability to cope with stress depends in part on his or her interpretation of the event. One person may regard a stressful event as a challenge that can be surmounted while another views it as a problem with no solution. The person's resources, previous physical and psychological health, and previous life experience affect interpretation of the event. Someone who has had good experiences of overcoming hardships is more likely to develop a positive interpretation of stressful events than someone who has been repeatedly beaten down by abuse and later traumas.

Coping styles

The ways in which people cope with stress can be categorized according to two different sets of distinctions. One is the distinction between emotion-focused and problem-focused styles of coping, which was described earlier in connection with substance abuse. Problem-focused cop-

ing is believed to lower the impact of stress on health; people who use problem-focused coping have fewer illnesses, are less likely to become emotionally exhausted, and report higher levels of satisfaction in their work and feelings of personal accomplishment. Emotion-focused coping, on the other hand, is associated with higher levels of interpersonal problems, depression, and social isolation. Although some studies reported that men are more likely to use problem-focused coping and women to use emotion-focused coping, other research done in the last decade has found no significant gender differences in coping styles.

The second set of categories distinguishes between control-related and escape-related coping styles. Control-related coping styles include direct action, behavior that can be done alone; help-seeking, behavior that involves social support; and positive thinking, a cognitive style that involves giving oneself pep talks. Escape-related coping styles include avoidance/resignation, as in distancing oneself from the stressful event, and alcohol use. There appears to be no relationship between gender and a preference for control-related or escape-related coping.

Stress management

Stress management refers to a set of programs or techniques intended to help people deal more effectively with stress. Many of these programs are oriented toward job- or workplace-related stress in that burnout is a frequent result of long-term occupational stress. Most stress management programs ask participants to analyze or identify the specific aspects of their job that they find stressful, and then plan a course of positive action to minimize the stress. In general, the severity of job-related stress appears to be related to two factors: the magnitude of the demands being made on the worker, and the degree of control that she or he has in dealing with the demands. The workers who are most vulnerable to stress-related heart disease are those who are subjected to high demands but have little control over the way they do their job. In many cases, stress management recommendations include giving an employee more decision-making power.

Treatments for stress

There are a number of allopathic and alternative/complementary treatments that are effective in relieving the symptoms of stress-related disorders:

- Medications may include drugs to control anxiety and depression as well as drugs that treat such physical symptoms of stress as indigestion or high blood pressure.
- Psychotherapy, including insight-oriented and cognitive/behavioral approaches, is effective in helping people understand how they learned to overreact to stressors, and in helping them reframe their perceptions and

interpretations of stressful events. Anger management techniques are recommended for people who have stress-related symptoms due to chronic anger.

- Relaxation techniques, **anxiety reduction techniques**, breathing exercises, **yoga**, and other physical exercise programs that improve the body's relaxation response.
- Therapeutic massage, hydrotherapy, and **bodywork** are forms of treatment that are particularly helpful for people who tend to carry stress in their muscles and joints.
- **Aromatherapy**, pet therapy, humor therapy, music therapy, and other approaches that emphasize sensory pleasure are suggested for severely stressed people who lose their capacity to enjoy life; sensory-based therapies can counteract this tendency.
- Naturopathic recommendations regarding diet, exercise, and adequate sleep, and the holistic approach of naturopathic medicine can help persons with stress-related disorders to recognize and activate the body's own capacities for self-healing.

Stroke

Definition

A stroke, also called a cerebral vascular accident (CVA), is the sudden death of cells in a specific area of the **brain** due to inadequate blood flow.

KEY TERMS

Aneurysm—A symptomless bulging of a weak arterial wall that can rupture, leading to stroke.

Angiography—A procedure in which a contrast medium is injected into the bloodstream (through an artery in the neck) and its progress through the brain is tracked. This illustrates where a blockage or hemorrhage has occurred.

Anticoagulant—A medication (such as warfarin, Coumadin, or Heparin) that decreases the blood's clotting ability preventing the formation of new clots. Although anticoagulants will not dissolve existing clots, they can stop them from getting larger. These drugs are commonly called blood thinners.

Atrial fibrillation—A disorder in which the upper chambers (atria) of the heart do not completely empty with each contraction (heartbeat). This can allow blood clots to form and is associated with a higher risk of stroke.

Electrocardiogram—(EKG) A test that measures the electrical activity of the heart as it beats. An abnormal EKG can indicate possible cardiac disease.

Electroencephalogram—(EEG) A test that measures the electrical activity of the brain by means of electrodes placed on the scalp or on or in the brain itself. It may be used to determine whether or not a stroke victim has had a seizure.

Hypertension—High blood pressure, often brought on by smoking, obesity, or other causes; one of the major causes of strokes.

Pressure ulcers—Also known as pressure sores or bed sores, these can develop in stroke patients who are unable to move. If not treated properly, they can become infected.

Tissue plasminogen activator (tPA)—A drug that is sometimes given to patients within three hours of a stroke to dissolve blood clots within the brain; also used to treat heart attack victims.

Ultrasound—A noninvasive test in which high-frequency sound waves are reflected off a patient's internal organs allowing them to be viewed. In stroke victims, a cardiac ultrasound, or echocardiogram, allows the beating heart to be examined.

Description

A stroke occurs when blood flow is interrupted to a part of the brain, either when an artery bursts or becomes closed when a blood clot lodges in it. Blood circulation to the area of the brain served by that artery stops at the point of disturbance, and the brain tissue beyond that is damaged or dies. (Brain cells need blood to supply oxygen and nutrients and to remove waste products.) Depending on the region of the brain affected, a stroke can cause paralysis, loss of vision, speech impairment, memory loss and reasoning ability, coma, or death. The effects of a stroke are determined by how much damage occurs, and which portion of the brain is affected.

About a third of all strokes are preceded by transient ischemic attacks (TIAs), or mini-strokes, that temporarily interrupt blood flow to the brain. While TIAs cause similar symptoms (such as sudden vision loss or temporary weakness in a limb), they abate much more quickly than full-fledged strokes, usually within a few hours—sometimes as quickly as a few minutes.

Stroke is a medical emergency requiring immediate treatment. Prompt treatment improves the chances of survival and increases the degree of recovery that may be expected. A person who may have suffered a stroke should be seen in a hospital emergency room without delay. Treatment to break up a blood clot, the major cause of stroke, must begin within three hours of the stroke to be most effective. Improved medical treatment of all types of stroke has resulted in a dramatic decline in death rates in recent decades. In 1950 nine in ten stroke victims died, compared to slightly less than one in three today.

Causes and symptoms

Causes

There are four main types of stroke: cerebral thrombosis, cerebral embolism, subarachnoid hemorrhage, and intracerebral hemorrhage. *Cerebral thrombosis* and *cerebral embolism*, known as *ischemic strokes*, are caused by blood clots that block an artery supplying the brain, either in the brain itself or in the neck. They account for 70–80% of all strokes. *Subarachnoid hemorrhage* and *intracerebral hemorrhage* are *hemorrhagic strokes* that occur when a blood vessel bursts around or in the brain, either from trauma or excess internal pressure. Hypertension (high blood pressure) and atherosclerosis are usually contributing factors in these types of strokes.

CEREBRAL THROMBOSIS. Cerebral thrombosis, the most common type of stroke, occurs when a blood clot, or thrombus, forms within the brain itself, blocking blood

flow through the affected vessel. This is usually due to atherosclerosis (hardening) of brain arteries, caused by a buildup of fatty deposits inside the blood vessels. Cerebral thrombosis occurs most often at night or early in the morning, and is often preceded by a TIA. Recognizing the occurrence of a TIA, and seeking immediate treatment, is an important step in stroke prevention.

CEREBRAL EMBOLISM. Cerebral embolism occurs when a blood clot from elsewhere in the circulatory system breaks free. If it becomes lodged in an artery supplying the brain, either in the brain or in the neck, it can cause a stroke. The most common cause of cerebral embolism is atrial fibrillation, which occurs when the upper chambers (atria) of the heart beat weakly and rapidly, instead of slowly and steadily. Blood within the atria does not empty completely, and may form clots that can then break off and enter the circulation. Atrial fibrillation is a factor in about 15% of all strokes, but this risk can be dramatically reduced with daily use of anticoagulant medication (such as Heparin or Coumadin).

SUBARACHNOID HEMORRHAGE. In this type of stroke, blood spills into the subarachnoid space between the brain and cranium. As fluid builds up, pressure on the brain increases, impairing its function. Hypertension is a frequent cause of these types of stroke, but vessels with preexisting defects, such as an aneurysm, are also at risk for rupture. Aneurysms are most likely to burst when blood pressure is highest, and controlling blood pressure is an important preventive strategy. Subarachnoid hemorrhages account for about 7% of all strokes.

INTRACEREBRAL HEMORRHAGE. Representing about 10% of all strokes, intracerebral hemorrhage affects vessels and tissue within the brain itself. As with subarachnoid hemorrhage, bleeding deprives affected tissues of blood supply, and the accumulation of fluid within the inflexible skull creates pressure on the brain that can quickly become fatal. Despite this, recovery may be more complete for a person who survives hemorrhage than for one who survives a clot, because the effects of blood deprivation are usually not as severe.

Risk factors

Risk factors for stroke involve:

- *Age and sex*—the risk of stroke increases with age, doubling for each decade after age 55. Men are more likely to have a stroke than women.
- *Heredity*—People with a family history of stroke have an increased risk of stroke themselves. In addition, African-Americans, Asians, and Hispanics all have

higher rates of stroke than whites, related partly to higher blood pressure.

- *Diseases*—People with diabetes, heart disease (especially atrial fibrillation), high blood pressure, or prior stroke are at greater risk for stroke. Patients with one or more TIAs have ten times the risk.
- *Other medical conditions*—Stroke risk increases with **obesity**, high blood cholesterol, or high red blood cell count.
- *Lifestyle choices*—Stroke risk increases with cigarette smoking (especially if combined with the use of oral contraceptives), a sedentary lifestyle, alcohol consumption above two drinks per day, and/or the use of cocaine or intravenous drugs.

Symptoms

Knowing the symptoms of stroke is as important as knowing those of a heart attack. Patients with stroke symptoms should seek emergency treatment without delay, which may mean dialing 911 rather than their family physician. Specific symptoms of a stroke depend on the type, but all types share some characteristics in common.

An embolic stroke usually comes on quite suddenly and is intense right from the start, while symptoms of a thrombotic stroke come on more gradually. Symptoms for these ischemic strokes may include:

- blurring or decreased vision in one or both eyes
- severe headache, often described as “the worst headache of my life”
- weakness, numbness, or paralysis of the face, arm, or leg, usually confined to one side of the body
- dizziness, loss of balance or coordination, especially when combined with other symptoms

Hemorrhagic strokes are somewhat different. An intracranial hemorrhage exhibits any or all of the following symptoms:

- loss of consciousness
- altered mental state
- seizure
- vomiting or severe nausea
- extreme hypertension
- weakness, numbness, or paralysis, especially on one side of the body
- sudden, severe headache

Symptoms of a subarachnoid hemorrhage include:

- severe headache that begins suddenly

- nausea or vomiting
- stiff neck
- light intolerance
- loss of consciousness

Demographics

Each year, more than half a million people in the United States have a stroke. It is the third leading cause of death, killing about a third of its victims—approximately 150,000 Americans each year. For those that survive, stroke is the leading cause of disability. Two-thirds of all strokes occur in people over age 65, with men more affected than women, although women are more likely to die from a stroke. African-Americans suffer strokes more often than whites, and are more likely to die from them as well. This may be because African-Americans tend to suffer from hypertension more frequently than other groups.

Diagnosis

Diagnosing a stroke begins with a careful medical history, especially concerning the onset and distribution of symptoms, presence of risk factors; in this way other possible causes are excluded. A brief neurological exam is performed to identify the degree and location of any deficits, such as weakness, lack of coordination, or vision loss.

Once stroke is suspected, imaging technology is used to determine what type the patient has suffered—a critical distinction that guides therapy. A noncontrast **computed tomography** scan (CT scan) can reliably identify hemorrhagic strokes, caused by uncontrolled bleeding in the brain. **Magnetic resonance imaging** (MRI), on the other hand, particularly diffusion-weighted imaging, can detect ischemic strokes, caused by blood clots, earlier and more reliably than CT scanning.

Blood and urine tests are also run to look for possible abnormalities. Other investigations that may be per-

formed to guide treatment include electrocardiogram, angiography, ultrasound, and electroencephalogram.

Treatment

When brain cells die during a stroke, they release toxic chemicals that can trigger a chain reaction that can injure or kill other nearby cells. Damage from stroke may be significantly reduced by emergency treatment, and is a significant factor in how fully a patient will recover.

Emergency treatment

Emergency treatment of an ischemic stroke attempts to dissolve the clot. This “thrombolytic therapy” is performed most often with tissue plasminogen activator (t-PA), which must be administered within three hours of the stroke event. (Patients who awaken with stroke symptoms are ineligible for this type of therapy, since the time of onset cannot be reliably determined.) t-PA therapy has been shown to improve recovery and decrease long-term disability in patients. It carries a 6.4% risk of inducing a cerebral hemorrhage, however, and is not appropriate for patients with bleeding disorders, very high blood pressure, known aneurysms, any evidence of intracranial hemorrhage, or incidence of stroke, head trauma, or intracranial surgery within the past three months. Patients with clot-related stroke who are ineligible for t-PA treatment may be treated with heparin or other blood thinners, or with aspirin or other anticlotting agents in some cases.

Emergency treatment of hemorrhagic stroke is aimed at controlling intracranial pressure that accompanies these types of strokes. New surgical techniques can effectively relieve the pressure, especially when begun soon after the stroke event occurs. Surgery for hemorrhage due to aneurysm may be performed if the aneurysm is close enough to the cranial surface to allow access. Ruptured vessels are closed off to prevent rebleeding. For aneurysms that are difficult to reach surgically, endovascular treatment, in which a catheter is guided from a larger artery up into the brain to reach the aneurysm, may be effective. Small coils of wire are discharged into the aneurysm, which plug it up and block off blood flow from the main artery.

Rehabilitation

Rehabilitation refers to a comprehensive program designed to regain as much function as possible and compensate for permanent losses. Approximately 10% of stroke survivors are without any significant disability and able to function independently. Another 10% are so severely affected that they must remain institutionalized for severe disability. The remaining 80% can return home with appropriate therapy, training, support, and care.

Rehabilitation is coordinated by a team of medical professionals and may include the services of a neurologist, a physician who specializes in rehabilitation medicine, a physical therapist, an occupational therapist, a speech-language pathologist, a nutritionist, a mental health professional, and a social worker. Rehabilitation services may be provided in an acute care hospital, rehabilitation hospital, long-term care facility, outpatient clinic, or at home.

The rehabilitation program is based on the patient’s individual deficits and strengths. Strokes on the left side of the brain primarily affect the right half of the body, and vice versa. In addition, in left brain-dominant people, who constitute a significant majority of the population, left-brain strokes usually lead to speech and language deficits, while right-brain strokes may affect spatial perception. Patients with right-brain strokes may also deny their illness, neglect the affected side of their body, and behave impulsively.

Rehabilitation may be complicated by cognitive losses, including diminished ability to understand and follow directions. Poor results are more likely in patients whose strokes left them with significant or prolonged cognitive changes, sensory losses, language deficits, or incontinence.

PREVENTING COMPLICATIONS. Rehabilitation begins with prevention of medical complications, including stroke recurrence, using many of the same measures used to prevent stroke, such as smoking cessation and getting hypertension under control.

One of the most common medical complications following stroke is deep venous thrombosis, in which a clot forms within a limb immobilized by paralysis. Clots can also become lodged in an artery feeding the lungs, a condition called pulmonary embolism, that is a common cause of death in the weeks following a stroke. Resuming activity within a day or two after the stroke is an important preventive measure, along with use of elastic stockings on the lower limbs. Drugs that prevent clotting may also be given, including intravenous heparin and oral warfarin.

Weakness and loss of coordination of the swallowing muscles may impair swallowing (dysphagia), and allow food to enter the lower airway. This may lead to aspiration pneumonia, another common cause of death shortly after a stroke. Dysphagia may be treated with retraining exercises and temporary use of pureed foods.

Other medical complications include urinary tract infections, pressure ulcers, falls, and **seizures**. Not surprisingly, depression occurs in 30–60% of stroke patients; its severity is usually related to the level of per-

manent functional impairment It can be treated with antidepressants and **psychotherapy**.

TYPES OF REHABILITATIVE THERAPY. Brain tissue that dies in a stroke cannot regenerate. In some cases, however, rehabilitation training can help other brain regions perform the same functions of that tissue. In other cases, compensatory actions may be developed to replace lost abilities.

Physical therapy is used to maintain and restore range of motion and strength in affected limbs, and to maximize mobility in walking, wheelchair use, and transferring (from wheelchair to toilet or from standing to sitting, for instance). The physical therapist advises patients on mobility aids such as wheelchairs, braces, and canes. In the recovery period, a stroke patient may develop muscle spasticity and contractures (abnormal muscle contractions) that can be treated with a combination of stretching and splinting.

Occupational therapy improves self-care skills such as feeding, bathing, and dressing, and helps develop effective compensatory strategies and devices for activities of daily living. A speech-language pathologist focuses on communication and swallowing skills. When dysphagia is a problem, a nutritionist can advise alternative meals that provide adequate nutrition.

Psychological therapy can help treat depression or loss of thinking (cognitive) skills. A social worker may help coordinate services and ease the transition out of the hospital back into the home. Both **social workers** and mental health professionals help counsel the patient and family during the difficult rehabilitation period. Caring for a person affected with stroke requires a new set of skills and adaptation to new demands and limitations. Home caregivers may develop **stress**, anxiety, and depression—caring for the caregiver is an important part of the overall stroke treatment program. **Support groups** can provide an important source of information, advice, and comfort for stroke patients and caregivers; joining one can be an important step in the rehabilitation process.

Prognosis

Stroke is fatal for about 27% of white males, 52% of African-American males, 23% of white females, and 40% of African-American females. Stroke survivors may be left with significant deficits. Emergency treatment and comprehensive rehabilitation can significantly improve both survival and recovery.

Prevention

The risk of stroke can be reduced through lifestyle changes:

- stop smoking
- control blood pressure
- get regular exercise
- maintain a healthy weight
- avoid excessive alcohol consumption
- get regular checkups and follow the doctor's advice regarding diet and medicines

Use of high-estrogen dose oral contraceptives increase the chances for developing stroke, particularly in women who smoke and/or who are over 35. Currently, there are low-estrogen dose oral contraceptives, for which a clear relationship with stroke development is unclear.

Treatment of atrial fibrillation may also significantly reduce the risk of stroke. Preventive anticoagulant therapy may benefit those with untreated atrial fibrillation. Warfarin (Coumadin) has proven to be more effective than aspirin for those with higher risk.

Screening for aneurysms may be an effective preventive measure in those with a family history of aneurysms or autosomal polycystic kidney disease, which tends to be associated with aneurysms.

Stuttering

Definition

There is no standard definition of stuttering, but most attempt to define stuttering as the blockages, discoordination, or fragmentations of the forward flow of speech (fluency). These stoppages, referred to as disfluencies, are often excessive and characterized by specific types of disfluency. These types of disfluencies include repetitions of sounds and syllables, prolongation of sounds, and blockages of airflow. Individuals who stutter are often aware of their stuttering and feel a loss of control when they are disfluent. Both children and adults stutterers expend an excessive amount of physical and mental energy when speaking. Older children and adults who stutter show myriad negative reactive behaviors, feelings, and attitudes. These behaviors, referred to as “secondary behaviors,” make the disorder more severe and difficult.

Description

Stuttering is a confusing and often misunderstood developmental speech and language disorder. Before discussing stuttering, it is important to understand the concepts of speech fluency and disfluency. Fluency is generally described as the forward flow of speech. For most speakers, fluent speech is easy and effortless. Fluent speech is free of any interruptions, blockages, or fragmentations. Disfluency is defined as a breakdown or blockage in the forward flow of speech, or fluency. For all speakers, some occurrence of disfluency is normal. For example, people may insert short sounds or words, referred to as “interjections,” when speaking; examples of such are “um,” “like,” or “uh.” Also, speakers might repeat phrases, revise words or phrases, or sometimes repeat whole words for the purpose of clarification. For young children, disfluency is a part of the normal development of speech and language, especially during the preschool years (between the ages of two and five years).

The occurrence of disfluency is not the same as stuttering, though stuttered speech is characterized by an excessive amount of disfluency. The disfluencies produced by people who stutter will often be similar to those in the speech of individuals who do not stutter; however, certain types of disfluent behavior are likely to appear only in the speech of people who stutter. These disfluencies are sound and syllable repetitions (i.e., ca-ca-ca-cat), sound prolongations (“sssss-salad,” “ffffff-fish”), and complete blockages of airflow. These behaviors, often referred to as stuttering type disfluencies, distinguish stuttered speech from nonstuttered speech.

KEY TERMS

Disfluency—Disruptions, breakage, or blockages in the forward flow of speech.

Secondary behaviors—Negative behavioral, emotional, or cognitive reactions to stuttering.

Speech-language pathologist—Specialists trained in assessment and diagnosis of communication disorders.

Unlike speakers who do not stutter, most people who stutter react negatively to their disfluencies. A person may develop a number of physical reactions, including tension of the muscles involved in speech (tongue, jaw, lips, or chest, for example) and tension in muscles not related to speech (such as shoulders, limbs, and forehead). In addition to these physiological reactions, people who stutter will often have negative emotional reactions to the disorder. Among the emotions that people who stutter report are embarrassment, guilt, and frustration.

Finally, many people who stutter will develop a number of negative attitudes and beliefs regarding themselves and speaking—because of their stuttering. These may be negative attitudes and beliefs in certain speaking situations, with people with whom they interact, and in their own abilities. These physiological, emotional, and attitudinal (cognitive) reactions to stuttering, described as secondary stuttering behaviors, are often very disruptive to the communication process and the person’s life.

Stuttering behaviors can develop and vary throughout the life span. Sometimes, children will experience periods when the stuttering appears to “go away,” only to return in a more severe pattern. Many children, (estimates range between 50 and 80%) will develop normal fluency after periods of stuttering. For those who continue to stutter during late childhood, adolescence, and into adulthood, stuttering can become a chronic problem. Lifelong efforts will be needed to cope successfully with the behavior.

Due to the effect that stuttering has on communication, the person who stutters may experience certain difficulties in various parts of his/her life. These problems might be secondary to factors inside the person (symptoms of stuttering) and outside the person (society’s attitudes toward stuttering and other barriers). For example, many people who stutter report difficulties in social settings. Children who stutter often experience teasing and other social penalties. Adolescents and adults also report a variety of social problems. Academic settings may be

difficult for children who stutter because of the emphasis schools place on verbal performance.

Finally, there appears to be some evidence that people who stutter might confront barriers in employment. These barriers might take the form of inability to do certain tasks easily (talking on the phone, for example), limitations in job choices, and discrimination in the hiring and promotion processes.

Causes and symptoms

Though research has not identified a single cause, there appears to be several factors that are viewed as being important to the onset and development of stuttering. Therefore, stuttering is often described as being related to multiple factors and having possibly multiple causes. First, there is a genetic predisposition to stutter, as evidenced by studies of families and twins. A second important factor in the onset of stuttering is the physiological makeup of people who stutter. Research suggests that the brains of people who stutter may function abnormally during speech production. These differences in functioning may lead to breakdowns in speech production and to the development of disfluent speech.

Third, there is some evidence that speech and language development is an important issue in understanding the development of stuttering. Studies have found some evidence that children who are showing stuttering type behaviors may also have other difficulties with speech-language. Additionally, children with speech-language delays will often show stuttering type behaviors. Finally, environmental issues have a significant impact on the development of stuttering behaviors. An environment that is overly stressful or demanding, may cause children to have difficulties developing fluent speech. Though the environment, in particular parental behaviors, does not cause stuttering, it is an important factor that might adversely affect a child who is operating at a reduced capacity for developing fluent speech.

There is no evidence that stuttering is secondary to a psychological disturbance. It is reasonable to assume that stuttering might have some effect on psychological adjustment and a person's ability to cope with speaking situations. People who stutter might experience a lower self-esteem and some might report feeling depressed. These feelings and difficulties with coping are most likely the result and not the cause of stuttering. In addition, several research studies have reported that many people who stutter report high levels of anxiety and **stress** when they are talking and stuttering. These feelings, psychological states, and difficulties with coping are most likely the result and not the cause of stuttering.

Generally, children begin to stutter between the ages of two and five years. Nevertheless, there are instances when individuals begin to show stuttering type behaviors in late childhood or as adults. These instances are often related to specific causes such as a **stroke** or a degenerative neurological disease. This type of stuttering, stuttering secondary to a specific neurological process, is referred to as neurogenic stuttering. In other cases, stuttering may be secondary to a psychological **conversion disorder** due to a psychologically traumatic event. When stuttering has abrupt onset secondary to a psychological trauma, it is described as psychogenic stuttering.

As stated earlier, the primary symptoms of stuttering include excessive disfluency, both stuttering and normal types (core behaviors), as well as physical, emotional, and cognitive reactions to the problem. These behaviors will vary in severity across people who stutter from very mild to very severe. Additionally, the behaviors will vary considerably across different speaking situations. There are specific situations when people tend to experience more stuttering (such as talking on the phone or with an authority figure) or less stuttering (speaking with a pet or to themselves, for example). It is likely that this variability might even extend to people having periods (days and even weeks) when they can maintain normally fluent or nonstuttered speech.

Demographics

Stuttering is a relatively low-prevalence disorder. Across all cultures, roughly 1% of people currently has a stuttering disorder. This differs from incidence, or number of individuals who have been diagnosed with stuttering at some point in their lives. Research suggests that roughly 5% of the population has ever been diagnosed with a stuttering disorder. This difference suggests that a significant number of individuals who stutter will someday develop through or “grow out of” the problem. Research suggests that roughly 50-80% of all children who begin to stutter will stop stuttering. In addition, approximately three times as many men stutter as women. This ratio seems to be lower early in childhood, with a similar number of girls and boys stuttering. The ratio of boys to girls appears to get larger as children become older. This phenomenon suggests that males are more likely to continue to stutter than females.

Diagnosis

Speech-language pathologists are responsible for making the **diagnosis** and managing the treatment of adults and children who stutter. Preferably, a board-certified speech-language pathologist board should be sought for direct **intervention** or consulting. Diagnosis of stut-

tering, or identifying children at risk for stuttering, is difficult because most children will show excessive disfluencies in their speech. With children, diagnostic procedures include the collection and analysis of speech and disfluent behaviors in a variety of situations. In addition, the child's general speech-language abilities will be evaluated.

Finally, the speech-language pathologist will interview parents and teachers regarding the child's general developmental, speech-language development, and their perceptions of the child's stuttering behaviors. For adults and older children, the diagnostic procedures will also include gathering and analyzing speech samples from a variety of settings. In addition, the speech-language pathologist will conduct a lengthy interview with the person about their stuttering and history of their stuttering problem. Finally, the person who stutters might be asked to report his/her attitudes and feelings related to stuttering, either while being interviewed or by completing a series of questionnaires.

Treatments

General considerations

It is generally accepted that conducting interventions with children and families early in childhood (preschool) is the most effective means of total recovery from stuttering. The chances for a person to fully recover from stuttering by obtaining near-normal fluency are reduced as the person ages. This is why early intervention is critical. For older children and adults for which stuttering has become a chronic disorder, the focus of therapy is on developing positive coping mechanisms for dealing with the problem. This therapy varies in success based on the individual.

Treatment options for young children

Treatment of young children generally follows one of two basic approaches. These approaches may also be combined into a single treatment program. The first type of approach, often referred to as indirect therapy, focuses on altering the environment to allow the child opportunities to develop fluent speech. With this approach, counseling parents regarding the alteration of behaviors that affect fluency is the focus. For example, parents may be taught to reduce the amount of household stress or in the level of speech-language demands being placed on the child. In addition, parents may be advised to change characteristics of their speech, such as their speech rate and turn-taking style; this is done to help their children develop more fluent speech.

The other basic approach in treatment with young children targets the development of fluent speech. This type of approach, often referred to as direct therapy,

teaches children to use skills that will help them improve fluency and they are sometimes given verbal rewards for producing fluent speech.

Treatment options for older children and adults

Treatment approaches for older children and adults usually take one of two forms. These approaches target either helping the person to modify his/her stuttering or modify his/her fluency. Approaches that focus on modifying stuttering will usually teach individuals to reduce the severity of their stuttering behaviors by identifying and eliminating all of the secondary or reactive behaviors. Individuals will also work to reduce the amount of emotional reaction toward stuttering.

Finally, the speech-language pathologist will help the individual to learn techniques that allow them to stutter in an easier manner. Therapy does not focus on helping the individual to speak fluently, though most individuals will attain higher levels of fluency if this approach is successful. The other groups of approaches will focus on assisting adults and children who stutter to speak more fluently. This type of therapy, which focuses less on changing secondary and emotional reactions, helps the person to modify their speech movements in a specific manner that allows for fluent sounding speech. These procedures require the individual to focus on developing new speech patterns. This often requires a significant amount of practice and skill. The successful outcome of these approaches is nonstuttered, fluent sounding speech. Many therapists will integrate stuttering modification and fluency shaping approaches into more complete treatment programs. In addition, psychological counseling may be used to supplement traditional speech therapy.

Prognosis

Complete alleviation of recovery from stuttering is most likely possible when children and their families receive treatment close to the time of onset. Thus, early identification and treatment of stuttering is critical. For older children and adults, stuttering becomes a chronic problem that requires a lifetime of formal and self-directed therapy. For individuals who show this more chronic form of the disorder, internal motivation for change and support from significant others is an important part of recovery.

Substance abuse and related disorders

Definition

Substance-related disorders are disorders of intoxication, dependence, abuse, and substance withdrawal caused by various substances, both legal and illegal. These substances include: alcohol, **amphetamines**, caffeine, inhalants, nicotine, prescription medications that may be abused (such as sedatives), opioids (morphine, heroin), marijuana (cannabis), cocaine, hallucinogens, and phencyclidine (PCP).

Description

According to the mental health clinician's handbook, *Diagnostic and Statistical Manual of Mental Disorders* (the *DSM*), fourth edition text revised (*DSM-IV-TR*), all of the substances listed above, with the exceptions of nicotine and caffeine, have disorders of two types: substance use disorders and substance-induced disorders. Substance use disorders include abuse and dependence. Substance-induced disorders include intoxication, withdrawal, and various mental states (**dementia**, **psychosis**, anxiety, mood disorder, etc.) that the substance induces when it is used.

Substance dependence is characterized by continued use of a substance even after the user has experienced serious substance-related problems. The dependent user desires the substance ("craving") and needs more of the substance to achieve the effect that a lesser amount of the substance induced in the past. This phenomenon is known as tolerance. The dependent user also experiences withdrawal symptoms when the substance is not used. Withdrawal symptoms vary with the substance, but some

symptoms may include increased heart rate, shaking, **insomnia**, **fatigue**, and irritability.

Substance abuse is continued use of a substance in spite of school- or work-related or interpersonal problems, but the user has not gotten dependent on the substance. The individual who abuses a substance may experience legal problems and may have problems fulfilling responsibilities, such as caring for a child.

Intoxication is the direct effect of the substance after an individual has used or has been exposed to the substance. Different substances affect individuals in various ways, but some of the effects seen in intoxication might include impaired judgment, emotional instability, increase or decrease in appetite, or changed sleep patterns.

The *DSM-IV-TR* does not recognize caffeine abuse or dependence, but does recognize the caffeine-induced disorders caffeine intoxication (restlessness, nervousness, excitement, etc. after caffeine consumption), caffeine-induced anxiety disorder (feelings of anxiety or panic attacks after caffeine consumption), and caffeine-induced sleep disorder (usually insomnia, but some may experience excessive sleepiness when caffeine is not consumed). As for nicotine, the *DSM-IV-TR* recognizes nicotine dependence and nicotine withdrawal.

The *DSM-IV-TR* lists disorders in the following categories:

- alcohol-related disorders
- amphetamine-related disorders
- caffeine-related disorders
- cannabis-related disorders
- cocaine-related disorders
- hallucinogen-related disorders
- inhalant-related disorders
- nicotine-related disorders
- opioid-related disorders
- phencyclidine-related disorders
- sedative-, hypnotic-, or anxiolytic-related disorders
- polysubstance dependence

KEY TERMS

Amphetamines—A group of powerful and highly addictive substances that stimulate the central nervous system. May be prescribed for various medical conditions, but are often purchased illicitly and abused.

Anxiety—A feeling of apprehension and fear characterized by physical symptoms (heart palpitations, sweating, and feelings of stress, for example).

Anxiolytic—A preparation or substance given to relieve anxiety; a tranquilizer.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Hallucinogens—Substances that cause hallucinations.

Hypnotic—A type of medication that induces sleep.

Inhalants—A class of drugs that are inhaled in order for the user to experience a temporary "high." These chemicals include volatile solvents (liquids

that vaporize at room temperature) and aerosols (sprays that contain solvents and propellants), and include glue, gasoline, paint thinner, hair spray, and others. They are dangerous because they can cause hallucinations, delusions, difficulty breathing, headache, nausea, vomiting, and even "sudden sniffing death." Inhalants can also cause permanent damage to the brain, lung, kidney, muscle, and heart.

Opioids—Substances that reduce pain and may induce sleep. Some opioids are endogenous, which means that they are produced within the human body. Other opioids are produced by plants or formulated synthetically in the laboratory.

Phencyclidine—The full name of the drug commonly called PCP that is often abused to induce hallucinations.

Psychosis—Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an over-arching disorder, not a disorder in itself. (Plural: psychoses)

Sedative—A medication that induces relaxation and sleep.

Substance Abuse Subtle Screening Inventory

Definition

The Substance Abuse Subtle Screening Inventory is also referred to as the SASSI. Dr. Glenn A. Miller developed the SASSI as a screening questionnaire for identifying people with a high probability of having a substance dependence disorder.

Purpose

The SASSI is intended for gathering information, organizing it, and using it to help make decisions about the likelihood of an individual having a substance dependence disorder, even if the individual does not acknowledge symptoms of the disorder or misuse of substances. Guidelines are available for professionals to flag individuals with a potential substance abuse disorder for further evaluation. Interpreting the results of the SASSI helps professionals understand their clients better and plan their treatment.

Precautions

When used by trained professionals, the SASSI can be an important tool in the assessment of substance use disorders. The SASSI is not intended to prove or diagnose an individual as an alcoholic or addict; it is intended to screen for a person who has a "high probability of having a substance dependence disorder." It should be kept in mind that a thorough assessment integrates other

available information, such as self-report and family history, and is done by a skilled professional. This comprehensive assessment is required to determine if an individual meets the accepted standards in the mental health professional's handbook, *Diagnostic and Statistical Manual of Mental Disorders*, for a clinical diagnosis of a substance-related disorder.

The accuracy rate of the SASSI is 94%. Although that is very high, this means that there is a 6% probability that an individual will be misclassified based on SASSI scores. While the SASSI is a popular and widely used screening questionnaire, independent research on it has been limited. Some researchers have questions about the SASSI regarding the extent to which subscales measure what they are intended to measure and the accuracy of classification based on direct versus indirect scales. In addition, the SASSI is not to be used to discriminate against individuals, including disqualifying job applicants. It would be a violation of the Americans With Disabilities Act to eliminate a job applicant based on SASSI scores.

Description

The SASSI is a simple, brief one-page paper-and-pencil questionnaire that can be answered in 10 to 15 minutes. The SASSI is easy to administer, to individuals or groups, and can be objectively scored by hand and interpreted, based on objective decision rules, in a minute or two. Optical scanning equipment is available for mass scoring and interpretation. The SASSI does not require a high level of reading ability. The SASSI may be used by a variety of programs and professionals, including school counselors, student assistance programs, employee assistance programs, vocational counselors, psychotherapists, medical personnel, criminal justice programs, and other human service providers.

The SASSI went through rigorous scientific development over a 16-year period before it was first published in 1988. Two new scales were added, and the SASSI-2 was published in 1994. In 1997 the SASSI-3 was published with a new scale and increased accuracy. Items on the SASSI were selected based on established research methods and statistical analysis. Items were included that identified individuals with substance dependence disorders. The selected items were consistently answered differently by individuals with a substance dependence disorder compared to individuals without a substance dependence disorder.

In 1996, a Spanish version was made available. In addition to the paper and pencil format, computer versions of the SASSI, in several formats, are available.

Some questions on the SASSI ask how frequently clients have had certain experiences directly related to alcohol and other drugs. These are answered on a four-point scale, ranging from never to repeatedly. Some items that may appear to be unrelated to substance use (indirect or subtle items) are in a true/false format. Overall, the items make up 10 subscales. The results are reported on a profile form that is discussed with the client. There are separate profile forms for males and females. The objective scoring system results in a yes or no answer about whether the client has a high probability of having a substance dependence disorder. The SASSI-3 has been empirically tested and can identify substance dependence disorder with an overall accuracy of 94%. More specifically, the SASSI identifies individuals with a substance dependence disorder with 94% accuracy, and it identifies those without a substance dependence disorder with 94% accuracy. The accuracy of the SASSI is not significantly affected by gender, age, socioeconomic status, ethnicity, occupational status, marital status, educational level, drug of choice, and general level of functioning. Research is ongoing to improve the accuracy and usefulness of the SASSI.

Since 1990 an adolescent version of the SASSI has been available. The second version of the Adolescent SASSI (SASSI-A2) has a 94% overall accuracy of identifying an adolescent with a substance dependence disorder, including both substance abuse and substance dependence. The SASSI-A2 is designed to screen individuals who are 12 to 18 years old. The accuracy of the SASSI-A2 is not affected by the respondent's gender, age, ethnicity, education, employment status, living situation, prior legal history, or general level of functioning.

Results

A profile of the SASSI results will be reviewed with the client. The actual scores are plotted on a profile graph in comparison to a sample of people who were not being evaluated or treated for addictions or other clinical problems (also called a normative sample). Feedback is then given in terms of whether the individual has a high or low probability of having a substance dependence disorder. Individual scale scores may be used to come up with ideas or hypotheses for further evaluation and treatment. This information is based on clinical experience with the SASSI. The results may indicate issues that are important for treatment (such as difficulty acknowledging personal shortcomings, or primarily focusing on others' needs while unaware of one's own needs). The results may suggest an approach to take with the client (such as increasing awareness, or acknowledging and validating their feelings). The results may suggest a

treatment plan that the client may respond to (such as addiction self-help groups or an education-focused program). Finally, the results may indicate appropriate treatment goals for the client (anger management and/or social skills, for example). The goal of providing feedback about SASSI results is to have a two-way sharing and understanding of information that is descriptive and not judgmental.

Substance-induced anxiety disorder

Definition

Prominent anxiety symptoms (i.e., generalized anxiety, panic attacks, obsessive-compulsive symptoms, or phobia symptoms) determined to be caused by the effects of a psychoactive substance is the primary feature of a **substance-induced psychotic disorder**. A substance may induce psychotic symptoms during intoxication (i.e., while the individual is under the influence of the drug) or during withdrawal (i.e., after an individual stops using the drug).

Description

A substance-induced anxiety disorder is subtyped or categorized based on whether the prominent feature is generalized anxiety, panic attacks, obsessive-compulsive symptoms, or phobia symptoms. In addition, the disorder is subtyped based on whether it began during intoxica-

KEY TERMS

Anticholinergic agents—Medicines that include atropine, belladonna, hyoscyamine, scopolamine, and related products; used to relieve cramps or spasms of the stomach, intestines, and bladder.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Obsessive-compulsive—Characterized by obsessive and compulsive behaviors.

Phobia—Irrational fear of places, things, or situations that lead to avoidance.

Psychoactive substance—A drug that produces mood changes and distorted perceptions; mind-altering drug.

Sympathomimetics—Drugs that mimic the effects of impulses conveyed by adrenergic postganglionic fibres of the sympathetic nervous system.

tion on a substance or during withdrawal from a substance. A substance-induced anxiety disorder that begins during substance use can last as long as the drug is used. A substance-induced anxiety disorder that begins during withdrawal may first manifest up to four weeks after an individual stops using the substance.

Causes and symptoms

Causes

A substance-induced anxiety disorder, by definition, is directly caused by the effects of drugs—including alcohol, medications, and toxins. Anxiety symptoms can result from intoxication on alcohol, **amphetamines** (and related substances), caffeine, cannabis (marijuana), cocaine, hallucinogens, inhalants, phencyclidine (PCP) and related substances, and other or unknown substances. Anxiety symptoms can also result from withdrawal from alcohol, sedatives, hypnotics, and anxiolytics, cocaine, and other or unknown substances. Some of the medications which may induce anxiety symptoms include anes-

thetics and analgesics, sympathomimetics (epinephrine or norepinephrine, for example) or other bronchodilators, anticholinergic agents, anticonvulsants, antihistamines, insulin, thyroid preparations, oral contraceptives, antihypertensive and cardiovascular medications, antiparkinsonian medications, corticosteroids, antidepressant medications, **lithium carbonate**, and antipsychotic medications. Heavy metals and toxins, such as volatile substances like fuel and paint, organophosphate insecticides, nerve gases, carbon monoxide, and carbon dioxide may also induce anxiety.

Symptoms

The *Diagnostic and Statistical Manual of Mental Disorders*, (*DSM-IV-TR*)—produced by the American Psychiatric Association and used by most mental health professionals in North America and Europe to diagnose mental disorders—notes that a **diagnosis** is made only when the anxiety symptoms are above and beyond what would be expected during intoxication or withdrawal and when severe. The following list is the criteria necessary for the diagnosis of a substance-induced anxiety disorder as listed in the *DSM-IV-TR*:

- Prominent anxiety, panic attacks, or obsessions or compulsions.
- Symptoms develop during, or within one month, of intoxication or withdrawal from a substance or medication known to cause anxiety symptoms.
- Symptoms are not actually part of another anxiety disorder (such as **generalized anxiety disorder**, phobias, **panic disorder**, or **obsessive-compulsive personality disorder**) that is not substance induced. For instance, if the anxiety symptoms began prior to substance or medication use, then another anxiety disorder is likely.
- Symptoms do not occur only during **delirium**.
- Symptoms cause significant distress or impairment in functioning.

Demographics

Little is known regarding the demographics of substance-induced anxiety disorders. However, it is clear that they occur more commonly in individuals who abuse alcohol or other drugs.

Diagnosis

Diagnosis of a substance-induced anxiety disorder must be differentiated from an anxiety disorder due to a general medical condition. There are some medical conditions (such as hyperthyroidism, hypothyroidism, or hypo-

glycemia) that can produce anxiety symptoms, and since individuals are likely to be taking medications for these conditions, it can be difficult to determine the cause of the anxiety symptoms. If the symptoms are determined to be due to the medical condition, then a diagnosis of an anxiety disorder due to a general medical condition is warranted. Substance-induced anxiety disorders also need to be distinguished from delirium, **dementia**, primary psychotic disorders, and substance intoxication and withdrawal.

Clinical history and physical examination are the best methods to help diagnose anxiety disorders in general; however, appropriate laboratory testing will most likely be necessary to specifically identify substance-induced anxiety disorder. Lab tests may include:

- complete blood count (CBC)
- chemistry panels
- serum and/or urine screens for drugs

Treatments

The underlying cause of the anxiety symptoms, as well as the specific type of symptoms, determine course of treatment and is often similar to treatment for a primary anxiety disorder such as generalized anxiety disorder, phobias, panic disorder, or **obsessive-compulsive disorder**. Appropriate treatment usually includes medication (antianxiety or antidepressant medication, for example).

Prognosis

Anxiety symptoms induced by substance intoxication usually subside once the substance responsible is eliminated. Symptoms persist depending on the half-life of the substances (i.e., how long it takes the before the substance is no longer present in an individual's system). Symptoms, therefore, can persist for hours, days, or weeks after a substance is last used. Obsessive-compulsive symptoms induced by substances sometimes do not disappear, even although the substance inducing them has been eliminated. More intensive treatment for the obsessive-compulsive symptoms would be necessary and should include a combination of medication and behavioral therapy.

Prevention

Little is documented regarding the prevention of substance-induced anxiety disorder. However, abstaining from drugs and alcohol, or using these substances only in moderation, would clearly reduce the risk of developing this disorder. In addition, taking medication under the supervision of an appropriately trained physician should

reduce the likelihood of a medication-induced anxiety disorder. Finally, reducing one's exposure to toxins and heavy metals would reduce the risk of toxin-induced anxiety disorder.

A substance-induced psychotic disorder that begins during substance use can last as long as the drug is used. A substance-induced psychotic disorder that begins during withdrawal may first manifest up to four weeks after an individual stops using the substance.

Causes and symptoms

Causes

A substance-induced psychotic disorder, by definition, is directly caused by the effects of drugs including alcohol, medications, and toxins. Psychotic symptoms can result from intoxication on alcohol, **amphetamines** (and related substances), cannabis (marijuana), cocaine, hallucinogens, inhalants, opioids, phencyclidine (PCP)

and related substances, sedatives, hypnotics, anxiolytics, and other or unknown substances. Psychotic symptoms can also result from withdrawal from alcohol, sedatives, hypnotics, anxiolytics, and other or unknown substances.

Some medications that may induce psychotic symptoms include anesthetics and analgesics, anticholinergic agents, anticonvulsants, antihistamines, antihypertensive and cardiovascular medications, antimicrobial medications, antiparkinsonian medications, chemotherapeutic agents, corticosteroids, gastrointestinal medications, muscle relaxants, nonsteroidal anti-inflammatory medications, other over-the-counter medications, antidepressant medications, and **disulfiram**. Toxins that may induce psychotic symptoms include anticholinesterase, organophosphate insecticides, nerve gases, carbon monoxide, carbon dioxide, and volatile substances (such as fuel or paint).

The speed of onset of psychotic symptoms varies depending on the type of substance. For example, using a lot of cocaine can produce psychotic symptoms within minutes. On the other hand, psychotic symptoms may result from alcohol use only after days or weeks of intensive use.

The type of psychotic symptoms also tends to vary according to the type of substance. For instance, auditory hallucinations (specifically, hearing voices), visual hallucinations, and tactile hallucinations are most common in an alcohol-induced psychotic disorder, whereas persecutory delusions and tactile hallucinations (especially formication) are commonly seen in a cocaine- or amphetamine-induced psychotic disorder.

Symptoms

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* notes that a **diagnosis** is made only when the psychotic symptoms are above and beyond what would be expected during intoxication or withdrawal and when the psychotic symptoms are severe. Following are criteria necessary for diagnosis of a substance-induced psychotic disorder as listed in the *DSM-IV-TR*:

- Presence of prominent hallucinations or delusions.
- Hallucinations and/or delusions develop during, or within one month of, intoxication or withdrawal from a substance or medication known to cause psychotic symptoms.
- Psychotic symptoms are not actually part of another psychotic disorder (such as **schizophrenia**, **schizophreniform disorder**, **schizoaffective disorder**) that is not substance induced. For instance, if the psychotic symptoms began prior to substance or medication use, then another psychotic disorder is likely.
- Psychotic symptoms do not only occur during **delirium**.

Demographics

Little is known regarding the demographics of substance-induced **psychosis**. However, it is clear that substance-induced psychotic disorders occur more commonly in individuals who abuse alcohol or other drugs.

Diagnosis

Diagnosis of a substance-induced psychotic disorder must be differentiated from a psychotic disorder due to a general medical condition. Some medical conditions (such as temporal lobe epilepsy or Huntington's chorea) can produce psychotic symptoms, and, since individuals are likely to be taking medications for these conditions, it can be difficult to determine the cause of the psychotic symptoms. If the symptoms are determined to be due to the medical condition, then a diagnosis of a psychotic disorder due to a general medical condition is warranted.

Substance-induced psychotic disorder also needs to be distinguished from delirium, **dementia**, primary psychotic disorders, and substance intoxication and withdrawal. While there are no absolute means of determining substance use as a cause, a good patient history that includes careful assessment of onset and course of symptoms, along with that of substance use, is imperative. Often, the patient's testimony is unreliable, necessitating the gathering of information from family, friends, coworkers, employment records, medical records, and the like. Differentiating between substance-induced disorder and a psychiatric disorder may be aided by the following:

- Time of onset: If symptoms began prior to substance use, it is most likely a psychiatric disorder.
- Substance use patterns: If symptoms persist for three months or longer after substance is discontinued, a psychiatric disorder is probable.
- Consistency of symptoms: Symptoms more exaggerated than one would expect with a particular substance type and dose most likely amounts to a psychiatric disorder.
- Family history: A family history of mental illness may indicate a psychiatric disorder.
- Response to substance abuse treatment: Clients with both psychiatric and substance use disorders often have serious difficulty with traditional substance abuse treatment programs and relapse during or shortly after treatment cessation.
- Client's stated reason for substance use: Those with a primary psychiatric diagnosis and secondary substance use disorder will often indicate they "medicate symptoms," for example, drink to dispel auditory hallucina-

tions, use stimulants to combat depression, use depressants to reduce anxiety or soothe a manic phase. While such substance use most often exacerbates the psychotic condition, it does not necessarily mean it is a substance-induced psychotic disorder.

Unfortunately, psychological tests are not always helpful in determining if a psychotic disorder is caused by substance use or is being exacerbated by it. However, evaluations, such as the MMPI-2 MAC-R scale or the Wechsler Memory Scale—Revised, can be useful in making a differential diagnosis.

Treatments

Treatment is determined by the underlying cause and severity of psychotic symptoms. However, treatment of a substance-induced psychotic disorder is often similar to treatment for a primary psychotic disorder such as schizophrenia. Appropriate treatments may include psychiatric **hospitalization** and antipsychotic medication.

Prognosis

Psychotic symptoms induced by substance intoxication usually subside once the substance is eliminated. Symptoms persist depending on the half-life of the substances (i.e., how long it takes the before the substance is no longer present in an individual's system). Symptoms, therefore, can persist for hours, days, or weeks after a substance is last used.

Prevention

There is very little documented regarding prevention of substance-induced psychotic disorder. However, abstaining from drugs and alcohol or using these substances only in moderation would clearly reduce the risk of developing this disorder. In addition, taking medication under the supervision of an appropriately trained physician should reduce the likelihood of a medication-induced psychotic disorder. Suicide

Definition

Suicide is defined as the intentional taking of one's own life. In some European languages, the word for suicide translates into English as "self-murder." Until the end of the twentieth century, approximately, suicide was considered a criminal act; legal terminology used the Latin phrase *felo-de-se*, which means "a crime against the self." Much of the social **stigma** that is still associated with suicide derives from its former connection with legal judgment, as well as with religious condemnation.

In the social climate of 2002, suicidal behavior is most commonly regarded—and responded to—as a psychiatric emergency.

Demographics of suicide

In the United States, the rate of suicide has continued to rise since the 1950s. More people die from suicide than from homicide in North America. Suicide is the eighth leading cause of death in the U.S., and the third leading cause of death for people aged 15 to 24. There are over 30,000 suicides per year in the U.S., or about 86 per day; each day about 1,500 people attempt suicide.

The demographics of suicide vary considerably from state to state. Some states, like Pennsylvania, have suicide rates that are very close to the national average; others, such as Connecticut, have significantly lower rates. However, other states have much higher rates than the national average. These variations are due in part to differences among age groups and racial groups, and between men and women. Males are three to five times more likely to succeed in their suicide attempts than females, but females are more likely to attempt suicide. Most suicides occur in persons below the age of 40; how-

KEY TERMS

Assisted suicide—A form of self-inflicted death in which a person voluntarily brings about his or her own death with the help of another, usually a physician, relative, or friend.

Cortisol—A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress. Cortisol levels are now considered a biological marker of suicide risk.

Diathesis—The medical term for predisposition. The stress/diathesis model is a diagram that is used to explain why some people are at greater risk of suicidal behavior than others.

Euthanasia—The act of putting a person or animal to death painlessly or allowing them to die by withholding medical services, usually because of a painful and incurable disease. Mercy killing is another term for euthanasia.

Frontal cortex—The part of the human brain associated with aggressiveness and impulse control. Abnormalities in the frontal cortex are associated with an increased risk of suicide.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Slow suicide—A term used to refer to lifestyle behaviors known to shorten life expectancy, such as smoking, drinking heavily, having unsafe sex, etc.

Suicide gesture—Attempted suicide characterized by a low-lethality method, low level of intent or planning, and little physical damage. Pseudocide is another term for a suicide gesture.

ever, elderly Caucasians are the sector of the population with the highest suicide rate.

Race is also a factor in the demographics of suicide. Between 1979 and 1992, the suicide rate of Native Americans was 1.5 times the national average, with young males between the ages of 15 and 24 accounted for 64% of Native American deaths by suicide. Asian-American women have the highest suicide rate among all women over the age of 65. Further, between 1980 and

1996 the suicide rate more than doubled for African-American males between the ages of 15 and 19.

High-risk factors

Research indicates that the following factors increase a person's risk of suicide:

- Male sex.
- Age over 75.
- A family history of suicide.
- A history of suicide attempts.
- A history of **abuse** in childhood.
- Traumatic experiences after childhood
- Recent stressful events, such as separation or divorce, job loss, or death of spouse.
- Chronic medical illness. Patients with AIDS have a rate of suicide 20 times that of the general population.
- Access to a gun. Death by firearms is now the fastest-growing method of suicide among men and women. Nearly 57% of deaths caused by guns in the U.S. are suicides.
- Alcohol or substance abuse. While mood-altering substances do not cause a person to kill himself/herself, they weaken impulse control.
- High blood cholesterol levels.
- Presence of a psychiatric illness. Over 90% of Americans who commit suicide have a mental illness. Major depression accounts for 60% of suicides, followed by **schizophrenia**, alcoholism, substance abuse, **borderline personality disorder**, Huntington's disease, and epilepsy. The lifetime mortality due to suicide in psychiatric patients is 15% for major depression; 20% for **bipolar disorder**; 18% for alcoholism; 10% for schizophrenia; and 5–10% for borderline and certain other personality disorders.

Low-risk factors

Factors that lower a person's risk of suicide include:

- a significant friendship network outside the workplace
- religious faith and practice
- a stable marriage
- a close-knit extended family
- a strong interest in or commitment to a project or cause that brings people together, including community service, environmental concerns, neighborhood associations, animal rescue groups, etc.

Suicide in other countries

Suicide has become a major social and medical problem around the world. The World Health Organization (WHO) reported that one million people worldwide died from suicide in the year 2000. That is a global mortality rate of 16:100,000—or one death by suicide every 40 seconds. Since the mid-1950s, suicide rates around the world have risen by 60%. Rates among young people have risen even faster, to the point where they are now the age group at highest risk in 35% of the world's countries.

The specific demographics, however, vary from country to country. China's pattern, for example, is very different from that of most other countries. China has a suicide mortality rate of 23:100,000, with a total of 287,000 deaths by suicide each year. The rate for women is 25% higher than that for men, and rates in rural areas are three times higher than in cities. The means also vary; In China, Sri Lanka, and Turkey the primary means of suicide is ingestion of pesticides, rather than using guns.

Suicide in children and adolescents

The suicide rate among children and adolescents in the U.S. has risen faster than that of the world population as a whole. The suicide rate for Caucasian males aged 15 to 24 years has tripled since 1950; and it has more than doubled for Caucasian females in the same age bracket. In 1999, a survey of high school students found that 20% had seriously considered suicide or attempted it in the previous year. Of adolescents who do commit suicide, 90% have at least one diagnosable psychiatric disorder at the time of their death. Most frequently it is major depression, substance abuse disorder, or **conduct disorder**. Adolescents are particularly susceptible to dramatic or glamorized portrayals of suicide in the mass media.

Causes

Suicide is an act that represents the end result of a combination of factors in any individual. One model that has been used by clinicians to explain why people suffering under the same life stresses respond differently is known as the stress/diathesis model. Diathesis is a medical term for a predisposition that makes some people more vulnerable to thoughts of suicide. Components of a person's diathesis may include:

Neurobiological and genetic factors

Post-mortem studies of the brains of suicide victims indicate that the part of the brain associated with controlling aggression and other impulsive behaviors (the frontal cortex) has a significantly lower level of serotonin, a neurotransmitter associated with mood disorders. Low sero-

tonin levels are correlated with major depression. In addition, suicide victims have higher than normal levels of cortisol, a hormone produced in stressful situations, in the tissues of their central nervous system. Studies of the levels of other neurotransmitters in brain tissue are underway.

Other research has indicated that abuse in childhood may have permanent effects on the level of serotonin in the brain, possibly "resetting" the level abnormally low. In addition, twin studies have suggested that there may be genetic susceptibility in males to both suicidal ideation and suicide attempts which cannot be explained by inheritance of common psychiatric disorders. No twin studies of susceptibility to suicide in women have yet been reported.

History and lifestyle

Other components of a diathesis include:

- Chronic illness
- Traumatic experiences after childhood
- Alcohol or substance abuse
- High blood cholesterol levels.

Factors in the wider society

In addition to factors at the individual level, factors in the wider society have been identified as contributing to the rising rate of suicide in the United States:

- Stresses on the nuclear family, including divorce and economic hardship.
- The loss of a set of moral values held in common by the entire society.
- The weakening of churches, synagogues, and other mid-range social groups outside the family. In the past, these institutions often provided a sense of belonging for people from troubled or emotionally distant families.
- Frequent geographical moves, which makes it hard for people to make and keep long-term friendships outside their immediate family.
- Sensationalized treatment of suicide in the mass media. A number of research studies have shown that there is a definite risk of "contagion" suicides from irresponsible reporting, particularly among impressionable adolescents.
- The development over the past century of medications that allow relatively painless suicide. For most of human history, the available means of suicide were uncertain, painful, or both.
- The easy availability of firearms in the United States.

Treatment of attempted suicide

Researchers estimate that 8–25 people attempt suicide for every person who completes the act. Suicide attempts can be broadly categorized along a continuum that ranges from seriously planned attempts involving a highly lethal method that fail by good fortune, to impulsive or poorly planned attempts using a less lethal method. Suicide attempts at the lower end of the spectrum are sometimes referred to as suicide gestures or pseudocide.

A suicide attempt of any kind, however, is treated as a psychiatric emergency by rescue personnel. Treatment in a hospital emergency room includes a complete psychiatric evaluation, a mental status examination, and a detailed assessment of the circumstances surrounding the attempt. The physician will interview relatives or anyone else who accompanied the patient in order to obtain as much information as possible. As a rule, suicide attempts requiring advance planning, including precautions taken against discovery, and the use of violent or highly lethal methods are regarded as the most serious. The patient will be kept under observation while decisions are made about the need for **hospitalization**.

A person who has attempted suicide and who is considered a serious danger to him- or herself or to others can be hospitalized against their will. The doctor will base the decision on the severity of the patient's depression or agitation; availability of friends, relatives, or other social support; and the presence of other suicide risk factors, including a history of previous suicide attempts, substance abuse, recent stressful events, and symptoms of **psychosis**. If the attempt is judged to be a nonlethal suicide gesture, the patient may be released after the psychiatric assessment is completed.

Related issues

Survivors of suicide

One group of people that is often overlooked in discussions of suicide is the friends and family bereaved by the suicide. It is estimated that each person who kills him- or herself leaves six survivors to deal with the aftermath. On the basis of this figure, there are at least 4.5 million survivors of suicide in the United States. In addition to the **grief** that ordinarily accompanies death, survivors of suicide often struggle with feelings of guilt and shame as well. In spite of a general liberalization of social attitudes since World War II, suicide is still stigmatized in many parts of Europe and the United States. Survivors often benefit from group or individual **psychotherapy** in order to work through such issues as wondering whether they could have prevented the suicide or

whether they are likely to commit suicide themselves. Increasing numbers of clergy as well as mental health professionals are taking advanced training in counseling survivors of suicide.

Assisted suicide

One question that has been raised in developed countries as the average life expectancy increases is the legalization of assisted suicide for persons suffering from a painful terminal illness. Physician-assisted suicide has become a topic of concern since it was legalized by recent legislation in the Netherlands (in April 2001) and in the state of Oregon. It is important to distinguish between physician-assisted suicide and euthanasia, or "mercy killing." Assisted suicide, which is often called "self-deliverance" in Britain, refers to a person's bringing about his or her own death with the help of another person. Because the other person is often a physician, the act is often called "doctor-assisted suicide." Euthanasia strictly speaking means that the physician or other person is the one who performs the last act that causes death. For example, if a physician injects a patient with a lethal overdose of a pain-killing medication, he or she is performing euthanasia. If the physician leaves the patient with a loaded syringe and the patient injects himself or herself with it, the act is an assisted suicide. As of 2002, assisted suicide is illegal everywhere in the United States except for Oregon, and euthanasia is illegal in all fifty states.

Media treatment of suicide

In 1989, the Centers for Disease Control (CDC) sponsored a national workshop to address the issue of the connection between sensationalized media treatments of suicide and the rising rate of suicide among American youth. The CDC and the American Association of Suicidology subsequently adopted a set of guidelines for media coverage of suicide intended to reduce the risk of suicide by contagion.

The CDC guidelines point out that the following types of reporting may increase the risk of "copycat" suicides:

- Presenting oversimplified explanations of suicide, when in fact many factors usually contribute to it. One example concerns the suicide of the widow of a man who was killed in the collapse of the World Trade Center on September 11, 2001. Most newspapers that covered the story described her death as due solely to the act of terrorism, even though she had a history of depressive illness.

- Excessive, ongoing, or repetitive coverage of the suicide.
- Sensationalizing the suicide by inclusion of morbid details or dramatic photographs. Some news accounts of the suicide of an Enron executive in January 2002 are examples of this problem.
- Giving “how-to” descriptions of the method of suicide.
- Referring to suicide as an effective coping strategy or as a way to achieve certain goals.
- Glorifying the act of suicide or the person who commits suicide.
- Focusing on the person’s positive traits without mentioning his or her problems.

Prevention

Brain research is an important aspect of suicide prevention as of 2002. Since major depression is the single most common **diagnosis** in suicidal people, earlier and more effective recognition of depression is a necessary preventive measure. Known biological markers for an increased risk of suicide can now be correlated with personality profiles linked to suicidal behavior under **stress** to help identify individuals at risk. In addition, brain **imaging studies** using **positron emission tomography** (PET) are presently in use to detect abnormal patterns of serotonin uptake in specific regions of the brain. Genetic studies are also yielding new information about inherited predispositions to suicide.

A second major preventive measure is education of clinicians, media people, and the general public. Public health studies carried out in Sweden have shown that seminars for primary care physicians in the recognition and treatment of depression resulted in a rise in the number of prescriptions for antidepressants and a drop in suicide rates. Education of the general public includes a growing number of CDC, NIMH, and other web sites posting information about suicide, tips for identifying symptoms of depressed and suicidal thinking, and advice about helping friends or loved ones who may be at risk. Many of these web sites have direct connections to suicide hotlines.

An additional preventive strategy is restricting access to firearms in the developed countries and to pesticides and other poisons in countries where these are the preferred method of suicide.

Support groups

Definition

Support groups are an informal resource that attempts to provide healing components to a variety of problems and challenges. An informal support outside of family, friends, or professionals often provides greater understanding, more similarity (from individuals experiencing similar life events), an opportunity for empathy and altruism, and a sense of identity for participants. Learning new ways to handle challenges, cope with changes, and maintain new behaviors are all important aspects of the support group experience.

A characteristic unique to support groups is the mutual support members are able to provide one another. This support and validation from other group members help facilitate personal growth and change in a way that individual therapy cannot. Although experts and professionals can provide support and positive direction, the mutual exchange of information between group members is a powerful experience that often induces lasting change.

Description

Most support groups are facilitated or led by lay persons, often in conjunction with existing organizations (such as NAMI, the National Alliance for the Mentally Ill, or AA, Alcoholics Anonymous). Support groups usually have a set meeting time (generally weekly or monthly), and an open format. Open format means that the groups are ongoing, and members have the option of attending when it is convenient for them. This is in contrast to other types of structured treatment or psycho-edu-

cational groups that may meet for a certain number of sessions, with the expectation that participants attend every meeting. The open format allows members to feel some degree of anonymity, and to participate as they are comfortable. For some people, simply attending meetings and listening to the experiences of others can be helpful.

The healing power of groups is well documented, and support groups offer many of the same therapeutic characteristics as more structured groups. These factors include: altruism (chance to help others), belongingness, universality (there are others who struggle with similar challenges), interpersonal learning, guidance, catharsis, identification, self-understanding, instillation of hope, and existential factors (such as the search for larger meaning in life). Each of these factors is directly related to the mutual support that members provide one another.

Support groups are generally less structured than psycho-educational groups or therapy groups; however, each group usually sets its own norms, rules, and schedules. Some groups, such as AA, traditionally reserve time for individual members to discuss their own challenges and progress in front of the group. Others bring in speakers periodically to provide information about disorders or specific coping skills. However, the strength of support groups lies in its members, and their willingness to share their own experiences, challenges, and solutions in the context of the group.

In addition to these traditional, face-to-face support groups, technology has had an impact on the functioning and availability of support groups. There are many listserves, e-mail groups, and chat groups that provide information about specific life problems (adoption of children outside the United States, for example), certain types of mental illness, and specific health problems. While there is always the risk of communicating with others who are not honest, many people benefit from these Internet interactions. Some individuals are actually more comfortable participating in Internet support groups due to the greater anonymity they offer.

There are a variety of problems and challenges that are addressed in support groups. Generally speaking, the severity of the symptom, as well as the phase of the illness or disorder, will determine whether participation in a support group is appropriate. For more severe types of mental illness, such as **schizophrenia**, or depression with psychotic episodes, a support group is probably not the optimal **intervention**, particularly at initial onset. After stabilization through therapy and medication (as appropriate), a support group may offer an important addition to more formal treatment. In these cases, the

socialization, interpersonal relationships, and social support that can be gained through the group may not be available elsewhere, and as such, it can be a very positive experience for the participant. In a group situation, a participant can learn how to express feelings in a healthy and positive way, practice assertive communication, receive feedback about appropriate and inappropriate content for conversation, receive feedback about nonverbal communication, learn new ways to ask for help from others, be able to help others, learn how to form friendships, and learn new coping skills and behaviors.

Types of support groups

Various types of support groups exist. Some groups provide support for very specific types of loss, illness, or life adjustment. A representative sample is listed below.

BEREAVEMENT/GRIEF COUNSELING GROUPS. Bereavement and **grief counseling** groups provide support to people who have experienced a loss. There are groups for people who have lost a spouse or partner, parents, children, or pets. There are specific groups for people who have lost a loved one due to homicide, **suicide**, SIDS, cancer, or miscarriage. These groups help individuals adjust to the death of a family member or friend, learn how to accept the loss, honor the memory of their loved one, and adjust to life after the loss.

MEDICAL SUPPORT GROUPS. Medical support groups may be more short-term than other types of support groups, depending on the specific disorder. Some groups are formed to help patients adjust to specific treatments, such as chemotherapy or radiation, while others focus on longer-term adjustment and recovery issues, such as a breast cancer support group. These groups may have a stronger educational component to help members understand physical changes they may be experiencing as a result of their medical procedures.

WEIGHT LOSS GROUPS. Although these groups are very specific in their focus, their individual structures can vary greatly. Some weight loss support groups are actively involved in the process of losing weight, and may include monitoring of diet and exercise, while others focus on maintaining weight loss, and, therefore, may focus more on social support.

MENTAL HEALTH/ILLNESS SUPPORT GROUPS. These groups usually focus on specific disorders, such as bipolar or eating disorders. Members of these support groups are often at different phases in dealing with their illnesses, and, therefore, the needs and contributions of individual members may vary greatly from meeting to meeting.

Most support groups are facilitated by lay persons, and usually have a set meeting time (generally weekly or monthly), and an open format. The open format allows members to feel some degree of anonymity, and to participate as they are comfortable. For some people, simply attending meetings and listening to the experiences of others can be helpful. (Richard T. Nowitz/CORBIS. Photo reproduced by permission.)

FAMILY SUPPORT GROUPS. Family support groups, such as CHADD for parents of children with ADD, or NAMI for families with members who struggle with any type of mental illness, provide support from other parents and children who may be feeling the same level of frustration and exasperation. Meeting others who truly understand one's experience has a very powerful effect. For many parents, participation in a support group is the first opportunity to learn that there are other parents who are experiencing the same challenges and frustrations.

LIFE TRANSITIONS GROUPS. Life transitions groups include divorce and aging support groups. Support groups for children of divorce also exist in many communities and schools.

ADDICTIONS SUPPORT GROUPS. Traditional **addiction** support groups include Alcoholics Anonymous (AA), Narcotics Anonymous (NA), and Gambler's Anonymous (GA). Many of these groups follow the traditional "12-step" program of working through various aspects of the addiction, and, as such, are more structured than many other types of support groups.

Support group locations

Support groups meet in many different locations within a community. Hospitals and medical centers may provide meeting locations for medical support groups. **Community mental health** centers, inpatient psychiatric programs, and residential treatment centers are com-

mon locations for mental health and mental illness-related support groups. Life transition groups are often provided through schools, senior centers, and daycare centers. Bereavement groups and addiction support groups often meet in churches, community meeting rooms of local businesses, and mental health agencies.

Structure of support groups

Support groups are most successful when composed of persons close in age who are experiencing similar life challenges. Support groups are usually led by members of the group, such as the chapter president or another member of the organizing group. Some support groups may be led by paraprofessionals if they are offered as part of an aftercare program associated with a treatment facility.

Support groups usually have explicit norms and expectations for member participation, such as respecting members' feelings and opinions, and coming to meetings free from drugs or alcohol. Due to the open nature of most support groups, members typically feel free to miss a session here or there, which is usually not acceptable in a treatment or therapy group.

Conclusion

Group experiences can be very powerful in changing behavior and maintaining that change. The support group becomes part of the individual's daily life, and promotes healthy functioning by providing reminders about change and support when he or she is feeling down or is drawn toward old patterns. It also provides opportunities to own one's change by helping others. These factors contribute to the positive prognosis for most who participate in a group experience. However, a person could be harmed by a group experience as well. Much of this risk is dependent on the characteristics of individual members, particularly in support groups that operate without professional guidance. For example, if certain individuals dominate the group with their own agenda, perhaps at the expense of other group members, then the experience may have a negative impact on more vulnerable individuals.

Systematic desensitization

Definition

Systematic desensitization is a technique used to treat phobias and other extreme or erroneous fears based on principles of **behavior modification**.

Purpose

Systematic desensitization is used to help the client cope with phobias and other fears, and to induce relaxation. In progressive relaxation, one first tightens and then relaxes various muscle groups in the body. During the alternating clenching and relaxing, the client should be focusing on the contrast between the initial tension and the subsequent feelings of relaxation and softening that develop once the tightened muscles are released. After discovering how muscles feel when they are

deeply relaxed, repeated practice enables a person to recreate the relaxed sensation intentionally in a variety of situations.

After learning relaxation skills, the client and therapist create an “anxiety hierarchy.” The hierarchy is a catalogue of anxiety-provoking situations or stimuli arranged in order from least to most distressing. For a person who is frightened by snakes, the anxiety hierarchy might start with seeing a picture of a snake, eventually move to viewing a caged snake from a distance, and culminate in actually handling a snake. With the therapist’s support and assistance, the client proceeds through the anxiety hierarchy, responding to the presentation of each fearful image or act by producing the state of relaxation. The person undergoing treatment stays with each step until a relaxed state is reliably produced when faced with each item. As tolerance develops for each identified item in the series, the client moves on to the next. In facing more menacing situations progressively, and developing a consistent pairing of relaxation with the feared object, relaxation rather than anxiety becomes associated with the source of their anxiety. Thus, a gradual desensitization occurs, with relaxation replacing alarm. Several means of confronting the feared situations can be used. In the pre-computer era, the exposure occurred either through imagination and visualization (imagining a plane flight) or through actual real-life — or so-called *in vivo* — encounters with the feared situation (going on an actual plane flight). More recently, during the 1990s, virtual reality or computer simulated exposure has come to be utilized in lieu of *in vivo* exposure. Research findings indicate that mental imagery is the least effective means of exposure; *in vivo* and virtual reality exposure appear to be indistinguishable in terms of effectiveness.

Description

Systematic desensitization is a therapeutic **intervention** that reduces the learned link between anxiety and objects or situations that are typically fear-producing. The aim of systematic desensitization is to reduce or eliminate fears or phobias that sufferers find are distressing or that impair their ability to manage daily life. By substituting a new response to a feared situation — a trained contradictory response of relaxation which is irreconcilable with an anxious response — phobic reactions are diminished or eradicated.

This behavior modification technique, which is founded on the principles of classical conditioning, was developed by Joseph Wolpe in the 1950s. Some of the most common fears treated with desensitization include fear of public speaking, fear of flying, stage fright, ele-

KEY TERMS

Behavior modification—An approach to therapy based on the principles of operant conditioning. Behavior modification seeks to replace undesirable behaviors with preferable behaviors through the use of positive or negative reinforcement.

Classical conditioning—In psychology, a process in which a previously neutral stimulus eventually produces a specific response by being paired repeatedly with another stimulus that produces that response. The best-known example of classical conditioning is Pavlov’s dogs, who were conditioned to salivate when they heard a bell ring (the previously neutral stimulus) because the sound had been paired repeatedly with their feeding time.

vator phobias, driving phobias and animal phobias. Relaxation responses are trained to occur through *progressive relaxation training*, a technique initially perfected by Edmund Jacobson during the 1930s.

Precautions

Because of the potential for extreme panic reactions to occur, which can increase the phobia, this technique should only be conducted by a well-qualified, trained professional. Also, the relaxation response should be thoroughly learned before confronting the anxiety-provoking hierarchy.

Normal results

Desensitization is an effective form of therapy. Individuals who have a positive response are enabled to resume daily activities that were previously avoided. The majority of persons undergoing this treatment show symptom reduction.

Tacrine

Definition

Tacrine is a drug used to treat **dementia** associated with **Alzheimer's disease**. In the United States tacrine is sold under the brand name drug Cognex. It is also sometimes called tetrahydroaminoacridine or THA.

Purpose

Tacrine is used to treat symptoms of Alzheimer's disease in people with mild to moderate illness. The drug may result in mild improvements in thinking for a short period. Tacrine does not cure or stop the progression of Alzheimer's disease.

Description

The Food and Drug Administration approved tacrine in 1993 for treating Alzheimer's disease. In Alzheimer's disease, some cells in specific regions of the **brain** die. Because of this cell death, these brain cells lose their ability to transmit nerve impulses. Brain cells normally transmit nerve impulses another by secreting various chemicals known as **neurotransmitters**.

Brain cells that make and secrete a neurotransmitter called acetylcholine are affected early in the course of Alzheimer's disease. Tacrine helps prevent the breakdown of acetylcholine in the brain, thus temporarily increasing its concentration. In doing so, tacrine may improve the thinking process by facilitating nerve impulse transmission within the brain.

Tacrine is available as capsules in several different strengths. Tacrine is broken down by the liver.

Recommended dosage

The dose of tacrine will be different for different people. An initial dosage of tacrine is usually 10 mg

taken four times per day. This dose should be continued for four weeks while liver function is monitored. If no adverse liver effects are detected, the dosage should be increased to 20 mg taken four times per day. Higher dosages such as 30-40 mg given four times per day may also be used. Liver function must be monitored every other week during the first 16 weeks of treatment. After 16 weeks of tacrine therapy, liver function can be assessed every three months. Dosage increases should not occur more often than every four weeks. Tacrine should be taken on an empty stomach between meals, but if stomach upset occurs, it may be taken with food.

If problems in liver function arise, tacrine may be stopped, or the dosage reduced, until liver function returns to normal. Very specific guidelines should be followed by physicians with regard to dosage adjustments based upon the severity of liver effects. Newer drugs that work in the same manner as tacrine are not as toxic to the liver and may be preferred for patients just beginning therapy for Alzheimer's-type dementia.

Precautions

Tacrine may cause liver damage. It may not be the best drug to treat symptoms of Alzheimer's disease in people with known liver damage. If these individuals take tacrine, their liver function should be closely monitored. Tacrine may also slow heart rates, increase acid secretion in the stomach, make urination difficult, cause breathing difficulties, or contribute to **seizures**. As a result, it should be used carefully in people with certain heart conditions, those who are prone to stomach ulcers, people with bladder obstruction, individuals with asthma, and those with a history of seizure disorders.

People should not stop taking tacrine suddenly because this could cause behavioral disturbances. The drug may be stopped slowly if improvements are not noted by caregivers or physicians.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Milligram (mg)—One-thousandth of a gram. A gram is the metric measure that equals about 0.035 ounces.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Placebo—An inactive substance or preparation used as a control in experiments with human subjects to test the effectiveness of a drug or herbal preparation. Some patients may experience a medicinal response or experience side effects to a placebo simply because they have faith in its powers even though it contains no medicine.

Side effects

The most common side effect of tacrine is impaired liver function. This causes 8% of people to stop taking the drug. Other common side effects occurring in at least 5% of people and at twice the rate of placebo are stomach upset (nausea, vomiting, diarrhea, indigestion, or anorexia), muscle aches, and difficulty walking. Side effects affecting the stomach appear to be more severe at higher dosages.

Side effects that occur less often are behavioral disturbances, abnormal thinking, hostility, tremor, inability to sleep, slow heart rates, changes in blood pressure, urinary difficulties, rash, flushing, aggravation of asthma, or cold-like symptoms.

Health care providers should be informed immediately if nausea, vomiting, loose stools, or diarrhea occur

soon after the dose of tacrine is increased or if rash, jaundice (yellow tinge to eyes or skin), or changes in stool color occur at any time.

Interactions

Many drugs can alter the effects of tacrine. Some drugs such as dicyclomine may lessen the effects of tacrine. Other drugs such as **propranolol**, cimetidine, ciprofloxacin, **fluoxetine**, **fluvoxamine**, neostigmine, or bethanechol may increase some of tacrine's side effects. **Rivastigmine** may interact with some of the drugs used to relax muscles during surgery. The interaction increases the effects of both drugs.

Tacrine may also diminish the effects of levodopa and increase the side effects of theophylline. Smoking cigarettes may reduce the effectiveness of tacrine.

Talk therapy

Definition

Talk therapy is an alternate name for the various forms of **psychotherapy** that emphasize the importance of the client or patient speaking to the therapist as the main means of expressing and resolving issues.

Description

Psychoanalysis, the first modern form of psychotherapy, was called the "talking cure," and the many varieties of therapy practiced today are still characterized by their common dependence on a verbal exchange between the counselor or therapist and the person seeking help. Some of these therapies that are characterized

by the verbal exchange include: **cognitive-behavioral therapy**, behavior therapy, **couples therapy**, **family therapy**, **grief counseling** and therapy, **group therapy**, **interpersonal therapy**, **person-centered therapy**, **psychodynamic psychotherapy**, and **rational emotive therapy**. Tardive dyskinesia

Definition

Tardive dyskinesia is a neurological disorder consisting of abnormal, involuntary body movements caused by certain medicines. It is usually associated with long-term use of medicines for treating **schizophrenia** and other psychotic disorders.

Description

Tardive means “late” and dyskinesia means “abnormal movements.” It refers to abnormal body movements that occur after a person has been taking a certain medicine for a long period of time. It sometimes starts after the medicine has been discontinued. In the early stages, the movements may be so subtle that neither the person nor the people around him or her notice them. For instance, the person may blink rapidly or lick their lips often. In later stages, the movements become noticeable and may affect the person’s physical abilities.

Other types of tardive dyskinesia can occur. In tardive dystonia, there are abnormal contractions of the neck and shoulder muscles. In tardive akathisia, the person feels restless all the time.

Causes and symptoms

Causes

It is not altogether certain what causes tardive dyskinesia. The medicines that cause it affect how nerve impulses are transmitted across gaps between nerve cells (synapses). They do this in part by blocking a chemical made by the body called dopamine. After a while, the nerves seem to become hypersensitive to dopamine. Stimulation by even a little bit of dopamine may cause the abnormal movements.

KEY TERMS

Akathisia—An uncontrollable feeling of restlessness.

Dystonia—A neurological disorder characterized by involuntary muscle spasms. The spasms can cause a painful twisting of the body and difficulty walking or moving.

The medicines most commonly associated with tardive dyskinesia include:

- Antipsychotic medicines used to treat schizophrenia and other psychoses. These are also known as neuroleptic medicines.
- Levodopa or L-dopa, which is used to treat Parkinson’s disease (although high doses of L-dopa may actually help control tardive dyskinesia).
- Antiemetic medicines used to control nausea and vomiting.
- Tricyclic antidepressants used to treat depression and other mood disorders.
- Other medicines that block dopamine.

Symptoms

Symptoms of tardive dyskinesia include:

- involuntary movements of the face, including frowning, blinking, smiling, lip licking, mouth puckering, biting or chewing, clenching the jaw, sticking out the tongue, or rolling the tongue around in the mouth
- involuntary movements of the hands, arms, feet, or legs, such as twitching the hands or tapping the feet
- trunk movements, such as rocking, twisting, or squirming
- grunting or trouble speaking because of involuntary movements of the diaphragm

Movements may be rapid or slow and complicated. They are usually irregular and do not follow a pattern.

Demographics

Tardive dyskinesia develops in about a third of all people who take antipsychotic medicines for several years. The risk is higher in older patients. Approximately 5% of young adults taking antipsychotic medicines will develop tardive dyskinesia after a year of treatment, compared with a rate of 30% in elderly patients.

Treatments

Each case is treated differently. In some cases, the medicine causing the problem can be stopped. However, most people taking antipsychotic medicine cannot stop taking the medicine because of the high risk that their **psychosis** will return. Some newer antipsychotic medicines such as **clozapine** (Clozaril) do not seem to cause tardive dyskinesia. It may be possible to switch to a newer antipsychotic medication. If not, it may be possible to lower the dose to a level that does not cause the movements. There is controversy about whether or not “drug holidays” reduce the likelihood of developing tardive dyskinesia. “Drug holidays” are planned periods of time in which the person goes off the medicine, then resumes it.

Vitamin E has been shown to be helpful in patients, especially those who have had the problem for less than five years. L-dopa and some other medicines are sometimes helpful.

Prognosis

The earlier the problem is noticed and treatment begun, the better chance there is that the abnormal movements will go away. Most patients have a noticeable improvement in their symptoms within a year and a half. However, some abnormal movements may remain. People who are over 60 have a greater chance of having the problem go away on its own.

Temazepam

Definition

Temazepam is a drug that belongs to a family of drugs known as benzodiazepines. Temazepam is sold under the brand name Restoril in the United States. Temazepam is also available as a generic.

Purpose

Temazepam is given to patients with sleeping problems (**insomnia**). It is often prescribed for insomnia characterized by frequent awakening during the night or by awakening early in the morning.

Description

Temazepam is one of several drugs in the class known as benzodiazepines. These drugs produce a variety of effects, but most cause some degree of drowsiness (sedation). Temazepam is used almost exclusively as a hypnotic, or drug given to help people fall asleep. It is nearly always taken just before bedtime. This drug produces its effects in the body by slowing down certain impulses in the **brain**, allowing the patient to fall asleep.

Recommended dosage

The typical dose starting for adults is 7.5–15 mg taken *just before* bedtime. The maximum recommended dose is 30 mg. Elderly patients and those in a weakened condition may need only 7.5 mg. The doctor should determine the dose in children 18 years of age and younger on an individual basis.

Precautions

The doctor should monitor any patient taking this drug to ensure that significant side effects do not develop. Insomnia that lasts longer than seven to 10 days may point to a significant medical problem that should be thoroughly evaluated. Temazepam should not be combined with alcohol or other drugs that lower the level of activity in the central nervous system. Examples of such drugs include prescription pain medications, antihistamines, **barbiturates**, and muscle relaxants. Some people may develop dizziness, lightheadedness, and clumsiness after taking temazepam. These side effects are especially common in the elderly.

Those with a history of anemia, liver disease, kidney disease, drug abuse, serious psychological disorders, and **suicide** attempts should be given temazepam only after being thoroughly evaluated by their physician. This cau-

tion also applies to persons with a history of lung disease, seizure disorders, and narrow-angle glaucoma.

People who are taking temazepam should not stop taking it abruptly. Instead, the dose should be reduced gradually. Withdrawal symptoms, including depressed mood, sweating, abdominal cramps, muscle cramps, vomiting, **seizures**, and shakiness can develop if the medication is stopped suddenly.

Although patients are instructed to take temazepam in the evening before bedtime, they often experience side effects the next day, particularly drowsiness and loss of coordination or clumsiness. Pregnant women should not use this drug because it increases the risk of birth defects in the baby. Nursing mothers should not be given temazepam because it can make their babies drowsy and unable to nurse properly. Patients should not operate heavy machinery or drive a car while they are taking temazepam or any other benzodiazepine.

Side effects

Temazepam is a relatively safe drug, safer than most of the benzodiazepines. Its less serious but more common side effects include clumsiness or unsteady behavior, dizziness, drowsiness, and slurred speech. Some patients taking temazepam experience abdominal cramps, dry mouth, constipation, diarrhea, headache, nausea, vomiting, a giddy sense of well-being, and changes in sexual drive.

A small number of patients taking temazepam have experienced anger outbursts, confusion, mental depression, unusually low blood pressure, memory difficulties, nervousness, irritability, and muscle weakness. As they can with many prescription drugs, people can overdose on temazepam. Symptoms of a temazepam overdose include extreme drowsiness, significant confusion, breathing difficulties, a very slow heartbeat, and staggering.

Rebound insomnia is one of the more common side effects of tapering a patient's dose of temazepam. Rebound insomnia is a reaction characterized by the re-emergence of the symptom that the drug was originally given to suppress, namely problems with falling or staying asleep. When a person takes a medication for sleep on a regular basis, the body adjusts to the presence of the drug. It tries to counteract the effects of the medication. As a result, when the person stops taking the sleeping medication, the body will take a few nights to return to its normal condition. During this period of readjustment, the person may experience a few sleepless hours each night. In addition, people often mistake the rebound insomnia for the ordinary variety, and consider it a good reason to continue taking the temazepam.

KEY TERMS

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

Barbiturates—A class of medications (including Seconal and Nembutal) that causes sedation and drowsiness. They may be prescribed legally, but may also be used as drugs of abuse.

Generic—A term that refers to a medication that is not protected by a registered trademark.

Hypnotic—A type of medication that induces sleep.

Insomnia—A chronic inability to sleep or to remain asleep throughout the night.

Narrow-angle glaucoma—An eye disorder caused by a buildup of fluid pressure inside the eyeball due to an abnormally small angle between the iris (the colored portion of the eye) and the cornea (the transparent front part of the eye).

Rebound effect—A physical reaction to stopping a medication characterized by the reappearance of the symptom(s) that the medication was given to suppress. For example, people who stop taking temazepam may experience rebound excitability and sleeping problems.

Sedation—A state of emotional or physical relaxation. The term is usually used to refer to this condition when it is produced by a medication.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

People can also develop withdrawal symptoms even when they are gradually decreasing their dose of temazepam, particularly if the original dose was high. The more common withdrawal symptoms include sleeping difficulties, irritability, and nervousness. Less common withdrawal side effects include abdominal cramps, confusion, sweating, nausea, trembling, increased heart rate, and mental depression.

Interactions

Patients should always inform any health care provider that they see—doctors, dentists, nurses, and others—about all the medications they are taking, including temazepam. This information is important because temazepam interacts with certain other drugs, including

cimetidine (an antihistamine); **disulfiram** (a drug given to help patients control cravings for alcohol); or **clozapine** (an antipsychotic medication). Rifampin, which is an antibiotic, may decrease the effectiveness of the temazepam if the two are taken together. The most important warning, however, is that the patient should avoid drinking alcohol or taking other medications that cause drowsiness (such as antihistamines) while taking temazepam, because these substances will intensify its effects. Heavy smoking, however, interferes with the effectiveness of temazepam.

Thematic Apperception Test

Definition

The Thematic Apperception Test, or TAT, is a projective measure intended to evaluate a person's patterns of thought, attitudes, observational capacity, and emotional responses to ambiguous test materials. In the case of the TAT, the ambiguous materials consist of a set of cards that portray human figures in a variety of settings and situations. The subject is asked to tell the examiner a story about each card that includes the following elements: the event shown in the picture; what has led up to it; what the characters in the picture are feeling and thinking; and the outcome of the event.

Because the TAT is an example of a *projective* instrument— that is, it asks the subject to project his or her habitual patterns of thought and emotional responses onto the pictures on the cards— many psychologists prefer not to call it a “test,” because it implies that there are

“right” and “wrong” answers to the questions. They consider the term “technique” to be a more accurate description of the TAT and other projective assessments.

Purpose

Individual assessments

The TAT is often administered to individuals as part of a battery, or group, of tests intended to evaluate personality. It is considered to be effective in eliciting information about a person's view of the world and his or her attitudes toward the self and others. As people taking the TAT proceed through the various story cards and tell stories about the pictures, they reveal their expectations of relationships with peers, parents or other authority figures, subordinates, and possible romantic partners. In addition to assessing the content of the stories that the subject is telling, the examiner evaluates the subject's manner, vocal tone, posture, hesitations, and other signs of an emotional response to a particular story picture. For example, a person who is made anxious by a certain picture may make comments about the artistic style of the picture, or remark that he or she does not like the picture; this is a way of avoiding telling a story about it.

The TAT is often used in individual assessments of candidates for employment in fields requiring a high degree of skill in dealing with other people and/or ability to cope with high levels of psychological stress— such as law enforcement, military leadership positions, religious ministry, education, diplomatic service, etc. Although the TAT should not be used in the differential **diagnosis** of mental disorders, it is often administered to individuals who have already received a diagnosis in order to match them with the type of **psychotherapy** best suited to their personalities. Lastly, the TAT is sometimes used for forensic purposes in evaluating the motivations and general attitudes of persons accused of violent crimes. For example, the TAT was recently administered to a 24-year-old man in prison for a series of sexual murders. The results indicated that his attitudes toward other people are not only outside normal limits but are similar to those of other persons found guilty of the same type of crime.

The TAT can be given repeatedly to an individual as a way of measuring progress in psychotherapy or, in some cases, to help the therapist understand why the treatment seems to be stalled or blocked.

Research

In addition to its application in individual assessments, the TAT is frequently used for research into specific aspects of human personality, most often needs for achievement, fears of failure, hostility and aggression,

and interpersonal object relations. “Object relations” is a phrase used in psychiatry and psychology to refer to the ways people internalize their relationships with others and the emotional tone of their relationships. Research into object relations using the TAT investigates a variety of different topics, including the extent to which people are emotionally involved in relationships with others; their ability to understand the complexities of human relationships; their ability to distinguish between their viewpoint on a situation and the perspectives of others involved; their ability to control aggressive impulses; self-esteem issues; and issues of personal identity. For example, one recent study compared responses to the TAT from a group of psychiatric inpatients diagnosed with dissociative disorders with responses from a group of non-dissociative inpatients, in order to investigate some of the controversies about **dissociative identity disorder** (formerly called multiple personality disorder).

Precautions

Students in medicine, psychology, or other fields who are learning to administer and interpret the TAT receive detailed instructions about the number of factors that can influence a person’s responses to the story cards. In general, they are advised to be conservative in their interpretations, and to err “on the side of health” rather than of psychopathology when evaluating a subject’s responses. In addition, the 1992 Code of Ethics of the American Psychological Association requires examiners to be knowledgeable about cultural and social differences, and to be responsible in interpreting test results with regard to these differences.

Experts in the use of the TAT recommend obtaining a personal and medical history from the subject before giving the TAT, in order to have some context for evaluating what might otherwise appear to be abnormal or unusual responses. For example, frequent references to death or **grief** in the stories would not be particularly surprising from a subject who had recently been bereaved. In addition, the TAT should not be used as the sole examination in evaluating an individual; it should be combined with other interviews and tests.

Cultural, gender, and class issues

The large number of research studies that have used the TAT have indicated that cultural, gender, and class issues must be taken into account when determining whether a specific response to a story card is “abnormal” strictly speaking, or whether it may be a normal response from a person in a particular group. For example, the card labeled 6GF shows a younger woman who is seated turning toward a somewhat older man who is

KEY TERMS

Apperception—The process of understanding through linkage with previous experience. The term was coined by one of the authors of the TAT to underscore the fact that people don’t “perceive” the story cards in a vacuum; rather, they construct their stories on the basis of past experiences as well as present personality traits.

Battery—A number of separate items (such as tests) used together. In psychology, a group or series of tests given with a common purpose, such as personality assessment or measurement of intelligence.

Forensic—Pertaining to courtroom procedure or evidence used in courts of law.

Idiographic—An approach to interpreting the results of a projective test within the context of the individual subject’s record.

Nomothetic—An approach to interpreting the results of a projective test in which the subject’s answers are measured against a normative comparison sample.

Object relations—In psychology, a phrase that refers to the way in which a subject describes relationships with other people in their environment, and the ways in which he or she has internalized interpersonal relationships.

Projective test or projective measure—A type of psychological evaluation that assesses a person’s thinking patterns, observational ability, feelings, and attitudes on the basis of responses to ambiguous test materials. Projective measures are not intended to diagnose psychiatric disorders, although they are often used in outcome studies to compare the effectiveness of different forms of psychotherapy.

Rorschach test—A commonly administered projective measure in which subjects are asked to describe a series of black or colored inkblots.

standing behind her and smoking a pipe. Most male subjects do not react to this picture as implying aggressiveness, but most female subjects regard it as a very aggressive picture, with unpleasant overtones of intrusiveness and danger. Many researchers consider the gender difference in responses to this card as a reflection of the general imbalance in power between men and women in the larger society.

In the TAT, the test subject (the boy shown here) examines a set of cards that portray human figures in a variety of settings and situations, and is asked to tell a story about each card. The story includes the event shown in the picture, preceding events, emotions and thoughts of those portrayed, and the outcome of the event shown. The story content and structure are thought to reveal the subject's attitudes, inner conflicts, and views. (Lew Merrim/ Science Source. Photo Researchers, Inc. Reproduced by permission.)

Race is another issue related to the TAT story cards. The original story cards, which were created in 1935, all involved Caucasian figures. As early as 1949, researchers who were administering the TAT to African Americans asked whether the race of the figures in the cards would influence the subjects' responses. Newer sets of TAT story cards have introduced figures representing a wider variety of races and ethnic groups. As of 2002, however, it is not clear whether a subject's ability to identify with the race of the figures in the story cards improves the results of a TAT assessment.

Multiplicity of scoring systems

One precaution required in general assessment of the TAT is the absence of a normative scoring system for responses. The original scoring system devised in 1943 by Henry Murray, one of the authors of the TAT, attempted to account for every variable that it measures. Murray's scoring system is time-consuming and unwieldy, and as a result has been little used by later interpreters. Other scoring systems have since been intro-

duced that focus on one or two specific variables—for example, hostility or depression. While these systems are more practical for clinical use, they lack comprehensiveness. No single system presently used for scoring the TAT has achieved widespread acceptance. The basic drawback of any scoring system in evaluating responses to the TAT story cards is that information that is not relevant to that particular system is simply lost.

Computer scoring

A recent subject of controversy in TAT interpretation concerns the use of computers to evaluate responses. While computers were used initially only to score tests with simple yes/no answers, they were soon applied to interpretation of projective measures. A computerized system for interpreting the Rorschach was devised as early as 1964. As of 2002, there are no computerized systems for evaluating responses to the TAT; however, users of the TAT should be aware of the controversies in this field. Computers have two basic limitations for use with the TAT: the first is that they cannot observe and record

the subject's vocal tone, eye contact, and other aspects of behavior that a human examiner can note. Second, computers are not adequate for the interpretation of unusual subject profiles.

Description

The TAT is one of the oldest projective measures in continuous use. It has become the most popular projective technique among English-speaking psychiatrists and psychologists, and is better accepted among clinicians than the Rorschach.

History of the TAT

The TAT was first developed in 1935 by Henry Murray, Christiana Morgan, and their colleagues at the Harvard Psychological Clinic. The early versions of the TAT listed Morgan as the first author, but later versions dropped her name. One of the controversies surrounding the history of the TAT concerns the long and conflict-ridden extramarital relationship between Morgan and Murray, and its reinforcement of the prejudices that existed in the 1930s against women in academic psychology and psychiatry.

It is generally agreed, however, that the basic idea behind the TAT came from one of Murray's undergraduate students. The student mentioned that her son had spent his time recuperating from an illness by cutting pictures out of magazines and making up stories about them. The student wondered whether similar pictures could be used in therapy to tap into the nature of a patient's fantasies.

Administration

The TAT is usually administered to individuals in a quiet room free from interruptions or distractions. The subject sits at the edge of a table or desk next to the examiner. The examiner shows the subject a series of story cards taken from the full set of 31 TAT cards. The usual number of cards shown to the subject is between 10 and 14, although Murray recommended the use of 20 cards, administered in two separate one-hour sessions with the subject. The original 31 cards were divided into three categories, for use with men only, with women only, or for use with subjects of either sex. Recent practice has moved away from the use of separate sets of cards for men and women.

The subject is then instructed to tell a story about the picture on each card, with specific instructions to include a description of the event in the picture, the developments that led up to the event, the thoughts and feelings of the people in the picture, and the outcome of the story.

The examiner keeps the cards in a pile face down in front of him or her, gives them to the subject one at a time, and asks the subject to place each card face down as its story is completed. Administration of the TAT usually takes about an hour.

Recording

Murray's original practice was to take notes by hand on the subject's responses, including his or her nonverbal behaviors. Research has indicated, however, that a great deal of significant material is lost when notes are recorded in this way. As a result, some examiners now use a tape recorder to record subjects' answers. Another option involves asking the subject to write down his or her answers.

Interpretation

There are two basic approaches to interpreting responses to the TAT, called *nomothetic* and *idiographic* respectively. Nomothetic interpretation refers to the practice of establishing norms for answers from subjects in specific age, gender, racial, or educational level groups and then measuring a given subject's responses against those norms. Idiographic interpretation refers to evaluating the unique features of the subject's view of the world and relationships. Most psychologists would classify the TAT as better suited to idiographic than nomothetic interpretation.

In interpreting responses to the TAT, examiners typically focus their attention on one of three areas: the content of the stories that the subject tells; the feeling or tone of the stories; or the subject's behaviors apart from responses. These behaviors may include verbal remarks (for example, comments about feeling stressed by the situation or not being a good storyteller) as well as nonverbal actions or signs (blushing, stammering, fidgeting in the chair, difficulties making eye contact with the examiner, etc.) The story content usually reveals the subject's attitudes, fantasies, wishes, inner conflicts, and view of the outside world. The story structure typically reflects the subject's feelings, assumptions about the world, and an underlying attitude of optimism or pessimism.

Results

The results of the TAT must be interpreted in the context of the subject's personal history, age, sex, level of education, occupation, racial or ethnic identification, first language, and other characteristics that may be important. "Normal" results are difficult to define in a complex multicultural society like the contemporary United States.

Thioridazine

Definition

Thioridazine is a potent antianxiety and antipsychotic agent. It is a member of the phenothiazine family of compounds. In the United States, thioridazine is sold as under the brand name of Mellaril and is also available under its generic name.

Purpose

Thioridazine is used to manage psychotic disorders. It reduces excitement, abnormal levels of energy, excessive movements (hypermotility), and agitation. The drug is also useful in the short-term treatment of depression that accompanies anxiety, sleep disturbances, agitation, and tension. Thioridazine is used in short-term treatment of children who display seriously inappropriate responses to exciting stimuli.

Description

Thioridazine is used in treating anxiety and **psychosis**. When used for the treatment of **schizophrenia**, thioridazine reduces symptoms of emotional withdrawal, anxiety, tension, **hallucinations**, and suspiciousness. Compared to other phenothiazine drugs, it is less likely to cause vomiting and Parkinson-like symptoms.

It is often successfully used to treat children who have impulsive conduct, difficulty in maintaining attention, or show high levels of aggression or have poor tolerance for frustration when other drugs have failed.

Recommended dosage

The dosage of thioridazine must be adjusted to each individual for whom it is prescribed to achieve maximum therapeutic effects and to minimize side effects. The usual initial dosage for adults is 50 to 100 mg three times a day. This may be gradually increased to a maximum of 800 mg per day. Once the desired therapeutic effect has been achieved, the dosage should be stabilized. A typical maintenance dosage is 200 to 800 mg per day, given in three to four doses.

The usual initial dosage for adults being treated for symptoms of anxiety is 25 mg three times per day. After reaching equilibrium and controlling undesired symptoms, the typical maintenance dosage is 20 to 200 mg per day divided into three or four doses.

For children between the ages of two and 12, the usual daily dosage of thioridazine is 0.5 to 3.0 mg per kg of body weight. Severely psychotic children who are hospitalized may receive 25 mg twice each day.

Precautions

It is dangerous to give thioridazine to persons in a comatose state. **Seizures** due to thioridazine therapy have been reported but are unusual. A sudden decrease in blood pressure due to a change in body position (orthostatic hypotension) with accompanying lightheadedness,

may occur in people who have taken the drug. This is more common among women than among men.

Thioridazine increases the level of prolactin, a hormone that stimulates the mammary glands in the breast, in the blood. This is a potential problem for persons with a personal or family history of breast cancer and may increase the risk of breast cancer. For this reason, the benefits and risks of the drug must be carefully evaluated before it is administered.

Long-term use of thioridazine increases the probability of developing **tardive dyskinesia** (See below). Because of potentially serious side effects, the risks and benefits of thioridazine must be carefully explained and understood before the drug is started.

Side effects

A common side effect of thioridazine is drowsiness and lack of physical and mental alertness. This side effect is especially noticeable early in therapy. Patients taking it should refrain from performing hazardous activities requiring mental alertness or coordination. Other common side effects include greater sensitivity to the sun and increased risk of serious sunburn, dry mouth, constipation, and urinary retention. Urinary retention (difficulty starting a urine flow or passing urine,) is a particular problem in men with enlarged prostates.

Thioridazine use may lead to the development of symptoms that resemble Parkinson's disease, but that are not caused by Parkinson's. These symptoms may include a taut or mask-like expression on the face, drooling, tremors, pill-rolling motions in the hands, cogwheel rigidity (abnormal rigidity in muscles, characterized by jerky movements when the muscle is passively stretched), and a shuffling gait. Taking anti-Parkinson drugs **benztropine** mesylate or **trihexyphenidyl** hydrochloride along with **trifluoperazine** usually readily controls these symptoms.

Thioridazine has the potential to produce a serious side effect called tardive dyskinesia. This syndrome consists of involuntary, uncoordinated movements that may not disappear or may only partially improve after the drug is stopped. Tardive dyskinesia involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles. The incidence of tardive dyskinesia increases with increasing age and with increasing dosage of thioridazine. It may also appear after thioridazine use has been discontinued. Women are at greater risk than men for developing tardive dyskinesia. There is no known effective treatment for tardive dyskinesia, although gradual (but rarely complete) improvement may occur over a long period.

KEY TERMS

Akathisia—Agitated or restless movement, usually affecting the legs. Movement is accompanied by a sense of discomfort and an inability to sit, stand still, or remain inactive for periods of time. Akathisia is a common side effect of some neuroleptic (antipsychotic) medications.

Dystonia—A neurological disorder characterized by involuntary muscle spasms. The spasms can cause a painful twisting of the body and difficulty walking or moving.

Orthostatic hypotension—A sudden decrease in blood pressure due to a change in body position, as when moving from a sitting to standing position.

Prolactin—A hormone that stimulates milk production and breast development.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Tardive dyskinesia—A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs either late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

An occasionally reported side effect of thioridazine is neuroleptic malignant syndrome. This is a complicated and potentially fatal condition characterized by muscle rigidity, high fever, alterations in mental status, and cardiac symptoms such as irregular pulse or blood pressure, sweating, tachycardia (fast heartbeat), and arrhythmias (irregular heartbeat). People who think they may be experiencing any side effects from this or any other medication should talk to their physician promptly.

Interactions

Thioridazine increases the effect of drugs and substances that depress the central nervous system. This class of drugs includes anesthetics, opiates, **barbiturates**, atropine, and alcohol. These substances should be avoided or used sparingly by people taking thioridazine.

Propranolol increases the concentration of thioridazine. Concurrent administration of pindolol also increases the concentration of thioridazine. The reverse effect also occurs: thioridazine increases the concentration of pindolol in the body. Thioridazine may interact with other drugs used to treat mental disorders. People planning to take this drug should review the other medications they are taking with their doctor and pharmacist before starting the drug.

Thiothixene

Definition

Thiothixene is in a class of drugs called antipsychotics. It is available with a prescription under the generic name of thiothixene or the brand name Navane.

Purpose

Thiothixene is a drug used to treat symptoms of **schizophrenia**. It is also sometimes used to calm severely agitated people.

Description

Thiothixene has been used in the United States for many years as a treatment for schizophrenia. It is believed to modify the balance of naturally occurring chemicals in the **brain** called **neurotransmitters** that regulate the transmission of nerve impulses from cell to cell. The proper balance between neurotransmitters is responsible, in part, for maintaining mental well-being. Thiothixene is thought to alter the balance among neurotransmitters in a way that improves symptoms of schizophrenia.

Thiothixene is available in several different strengths as capsules, as an injection, and as a concentrated liquid form taken by mouth. It is broken down by the liver and eliminated from the body by the kidneys.

Recommended dosage

The dosage of thiothixene varies widely from one individual to another. Initially, 2 mg of thiothixene taken by mouth three times daily is used in milder cases. This dosage may be increased slowly. Fifteen to 30 mg per day is often an effective range.

For more severe cases, 5 mg taken by mouth twice per day is a common starting dosage, with slow increases to 20–30 mg per day. Up to 60 mg of thiothixene may

be taken daily. Doses greater than 60 mg per day usually do not provide any additional benefit, but may increase side effects.

Precautions

Thiothixene may alter the rhythm of the heart. As a result, it should not be used by people with a history of irregular or prolonged heart rhythms (long QT syndrome), those with heart failure, or people who have recently had a heart attack. People with other heart conditions should discuss with their physician whether thiothixene is the right antipsychotic drug for them.

Thiothixene may increase the tendency to have **seizures**. People who have had seizures in the past, including alcohol or drug-induced seizures, should take thiothixene only after discussing the risks and benefits with their physician. People taking thiothixene should call their doctor immediately if they experience any abnormal, involuntary muscle movements, because this adverse effect may be permanent. The risk of abnormal, involuntary muscle movements is believed to increase with long-term use of thiothixene and high dosages.

Thiothixene may increase body temperatures to dangerously high levels. People who exercise strenuously, those exposed to extreme heat, individuals taking drugs with anticholinergic effects (this includes many common antidepressants), and those prone to dehydration, should be alert to increased body temperatures and dehydration-related side effects. Fevers, difficulty moving muscles, irregular heartbeats, rapid heartbeats, or excessive sweating are warning signs of possible overheating that should be addressed by a physician immediately.

People taking thiothixene should have regular eye examinations, since use of thiothixene has been associated with abnormalities of the retina, the light-sensitive layer of the eye. Thiothixene may also alter reproductive hormone levels causing irregular menstrual periods, difficulty getting pregnant, enlarged breasts, and breast milk production. Thiothixene can cause enlarged breasts and breast milk secretion in men as well as women. People who have had breast cancer should not take thiothixene unless the benefits of this drug substantially outweigh the risks.

Thiothixene may cause drowsiness. People should not perform hazardous tasks that require mental alertness until they see how the drug affects them. This side effect usually diminishes with continued use of the drug. Thiothixene may make it more difficult to make a patient vomit after a drug overdose or accidental poisoning. Because there is a high incidence of **suicide** in all patients with psychotic illnesses, people using thiothixene should be observed care-

KEY TERMS

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

Antipsychotic—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Milligram (mg)—One-thousandth of a gram. A gram is the metric measure that equals about 0.035 ounces.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

fully for signs of suicidal behavior. Women who are pregnant or breast-feeding should not take thiothixene.

Side effects

Common side effects associated with the use of thiothixene are abnormal muscle movements and muscle stiffness, muscle tremors, weight gain, sleepiness, dry mouth, dry eyes, difficulty urinating, constipation, and sudden decreases in blood pressure that cause dizziness when standing up suddenly.

Other side effects that may occur when using thiothixene are headaches, seizures, high blood pressure, rapid heartbeats, blurred vision, liver changes, irregular menstrual periods, abnormal blood cell counts, difficulty breathing, and rash.

Uncommon and serious side effects include neuroleptic malignant syndrome and **tardive dyskinesia**. Neuroleptic malignant syndrome is an unusual but potentially life-threatening condition. The person with

this syndrome becomes extremely rigid, has a high fever, rapid heart rate, and abnormalities on blood tests. The affected person also may have a difficult time breathing and may sweat, and will be admitted to the hospital. Tardive dyskinesia (TD) is a condition that may occur after a long period of using antipsychotic medications. TD is characterized by involuntary movements of the facial muscles and tongue, and may also involve muscles in the trunk or hands or feet. TD may disappear as soon as the medication is stopped, but it may not; if it does not, it is difficult to treat. These potential side effects should be discussed with the patient's doctor.

Interactions

When thiothixene is used with drugs such as bethanechol, **propranolol**, levodopa, and some antidepressants, some of the side effects associated with thiothixene may increase. Use of narcotic drugs with thiothixene may cause blood pressure to fall to dangerously low levels. If thiothixene is used with levodopa, the actions of levodopa may be diminished.

When thiothixene is used with **barbiturates** or lithium, thiothixene may be less effective. Because thiothixene may cause sleepiness, it should not be used with other drugs that also cause drowsiness, such as antidepressants, antihistamines, some pain relievers, and alcohol.

Tic disorders

Definition

Tic disorders are characterized by the persistent presence of tics, which are abrupt, repetitive involuntary movements and sounds that have been described as cari-

captures of normal physical acts. The best known of these disorders is Tourette's disorder, or Tourette's syndrome.

Description

Tics are sudden, painless, nonrhythmic behaviors that are either motor (related to movement) or vocal and that appear out of context—for example, knee bends in science class. They are fairly common in childhood; in the vast majority of cases, they are temporary conditions that resolve on their own. In some children, however, the tics persist over time, becoming more complex and severe.

Tics may be simple (using only a few muscles or simple sounds) or complex (using many muscle groups or full words and sentences). Simple motor tics are brief, meaningless movements like eye blinking, facial grimacing, head jerks or shoulder shrugs. They usually last less than one second. Complex motor tics involve slower, longer, and more purposeful movements like sustained looks, facial gestures, biting, banging, whirling or twisting around, or copropraxia (obscene gestures).

Simple phonic tics are meaningless sounds or noises like throat clearing, coughing, sniffing, barking, or hissing. Complex phonic tics include syllables, words, phrases, and such statements as "Shut up!" or "Now you've done it!" The child's speech may be abnormal, with unusual rhythms, tones, accents or intensities. The echo phenomenon is a tic characterized by the immediate repetition of one's own or another's words. Coprolalia is a tic made up of obscene, inappropriate or aggressive words and statements. It occurs in fewer than 10% of people with tic disorders.

Children under the age of 10 with simple tics find them to be difficult to suppress, or control. Many older patients and children with complex tics describe feeling strong sensory urges in their joints, muscles and bones that are relieved by the performance of a motor tic in that particular body part. These patients also report inner conflict over whether and when to yield to these urges. A sensation of relief and reduction of anxiety frequently follows the performance of a tic. Unless the tic disorder is very severe, most people with tics can suppress them for varying periods of time.

Motor and vocal tics may be worsened by anxiety, **stress**, boredom, **fatigue**, or excitement. Some people have reported that tics are intensified by premenstrual syndrome, additives in food, and stimulants. The symptoms of tic disorders may be lessened while the patient is asleep. Cannabis (marijuana), alcohol, relaxation, playing a sport, or concentrating on an enjoyable task are also reported to reduce the severity and frequency of symptoms.

Tics are the core symptom shared by transient tic disorder, chronic motor or vocal tic disorder, and Tourette's disorder. It is the severity and course that distinguishes these disorders from one another. The age of onset for these disorders is between two and 15 years. In 75% of Tourette's disorder patients, the symptoms appear by age 11.

Causes and symptoms

Causes

Emotional factors were once viewed as the cause of tics, but this explanation has been largely discounted. The search for causes now focuses on biological, chemical and environmental factors. As of 2002, however, no definitive cause of tics has been discovered.

There appear to be both functional and structural abnormalities in the brains of people with tic disorders. While the exact neurochemical cause is unknown, it is believed that abnormal **neurotransmitters** (chemical messengers within the **brain**) contribute to the disorders. The affected neurotransmitters are dopamine, serotonin, and cyclic AMP. Researchers have also found changes within the brain itself, specifically in the basal ganglia (an area of the brain concerned with movement) and the anterior cingulate cortex. Functional imaging using **positron emission tomography** (PET) and **single photon emission computerized tomography** (SPECT) has highlighted abnormal patterns of blood flow and metabolism in the basal ganglia, thalamus, and frontal and temporal cortical areas of the brain. [The reader may wish to consult the "Brain" entry for a diagram of the brain's structures.]

Vulnerability to tic disorders appears to be genetic, or transmitted within families. Genetic factors are present in 75% of cases, although no single gene has been found to cause tic disorders. Researchers have not found a pattern suggesting that certain types of parenting or childhood experiences lead to the development of tic disorders, although some think that there is an interaction between genetic and environmental factors. Researchers are paying close attention to prenatal factors, which are thought to influence the development of the disorders.

In some cases, tic disorders appear to be caused or worsened by recreational drugs or prescription medications. The drugs most commonly involved are such psychomotor stimulants as **methylphenidate** (Ritalin); **pemoline** (Cylert); **amphetamines**; and cocaine. It is not clear whether tics would have developed anyway if stimulants had not been used. In a smaller percentage of cases, antihistamines, tricyclic antidepressants, antiseizure medications, and opioids have been shown to worsen tics.

Some forms of tic may be triggered by the environment. A cough that began during an upper respiratory infection may continue as an involuntary vocal tic. New tics may also begin as imitations of normally occurring events, such as mimicking a dog barking. How these particular triggers come to form enduring symptoms is a matter for further study.

In some cases, neuropsychiatric disorders, such as tic disorders and **obsessive-compulsive disorder**, have been shown to develop after streptococcal infection. No precise mechanism for this connection has been determined, although it appears to be related to the autoimmune system. There are other illness-related causes of tics, though they appear to be rare. These include the development of tics after head trauma, viral encephalitis or **stroke**.

Symptoms

The diagnostic criteria of all tic disorders specify that the symptoms must appear before the age of 18, and that they cannot result from ingestion of such substances as stimulants, or from such general medical conditions as Huntington's disease. Tic disorders can be seen as occurring along a continuum of least to most severe in terms of disruption and impairment, with transient tic disorder at one end and Tourette's disorder at the other.

Tics increase in frequency when a person is under any form of mental or physical stress, even if it is of a positive nature (excitement about an upcoming holiday, for example). Some people's tics are most obvious when the person is in a relaxed situation, such as quietly watching television. Tics tend to diminish when the person is placed in a new or highly structured situation, such as a doctor's office—a factor that can complicate **diagnosis**. When the symptoms of a tic are present over long time periods, they do not remain constant but will wax and wane in their severity.

Transient tic disorder occurs in approximately 4%–24% of schoolchildren. It is the mildest form of tic disorder, and may be underreported because of its temporary nature. In transient tic disorder, there may be single or multiple motor and/or vocal tics that occur many times a day nearly every day for at least four weeks, but not for longer than one year. If the criteria have been met at one time for Tourette's disorder or for chronic motor or vocal tic disorder, transient tic disorder may not be diagnosed.

Chronic motor or vocal tic disorder is characterized by either motor tics or vocal tics, but not both. The tics occur many times a day nearly every day, or intermittently for a period of more than one year. During that

KEY TERMS

Atypical antipsychotics—A group of newer medications for the treatment of psychotic symptoms that were introduced in the 1990s. The atypical antipsychotics include clozapine, risperidone, quetiapine, ziprasidone, and olanzapine. They are sometimes called serotonin dopamine antagonists, or SDAs.

Basal ganglia—A group of masses of gray matter located in the cerebral hemispheres of the brain that control movement as well as some aspects of emotion and cognition.

Behavioral therapy—An approach to treatment that focuses on extinguishing undesirable behavior and replacing it with desired behavior.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Cognitive-behavioral therapy—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Comorbidity—Association or presence of two or more mental disorders in the same patient. A disorder that is said to have a high degree of comorbidity is likely to occur in patients diagnosed with other disorders that may share or reinforce some of its symptoms.

Compulsion—A strong impulse to perform an act, particularly one that is irrational or contrary to one's will.

Coprolalia—A vocal tic characterized by uttering obscene, hostile, or inappropriate words. A motor tic characterized by obscene gestures is called copropraxia.

Cyclic AMP—A small molecule of adenosine monophosphate (AMP) that activates enzymes and increases the effects of hormones and other neurotransmitters.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Holistic—A treatment approach that is comprehensive and respectful of a person's emotional, social, cognitive, and interpersonal needs.

Neuroleptic—Another name for the older antipsychotic medications, such as haloperidol (Haldol) and chlorpromazine (Thorazine).

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Obsession—A persistent image, idea, or desire that dominates a person's thoughts or feelings.

Onset—The point in time at which the symptoms of a disorder first became apparent.

Phenothiazines—A class of drugs widely used in the treatment of psychosis.

Remission—In the course of an illness or disorder, a period of time when symptoms are absent.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Stigma—A mark or characteristic trait of a disease or defect; by extension, a cause for reproach or a stain on one's reputation. Tic disorders are sometimes regarded as a stigma by the patient's family.

Tardive dyskinesia—A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs either late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

Thalamus—The middle part of the diencephalon (a part of the human forebrain), responsible for transmitting and integrating information from the senses.

Tic—A sudden involuntary behavior that is difficult or impossible for the person to suppress. Tics may be either motor (related to movement) or vocal, and may become more pronounced under stress.

time, the patient is never without symptoms for more than three consecutive months. The severity of the symptoms and functional impairment is usually much less than for patients with Tourette's disorder.

For a diagnosis of Tourette's disorder, a patient must have experienced both multiple motor and one or more vocal tics at some time during the illness, though they do not have to occur at the same time. The tics occur many

times a day, usually in bouts, nearly every day or intermittently for a period of more than one year. The patient is never symptom-free for more than three months at a time.

Children and adolescents with Tourette's disorder frequently experience additional problems including aggressiveness, self-harming behaviors, emotional immaturity, social withdrawal, physical complaints, conduct disorders, affective disorders, anxiety, panic attacks, **stuttering**, **sleep disorders**, migraine headaches, and inappropriate sexual behaviors.

Tics seem to worsen during the patient's adolescence, although some clinicians think that the symptoms become more problematic rather than more severe, because the patient experiences them as more embarrassing than previously. The symptoms do become more unpredictable from day to day during adolescence. Many teenagers may refuse to go to school when their tics are severe. Coprolalia often appears first in adolescence; this symptom causes considerable distress for individuals and their families.

Behavioral problems also become more prominent in adolescence. There is some evidence that temper tantrums, aggressiveness, and explosive behavior appear in preadolescence, intensify in adolescence, and gradually diminish by early adulthood. Interestingly, aggression appears to increase at approximately the same time that the tics decrease in severity.

Demographics

Tourette's disorder is three to four times more common in males than females. Tic disorders have been reported in people of all races, ethnic groups, and socioeconomic classes. Tic disorders appear to occur more frequently in Caucasians than African Americans.

Diagnosis

There are no diagnostic laboratory tests to screen for tic disorders. Except for the tics, the results of the patient's physical and neurological examinations are normal. The doctor takes a complete medical history including a detailed account of prenatal events, birth history, head injuries, episodes of encephalitis or meningitis, poisonings, and medication or drug use. The patient's developmental, behavioral, and academic histories are also important.

There is an average delay of five to 12 years between the initial symptoms of a tic disorder and the correct diagnosis. This delay is largely related to the misperception that tics are caused by anxiety and should be treated by **psychotherapy**. This misperception in turn is fueled by the fact that tics tend to increase in severity when the

affected person is angry, anxious, excited or fatigued. It is also common for the patient to manifest fewer tics in a doctor's office than at home, leaving parents feeling frustrated and undermined and physicians confused. In addition, children quickly learn to mask their symptoms by converting them to more socially acceptable movements and sounds. The diagnosis of a tic disorder can be aided in some cases by directly observing, videotaping or audiotaping the patient in a more natural setting.

Clinicians can also become confused by such additional symptoms of tic disorders as touching, hitting, jumping, smelling hands or objects, stomping, twirling and doing deep knee bends. They disagree, however, as to whether such symptoms should be classified as tics or compulsions. There appears to be a significant overlap between the symptoms of tic disorders and those of obsessive-compulsive disorder (OCD).

Abnormal obsessive-compulsive behavior has been found in 40% of patients with Tourette's disorder between the ages of six and 10 years. Obsessions are persistent ideas, thoughts, impulses, or images that are experienced as intrusive, inappropriate, senseless, and repetitive. Compulsions are defined as repetitive behaviors performed to reduce the anxiety or distress caused by the obsessions. For those diagnosed with OCD, common obsessions have to do with dirt, germs, and contamination. Patients with Tourette's disorder often have obsessions that involve violent scenes, sexual thoughts, and counting; their compulsions are often related to symmetry (lining things up and getting them "just right," for example). OCD symptoms occur considerably later than tics, and appear to worsen with age. Some theorists have suggested that obsessive thoughts are cognitive tics.

Tic disorders can be differentiated from **movement disorders** by the following characteristics: they are suppressible; they tend to persist during sleep; they are preceded by sensory symptoms; they have both phonic and motor components; and they wax and wane.

Dual diagnoses

Children and adults with tic disorders are at increased risk for depression and other mood disorders, as well as anxiety disorders. This comorbidity may be due to the burden of dealing with a chronic, disruptive, and often stigmatizing disorder. The energy and watchfulness required to suppress tic symptoms may contribute to social anxiety, social withdrawal, self-preoccupation, and fatigue. Low self-esteem and feelings of hopelessness are common in patients diagnosed with tic disorders.

While OCD behaviors have been noted in as many as 80% of individuals with tic disorders, only 30% meet the full criteria for OCD. Distinguishing complex tics

from simple compulsions can be difficult. Touching compulsions appear to be characteristic of the tic-related type of OCD. Compared to obsessive-compulsive disorder in persons without a history of tics, there will likely be an earlier age of onset, a greater proportion of males, a more frequent family history of chronic tics, and a poorer therapeutic response to selective serotonin reuptake inhibitors (SSRIs)—although the addition of a neuroleptic to the treatment regimen sometimes brings about improvement.

As many as 50%–80% of children with Tourette's disorder have some symptoms of **attention-deficit/hyperactivity disorder** (ADHD), including a short attention span, restlessness, poor concentration, and diminished impulse control. On average, ADHD will manifest two and a half years before the tics appear. A **dual diagnosis** of ADHD and tic disorder is associated with more severe tics and greater social impairment than for tic disorder by itself. Over time, the problems caused by the inattention, impulsivity, motor overactivity and the resultant underachievement in school associated with ADHD are often more disabling than the tics themselves.

Children with tic disorders are five times as likely as other children to require special education programs. The tics may be disruptive and mistakenly interpreted by teachers as intended to disturb the class. Often, children with tic disorders have underlying learning disabilities as well. While there does not appear to be any impairment in general intellectual functioning, researchers have identified patterns of specific learning problems in children with tic disorders. These problems include abnormal visual-perceptual performance, reduced visual-motor skills, and discrepancies between verbal and performance IQ. Many of these learning difficulties are also commonly found in children with ADHD.

Increasing numbers of children with tic disorders are also diagnosed with a **conduct disorder**. Children with conduct disorder show inappropriate and sometimes severe aggression toward people and animals. They may also act out other destructive impulses. Unfortunately, some of these children grow up to develop a personality disorder.

Treatments

A holistic approach is recommended for the treatment of tic disorders. A multidisciplinary team should work together with the affected child's parents and teachers to put together a comprehensive treatment plan. Treatment should include the following:

- Educating the patient and family about the course of the disorder in a reassuring manner.

- Completion of necessary diagnostic tests, including self-reports (by child and parents); clinician-administered ratings; and direct observational methods.
- Comprehensive assessment, including the child's cognitive abilities, perception, motor skills, behavior and adaptive functioning.
- Collaboration with school personnel to create a learning environment conducive to academic success.
- Therapy, most often behavioral or cognitive-behavioral, though other modalities may be appropriate.
- If necessary, evaluation for medication.

Behavioral and cognitive-behavioral therapy

Massed negative practice has been one of the most frequently used behavioral therapy techniques in the treatment of children with tic disorder. The patient is asked to deliberately perform the tic movement for specified periods of time interspersed with brief periods of rest. Patients have shown some decrease in tic frequency, but the long-term benefits of massed negative practice are unclear.

Contingency management is another behavioral treatment. It is based on positive **reinforcement**, usually administered by parents. Children are praised and rewarded for not performing tics and for replacing them with alternative behaviors. Contingency management, however, appears to be of limited use outside of such controlled settings as schools or institutions.

Self-monitoring consists of having the patient record tics by using a wrist counter or small notebook. It is fairly effective in reducing some tics by increasing the child's awareness.

Habit reversal is the most commonly used technique, combining relaxation exercises, awareness training, and contingency management for positive reinforcement. This method shows a 64%–100% success rate.

Adding a cognitive component to habit reversal involves the introduction of flexibility into rigid thinking, and confronting the child's irrational expectations and unrealistic anticipations. It has not been shown as of 2002 to increase treatment effectiveness. The specific cognitive technique of distraction, however, has been shown to help patients resist sensory urges and to restore the patient's sense of control over the tic.

Medications

Medication is the main treatment for motor and vocal tics. Patients and their families, however, should be

evaluated fully and use other treatment methods in conjunction with medication. Because the symptoms of tic disorders overlap those of OCD and ADHD, it is essential to determine which symptoms are causing the greatest concern and impairment, and treat the patient according to the single diagnostic category that best fits him or her, whether it is a tic disorder, OCD, or ADHD.

Medications prescribed for patients with tic disorders include:

- Typical neuroleptics (antipsychotic medications), including **haloperidol** (Haldol) and **pimozide** (Orap). Neuroleptics can have significant side effects, which include concentration problems, cognitive blunting, and rarely, **tardive dyskinesia** (a movement disorder that consists of lip, mouth, and tongue movements). Such side effects as stiffness, rigidity, tremor, sedation, and depression are common with haloperidol, but are less so with pimozide.
- Alpha-adrenergic receptor agonists, including **clonidine** (Catapres) and guanfacine (Tenex). Clonidine has fewer and milder side effects than the neuroleptics in general, with the most common being sedation. Sedation occurs in 10%–20% of cases and can often be controlled through adjusting the dosage.
- The phenothiazines may be used when haloperidol or pimozide has proven ineffective.
- Atypical antipsychotics and other agents that block dopamine receptors include **risperidone** (Risperdal) and **clozapine** (Clozaril).
- Tetrabenazine is a promising new medication with fewer side effects than other typical neuroleptics. It can be used in combination with the older antipsychotic medications, allowing for lower doses of both medications with substantial relief.
- Selective serotonin reuptake inhibitors (SSRIs), which include such medications as **fluoxetine** (Prozac) and **sertraline** (Zoloft), can be used to treat the obsessive-compulsive behaviors associated with Tourette's disorder. They can also be helpful with depression and impulse control difficulties, though they must be given at higher dosages for OCD than for depression. The SSRIs, however, can cause gastric upset and nausea.
- Benzodiazepines are used in some cases to lower the patient's anxiety level, but are often avoided because they can cause dependence and tolerance.
- Nicotine chewing gum appears to reduce tics when added to ongoing treatment with haloperidol, but is in need of further study.

Alternative therapies

There is growing interest in dietary changes and nutritional supplements to prevent and manage the symptoms of tic disorders, although formal studies have not yet been conducted in this area. Some theorists have suggested that hidden food and chemical allergies or nutritional deficiencies may influence the development and maintenance of tic disorders. Recommendations include eating organic food and avoiding pesticides; taking antioxidants; increasing intake of folic acid and the B vitamins; eating foods high in zinc and magnesium; eliminating caffeine from the diet; and avoiding artificial sweeteners, colors and dyes.

Prognosis

There is presently no cure for tic disorders, and there is no evidence that early treatment alters prognosis. When a child is first evaluated, it is not possible to determine whether the tics will be chronic or transient, mild or severe.

As recently as twenty years ago, tic disorders were considered to be lifelong conditions, with remissions believed to be rare. There is now a general consensus that if a tic disorder is the only diagnosis, the prognosis is favorable. Up to 73% of patients report that their tics decreased markedly or disappeared as they entered the later years of adolescence or early adulthood.

In a small number of patients, the most severe and debilitating forms of a tic disorder occur in adult life. In addition, stress in later life can cause tics to re-emerge. In rare cases, the tics may be new developments in adulthood, though this phenomenon may be more common than previously thought. Remission rates for tic disorders are difficult to pinpoint among this seldom-studied population, but appear to be extremely low.

While the tics themselves may decline, however, the associated problems often continue into adult life. Obsessive-compulsive symptoms and other behavioral problems, as well as learning disabilities, may grow worse. Obsessive-compulsive behaviors become most pronounced at age 15 and remain at that level. Panic attacks, depression, **agoraphobia** and alcoholism are most significant in the early adult years, while a tendency toward **obesity** increases steadily with age, particularly in women.

In adulthood, a patient's repertoire of tics is reduced and becomes predictable during periods of fatigue and heightened emotionality. Some studies suggest remission rates, with the complete cessation of symptoms, to be as high as 50%. Cases of total remission appear to be relat-

ed to the family's treatment of the patient when he or she was a child. Persons who were punished, misunderstood and stigmatized experience greater functional impairment as adults than those who were supported and understood as children.

Prevention

There are few preventive strategies for tic disorders. There is some evidence that maternal emotional stress during pregnancy and severe nausea and vomiting during the first trimester may affect tic severity. Attempting to minimize prenatal stress may possibly serve a limited preventive function.

Similarly, because people with tic disorders are sensitive to stress, attempting to maintain a low-stress environment can help minimize the number or severity of tics (reducing the number of social gatherings, which can be anxiety-provoking, for example). This approach cannot prevent tics altogether, and must be undertaken with an awareness that it is neither healthful nor advisable to attempt to eliminate all stressful events in life.

Token economy system

Definition

A token economy is a form of **behavior modification** designed to increase desirable behavior and decrease undesirable behavior with the use of tokens. Individuals receive tokens immediately after displaying desirable behavior. The tokens are collected and later exchanged for a meaningful object or privilege.

Purpose

The primary goal of a token economy is to increase desirable behavior and decrease undesirable behavior. Often token economies are used in institutional settings (such as psychiatric hospitals or correctional facilities) to manage the behavior of individuals who may be aggressive or unpredictable. However, the larger goal of token economies is to teach appropriate behavior and social skills that can be used in one's natural environment. Special education (for children with developmental or learning disabilities, hyperactivity, attention deficit, or behavioral disorders), regular education, colleges, various types of **group homes**, military divi-

sions, nursing homes, **addiction** treatment programs, occupational settings, family homes (for marital or parenting difficulties), and hospitals may also use token economies. Token economies can be used individually or in groups.

Description

Several elements are necessary in every token economy:

- **Tokens:** Anything that is visible and countable can be used as a token. Tokens should preferably be attractive, easy to carry and dispense, and difficult to counterfeit. Commonly used items include poker chips, stickers, point tallies, or play money. When an individual displays desirable behavior, he or she is immediately given a designated number of tokens. Tokens have no value of their own. They are collected and later exchanged for meaningful objects, privileges or activities. Individuals can also lose tokens (response cost) for displaying undesirable behavior.
- **A clearly defined target behavior:** Individuals participating in a token economy need to know exactly what they must do in order to receive tokens. Desirable and undesirable behavior is explained ahead of time in simple, specific terms. The number of tokens awarded or lost for each particular behavior is also specified.
- **Back-up reinforcers:** Back-up reinforcers are the meaningful objects, privileges, or activities that individuals receive in exchange for their tokens. Examples include food items, toys, extra free time, or outings. The success of a token economy depends on the appeal of the back-up reinforcers. Individuals will only be motivated to earn tokens if they anticipate the future reward represented by the tokens. A well-designed token economy will use back-up reinforcers chosen by individuals in treatment rather than by staff.
- **A system for exchanging tokens:** A time and place for purchasing back-up reinforcers is necessary. The token value of each back-up reinforcer is pre-determined based on monetary value, demand, or therapeutic value. For example, if the reinforcer is expensive or highly attractive, the token value should be higher. If possession of or participation in the reinforcer would aid in the individual's acquisition of skills, the token value should be lower. If the token value is set too low, individuals will be less motivated to earn tokens. Conversely, if the value is set too high, individuals may become easily discouraged. It is important that each individual can earn at least some tokens.

KEY TERMS

Back-up reinforcer—A desirable item, privilege, or activity that is purchased with tokens and serves as a delayed reward and subsequent motivation for target (desired) behavior.

Baseline data—Information regarding the frequency and severity of behavior, gathered before treatment begins.

Behavior modification—An approach to therapy based on the principles of operant conditioning. Behavior modification seeks to replace undesirable behaviors with preferable behaviors through the use of positive or negative reinforcement.

Fading—Gradually decreasing the amount or frequency of a reinforcer so that the target behavior will begin to occur independent of any rewards.

Reinforcement schedule—The frequency and amount of reinforcers administered.

Reinforcer—Anything that causes an increase of a particular behavior.

Response cost—A behavioral technique that involves removing a stimulus from an individual's environment so that the response that directly precedes the removal is weakened. In a token economy system, response cost is a form of punishment involving loss of tokens due to inappropriate behavior, which consequently results in decreased ability to purchase back-up reinforcers.

Target behavior—The specific behavior to be increased or decreased during treatment.

Therapeutic value—The potential benefit of an object or situation, in terms of its ability to enhance functioning (social, emotional, intellectual, occupational, etc.) in an individual.

Token—Any item that can be seen and collected (such as stickers or points in a point tally) that has no value of its own, but is used as an immediate reward for desirable behavior that is later exchanged for back-up reinforcers.

- **A system for recording data:** Before treatment begins, information (baseline data) is gathered about each individual's current behavior. Changes in behavior are then recorded on daily data sheets. This information is used to measure individual progress, as well as the effectiveness of the token economy. Information regarding the exchange of tokens also needs to be recorded.

- Consistent implementation of the token economy by staff: In order for a token economy to succeed, all involved staff members must reward the same behaviors, use the appropriate amount of tokens, avoid dispensing back-up reinforcers for free, and prevent tokens from being counterfeited, stolen, or otherwise unjustly obtained. Staff responsibilities and the rules of the token economy should be described in a written manual. Staff members should also be evaluated periodically and given the opportunity to raise questions or concerns.

Initially tokens are awarded frequently and in higher amounts, but as individuals learn the desirable behavior, opportunities to earn tokens decrease. (The amount and frequency of token dispensing is called a **reinforcement schedule**.) For example, in a classroom, each student may earn 25 to 75 tokens the first day, so that they quickly learn the value of the tokens. Later, students may earn 15 to 30 tokens per day. By gradually decreasing the availability of tokens (fading), students should learn to display the desirable behavior independently, without the unnatural use of tokens. Reinforcers that individuals would normally encounter in society, such as verbal praise, should accompany the awarding of tokens to aid in the fading process.

Advantages of token economies are that behaviors can be rewarded immediately, rewards are the same for all members of a group, use of punishment (response cost) is less restrictive than other forms of punishment, and individuals can learn skills related to planning for the future. Disadvantages include considerable cost, effort, and extensive staff training and management. Some professionals find token economies to be time-consuming and impractical.

Risks

Risks involved in token economies are similar to those in other forms of behavior modification. Staff members implementing the therapy may intentionally or unintentionally neglect the rights of individuals receiving treatment. Token economies should never deprive individuals of their basic needs, such as sufficient food, comfortable bedding, or reasonable opportunities for leisure. If staff members are inadequately trained or there is a shortage of staff, desirable behaviors may not be rewarded or undesirable behaviors may be inadvertently rewarded, resulting in an increase of negative behavior. Controversy exists regarding placing individuals in treatment against their will (such as in a psychiatric hospital), and deciding which behaviors should be considered desirable and which should be considered undesirable.

Normal results

Ideally, individuals will use the skills learned in a token economy in their everyday surroundings. They will display the undesirable behavior less frequently or not at all. They will also engage in positive, adaptive behaviors more often.

Abnormal results

If the token economy was ineffective, or time spent in the token economy was limited, individuals may show no changes or increases in the undesirable behavior.

Transvestic fetishism

Definition

Transvestic **fetishism** is defined by the mental health professional's handbook, the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (2000), which is also called *DSM-IV-TR*, as one of the **paraphilias**. The paraphilias are a group of mental disorders characterized by **obsession** with unusual sexual practices or with sexual activity involving nonconsenting or inappropriate partners (such as children or animals). The essential feature of transvestic fetishism is recurrent intense sexual urges and sexually arousing fantasies involving dressing in clothing associated with members of the opposite sex. Another term for transvestic fetishism is cross-dressing; people who frequently engage in cross-dressing are sometimes called transvestites. A **diagnosis** of transvestic fetishism is made only if an individual has acted on these urges or is markedly distressed by them. In other systems of psychiatric classification, transvestic fetishism is considered a sexual deviation.

For some people who are diagnosed with transvestic fetishism, fantasies or stimuli associated with cross-dressing may always be necessary for erotic arousal and are always included in sexual activity, if not actually acted out alone or with a partner. In other patients, cross-dressing may occur only episodically, for example, during periods of **stress**. At other times the person is able to function sexually without the transvestic fetish or related stimuli.

Description

A person with a transvestic fetish derives sexual gratification from dressing in clothing appropriate for a member of the opposite sex. Almost all patients diagnosed with transvestic fetishism, however, are men dressing as women. This lopsided gender ratio may be partly due to the fact that contemporary Western societies allow women to dress in a wide range of clothing styles influenced by menswear, whereas the reverse is not the case. While it is not at all unusual to see women wearing jeans, tailored trousers, Western-style boots, or even tuxedos in some circumstances, men wearing dresses or high-heeled shoes look distinctly out of place.

A person's participation in transvestism is usually gradual. Over time, a person with a transvestic fetish assumes the role and appearance of a member of the opposite gender. It is important to note that this activity is closely associated with achieving sexual gratification. Persons who have had extensive experience with a transvestic fetish may be difficult to distinguish from members of the opposite sex. A so-called mature transvestic fetish involves

KEY TERMS

Cross-dressing—Wearing clothing and other attire appropriate to the opposite sex.

Fetishism—A paraphilia in which a person requires a nonliving object (or occasionally a non-genital part of the body, such as the partner's feet) in order to achieve sexual arousal and satisfaction.

Gender dysphoria—A state of persistent discomfort or depression associated with one's gender role or biological sex.

Paraphilias—A group of mental disorders that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Transvestite—A person who derives sexual pleasure or gratification from dressing in clothing of the opposite sex.

adopting all of the mannerisms, clothing, materials and other items associated with persons of the opposite sex.

Causes and symptoms

Causes

The basis for a transvestic fetish is obtaining sexual gratification by dressing in clothing appropriate for the opposite sex. The cause may be adolescent curiosity. A person with a transvestic fetish may not be aware of its roots. Transvestic fetishism sometimes begins when a young boy dresses up in the clothes of an older sister or his mother. The activity is continued because it is enjoyable but the reasons for the enjoyment remain unconscious. In other cases a boy's mother may initiate the cross-dressing by dressing him as if he were a girl. This behavior is sometimes related to the mother's anger at men or to a preference for having daughters rather than sons.

Persons with transvestic fetishes should not be assumed to be homosexual. According to *DSM-IV-TR*, most men who practice cross-dressing are basically heterosexual in their orientation. Some, however, have occasional sexual encounters with other men.

Symptoms

Early symptoms of transvestic fetishism involve touching or wearing items of clothing that are considered

typically feminine. This initial interest may progress to wearing undergarments or other items that can be hidden from the view of others while providing arousal to the wearer. Over time, the extent of dressing in women's clothing expands, sometimes to the point of dressing as a woman on a regular basis. A developed transvestic fetish often involves feminine hair styling and the use of women's cosmetics and accessories.

In some persons diagnosed with transvestic fetishism, the motivation for cross-dressing may change over time from a search for sexual excitement to simple relief from stress, depression, or anxiety.

In some cases, persons with a transvestic fetish discover that they are unhappy with their biological sex, a condition known as gender dysphoria. They may elect to have hormonal and surgical procedures to change their bodies. Some may choose to have gender reassignment surgery. The incidence of gender dysphoria and subsequent gender reassignment among persons diagnosed with transvestic fetishism is not known.

Demographics

Except for **sexual masochism**, in which the gender ratio is estimated to be 20 males for each female, paraphilias such as transvestic fetishism are practically never diagnosed in females, although a few cases have been reported. Virtually no information is available on family patterns of the disorder.

Diagnosis

Persons with transvestic fetishism may or may not seek **psychotherapy** on their own account. In some instances, the patient has agreed to consult a **psychiatrist** because his wife or girlfriend is distressed by the cross-dressing. The actual diagnosis of transvestic fetishism is most commonly made by taking a history or by direct observation. The diagnosis is made only if the patient has been markedly distressed by inability to dress in such a manner or if the disorder is interfering with his education, occupation, or social life. Dressing in women's clothing for such occasions as Halloween or a costume party is not sufficient for a diagnosis of transvestic fetishism.

Treatments

In the earliest period of behavior therapy, transvestic fetishes were narrowly viewed as inappropriate behavior that was confined to a limited range of situations, and were sometimes treated with **aversion therapy**, usually with electric shocks. This approach was largely un-

successful. Persons with fetishes have also been treated by using a form of behavioral therapy known as orgasmic reorientation, which attempts to help people learn to respond sexually to culturally appropriate stimuli. This treatment also has had limited success.

Most persons who have a transvestic fetish never seek treatment from professionals. Most are capable of achieving sexual gratification in culturally appropriate situations. Their preoccupation with cross-dressing is viewed as essentially harmless to other persons, since transvestism is not associated with criminal activities or forcing one's sexual preferences on others. As of 2002, American society has developed tolerance for transvestites, thus further reducing the demand for professional treatment.

Prognosis

The prognosis for treatment of transvestic fetishism is poor, as most persons with this disorder do not desire to change. Most cases in which treatment was demanded by a spouse as a condition of continuing in a marriage have not been successful. The prognosis for personal adjustment is good, however, as a person with a transvestic fetish and his related activities do not usually disturb others.

Prevention

Most experts agree that providing gender-appropriate guidance in a culturally appropriate situation will prevent the formation of a transvestic fetish. The origin of some cases of transvestism may be a random association between clothing inappropriate for one's own gender and sexual gratification. There is no reliable way to predict the formation of such associations. Supervision during childhood and adolescence, combined with acceptance of a child's biological sex, may be the best deterrent that parents can provide.

Tranlycypromine

Definition

Tranlycypromine is classified as a monoamine oxidase (MAO) inhibitor. It is used to treat serious depression. In the United States, tranlycypromine is sold under the brand name Parnate. As of 2002, there were no generic forms of tranlycypromine available in the United States.

KEY TERMS

Agoraphobia—People with this condition worry that they will not be able to get help or flee a place if they have a panic attack; or refusal to go to places that might trigger a panic attack.

Bulimia—An eating disorder characterized by binges in which large amounts of food are consumed, followed by forced vomiting.

Congestive heart failure—Condition characterized by abdominal pain, swelling in the lower extremities, and weakness caused by a reduced output of blood from the left side of the heart.

Diabetes mellitus—A chronic disease affecting the metabolism of carbohydrates that is caused by insufficient production of insulin in the body.

Panic disorder—An anxiety disorder in which an individual experiences sudden, debilitating attacks of intense fear.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Tyramine—Intermediate product between the chemicals tyrosine and epinephrine in the body and a substance normally found in many foods. Found especially in protein-rich foods that have been aged or fermented, pickled, or bacterially contaminated, such as cheese, beer, yeast, wine, and chicken liver.

Purpose

Tranlycypromine is used primarily to treat depression that does not respond to other types of drug therapy. It is also used occasionally to treat **panic disorder**, **agoraphobia**, and **bulimia nervosa**.

Description

Tranlycypromine is a member of a class of drugs called monoamine oxidase inhibitors. Monoamine oxidase, or MAO, is an enzyme found throughout the body. In the **brain**, MAO breaks down norepinephrine and serotonin, two naturally occurring chemicals that are important for maintaining mental well-being preventing depression. Monoamine oxidase inhibitors, such as

tranlycypromine, reduce the activity of MAO. Less norepinephrine and serotonin are broken down, so their levels rise. This helps to lift depression.

Tranlycypromine is effective for treating depression, especially complicated types of depression that have not responded to more traditional antidepressants. However, tranlycypromine also affects the MAO enzyme in many other areas of the body. This accounts for the large number of serious side effects and drug interactions it causes.

Recommended dosage

The typical starting dosage of tranlycypromine in adults is 10 mg taken twice per day. This dosage is sometimes increased to 30 mg per day after a two-week period. The maximum recommended amount is 60 mg per day. The elderly (over age 60) are usually started on a dose of 2.5 mg per day. After this, their doctor will make an individualized decision about increasing the dosage. Older adults typically take smaller doses and do not take more than 45 mg per day. A doctor must make an individual determination of whether to give tranlycypromine to youths under the age of 18 years, because guidelines for this age group have not been developed.

The benefits of this drug may not become apparent for several weeks. Patients should be aware of this and continue taking the drug as directed, even if they do not see an immediate improvement.

Precautions

People taking tranlycypromine should not eat foods rich in tyramine. These foods include yeast or meat extracts, fermented sausage, overripe fruit, sauerkraut, cheese, and fava beans. Alcohol should not be consumed, and the same holds true for alcohol-free beer and wine. Large amounts of caffeine-containing food and beverages, such as chocolate, tea, coffee, and cola should be avoided. The treating doctor needs to approve the use of any drug, including prescription, over-the-counter drugs, and herbal treatments, that the patient takes while taking tranlycypromine.

Tranlycypromine should be used with great caution in pregnant and nursing women only after the risks and benefits of treatment have been assessed. Likewise, this drug may not be appropriate for people with a history of **seizures**, children under age 18 years, people at risk for **suicide**, those with severe depression, a history of **schizophrenia**, or diabetes mellitus. People with these conditions should discuss the risks and benefits of this drug with their physician, and a decision to treat should be made on an individual basis. People should not stop tak-

ing tranlycypromine suddenly. Instead, the dose should be gradually reduced, then discontinued.

People with a history of high blood pressure, congestive heart failure, severe liver disease, severe kidney disease, severe heart disease, and blood vessel problems in the brain should not take tranlycypromine.

Side effects

The enzyme monoamine oxidase regulates functions throughout the body. Phenelzine decreases the activity of monoamine oxidase in all the areas of the body where it exists, not just in the brain. This is why tranlycypromine is capable of causing a wide variety of side effects in many different organ systems.

Tranlycypromine should be stopped if symptoms of unusually high blood pressure develop. These symptoms include severe chest pain, severe headache, nausea, vomiting, stiff or sore neck, enlarged pupils, and significant changes in heart rate. If these symptoms develop, it should be considered an emergency, and the affected person should get medical help immediately. Generally, these serious side effects are rare.

More common but less serious side effects include lightheadedness or dizziness when arising from a sitting position. These symptoms need to be reported to a doctor but are not considered an emergency. Less common symptoms that should be reported include pounding heartbeat, swelling of the lower extremities, nervousness, and diarrhea. Rare but reportable symptoms include fever, skin rash, dark urine, slurred speech, yellowing of the eyes or skin, and staggering when walking. Common but not serious side effects include decreased sexual performance, increased appetite, muscle twitching, trembling, blurred vision, and reduced urine output.

Overdose symptoms include confusion, seizures, severe dizziness, **hallucinations**, severe headache, severe drowsiness, significant changes in blood pressure, difficulty in sleeping, breathing difficulties, and increased irritability.

Interactions

Tranlycypromine interacts with a long list of drugs. Some of these interactions can cause death. This section is not a complete list of interactions, but it includes the most serious ones. Patients must make sure every health care professional who takes care of them (for example, doctors, dentists, podiatrists, optometrists, pharmacists, nurses) knows that they take tranlycypromine, as well as

all of the other prescription, nonprescription, and herbal drugs that they take.

The combination of tranylcypromine with any type of stimulant can increase the risk of developing serious increases in blood pressure. Tranylcypromine when taken with antidiabetic drugs can reduce blood sugar levels to far below normal. The combination of tranylcypromine with **barbiturates** can prolong the effects of the barbiturate drug.

Tranylcypromine should never be combined with other antidepressant drugs, especially the selective serotonin reuptake inhibitors (SSRIs), because of potentially severe or fatal reactions, including increased risk of dangerously high blood pressure. Patients taking tranylcypromine should stop the drug, then wait at least 14 days before starting any other antidepressant. The same holds true when discontinuing another antidepressant and starting tranylcypromine.

Alcohol combined with tranylcypromine can lead to significantly increased blood pressure. Tranylcypromine combined with the blood pressure drug guanethidine (Ismelin) can reduce the beneficial effects of the guanethidine. When tranylcypromine is combined with levodopa (Dopar, Larodopa), a drug used to treat Parkinson disease, severely increased blood pressure can develop. Tranylcypromine combined with lithium can cause fever. Meperidine (Demerol), when combined with tranylcypromine, can cause fever, seizures, increased blood pressure, and agitation. Tranylcypromine combined with norepinephrine can cause increased response to norepinephrine. Tranylcypromine combined with reserpine (Serpalan, Serpasil) can produce greatly increased blood pressure. When tranylcypromine is combined with the migraine drug sumatriptan (Imitrex), significantly increased concentrations of the latter drug develop that can produce potentially toxic effects.

Trazodone

Definition

Trazodone is an oral antidepressant. It is sold in the United States under the brand name Desyrel and is also available under its generic name.

Purpose

Trazodone is used to treat depression and to treat the combination of symptoms of anxiety and depression. Like most antidepressants, trazodone has also been used in limited numbers of patients to treat **panic disorder, obsessive-compulsive disorder, attention-deficit/hyperactivity disorder, enuresis** (bed-wetting), eating disorders such as **bulimia nervosa**, cocaine dependency, and the depressive phase of bipolar (manic-depressive) disorder. It should be noted, however, that trazodone has not received official approval from the United States Food and Drug Administration (FDA) for these secondary uses.

Description

Trazodone acts to change the balance of naturally occurring chemicals in the **brain** that regulate the transmission of nerve impulses between cells. Its action primarily increases the concentration of norepinephrine and serotonin (both chemicals that stimulate nerve cells) and, to a lesser extent, blocks the action of another brain chemical, acetylcholine. Trazodone is classified as an atypical antidepressant, but it shares many of the properties of tricyclic antidepressants (**amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, and trimipramine**). It also shares some of the properties of selective serotonin reuptake inhibitor antidepressants (**fluoxetine, paroxetine, and sertraline**). Trazodone is the most sedating, and least anticholinergic, of all the currently marketed antidepressants.

The therapeutic effects of trazodone, like other antidepressants, appear slowly. Maximum benefit is often not evident for at least two weeks after starting the drug. People taking trazodone should be aware of this and continue taking the drug as directed even if they do not see immediate improvement.

Recommended dosage

As with any antidepressant, trazodone must be carefully adjusted by the physician to produce the desired therapeutic effect. Trazodone is available as 50-mg, 100-mg, and 150-mg film-coated tablets that cannot be divid-

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that generally produces effects that are the opposite of those produced by dopamine and norepinephrine. Central nervous system well-being is dependent on a balance between acetylcholine, serotonin, dopamine and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical, acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Benign prostate hypertrophy—Enlargement of the prostate gland.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

ed, and 150-mg and 300-mg oral tablets that can be split. Therapy is usually started at a total of 150 mg per day divided into two or three doses. This dose is increased by 50 mg every three or four days until the desired effects are seen. Daily doses may be increased to a maximum of 400 mg per day in outpatients and up to 600 mg per day in hospitalized patients. In cases of extreme depression, daily doses of up to 800 mg have been used in hospitalized patients. To minimize daytime drowsiness, a major portion of the daily dose can be given at bedtime.

Precautions

The most common problem with trazodone is sedation (drowsiness, lack of mental and physical alertness). This side effect is especially noticeable early in therapy. In most patients, sedation decreases or disappears entirely with time, but until then patients taking trazodone should not perform hazardous activities requiring mental alertness or coordination, including driving and similar activities. The sedative effect is increased when tra-

zodone is taken with other central nervous system depressants, such as alcoholic beverages, sleeping medications, other sedatives, or antihistamines. It may be dangerous to take trazodone in combination with these substances.

Although lower in anticholinergic side effects than tricyclic antidepressants, trazodone should be used cautiously and with close physician supervision in people, especially the elderly, who have benign prostatic hypertrophy, urinary retention, and glaucoma, especially angle-closure glaucoma (the most severe form). Before starting treatment, people with these conditions should discuss the relative risks and benefits of treatment with their doctors to help determine if protriptyline is the right antidepressant for them.

Trazodone may increase heart rate and stress on the heart. It may be dangerous for people with cardiovascular disease, especially those who have recently had a heart attack, to take this drug. In rare cases where patients with cardiovascular disease must take trazodone, they should be monitored closely for cardiac rhythm disturbances and signs of cardiac stress or damage.

Side effects

Trazodone shares side effects common to many antidepressants. The most frequent of these are dry mouth, constipation, and urinary retention, though these are less common than with tricyclic antidepressants. Increased heart rate, sedation, irritability, dizziness, and decreased coordination can also occur. As with most side effects associated with antidepressants, the intensity is highest at the beginning of therapy and tends to decrease with continued use.

Dry mouth, if severe to the point of causing difficulty in speaking or swallowing, may be managed by dosage reduction or temporary discontinuation of the drug. Patients may also chew sugarless gum or suck on sugarless candy in order to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement who take trazodone may be especially likely to have problems with urinary retention. Symptoms include having difficulty starting a urine flow and more difficulty than usual passing urine. In most cases, urinary retention is managed with dose reduction or by switching to another type of antidepressant. In extreme cases, patients may require treatment with bethanechol, a drug that reverses this particular side effect. In rare cases, trazodone has also been known to cause priapism, a prolonged and painful penile erection. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Interactions

Because both trazodone and members of the class of antidepressants known as monoamine oxidase (MAO) inhibitors may increase serotonin levels in the brain, the combination of these drugs can lead to a condition known as serotonin syndrome. Symptoms of serotonin syndrome include a prolonged rapid heart rate, hypertension (high blood pressure), flushing of the skin, **hallucinations**, tremors, and hyperthermia (increased body temperature). Because of this, it can be dangerous to take trazodone in combination with MAO inhibitors such as Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate). The same holds true when combining trazodone with a selective serotonin uptake inhibitor (SSRI) antidepressant such as Prozac (fluoxetine), paroxetine, or sertraline.

Trazodone may increase the blood pressure-lowering effects in patients who are taking antihypertensive medications. Patients who take these drugs together should have their blood pressure monitored regularly so that their antihypertensive medications can be adjusted if their blood pressure becomes too low.

The sedative effects of trazodone are increased by other central nervous system depressants such as alcohol, sedatives, sleeping medications, or medications used for other mental disorders such as **schizophrenia**. The anticholinergic effects of trazodone may be additive with other anticholinergic drugs such as **benztropine**, **biperiden**, **trihexyphenidyl**, and antihistamines.

Triazolam

Definition

Triazolam is a hypnotic drug. It is a member of the benzodiazepine family of drugs. In the United States, it is sold under the brand name Halcion as well as under its generic name.

KEY TERMS

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy as well as by dissociation.

Euphoria—A feeling or state of well-being or elation.

Hypnotic—A type of medication that induces sleep.

Insomnia—A chronic inability to sleep or to remain asleep throughout the night.

Tachycardia—A pulse rate above 100 beats per minute.

Purpose

Triazolam is used for the short-term (generally seven to 10 days) treatment of **insomnia**. Continued usage for more than two to three weeks requires a complete re-evaluation of the person receiving the drug.

Description

Triazolam increases the speed with which people achieve sleep, it increases the duration of sleep, and decreases the likelihood of being awakened during sleep. The effect of triazolam decreases after 14 days of continuous use. Often, sleep patterns return to those experienced prior to beginning use of triazolam or worse. This is called rebound insomnia.

Recommended dosage

The recommended dose of triazolam is 0.25 mg before going to bed. Persons with smaller body masses and older individuals can receive a comparable effect with 0.125 mg of triazolam. The lowest effective dosage of drug should be used to minimize adverse reactions.

Precautions

Because of problems with rebound insomnia, patients should not receive triazolam for more than seven consecutive days. Accompanying rebound insomnia may be daytime anxiety.

Triazolam can cause serious birth defects. Women should not take this medicine if they are pregnant, think they may be pregnant, or are trying to get pregnant.

The drug may cause daytime anxiety after as few as 10 days of continuous usage. If this occurs, triazolam use should be discontinued.

Persons using triazolam should exercise caution when driving or using power tools or machinery.

People who use **temazepam** to reduce jet lag on long flights should be aware of a condition sometimes called “traveler’s amnesia.” This is a condition where the traveler completes the flight and carries on with normal activities but has no memory of these activities. The period of **amnesia** may last for a few minutes to a few hours. Traveler’s amnesia is most common when the traveler has had too little sleep or has been drinking alcohol.

Side effects

Triazolam has relatively few side effects. Those that have been reported include drowsiness, headache, dizziness, nervousness, a feeling of being light-headed, problems with coordination, nausea and vomiting.

Less frequent side effects include euphoria, tachycardia, **fatigue**, confusion, impaired memory, muscle cramping and pain and depression.

Interactions

Triazolam increases the effect of drugs and substances that depress the central nervous system. This class of drugs includes anesthetics, narcotics, sedatives and other sleeping pills, atropine and alcohol.

Some drugs and foods increase the effects of triazolam. They may also increase the chances of having side effects. These include cimetidine, isoniazid, oral contraceptives, and grapefruit juice.

Trichotillomania

Definition

Individuals with trichotillomania repetitively pull out their own hair. Trichotillomania as an impulse-control disorder. Some researchers view it as a type of affective or **obsessive-compulsive disorder**. Nail-biting, skin-picking, and thumb-sucking are considered to be related conditions.

Description

Trichotillomania involves hair-pulling episodes that result in noticeable hair loss. Although any area of the body can be a target, the most common areas are the scalp, followed by the eyelashes, eyebrows, and pubic region. Hair-pulling can occur without the individual’s awareness, but is frequently preceded by a sense of increasing tension and followed by a sense of relief or

gratification. The resulting hair loss can be a source of embarrassment or shame. Because of a tendency to hide symptoms, and because professionals are relatively unfamiliar with the disorder, individuals either may not seek, or are offered treatment. Untreated trichotillomania can result in impaired social functioning and medical complications.

Causes and symptoms

Causes

Scientific research regarding trichotillomania has been conducted primarily in the past 10 years and causes are only theoretical. Psychoanalytic theories suggest that the behavior is a way of dealing with unconscious conflicts or childhood trauma (such as sexual **abuse**). Biological theories look for a genetic basis. For instance, people with trichotillomania often have a first-degree relative with an obsessive-compulsive spectrum disorder. Researchers are also evaluating similarities between trichotillomania and Tourette's disorder. Behavioral theories assume that symptoms are learned, that a child may imitate a parent who engages in hair-pulling. The behavior may also be learned independently if it serves a purpose. For example, hair-pulling may begin as a response to **stress** and then develop into a habit.

Symptoms

According to the *Diagnostic and Statistical Manual of Mental Disorders, (DSM-IV-TR)*, produced by the American Psychiatric Association and used by most mental health professionals in North America and Europe to diagnose mental disorders, the following conditions must be present for a **diagnosis** of trichotillomania:

- noticeable hair loss (alopecia) due to recurrent hair-pulling
- tension immediately before hair-pulling, or when attempting to resist hair-pulling
- reduction of tension, or a feeling of pleasure or gratification, immediately following hair-pulling
- significant distress or impairment in social, occupational, or other important areas of functioning

In addition, the *DSM-IV-TR* requires that hair-pulling not be due to another medical or mental disorder. The tension-release requirement is controversial because 17% of people who otherwise qualify for this diagnosis do not experience this.

Symptoms usually emerge in early adolescence. Episodes may last a few minutes or a few hours during periods of stress or relaxation. Hairs with unique textures

KEY TERMS

Alopecia—Hair loss (also, loss of feathers or wool in animals).

Selective serotonin reuptake inhibitors—Commonly prescribed drugs for treating depression. SSRIs affect the chemicals that nerves in the brain use to send messages to one another. These chemical messengers (neurotransmitters) are released by one nerve cell and taken up by others. Neurotransmitters not taken up by other nerve cells are taken up by the same cells that released them. This process is termed “reuptake”. SSRIs work by inhibiting the reuptake of serotonin, an action which allows more serotonin to be taken up by other nerve cells.

Serotonergic—Containing, activating, or otherwise involving serotonin, which is a chemical that aids in the transmission of nerve impulses.

Trichobezoar—A hairball that results from a buildup of swallowed hairs becoming lodged in the digestive system.

Trichophagia—Eating hair.

Trichophagy—Biting hair.

or qualities may be preferred. The pulling may include rituals, such as twirling hair off or examining the root. Half of those individuals with trichotillomania engage in oral behaviors—running hair across the lips or through the teeth, biting off the root (trichophagy), or eating hair (trichophagia). They usually try to control their behavior in the presence of others and may hide the affected areas. Symptoms may come and go for weeks, months, or years at a time.

Demographics

Once regarded as rare, trichotillomania is now considered more common, affecting 1–4% of people in the general population. When the tension-release requirement is excluded, trichotillomania occurs in adult females (3.4%) more often than adult males (1.5%). Among children, both genders are affected equally.

Diagnosis

Other possible causes of symptoms must first be ruled out. Hair loss may have a medical cause, such as a dermatological condition. Hair-pulling may have another

Left side of a man's scalp showing the effects of trichotillomania. (Custom Medical Stock Photo. Reproduced by permission.)

psychological cause, such as a delusion or hallucination in **schizophrenia**.

Severity of symptoms is also important. Twisting or playing with hair when nervous does not qualify as trichotillomania. If symptoms are minor or undetectable, a diagnosis should be given only if the individual expresses significant distress. Children should be given the diagnosis only if symptoms persist because hair-pulling may be a temporary phase, much like thumb-sucking.

If individuals deny symptoms, hair-pulling behavior can be assessed by objective measures such as the presence of short, broken hairs or damaged follicles. Some psychological assessment instruments are also available.

Treatments

Treatment usually starts by determining the current frequency and severity of symptoms. This information, which serves as a measure of progress, is gathered by (a) self-report; (b) reports from significant others; (c) objective measures, such as saving pulled hairs, videotapes, or measuring areas of hair loss; or (d) a combination of these methods.

Primarily, three categories of therapy have been used in the treatment of trichotillomania:

- **Psychoanalysis** focuses on childhood experiences and unresolved conflicts during early development.
- **Medications.** Those typically used are antidepressants with serotonergic properties (also used with obsessive-compulsive disorders). **Clomipramine** (Anafranil) has proven most effective. The selective serotonin reuptake inhibitors (SSRIs) have had mixed results. Some

researchers recommend low doses of antipsychotic drugs (neuroleptics) in conjunction with SSRIs. Medications are usually combined with behavior therapy.

- **Behavior therapy.** This includes a number of different approaches: Punishment procedures such as electric shock, topical cream to enhance pain, or mittens placed on the person's hands, are effective but controversial. They are intrusive and are often used with individuals who may be unable to consent, such as children or people with developmental disabilities. Habit-reversal training is the most accepted approach. It teaches individuals to monitor their hair-pulling and substitute it for more healthy behaviors. Alternative forms of behavior therapy include **biofeedback** and hypnosis.

Prognosis

The effects of trichotillomania can be very serious: Associated feelings of shame may result in avoidance of social situations; chewing hair can result in dental erosion; eating hair may result in hairballs (trichobezoars) becoming lodged in the stomach or large intestine, which can lead to anemia, abdominal pain, nausea and vomiting, hematemesis (vomiting blood), or bowel obstruction or perforation.

Studies show low success rates with medications and traditional psychoanalysis. Behavioral therapy has reported long-term success rates of 90% or better. Follow-up sessions are encouraged to prevent relapse. A major issue in prognosis is whether an individual receives treatment. Professionals may not recognize or know how to treat trichotillomania effectively. Conversely, individuals with the disorder may be too embarrassed to address their symptoms.

Prevention

Because scientific research is lacking, no specific information is available regarding prevention.

Trifluoperazine

Definition

Trifluoperazine is a phenothiazine antipsychotic agent. In the United States, this drug is sold under the brand name Stelazine.

Purpose

Trifluoperazine is a drug used to treat psychotic disorders, agitation, and **dementia**.

Description

Trifluoperazine is an effective agent in treating symptoms of psychotic behavior. When used for the treatment of **schizophrenia**, trifluoperazine reduces symptoms of emotional withdrawal, anxiety, tension, **hallucinations**, and suspiciousness.

Recommended dosage

The dosage of trifluoperazine should be adjusted to the lowest level needed to control symptoms. The drug may be given orally or by intramuscular injection (a shot).

A useful initial dosage of trifluoperazine for psychotic adults is 2 to 5 mg two times each day. A common total dosage is 15 to 20 mg per day. Some persons may require up to 40 or more mg per day. When using deep intramuscular injection, 1 to 2 mg every four to six hours is usually sufficient to control symptoms within 24 hours.

KEY TERMS

Akathisia—Agitated or restless movement, usually affecting the legs. Movement is accompanied by a sense of discomfort and an inability to sit, stand still, or remain inactive for periods of time. Akathisia is a common side effect of some neuroleptic (antipsychotic) medications.

Amenorrhea—Absence of menstrual periods.

Anorexia—Loss of appetite or unwillingness to eat. Can be caused by medications, depression, or many other factors.

Cogwheel rigidity—An abnormal rigidity in muscles, characterized by jerky movements when the muscle is passively stretched.

Dystonia—A neurological disorder characterized by involuntary muscle spasms. The spasms can cause a painful twisting of the body and difficulty walking or moving.

Orthostatic hypotension—A sudden decrease in blood pressure due to a change in body position, as when moving from a sitting to standing position.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Tardive dyskinesia—A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs either late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

Total intramuscular trifluoperazine should not exceed 10 mg per day.

Control of psychotic symptoms in children between the ages of six and 12 can usually be achieved with 1 to 2 mg per day, given in 1-mg increments. Trifluoperazine is not recommended for use in children younger than six.

Precautions

Trifluoperazine increases the level of prolactin, a hormone that stimulates the mammary glands in the breast, in the blood. This is a potential problem for per-

sons with a personal or family history of breast cancer and may increase the risk of breast cancer. For this reason, the benefits and risks of the drug must be carefully evaluated before it is administered.

Side effects

Relatively common side effects that accompany trifluoperazine include drowsiness, dizziness, rash, dry mouth, **insomnia**, **fatigue**, muscular weakness, anorexia, blurred vision, some loss of muscular control, and amenorrhea (lack of menstruation) in women.

Dystonia (difficulty walking or moving) may occur with trifluoperazine use. This condition may subside in 24 to 48 hours even when the person continues taking the drug and usually disappears when trifluoperazine is discontinued.

Trifluoperazine use may lead to the development of symptoms that resemble Parkinson's disease. These symptoms may include a tight or mask-like expression on the face, drooling, tremors, pill-rolling motions in the hands, cogwheel rigidity (abnormal rigidity in muscles characterized by jerky movements when the muscle is passively stretched), and a shuffling gait. Taking anti-Parkinson drugs **benztropine** mesylate or **trihexyphenidyl** hydrochloride along with the trifluoperazine usually controls these symptoms.

Trifluoperazine has the potential to produce a serious side effect called **tardive dyskinesia**. This syndrome consists of involuntary, uncoordinated movements that may appear late in therapy and may not disappear even after the drug is stopped. Tardive dyskinesia involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles. The incidence of tardive dyskinesia increases with increasing age and with increasing dosage of trifluoperazine. Women are at greater risk than men for developing tardive dyskinesia. There is no known effective treatment for tardive dyskinesia, although gradual (but rarely complete) improvement may occur over a long period.

An occasionally reported side effect of trifluoperazine is neuroleptic malignant syndrome. This is a complicated and potentially fatal condition characterized by muscle rigidity, high fever, alterations in mental status, and cardiac symptoms such as irregular pulse or blood pressure, sweating, tachycardia (fast heartbeat), and arrhythmias (irregular heartbeat). People who think they may be experiencing any side effects from this or any other medication should talk to their physician promptly.

Interactions

Trifluoperazine may reduce the effectiveness of oral anticoagulant (blood thinning) drugs.

Trifluoperazine increases the effect of drugs and substances that depress the central nervous system and. These drugs include anesthetics, opiates, **barbiturates**, atropine, and alcohol. These substances should be avoided or used sparingly by people taking trifluoperazine.

Propranolol increases the concentration of trifluoperazine. The blood pressure-lowering effects of guanethidine may be diminished by trifluoperazine. The use of diuretics with trifluoperazine may cause a sudden decrease in blood pressure often accompanied by dizziness due to a change in body position (known as orthostatic hypotension).

The blood concentration of phenytoin is increased by trifluoperazine. This may lead to phenytoin toxicity.

Trihexyphenidyl

Definition

Trihexyphenidyl is classified as an antiparkinsonian agent. It is sold in the United States under the brand name Artane and is also available under its generic name.

Purpose

Trihexyphenidyl is used to treat a group of side effects (called parkinsonian side effects) that include tremors, difficulty walking, and slack muscle tone. These side effects may occur in patients who are taking antipsychotic medications used to treat mental disorders such as **schizophrenia**.

Description

Some medicines, called antipsychotic drugs, that are used to treat schizophrenia and other mental disorders can cause side effects that are similar to the symptoms of Parkinson's disease. The patient does not have Parkinson's disease, but he or she may experience shaking in muscles while at rest, difficulty with voluntary movements, and poor muscle tone. These symptoms are similar to the symptoms of Parkinson's disease.

One way to eliminate these undesirable side effects is to stop taking the antipsychotic medicine. Unfortunately, the symptoms of the original mental disorder usually come back, so in most cases simply stopping the antipsychotic medication is not a reasonable option. Some drugs such as trihexyphenidyl that control the symptoms of Parkinson's disease also control the parkinsonian side effects of antipsychotic medicines.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Catheterization—Placing a tube in the bladder so that it can be emptied of urine.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Neurotransmitter—A chemical involved in the transmission of nervous impulses from cell to cell.

Parkinsonian—Related to symptoms associated with Parkinson's disease, a nervous system disorder characterized by abnormal muscle movement of the tongue, face, and neck, inability to walk or move quickly, walking in a shuffling manner, restlessness, and/or tremors.

Trihexyphenidyl works by restoring the chemical balance between dopamine and acetylcholine, two neurotransmitter chemicals in the **brain**. Taking trihexyphenidyl along with the antipsychotic medicine helps to control symptoms of the mental disorder, while reducing parkinsonian side effects. Trihexyphenidyl is in the same family of drugs (commonly known as anticholinergic drugs) as **biperiden** and **benztropine**.

Recommended dosage

Trihexyphenidyl is available in 2-mg and 5-mg tablets and an elixir containing 2 mg per teaspoonful. For the treatment of tremor, poor muscle tone, and similar side effects, trihexyphenidyl should be started at a dose of 1 to 2 mg orally two to three times daily or as needed, to a maximum daily dose of 15 mg per day. Parkinson-like side effects caused by antipsychotic drugs may come

and go, so trihexyphenidyl may not be needed on a regular basis. Trihexyphenidyl may also be prescribed to prevent these side effects before they actually occur. This is called prophylactic (preventative) therapy.

Precautions

Trihexyphenidyl should never be used in children under age three. It should be used cautiously and with close physician supervision in older children and in people over age 60. Trihexyphenidyl, like all anticholinergic drugs, decreases sweating and the body's ability to cool itself. People who are unaccustomed to being outside in hot weather should take care to stay as cool as possible and drink extra fluids. People who are chronically ill, have a central nervous system disease, or who work outside during hot weather may need to avoid taking trihexyphenidyl.

People who have the following medical problems may experience increased negative side effects when taking trihexyphenidyl. Anyone with these problems should discuss their condition with their physician before starting the drug:

- glaucoma, especially closed-angle glaucoma
- intestinal obstruction
- prostate enlargement
- urinary bladder obstruction

Although rare, some patients experience euphoria while taking trihexyphenidyl and may abuse it for this reason. Euphoria can occur at doses only two to four times the normal daily dose. Patients with a history of drug abuse should be observed carefully for trihexyphenidyl abuse.

Side effects

Although trihexyphenidyl helps to control the side effects of antipsychotic drugs, it can produce side effects of its own. A person taking trihexyphenidyl may have some of the following reactions, which may vary in intensity:

- dry mouth
- dry skin
- blurred vision
- nausea or vomiting
- constipation
- disorientation
- drowsiness
- irritability

- increased heart rate
- urinary retention

Dry mouth, if severe to the point of causing difficulty speaking or swallowing, may be managed by reducing or temporarily discontinuing trihexyphenidyl. Chewing sugarless gum or sucking on sugarless candy may also help to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement may be especially prone to urinary retention. Symptoms of this problem include having difficulty starting a urine flow and more difficulty passing urine than usual. This side effect may be severe and require discontinuation of the drug. Urinary retention may require catheterization. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Patients who take an overdose of trihexyphenidyl are treated with forced vomiting, removal of stomach contents and stomach washing, activated charcoal, and respiratory support if needed. They are also given physostigmine, an antidote for anticholinergic drug poisoning.

Interactions

When drugs such as trihexyphenidyl are taken with antidepressants such as **amitriptyline**, **imipramine**, **trimipramine**, **desipramine**, **nortriptyline**, **protriptyline**, **amoxapine**, and **doxepin** or with many antihistamines that also have anticholinergic properties, the effects and side effects of trihexyphenidyl are usually intensified.

Drugs such as trihexyphenidyl decrease the speed with which food moves through the stomach and intestines. Because of this, the absorption of other drugs being taken may be enhanced by trihexyphenidyl. Patients receiving trihexyphenidyl should be alert to unusual responses to other drugs they might be taking and report any changes to their physician.

Trimipramine

Definition

Trimipramine is an oral tricyclic antidepressant. It is sold in the United States under the brand name Surmontil.

Purpose

Trimipramine is used primarily to treat depression and to treat the combination of symptoms of anxiety and depression. Like most antidepressants of this chemical and pharmacological class, trimipramine has also been used in limited numbers of patients to treat **panic disorder, obsessive-compulsive disorder, attention-deficit/hyperactivity disorder, enuresis** (bed-wetting), eating disorders such as **bulimia nervosa**, cocaine dependency, and the depressive phase of bipolar (manic-depressive) disorder.

Description

Tricyclic antidepressants act to change the balance of naturally occurring chemicals in the **brain** that regulate the transmission of nerve impulses between cells. Trimipramine acts primarily to increase the concentration of norepinephrine and serotonin (both chemicals that stimulate nerve cells) and, to a lesser extent, to block the action of another brain chemical, acetylcholine. Trimipramine shares most of the properties of other tricyclic antidepressants, such as **amitriptyline, amoxapine, clomipramine, desipramine, imipramine, nortriptyline, and protriptyline**. Studies comparing trimipramine with these other drugs have shown that trimipramine is no more or less effective than other antidepressants of its type. Its choice for treatment is as much a function of physician preference as any other factor.

The therapeutic effects of trimipramine, like other antidepressants, appear slowly. Maximum benefit is often not evident for at least two weeks after starting the drug. People taking trimipramine should be aware of this and continue taking the drug as directed even if they do not see immediate improvement.

Recommended dosage

As with any antidepressant, trimipramine must be carefully adjusted by a physician to produce the desired therapeutic effect. Trimipramine is available as 25-mg, 50-mg, and 100-mg oral capsules. Therapy is usually started at 75 to 100 mg per day and gradually increased up to 200 mg daily as needed. Hospitalized patients with more severe depression may require 300 mg per day.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Benign prostatic hypertrophy—Enlargement of the prostate gland.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Amounts up to 200 mg may be given as a single dose. In people over age 60 and in adolescents, the therapeutic dose should start at 50 mg per day and is rarely increased beyond 100 mg per day.

Precautions

Like all tricyclic antidepressants, trimipramine should be used cautiously and with close physician supervision in people, especially the elderly, who have benign prostatic hypertrophy, urinary retention, and glaucoma, especially angle-closure glaucoma (the most severe form). Before starting treatment, people with these conditions should discuss the relative risks and benefits of treatment with their doctors to help determine if trimipramine is the right antidepressant for them.

A common problem with tricyclic antidepressants is sedation (drowsiness, lack of physical and mental alert-

ness). This side effect is especially noticeable early in therapy. In most patients, sedation decreases or disappears entirely with time, but until then patients taking trimipramine should not perform hazardous activities requiring mental alertness or coordination. The sedative effect is increased when trimipramine is taken with other central nervous system depressants, such as alcoholic beverages, sleeping medications, other sedatives, or antihistamines. It may be dangerous to take trimipramine in combination with these substances. Trimipramine may increase the possibility of having **seizures**. Patients should tell their physician if they have a history of seizures, including seizures brought on by the abuse of drugs or alcohol. These people should use trimipramine only with caution and be closely monitored by their physician.

Trimipramine may increase heart rate and **stress** on the heart. It may be dangerous for people with cardiovascular disease, especially those who have recently had a heart attack, to take this drug or other antidepressants in the same pharmacological class. In rare cases where patients with cardiovascular disease must receive trimipramine, they should be monitored closely for cardiac rhythm disturbances and signs of cardiac stress or damage.

Side effects

Trimipramine shares side effects common to all tricyclic antidepressants. The most frequent of these are dry mouth, constipation, urinary retention, increased heart rate, sedation, irritability, dizziness, and decreased coordination. As with most side effects associated with tricyclic antidepressants, the intensity is highest at the beginning of therapy and tends to decrease with continued use.

Dry mouth, if severe to the point of causing difficulty speaking or swallowing, may be managed by dosage reduction or temporary discontinuation of the drug. Patients may also chew sugarless gum or suck on sugarless candy in order to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement who take trimipramine may be especially likely to have problems with urinary retention. Symptoms include having difficulty starting a urine flow and more difficulty than usual passing urine. In most cases, urinary retention is managed

with dose reduction or by switching to another type of antidepressant. In extreme cases, patients may require treatment with bethanechol, a drug that reverses this particular side effect. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Interactions

Dangerously high blood pressure has resulted from the combination of tricyclic antidepressants, such as trimipramine, and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Because of this, trimipramine should never be taken in combination with MAO inhibitors. Patient taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor then wait at least 14 days before starting trimipramine or any other tricyclic antidepressant. The same holds true when discontinuing trimipramine and starting an MAO inhibitor.

Trimipramine may decrease the blood pressure–lowering effects of **clonidine**. Patients who take both drugs should be monitored for loss of blood-pressure control and the dose of clonidine increased as needed.

The sedative effects of trimipramine are increased by other central nervous system depressants such as alcohol, sedatives, sleeping medications, or medications used for other mental disorders such as **schizophrenia**. The anticholinergic effects of trimipramine are additive with other anticholinergic drugs such as **benztropine**, **biperiden**, **trihexyphenidyl**, and antihistamines.

Undifferentiated somatoform disorder

Definition

Undifferentiated somatoform disorder occurs when a person has physical complaints for more than six months that cannot be attributed to a medical condition. If there is a medical condition present, the complaints must be far more severe than can be accounted for by the presence of the medical problem.

Description

The physical complaints that are expressed by people with undifferentiated somatoform disorder are many and varied. The similarity between all physical complaints associated with undifferentiated somatoform disorder is an absence of medical evidence for the symptoms or for their severity.

The physical complaints usually begin or worsen when the patient is under **stress**. People with undifferentiated somatoform disorder experience problems functioning in their daily lives due to the physical symptoms that they experience. Seeing multiple doctors in an effort to find a physical cause for the reported symptoms is typical of people with this disorder. Undifferentiated somatoform disorder is also sometimes referred to as somatization syndrome.

Causes and symptoms

The symptoms of undifferentiated somatoform disorder vary widely from person to person. Some of the most common physical complaints are pain, **fatigue**, appetite loss, and various gastrointestinal problems. The physical complaints generally last for long periods. Patients with undifferentiated somatoform disorder tend to complain of many different physical problems over time.

No matter what symptoms a person complains about, the overarching characteristic of the complaints is that no physical reason can be found for them. Laboratory tests and thorough examinations by doctors will reveal no medical reason for the pains or problems the person is having. The physical problems, however, persist after the person has been told no explanation can be found.

The causes of undifferentiated somatoform disorder are not clear. Some experts believe that problems in the family when the affected person was a child may be related to the development of this disorder. Depression and stress are thought to be other possible causes. Other possible causes, especially in people who overreact to even minor medical conditions, include paying obsessive attention to any minor changes or sensations that their bodies experience. They give the feelings undue weight and worry unnecessarily about them.

Demographics

Undifferentiated somatoform disorder is relatively common. It is estimated that between 4% and 11% of the population experience the disorder at some time in their lives. Women are more likely than men to have undifferentiated somatoform disorder, as are the elderly and people of lower socioeconomic backgrounds. Young women who have low socioeconomic status are the most likely group to have undifferentiated somatoform disorder. Fifty percent of the people with this disorder have other psychological or psychiatric disorders as well, such as anxiety or depression.

Diagnosis

A person with undifferentiated somatoform disorder usually begins by visiting physicians looking for treatments for physical complaints. Later, he or she may be referred to a mental health professional. Referring physicians may continue to see the patient, however, so that a trusting relationship can be established, and the patient does not continue to bounce from doctor to doctor.

Mental health professionals use the handbook called the *Diagnostic and Statistical Manual of Mental Disorders* to diagnose mental disorders. The book lists diagnostic criteria, and requires that the following conditions be met in order for the clinician to diagnose this disorder:

- There must be no underlying medical cause evident that could explain the patient's physical complaints. If there is a medical condition that could be related to the complaints, the symptoms reported must be far worse than any that could be explained by the existing medical problems.
- The unexplained physical symptoms must persist for at least six months.
- The symptoms must cause problems in the patient's daily life or relationships or interfere with the patient achieving his or her goals.
- There cannot be another mental disorder that accounts for the complaints.
- The patient cannot knowingly make false complaints of physical distress.

Somatization disorder

Somatization disorder is very similar to undifferentiated somatoform disorder and the two can be easily confused. The symptoms are the same, but the diagnostic criteria are much more specific for somatization disorder. To be diagnosed with somatization disorder, the patient must have four different pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudo-neurological symptom. These symptoms can occur at different times. The symptoms must be present for several years and must have begun before the patient was thirty years old. Just as with undifferentiated somatoform disorder, the complaints must not be traceable to any medical cause.

Hypochondriasis

Hypochondriasis is also similar in many ways to undifferentiated somatoform disorder. Patients with hypochondriasis are convinced that the physical symptoms they are experiencing are the signs of a major illness. Alternately, they may simply have an obsessive fear of contracting or developing a major illness. These patients often have a specific **diagnosis** in mind when they visit a doctor, unlike most patients with undifferentiated somatoform disorder who have complaints but do not have a cause in mind.

Treatments

Most treatments of undifferentiated somatoform disorder focus on treating any underlying psychological problems or stresses that may be causing the disorder. When the disorder occurs in conjunction with another mental health problem such as depression, treating that problem often helps to resolve or lessen the symptoms of undifferentiated somatoform disorder. Some studies indicate that antidepressants are effective in treating this disorder. Patients also may benefit from programs intended to teach them how to manage stress and to understand the correlation between psychological stressors and physiological symptoms. These programs also teach people how to cope with criticism and how to stop negative behavior patterns.

Prognosis

For many people, undifferentiated somatoform disorder is a life-long disorder. Often, the physical complaints increase or decrease in relation to stressors in the affected person's life. Many people with this disorder are eventually diagnosed with another mental disorder or with a legitimate medical problem. For some people, treatment can be successful at lessening or completely resolving symptoms.

Prevention

There are no known ways to prevent undifferentiated somatoform disorder; it is possible, however, for people who appear to be developing the disorder to enroll in programs designed to teach them coping strategies and about the relationship between psychological factors and physical symptoms.

Urine drug screening

Definition

Urine drug screening, or toxicological screening, is a process of chemical analysis designed to test patients for drug abuse, or to insure that a patient is substance-free before undergoing a medical procedure.

Description

Urine drug screening can be used to evaluate possible accidental or intentional overdose or poisoning, to assess the type and amount of prescribed and/or illicit drugs used by a person, or to determine the cause of acute drug toxicity. It is also used to monitor drug dependency or to determine the presence of drugs in the body for medical and legal purposes.

In many occupations, urine drug screening has become a required condition of employment. Nearly all workers in certain occupations, such as law enforcement and transportation, must submit to periodic, random, and post-incident drug screening. Federal laws mandate the administration of drug screens to workers in the transportation industry, including bus drivers, truckers, airline employees, and railroad workers. Federally required testing must be conducted by a laboratory certified by the Substance Abuse and Mental Health Services Administration. Other industries must follow state regulations, which vary considerably.

Urine screening tests are able to detect general classes of compounds, such as **amphetamines**, **barbiturates**, **benzodiazepines**, and **opiates**. Drug screening can also detect cocaine, marijuana, and phencyclidine (PCP). The screening tests themselves are unable to distinguish between illicit and prescription drugs within the same class. A patient taking prescribed codeine pills and an individual using heroin would both show positive urine screening tests for opiates. It is also possible for some over-the-counter medications to cause a positive drug screen in someone who has taken neither illegal nor prescription drugs. These incorrect reactions are known as “false-positives.”

Urine drug screens can detect the use of several drugs. Some of these drugs are as follows:

- cocaine
- amphetamines
- heroin
- morphine
- phencyclidine (PCP)
- benzodiazepines

KEY TERMS

Amphetamines—A group of powerful and highly addictive substances that stimulate the central nervous system. May be prescribed for various medical conditions, but are often purchased illicitly and abused.

Barbiturate—A class of medications (including Seconal and Nembutal) that causes sedation and drowsiness. They may be prescribed legally, but may also be used as drugs of abuse.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Cocaine—An illegal drug that increases energy and induces euphoria. It is addictive and is often abused.

Codeine—A medication that may be prescribed but also may be purchased illegally and is used to reduce pain.

False-positive—A test result that is positive for a specific condition or disorder, but this result is inaccurate.

Gas chromatography/mass spectrometry (GC/MS)—A definitive method of testing for specific drugs, used to confirm immunoassay results indicating drug use. GC/MS separates the substances present in the urine sample, then breaks them into unique molecular fragments, which are matched against a database of known substances.

Hydromorphone—A prescribed opiate (Dilaudid) used to treat severe pain; also abused illegally.

Immunoassay—The method used in routine or preliminary urine drug screening.

Methadone—A drug often prescribed legally as a replacement for heroin. It induces a slight high but blocks heroin from producing a more powerful euphoric effect. It may be used in heroin detoxification to ease the process, or it may be used daily after detoxification as maintenance therapy. Methadone maintenance therapy is controversial.

Tetrahydrocannabinol (THC)—The active substance in marijuana.

- alcohol
- hydromorphone

- tetrahydrocannabinol (THC)
- propoxyphene
- methadone
- codeine
- barbituates

Certain foods, such as poppy seeds, may result in a positive urine screen for opiates, since poppy seeds are derived from opium poppies. Preliminary urine screening results, when positive, should be confirmed by a more accurate method that can distinguish between poppy seed ingestion and use of heroin or other opiates. Poppy seeds and opiates produce different chemicals, known as metabolic breakdown products or metabolites, as they travel through the body, allowing them to be distinguished from one another.

Sample collection

The method of collecting a urine sample for drug screening can be important. Some illicit drug users may attempt to substitute another person's urine, or chemically alter their own specimen. If the urine drug screen is being used for an important decision, such as employment or legal action, procedures to minimize chances of an adulterated or substituted sample may be necessary. These include measuring the temperature or pH of the sample immediately after it is procured, and using tamper-proof containers. Supervised specimen collection may be conducted to ensure that the urine indeed comes from the person being screened.

The most commonly used method for urine drug screening is immunoassay, a rapid and accurate test that uses antibodies embedded on test strips to reveal drug use. Antibodies react only in the presence of very specif-

ic substances—in this case, drugs present in urine. When a sufficient concentration of a drug (or drugs) are present, the test strip will indicate which substances have been detected. A control band on each strip confirms that the test was done correctly.

Positive screening results should always be confirmed by a more sensitive method. The most widely accepted corroborative test for all drugs is gas chromatography/mass spectrometry (GC/MS), which can determine the specific substances in the body by recognizing not only the molecular structure of the original compound, but also its metabolite, a chemical created when the drug is metabolized.

Vaginismus

Definition

Vaginismus occurs when the muscles around the outer third of the vagina contract involuntarily when vaginal penetration is attempted during sexual intercourse.

Description

Vaginismus is a sexual disorder that is characterized by the outer third of the vaginal muscles tightening, often painfully. A woman with vaginismus does not willfully or intentionally contract her vaginal muscles. However, when the vagina is going to be penetrated, the muscles tighten spontaneously due to psychological or other reasons.

Vaginismus can occur under different circumstances. It can begin the first time vaginal penetration is attempted. This is known as “lifelong vaginismus.” Alternately, vaginismus can begin after a period of normal sexual functioning. This is known as “acquired-type vaginismus.” For some women, vaginal tightening occurs in all situations where vaginal penetration is attempted (generalized type). For other women, it occurs in only one or a few situations, such as during a gynecological examination at the doctor’s office, or with a specific sex partner (situational type). According to the professional’s handbook, the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, in order for a condition to be diagnosed as vaginismus, the response must be due to psychological factors or a combination of psychological and medical factors, but not to medical factors alone. Because of this *DSM-IV-TR* criterion, this entry focuses on the psychological causes and treatments of vaginismus.

Causes and symptoms

Causes

There are many possible causes of vaginismus. One example is an upbringing in which sex was considered

wrong or sinful—as in the case of some strict religious backgrounds. This is common among women with this disorder. Concern that penetration is going to be painful, such as during a first sexual experience, is another possible cause. It is also thought that women who feel threatened or powerless in their relationship may subconsciously use this tightening of the vaginal muscles as a defense or silent objection to the relationship. A traumatic childhood experience, such as sexual molestation, is thought to be a possible cause of vaginismus. Acquired-type vaginismus is often the result of sexual assault or rape.

Symptoms

Vaginismus can occur when any kind of penetration of the vagina is attempted. This includes attempted penetration by a penis, speculum, tampon, or other objects. The outer third of the vaginal muscles contract severely. This either prevents penetration completely, or makes it difficult and painful. The woman may truly believe that she wants to have sexual intercourse or allow the penetration. She may find that her subconscious desires or decisions do not allow her to relax the vaginal muscles.

Diagnosis

Diagnosing sexual disorders, including vaginismus, can often be very difficult. This is mainly due to lack of comfort many people feel in discussing sexual relations, even with their physicians. Often, cultural norms and taboos deter women from seeking assistance when they are experiencing such problems. When a physician or gynecologist is consulted, involuntary spasm during pelvic examination can confirm the **diagnosis** of vaginismus, and the physician will rule out any physiological causes for the condition. When psychological causes are suspected, referral should be made to a **psychologist** or **psychiatrist**.

According to the *DSM-IV-TR*, the first criterion for the diagnosis of vaginismus is the spasm of the muscles in the outer third of the vagina that are involuntary and recur-

KEY TERMS

Coitus—Sexual intercourse.

ring or persistent. The symptoms must cause physical or emotional distress, or, in particular, problems with relationships. The symptoms cannot occur during the course of another mental disorder that can account for them—they must exist on their own. As mentioned, the muscle spasm cannot be the direct result of any sort of physical or medical condition for vaginismus to be diagnosed.

Demographics

Although many women experience sexual disorders, it is hard to gather accurate data regarding the frequency of specific problems. Many cases go unreported. Vaginismus is thought to occur most often in women who are highly educated and of high socioeconomic status.

Treatment

There are many different treatments of vaginismus, as there is a multitude of ways to treat most sexual disorders. Therapists can use behavioral, hypnotic, psychological, educational, or **group therapy** techniques. Multiple techniques are often used simultaneously for the same patient. Much treatment is aimed at reducing the anxiety associated with penetration.

Psychotherapy

There are three settings in which psychological treatment can occur. These are in individual, couple, or group settings. During individual therapy, the treatment focuses on identifying and resolving any underlying psychological problems that could be causing the disorder. Problems stemming from issues such as childhood trauma or rape are often resolved this way. Revealing insecurities or fears about sex resulting from such things as parents' attitudes about it, or a religious upbringing, can often be discussed successfully if the affected woman can trust her therapist.

Couples therapy has been referred to as “dual-sex therapy.” The idea behind couples therapy is that any sexual problem should be treated as a problem for the couple as a whole, and not just addressed as a problem for one person. Because this view is taken, the therapist interacts with the patients both separately and as a couple. The therapist addresses both the couple's sexual history and any other problems that may be occurring in the relationship. Confronting these problems may help to

resolve the cause of the vaginismus. Working with a therapist on relationship problems can be very effective—perhaps especially so if the vaginismus is caused by a subconscious use of vaginal muscle spasms as a nonverbal form of protest about one or more aspects of the relationship. The couple is educated about vaginismus disorder and given advice on the kind of activities that can be engaged in at home that may be helpful in overcoming the disorder.

Group therapy, which can be very effective, is another form of therapy for vaginismus. In this form of therapy, couples or individuals who have the same or similar sexual disorders are brought together. For people who are embarrassed or ashamed of their disorder, this setting can provide comfort and strength. It is often very beneficial to witness another person discussing sex and sexual problems in an open and honest forum. It can also help to inspire patients to become more open and honest themselves.

Another positive feature of group therapy is that it provides a certain amount of pressure. Pressure to open up can help to provide a needed “push.” Also the group's expectations for each other can provide positive pressure and encouragement for the group members. For example, the therapist may recommend “homework” outside the therapy sessions, including masturbation or certain kinds of foreplay. The group members will expect each other to complete the homework, and that expectation may help individual couples overcome their aversions to completing the activities.

Hypnotherapy

Hypnotherapy is also effective for some patients. In general, hypnotherapy tends to focus on overcoming the vaginismus itself, as opposed to resolving any causes or conflicts behind it. The therapist will determine if hypnotherapy is appropriate for a particular patient. There are often a number of sessions, during which the patient and therapist work to define the goals of the hypnotherapy. When the actual hypnosis occurs, the suggestions made are intended to resolve underlying fears or concerns, and to alleviate symptoms. For example, the patient may be told that she can have coitus without it being a painful experience, and that she will be able to overcome the muscle spasm.

During hypnosis, the problems causing the vaginismus may be explored, or an attempt may even be made to reverse feelings or fears that could be causing the disorder. Exploring causal relationships, as well as suggesting to the woman she can overcome her vaginal muscle spasms, can be very effective for certain patients.

Other treatments

Behavioral therapy is also used to treat vaginismus. When behavioral therapy is chosen, it is assumed that the vaginismus is a learned behavior that can be unlearned. Behavioral therapy generally involves desensitization. Patients are exposed to situations that they find create a mild sense of psychological discomfort or anxiety. Once these situations are conquered, the patient is exposed to sexual situations that they find more threatening, until coitus is eventually achieved without difficulty.

Another type of treatment for vaginismus involves desensitization over a period of time using systematic vaginal dilation. In the beginning of the treatment, the woman inserts a small object into her vagina. Over time, she inserts larger and larger vaginal dilators. Eventually, a dilator the size of a penis can be inserted comfortably and sexual intercourse can be achieved. There is some debate about this procedure, as it treats the symptoms and not the underlying causes of the vaginismus disorder.

Prognosis

Vaginismus is generally considered to be the most treatable sexual disorder. Successful treatment has been reported to be 63% or higher. For different people, the possibility of success using different treatments varies, because different cases of vaginismus disorder have varying causes. Generally, a treatment plan combining two or more therapeutic techniques is recommended.

Prevention

There is no known way to successfully prevent vaginismus; however, maintaining open marital communication may help to prevent the disorder, or to encourage seeking help if it does arise.

Valerian

Definition

Valerian is an herbal remedy derived from the dried roots of the valerian plant, *Valeriana officinalis*. The plant belongs to the Valerianaceae family. It has been used for over a thousand years as a mild sedative and hypnotic (a preparation that brings on sleep). Valerian is native to Europe and parts of Asia; it has since been introduced in the United States, placed under cultivation and now growing in the wild, as well. It is often cultivated for its pinkish white or lavender flowers as well as for its medicinal uses. The name "valerian" is thought to derive from the Latin verb *valere*, which means "to be well." It is also sometimes said to derive from Valeria, the province of the Roman Empire where the plant may have originated.

According to one marketing research firm, valerian is the fastest-growing herbal remedy in the United States; its sales more than doubled between 2000 and 2001.

Purpose

Valerian is most commonly used to relieve mild cases of anxiety and **insomnia**. It was given during World War I to soldiers suffering from battle shock. It has also been recommended for the relief of menstrual cramps and as a carminative, or preparation that relieves gas in the stomach and intestines. Lotions made with valerian extract are said to soothe skin rashes and swollen joints.

Description

The valerian plant prefers the damp lime-rich soil near streams or rivers, where it may grow as tall as 5 ft (1.5 m). It can, however, be grown in drier soil at higher elevations, where it may grow only 2 ft (.67 m) tall. Some herbalists consider the drier-climate variety of valerian to have greater medicinal potency.

KEY TERMS

Carminative—A substance or preparation that relieves digestive gas.

Hypnotic—A type of medication that induces sleep.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Placebo—An inactive substance or preparation used as a control in experiments with human subjects to test the effectiveness of a drug or herbal preparation. Some patients may experience a medicinal response or experience side effects to a placebo simply because they have faith in its powers even though it contains no medicine.

Rhizome—The fleshy underground horizontal root of certain plants. Valerian preparations are made from dried rhizomes as well as from roots of the valerian plant.

Tincture—An alcohol-based herbal extract prepared by soaking parts of the plant in a mixture of alcohol and water. Established ratios and dilutions are followed.

Valerenic acid—The primary medicinal component in valerian preparations.

The parts of the plant that are used for medicinal purposes are the roots and rhizomes (horizontal underground stems), which are typically yellowish-brown in color. The roots and rhizomes are harvested in the autumn of the plant's second year. They can be freeze-dried and used to prepare tablets or capsules containing the ground herb. Juice can be pressed from the fresh root, or the root may be mixed with alcohol to become a fluid extract or tincture of valerian. When valerian is used to relieve tension or induce sleep, it is frequently combined with either **passionflower** (*Passiflora incarnata*), lemon balm (*Melissa officinalis*) or skullcap (*Scutellaria laterifolia*). Because valerian tea has a somewhat bitter taste, flavorings are often added, including peppermint or fruit flavor, to make a more pleasant-tasting drink.

Although not all the compounds in valerian that have medicinal value have been identified, two compounds in its essential oil—valerenic acid and bornyl—appear to be the most important. Like most prescription tranquilizers, valerian appears to affect a neurotransmitter (GABA) in the central nervous system.

There is some disagreement among researchers about the efficacy of valerian as a tranquilizer and aid to sleep. While a team of Swiss researchers found a valerian/lemon balm combination to be significantly more effective than a placebo in inducing sleep, another group in the United States concluded that valerian is overrated as a sedative. Further research may help to settle the question, but multiple studies that are currently available are inconclusive. It appears to have mild sedative properties.

Recommended dosage

Experts in herbal preparations recommend that valerian products should be standardized to contain 0.8% valerenic or valeric acid.

Adults may use the following amounts of valerian to reduce nervousness or relieve menstrual cramps:

- 2–3 g dried root in tea, up to several times daily
- 1/4–1/2 tsp (1–3 mL) valerian tincture, up to several times daily
- 1/4 tsp (1–2 mL) fluid extract
- 150–300 mg valerian extract, standardized to contain 0.8% valerenic acid

To relieve insomnia, one of the above dosages may be taken 30–45 min before bedtime. It may take one to two weeks of regular use before the herbal preparation takes effect.

When giving valerian to children, recommended adult dosages should be adjusted in proportion to the child's weight. Most dosages of herbal products are calculated for an adult weighing 150 lb (70 kg). A child weighing 75 lb (35 kg) should therefore receive 1/2 the adult dose.

Precautions

Persons who take valerian should consult an experienced herbalist about dosage and about reliable sources of the herb. Because herbal preparations are not regulated by the U. S. Food and Drug Administration, consumers cannot be certain of the freshness and potency of commercial herbal products. In July 2001, an independent laboratory published the results of its tests of 17 valerian products; only nine contained the amount of valerian that their labels claimed. Of the remaining eight products, four contained only half the amount of valerian that they should have, and the other four contained none at all.

Although valerian has a good reputation for safety when used as directed, it should not be used in high doses or taken continuously for longer than two to three weeks.

Side effects

Some people taking valerian may experience a paradoxical effect; that is, they may feel agitated or jittery instead of relaxed or sleepy. This side effect is not dangerous, but it should be reported to the patient's health care provider. If the dosage is too high, an individual could experience longer sleep than usual, and wake up not feeling well-rested.

Prolonged use of valerian results in tolerance, and increasing the dose may have serious side effects. According to some researchers, long-term use of valerian may cause psychological depression, damage to the liver, or damage to the central nervous system.

High short-term doses of valerian have been reported to cause headaches, muscle spasms, dizziness, digestive upsets, insomnia, and confusion.

Interactions

Although valerian has been regarded as a relatively safe herb because few interactions with prescription medications have been reported, newer research indicates that it should be used cautiously following surgery. Like **St. John's wort**, valerian can interact with anesthetics and other medications given to patients after surgery. Because valerian has a mild sedative effect, it should not be taken together with alcoholic beverages, benzodiazepines, **barbiturates**, or antihistamines. Some components of valerian are metabolized in the liver. This herb has the potential to interact with liver metabolized prescription medicines.

Valproic acid

Definition

Valproic acid is an anticonvulsant (anti-seizure) drug. In the United States, valproic acid is also known as valproate, and is sold under the brand name Depakene.

Purpose

The United States Food and Drug Administration (FDA) recognizes valproic acid for the treatment of epilepsy and for mania that occurs with **bipolar disorder** (previously called manic-depressive disorder). Valproic acid is also approved for the prevention of migraine headaches.

Description

Valproic acid's properties in preventing **seizures** were first discovered in Europe in 1963. The medication was first used clinically in the United States in 1978.

Valproic acid is effective in treating a variety of seizure types, which include simple and complex absence seizures, partial seizures, and clonic-tonic seizures (grand mal seizures). Valproic acid is effective in treating the manic episodes of patients with bipolar disorder. Patients who have bipolar disorder resulting from a head injury and patients who do not respond to or who cannot tolerate conventional lithium therapy (normally the therapy of choice for bipolar disorder) can be treated with valproic acid. In addition, valproic acid provides a 50% or greater reduction in the frequency of migraine headaches. Valproic acid is also safe and effective in preventing headaches that arise as a side effect of taking a class of drugs known as selective serotonin reuptake inhibitors (SSRI). These drugs include **sertraline** (Zoloft), **paroxetine** (Paxil), **fluoxetine** (Prozac), **fluvoxamine** (Luvox), and **citalopram** (Celexa).

Valproic acid comes in 250-mg gelatin capsule and in 250 mg/5ml-syrup.

Recommended dosage

The dosage of valproic acid used to treat epilepsy depends on the type of seizures the patient has. The doses are determined based on the patient's weight and never based on the patient's age.

KEY TERMS

Absence seizure—Absence (petit mal) seizures usually begin with a brief loss of consciousness and last between one and 10 seconds. People having a petit mal seizure become very quiet and may blink, stare blankly, roll their eyes, or move their lips. A petit mal seizure lasts 15–20 seconds. When it ends, the individual resumes whatever he or she was doing before the seizure began, and may not realize that anything unusual happened.

Clonic-tonic seizure—This is the most common type of seizure among all age groups and is categorized into several phases beginning with vague symptoms hours or days before an attack. These seizures are sometimes called grand mal seizures.

The initial dose of valproic acid used to treat mania is 750 mg daily. This dose is then reduced to the lowest dose that will achieve the desired effects. Another dosage strategy is based on patient weight. The starting dose is 30 mg per kilogram of body weight on days one and two followed by 20 mg per kg of body weight taken daily on days three through ten.

For prevention of migraine headaches, a dose of 250 mg twice daily is beneficial. It may take up to 1,000 mg of valproic acid to control migraine attacks.

Precautions

Patients who have liver disease should not take valproic acid. Pregnant women should not take valproic acid, because it can harm the developing fetus. Patients who are allergic to valproic acid should not take it.

When it is necessary for children under age two and patients who have pancreatitis to take valproic acid, the drug should be used cautiously and with close physician monitoring.

Side effects

Valproic acid can cause liver damage. Before starting valproic acid therapy, every patient should have a blood test to assess his or her liver function. The risk of valproic acid causing liver damage is greatest during the first six months of treatment. Liver function tests should be done once a month during the first three months, then every three to six months for as long as the patient continues to take the drug. Vomiting, lethargy, anorexia, and jaundice (yellowing of the skin) may precede signs of

liver damage. If a patient develops severe or unusual abdominal pain, this may be a sign of pancreatitis (inflammation of the pancreas). Pancreatitis can occur in both children and adults. It can develop shortly after valproic acid is started or after several years of use.

Other side effects of valproic acid may include nausea, vomiting, indigestion, and either diarrhea or constipation. Headaches, dizziness, lack of coordination, confusion, **fatigue**, tremor, drowsiness, and seizures have also been associated with the use of valproic acid. Behavioral changes associated with the drug including irritability, longer and deeper sleep, hyperactivity, increased sociability, increased sadness, happiness or aggression, are seen more often in children than in adults taking valproic acid.

Fewer than 1% of patients experience appetite changes. These changes may include either diminished or increased appetite. Skin rash, photosensitivity (acute sensitivity to the sun), hair loss, and other hair changes have also been reported in people using valproic acid.

Interactions

Using valproic acid with other anticonvulsant drugs, such as phenobarbital, **clonazepam**, and **lamotrigine** may cause excessive sedation (drowsiness and lack of physical and mental alertness). Valproic acid may diminish the benefits of phenytoin which is another commonly used anticonvulsant.

Taking aspirin during valproic acid therapy may cause valproic acid levels to increase to toxic (poisonous) levels. Other medications that may cause valproic acid toxicity are erythromycin, an antibiotic, and the antidepressant **amitriptyline**. Drugs that can decrease the effectiveness of valproic acid include **carbamazepine** and cholestyramine. **Ginkgo biloba**, an herbal supplement commonly available in the United States, may be prepared with a chemical called 4'-O-methylpyridoxine. If this chemical remains in the herbal preparation, it can cause seizures, and reduce the effectiveness of valproic acid. Severe central nervous depression has been reported with the use of valproic acid and another anticonvulsant called primidone.

Vascular dementia

Definition

Dementia is a decline in a person's mental capacities and intellectual abilities that is great enough to affect the person's normal daily functioning. Vascular dementia is dementia that is caused by disease of the blood vessels of the **brain** (cerebrovascular disease).

Description

Vascular dementia is caused by cerebrovascular disease that occurs almost entirely in the elderly. People with vascular dementia generally experience a decline in thought processes (cognitive function) that follows specific steps. This decline is often punctuated by small strokes—ruptures of tiny blood vessels in the brain. People experiencing vascular dementia often have problems with memory, abstract thinking, object identification or recognition, speech creation, speech comprehension, and motor activities.

Causes and symptoms

The signs of dementia often begin with impaired memory function. Sometimes a person has difficulty learning new things or remembering new events, and sometimes the person has difficulty recalling events or things that he or she used to know. Other signs of dementia include impairment in other areas of thought processing. Sometimes a person with vascular dementia may have difficulty producing coherent speech, or may have other language impairments, such as problems understanding spoken or written language. The signs of vascular dementia are similar to those of Alzheimer's disease (AD).

Difficulty with motor activities is a problem for some people with vascular dementia. Things that require hand-eye coordination, such as tying shoes or undoing buttons, are examples of motor activities that may be impaired. People with vascular dementia may also have difficulty recognizing familiar objects, or may be unable to name them. Problems organizing things, putting events

KEY TERMS

Cerebrovascular—Blood flow in the brain.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness.

Vascular—Pertaining to the bloodstream (arteries, veins, and blood vessels).

in sequence, or problems performing other types of abstract thinking may be present.

Some people with vascular dementia exhibit neurological signs that indicate the presence of cerebrovascular disease. They may have weakness of the arms or legs, abnormal reflexes, or abnormalities in the way they walk. Some people also exhibit behavioral disturbances related to the dementia. A person can be violent or aggressive towards others—often his or her caretaker. The person may act impulsively and irritably, and sometimes scream.

Vascular dementia is thought to be caused by small strokes that interfere with blood flow to the brain. Usually, vascular dementia is caused by many small strokes over time, rather than one large **stroke**. Sometimes this is referred to as multi-infarct dementia (MID). If the vascular dementia is caused by one large stroke, or develops in less than three months, then it is called "acute onset vascular dementia." Acute onset vascular dementia is rare.

Demographics

In most countries, vascular dementia is a much less common form of dementia than AD. This is true in North America and Europe, but is not so in Japan, where it is more common than AD. Overall, vascular dementia is the second most common form of dementia, after AD. About 10–20% of patients who experience dementia have the vascular form of the disorder. The difference in prevalence in different countries may result from different lifestyle factors rooted in the culture.

Vascular dementia is more common in men than in women, which may be because men are more likely than women to suffer from strokes. Vascular dementia becomes increasingly prevalent as people grow older. The number of people affected by vascular dementia rises dramatically during and after the sixth decade. Vascular dementia usually occurs at a younger age than AD.

Diagnosis

The first step in the **diagnosis** of vascular dementia is to verify that dementia is present. The *DSM* indicates that impairments to memory must be present for a diagnosis of vascular dementia. Memory problems can include difficulties in learning and retaining new information, problems remembering past events, or things that were learned before dementia took root.

In addition to memory impairment, the *DSM* also specifies that one or more other impairments must be present. These impairments can include language problems that encompass not being able to form speech and/or not being able to understand language, either spoken or written. The patient may have problems performing activities that require hand-eye coordination such as tying shoes, even though motor function is normal. Another possible impairment is a problem recognizing or identifying objects, although the person is able to use his or her sense organs fully. Also, problems doing tasks such as organizing things, planning events, putting things into sequence, or problems thinking abstractly may exist.

If the patient has memory problems and one or more other impairments, For a diagnosis of vascular dementia to be made, these impairments must cause problems for the patient's functioning in important parts of his or her daily life. Also, the patient must be significantly less able to function than during a previous time. In addition, the problems cannot occur during the course of an event that is categorized as a **delirium**. There must be evidence that the problem is a result of cerebrovascular disease.

If the dementia occurs without any other significant signs or symptoms, then it is classified as uncomplicated. There are three other possible classifications as given by the *DSM*. These are based on the predominant feature of the dementia. They are: vascular dementia with delirium, vascular dementia with **delusions**, and vascular dementia with depressed mood. If there are significant behavioral disturbances occurring as a result of the dementia, then that is specified.

Vascular dementia and AD are similar in many ways, and can be confused. The most significant difference between the two is that vascular dementia can be diagnosed using physiological evidence of cerebrovascular disease. Also, AD generally occurs first as a slow loss of memory function, and then as a gradual decline into eventual dementia. Vascular dementia, however, generally occurs suddenly. The patient often declines in a step-wise fashion, with each step occurring after a stroke.

Treatments

The treatments for vascular dementia focus on attempts to slow or halt the progression of the disorder and alleviate some of the symptoms. The disorder cannot be cured or reversed. The most common way to treat vascular dementia is to try to prevent further strokes. Treatments include diet and drug treatment for hypertension (high blood pressure), aspirin therapy, smoking cessation, avoidance of heavy alcohol use, and **stress** reduction. Some drugs that are used to treat mild AD are being studied for their effectiveness in treating vascular dementia.

Prognosis

Vascular dementia is a disorder that cannot be reversed. The progression of the disorder can, however, be slowed. Using drugs, along with lifestyle changes to prevent more strokes from occurring, can be effective at slowing the progression of vascular dementia.

Prevention

Vascular dementia is generally associated with a series of strokes causing increasing mental impairment. Measures generally recommended by physicians may prevent strokes and may be effective in helping to prevent vascular dementia. These measures include such things as quitting smoking, decreasing cholesterol levels, treating hypertension by reducing sodium (salt) intake, decreasing alcohol consumption, quitting smoking, and other lifestyle changes. One study illustrated that consuming a small amount of red wine regularly reduces the risk of all forms of dementia.

Venlafaxine

Definition

Venlafaxine is an antidepressant available in the United States under the trade name of Effexor or Effexor XR.

Purpose

Venlafaxine is used to treat depression and **generalized anxiety disorder**. It has also been used to treat **obsessive-compulsive disorder** and irritable bowel syndrome.

Description

Venlafaxine is an antidepressant. It has actions common to both the cyclic antidepressants such as **imipramine** (Tofranil) and **amitriptyline** (Elavil,) and the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), **sertraline** (Zoloft), and **paroxetine** (Paxil). It is believed to derive its actions by increasing levels of both norepinephrine and serotonin in the **brain**.

The therapeutic effects of venlafaxine, like other antidepressants, appear slowly. Maximum benefit is often not evident for at least two weeks after starting the drug. People taking venlafaxine should be aware of this and continue taking the drug as directed even if they do not see immediate improvement.

Venlafaxine is broken down by the liver and eliminated from the body by the kidneys. As a result, the dose of venlafaxine must be lowered in people with liver or kidney disease.

KEY TERMS

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

Antipsychotic—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Depression—A mental state characterized by excessive sadness. Other symptoms include altered sleep patterns, thoughts of suicide, difficulty concentrating, agitation, lack of energy, and loss of enjoyment in activities that are usually pleasurable.

Generalized anxiety disorder—A general form of fear that can dominate a person’s life.

Mania—An elevated or euphoric mood or irritable state that is characteristic of bipolar I disorder. This state is characterized by mental and physical hyperactivity, disorganization of behavior, and inappropriate elevation of mood.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Obsessive-compulsive disorder—Disorder in which the affected individual has an obsession (such as a fear of contamination, or thoughts he or she doesn’t like to have and can’t control) and feels compelled to perform a certain act to neutralize the obsession (such as repeated handwashing).

Serotonin syndrome—A condition characterized by at least three of the following symptoms: diarrhea, fever, extreme perspiration, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking. It is a result of too much serotonin in the body.

Venlafaxine is available in 25-mg, 37.5-mg, 50-mg, 75-mg, and 100-mg rapid-release tablets and 75-mg and 150-mg extended-action capsules.

Recommended dosage

The recommended initial dose of venlafaxine is 75 mg daily taken as two or three equal doses. The dose may be increased in 75-mg increments every four days as needed until symptoms of depression or anxiety resolve. Most commonly, dosages range between 150 mg to 225

mg daily. although in severe situations, 375 mg per day may be needed. Once patients are stabilized using the rapid-acting tablets, they may be converted over to the appropriate dose of extended-release capsules.

In people with liver disease, the daily dosage of venlafaxine should be cut in half. In patients with kidney disease, the daily dosage of venlafaxine should be reduced 25–50%, depending upon the extent of kidney damage. When stopping venlafaxine, the dosage should be reduced gradually over a period of at least two weeks before the drug is totally stopped.

Precautions

Patients taking venlafaxine should be monitored closely for **insomnia**, anxiety, mania, significant weight loss, **seizures**, and thoughts of **suicide**.

Caution should also be exercised when prescribing venlafaxine to patients with impaired liver or kidney function, the elderly (over age 60) children, individuals with known manic-depressive disorder or a history of seizures, people with diabetes, and individuals expressing ideas of committing suicide.

Individuals should not take MAO inhibitors such as Nardil during venlafaxine therapy, for two weeks prior to beginning venlafaxine therapy, and for five weeks after stopping venlafaxine therapy.

Care should be taken to weigh the risks and benefit of this drug in women who are, or wish to become, pregnant, as well as in breast-feeding mothers.

People with diabetes should monitor their blood or urine sugar more carefully, since venlafaxine may affect blood sugar.

Until an individual understands the effects that venlafaxine may have, he or she should avoid driving, operating dangerous machinery, or participating in hazardous activities. Alcohol should not be used while taking venlafaxine.

Side effects

More common side effects include decreased sexual drive, restlessness, difficulty sitting still, skin rash, hives, and itching.

Less common side effects include fever and/or chills, and pain in joints or muscles.

Rare side effects include pain or enlargement of breasts and/or abnormal milk production in women, seizures, fast heart rate, irregular heartbeats, red or purple spots on the skin, low blood sugar and its symptoms (anxiety, chills, cold sweats, confusion, difficulty con-

centrating, drowsiness, excess hunger, rapid heart rate, headache, shakiness or unsteadiness, severe **fatigue**), low blood sodium and its symptoms (including confusion, seizures, drowsiness, dry mouth, severe thirst, decreased energy), serotonin syndrome (usually at least three of the following: diarrhea, fever, sweateness, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking), excitability, agitation, irritability, pressured talking, difficulty breathing, and odd body or facial movements.

Interactions

Venlafaxine interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all their health care providers, including dentists, that they are taking venlafaxine.

Dangerously high blood pressure, rapid changes in heart rate, high fever, muscle stiffness, and sudden muscle spasms have resulted from the combination of antidepressants, such as venlafaxine, and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Because of these serious adverse reactions, venlafaxine should never be taken in combination with MAO inhibitors. Patient taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor then wait at least 14 days before starting venlafaxine or a tricyclic antidepressant. The same holds true when discontinuing venlafaxine and starting an MAO inhibitor.

Some other drugs such as **trazodone** (Desyrel), sibutramine (Meridia), and sumatriptan (Imitrex) also interact with venlafaxine and cause a syndrome known as neuroleptic malignant syndrome, characterized by irritability, muscle stiffness, shivering, muscle spasms, and altered consciousness.

The sedative effects (drowsiness, lack of mental clarity) of venlafaxine are increased by other central nervous system depressants such as alcohol, sedatives, sleeping medications, or other medications used for mental disorders such as **schizophrenia**.

Vocational rehabilitation

Definition

Vocational rehabilitation (VR) is a set of services offered to individuals with mental or physical disabilities. These services are designed to enable participants to attain skills, resources, attitudes, and expectations needed to compete in the interview process, get a job, and keep a job. Services offered may also help an individual retrain for employment after an injury or mental disorder has disrupted previous employment.

Purpose

Vocational rehabilitation services prepare qualified applicants to achieve a lifestyle of independence and integration within their workplace, family and local community. This transition is achieved through work evaluation and job readiness services, job counseling services, and medical and therapeutic services. For individuals with psychiatric disabilities, situational assessments are generally used to evaluate vocational skills and potential.

Precautions

Vocational rehabilitation as operated by state agencies is not an entitlement program. Only individuals considered eligible can receive VR services. Eligibility criteria require that an individual be at least 16 years old, unemployed or under-employed, and have a physical or mental disability that results in a substantial barrier to employment, such as psychotic disorders, alcohol and other drug abuse dependence, mental and emotional disorders, attention deficit disorders, specific learning disabilities, and physical and sensory disabilities. In addition, the individual must be able to benefit from VR services. An individual must also need help to prepare for, find, and succeed in paid employment. When resources are limited, individuals with the most significant disabilities must be served first.

KEY TERMS

IEP (Individualized Education Plan)—Under federal law governing special education, every child in public schools who is determined through assessment to have special mental disability needs has an IEP. An IEP is typically developed by a team of professionals that may include special education teachers, physical, occupational and speech therapists, psychologists, parents or guardians, and others who may be called on to provide expertise. The team meets at least once a year to set goals for the next school year and to assess progress on already established goals. Parents who are not satisfied with school-based assessments have the right to ask for independent assessments that must be paid for by the school system.

Integrated setting—Placing individuals in usual employment situations rather than making placements into sheltered workshops or other segregated settings.

Natural supports—Using a person's already existing support network to help the person reach a goal, such as the employment of their choice.

Person-centered planning—A technique in which a plan for a person's future is developed by a team consisting of the person, family members, service providers and friends (natural supports). The team develops a practical plan based on the person's wishes and dreams. Each team member agrees to perform certain tasks identified in the plan to help the person reach goals.

Section 504—This section of the Rehabilitation Act of 1973 provides that no person may be discriminated against because of a physical disability. For instance, a child who uses a wheelchair. If a science class is on the second floor and the building has no elevator, the school must find a way to ensure that children in wheelchairs have access to that science class. An educational plan for a child who has both cognitive and physical disabilities is developed under an IEP.

Description

Vocational rehabilitation services are based on individual needs and defined as any goods or services an individual might need to be employable, such as assistive technology devices and services. For instance, a person

who is blind would need screen reading software to access a computer and people with a cognitive or mental disability might need a talking electronic reminder device programmed to prompt them when it is time to perform certain tasks.

Vocational rehabilitation can be provided by private organizations, but is not typically funded under **managed care** arrangements. Thus, most people apply to state vocational rehabilitation agencies that are funded through federal and state monies. Typically, state agencies have offices in their state's major cities and towns. State VR agencies do not necessarily offer the same services or deliver services in the same way in every state, so individuals seeking services must learn how to access the VR program in their own state. The federal VR component is administered by the U.S. Department of Education Rehabilitation Services Administration and authorized by the Rehabilitation Act of 1973 as amended in the 1988 reauthorization.

Most vocational rehabilitation services are free for eligible applicants; however, applicants may be asked to use other benefits, such as: insurance, Pell grants or other financial aid for training or higher education, to pay part of program costs.

Best practices in vocational rehabilitation include individual choice, person-centered planning, integrated setting, natural supports, rapid placement, and career development. The term *integrated setting* refers to placing individuals in usual employment situations rather than making placements into sheltered workshops or other segregated settings. Natural supports are the person's already existing support network, including family members, service providers, and friends, who can help the person reach a goal, such as the employment of their choice. Person-centered planning is a technique in which a plan for a person's future is developed by a team consisting of the person and his or her natural supports, and the team develops a practical plan based on the person's wishes and dreams. Each team member agrees to perform certain tasks identified in the plan to help the person reach goals. Unfortunately, not all VR programs incorporate all of these best practices.

Preparation

Vocational rehabilitation transition planning services are required for all public and private education students aged 16 and over, who have Individualized Education Plans (IEPs) or Rehabilitation Act Section 504 Plans. Transition services help students make the transition from school to employment, training or higher education. Older individuals who have acquired disabilities and are applying for VR services must undergo medical and psy-

chological assessments at their local VR office to determine the extent of their disabilities, except for individuals receiving SSDI or SSI who are presumed eligible without assessments. Applicants may receive treatment and counseling, if needed, before training and employment. All VR services are described in an applicant's Individualized Plan for Employment (IPE). Applicants may design the IPE either on their own or with the assistance of their assigned VR counselor, usually a person with a master's degree in rehabilitation counseling.

Aftercare

A vocational rehabilitation counselor will assist an applicant gain access to an employment agency to help locate a job. Counselors may provide support (supported employment programs) if applicants need support to keep a job. This support may include job coaching, which includes working with the person in the workplace until the person is comfortable with the work. The counselors also act as resources if a job does not work out by assessing what happened and counseling the person on how to improve performance or change habits that were not perceived favorably in the workplace.

Risks

Applicants may not be satisfied with the pace of progress toward their employment goal through VR or they may not believe their wishes or talents and skills are being taken seriously. Applicants wanting to start their own businesses or engage in telecommuting may not be successful in receiving vocational rehabilitation assistance. Applicants may find that VR counselors tend to recommend low-level and low-paying jobs traditionally recommended for VR applicants, such as food service and janitorial work. Applicants may also be turned away by VR counselors because the counselors decide the applicant's disability is too severe for the person to benefit from VR services. An additional risk for individuals with mental disorders is a usual lack of coordination between VR and mental health systems.

To address these problems in the VR system, the United States Congress passed the Ticket To Work Act. Under this Act, persons with mental or physical disabilities will receive a ticket worth a certain amount of money. They may take this ticket to any private or public entity that provides job training and placement, including state VR programs. The entities providing the employment-related services will be able to redeem the tickets only after the person is gainfully employed for a certain period of time. States are on a staggered schedule to begin implementing the program; persons in the first

states started receiving tickets in 2001. All states will be instituting the Ticket to Work Act by 2004.

Normal results

Individuals with mental or physical disabilities will receive the assessments, counseling, training, placement, accommodations and long-term supports needed to allow them to engage in the gainful employment of their choice.

Abnormal results

Individuals with mental or physical disabilities remain unemployed or under employed. More than 70% of people with disabilities are unemployed; for people with mental disorders, that percentage ranges from 70-90%.

Voyeurism

Definition

Voyeurism is a psychosexual disorder in which a person derives sexual pleasure and gratification from looking at the naked bodies and genital organs or observing the sexual acts of others. The voyeur is usually hidden from view of others. Voyeurism is a form of paraphilia.

A variant form of voyeurism involves listening to erotic conversations. This is commonly referred to as telephone sex, although it is usually considered voyeurism primarily in the instance of listening to unsuspecting persons.

Description

The object of voyeurism is to observe unsuspecting individuals who are naked, in the process of undressing or engaging in sexual acts. The person being observed is usually a stranger to the observer. The act of looking or peeping is undertaken for the purpose of achieving sexual excitement. The observer generally does not seek to have sexual contact or activity with the person being observed.

If orgasm is sought, it is usually achieved through masturbation. This may occur during the act of observation or later, relying on the memory of the act that was observed.

KEY TERMS

Paraphilia—A disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Voyeur—A person who engages in the behavior of voyeurism.

Frequently, a voyeur may have a fantasy of engaging in sexual activity with the person being observed. In reality, this fantasy is rarely consummated.

A number of states have statutes that render voyeurism a crime. Such statutes vary widely regarding definitions of voyeurism. Most states specifically prohibit anyone from photographing or videotaping another person, without consent, while observing that person in the privacy of his home or some other private place.

Causes and symptoms

Causes

There is no scientific consensus concerning the basis for voyeurism. Most experts attribute the behavior to an initially random or accidental observation of an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity. Successive repetitions of the act tend to reinforce and perpetuate the voyeuristic behavior.

Symptoms

The act of voyeurism is the observation of an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity that provides sexual arousal. To be clinically diagnosed, the symptoms must include the following elements:

- recurrent, intense or sexually arousing fantasies, sexual urges, or behaviors
- fantasies, urges, or behaviors that cause significant distress to an individual or are disruptive of his or her everyday functioning.

Demographics

Voyeurism is apparently more common in men, but does occasionally occur in women. However, the prevalence of voyeurism is not known. Contemporary U.S.

society is increasingly voyeuristic (as in the example of “real” television); however **diagnosis** is made only when this is a preferred or exclusive means of sexual gratification.

The onset of voyeuristic activity is usually prior to the age of 15 years. There are no reliable statistics pertaining to the incidence of voyeurism in adulthood.

Diagnosis

According to the mental health professional's handbook, *Diagnostic and Statistical Manual of Mental Disorders*, two criteria are required to make a diagnosis of voyeurism:

- Over a period of at least six months, an individual must experience recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors that involve the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.
- The fantasies, sexual urges, or behaviors must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

In order for a condition to be labeled “voyeurism,” the fantasies, urges, or behaviors to watch other persons must cause significant distress in the individual or be disruptive to his or her everyday functioning.

Treatments

For treatment to be successful, a voyeur must want to modify existing patterns of behavior. This initial step is difficult for most voyeurs to admit and then take. Most must be compelled to accept treatment. This may often be the result of a court order.

Behavioral therapy is commonly used to try to treat voyeurism. The voyeur must learn to control the impulse to watch non-consenting victims, and just as importantly to acquire more acceptable means of sexual gratification. Outcomes of behavioral therapy are not known. There are no direct drug treatments for voyeurism.

Voyeurism is a criminal act in many jurisdictions. It is usually classified as a misdemeanor. As a result, legal penalties are often minor. The possibility of exposure and embarrassment may deter some voyeurs. It is also not easy to prosecute voyeurs as intent to watch is difficult to prove. In their defense statements, they usually claim that the observation was accidental.

Prognosis

Once voyeuristic activity is undertaken, it commonly does not stop. Over time, it may become the main form

of sexual gratification for the voyeur. Its course tends to be chronic.

The prognosis for eliminating voyeurism is poor because most voyeurs have no desire to change their pattern of behavior. Since voyeurism involves non-consenting partners and is against the law in many jurisdictions, the possibility of embarrassment may deter some individuals.

Prevention

Most experts agree that providing guidance regarding behavior that is culturally acceptable will prevent the development of a paraphilia such as voyeurism. The origin of some instances of voyeurism may be accidental observation with subsequent sexual gratification. There is no way to predict when such an event and association will occur.

Members of society at large can reduce the incidence of voyeurism by drawing curtains, dropping blinds or closing window curtains. Reducing opportunities for voyeurism may reduce the practice.

WAIS *see* **Wechsler Adult Intelligence Scale**

Wechsler adult intelligence scale

Definition

The Wechsler adult intelligence scale (WAIS) is an individually administered measure of intelligence, intended for adults aged 16–89.

Purpose

The WAIS is intended to measure human intelligence reflected in both verbal and performance abilities. Dr. David Wechsler, a clinical **psychologist**, believed that intelligence is a global construct, reflecting a variety of measurable skills and should be considered in the context of the overall personality. The WAIS is also administered as part of a test battery to make inferences about personality and pathology, both through the content of specific answers and patterns of subtest scores.

Besides being utilized as an intelligence assessment, the WAIS is used in neuropsychological evaluation, specifically with regard to **brain** dysfunction. Large differences in verbal and nonverbal intelligence may indicate specific types of brain damage.

The WAIS is also administered for diagnostic purposes. Intelligence quotient (IQ) scores reported by the WAIS can be used as part of the diagnostic criteria for **mental retardation**, specific learning disabilities, and **attention-deficit/hyperactivity disorder** (ADHD).

Precautions

The Wechsler intelligence scales are not considered adequate measures of extremely high and low intelligence

(IQ scores below 40 and above 160). The nature of the scoring process does not allow for scores outside of this range for test takers at particular ages. Wechsler himself was even more conservative, stressing that his scales were not appropriate for people with an IQ below 70 or above 130. Also, when administering the WAIS to people at extreme ends of the age range (below 20 years of age or above 70), caution should be used when interpreting scores. The age range for the WAIS overlaps with that of the **Wechsler Intelligence Scale for Children** (WISC) for people between 16 and 17 years of age, and it is suggested that the WISC provides a better measure for this age range.

Administration and scoring of the WAIS require an active test administrator who must interact with the test taker and must know test protocol and specifications. WAIS administrators must receive proper training and be aware of all test guidelines.

Description

The Wechsler **intelligence tests**, which include the WAIS, the WISC, and the WPPSI (Wechsler preschool and primary scale of intelligence), are the most widely used intelligence assessments and among the most widely used neuropsychological assessments. Wechsler published the first version of the WAIS in 1939, initially called the Wechsler-Bellevue. The newest version is the WAIS-III (the third edition, most recently updated in 1997). Since Wechsler's death in 1981, the Wechsler tests have been revised by the publisher, the Psychological Corporation.

The theoretical basis for the WAIS and the other Wechsler scales came from Wechsler's belief that intelligence is a complex ability involving a variety of skills. Because intelligence is multifaceted, Wechsler believed, a test measuring intelligence must reflect this multitude of skills. After dividing intelligence into two major types of skills—verbal and performance—Wechsler utilized the statistical technique of factor analysis to determine specific skills within these two major domains. These more specific factors formed the basis of the Wechsler subtests.

KEY TERMS

Factor Analysis—A statistical method for summarizing relationships between variables. With the WAIS, items that correlated highly with each other were considered to be part of certain factors underlying intelligence. These factors are the basis for the 14 WAIS subtests.

Indices—Scores based on performance in more than one area. On the WAIS, there are four index scores, each based on an individual's performance in more than one subtest.

Mean—The mathematical average of all scores in a set of scores. The WAIS has been standardized to have a mean of 100.

Percentile rank—The point at which a given percentage of people fall at or below the individual's test score being calculated. For example, if a person's test score was at the 60th percentile, 40% of other test takers received a higher score, while 60% received a score that was at or below that of the test taker.

Standard deviation—A measure of variability in a set of scores. The WAIS has been standardized to have a standard deviation of 15.

Standardization—The administration of a test to a sample group of people for the purpose of establishing scoring norms. Prior to the publication of each version of the WAIS, it is standardized.

The WAIS-III consists of 14 subtests and takes about 60–75 minutes to complete. The test is taken individually, with a test administrator present to give instructions. Each subtest is given separately, and proceeds from very easy items to very difficult ones. There is some flexibility in the administration of the WAIS—the administrator may end some subtests early if test takers seem to reach the limit of their capacity. Tasks on the WAIS include questions of general knowledge, traditional arithmetic problems, a test of vocabulary, completion of pictures with missing elements, arrangements of blocks and pictures, and assembly of objects.

The WAIS is considered to be a valid and reliable measure of general intelligence. When undergoing reliability and validity studies, other intelligence tests are often compared to the Wechsler scales. It is regularly used by researchers in many areas of psychology as a measure of intelligence. Research has demonstrated correlations between WAIS IQ scores and a variety of socioeconomic, physiological, and environmental characteristics.

The WAIS has also been found to be a good measure of both fluid and crystallized intelligence. Fluid intelligence refers to inductive and deductive reasoning, skills considered to be largely influenced by neurological and biological factors. In the WAIS, fluid intelligence is reflected in the performance subtests. Crystallized intelligence refers to knowledge and skills that are primarily influenced by environmental and sociocultural factors. In the WAIS, crystallized intelligence is reflected in the verbal subtests. Wechsler himself did not divide overall intelligence into these two types. However, the consideration of fluid and crystallized intelligence as two major categories of cognitive ability has been a focus for many intelligence theorists.

The Wechsler scales were originally developed and later revised using standardization samples. The samples were meant to be demographically representative of the United States population at the time of the standardization.

Results

The WAIS elicits three intelligence quotient scores, based on an average of 100, as well as subtest and index scores. WAIS subtests measure specific verbal abilities and specific performance abilities.

The WAIS elicits an overall intelligence quotient, called the full-scale IQ, as well as a verbal IQ and a performance IQ. The three IQ scores are standardized in such a way that the scores have a mean of 100 and a standard deviation of 15. Wechsler pioneered the use of deviation IQ scores, allowing test takers to be compared to others of different as well as the same age. WAIS scores are sometimes converted into percentile ranks. The verbal and performance IQ scores are based on scores on the 14 subtests. The 14 subtest scores have a mean of 10 and a standard deviation of three. The WAIS also elicits four indices, each based on a different set of subtests: verbal comprehension, perceptual organization, working memory, and processing speed.

The full-scale IQ is based on scores on all of the subtests and is a reflection of both verbal IQ and performance IQ. It is considered the single most reliable and valid score elicited by the WAIS. However, when an examinee's verbal and performance IQ scores differ significantly, the full-scale IQ should be interpreted cautiously.

The verbal IQ

The verbal IQ is derived from scores on seven of the subtests: information, digit span, vocabulary, arithmetic, comprehension, similarities, and letter-number sequenc-

ing. Letter-number sequencing is a new subtest added to the most recent edition of the WAIS (WAIS-III).

The information subtest is a test of general knowledge, including questions about geography and literature. The digit span subtest requires test takers to repeat strings of digits. The vocabulary and arithmetic subtests are general measures of a person's vocabulary and arithmetic skills. The comprehension subtest requires test takers to solve practical problems and explain the meaning of proverbs. The similarities subtest requires test takers to indicate the similarities between pairs of things. The letter-number sequencing subtest involves ordering numbers and letters presented in an unordered sequence. Scores on the verbal subtests are based primarily on correct answers.

The performance IQ

The performance IQ is derived from scores on the remaining seven subtests: picture completion, picture arrangement, block design, object assembly, digit symbol, matrix reasoning, and symbol search. Matrix reasoning and symbol search are new subtests and were added to the most recent edition of the WAIS (WAIS-III).

In the picture completion subtest, the test taker is required to complete pictures with missing elements. The picture arrangement subtest entails arranging pictures in order to tell a story. The block design subtest requires test takers to use blocks to make specific designs. The object assembly subtest requires people to assemble pieces in such a way that a whole object is built. In the digit symbol subtest, digits and symbols are presented as pairs and test takers then must pair additional digits and symbols. The matrix reasoning subtest requires test takers to identify geometric shapes. The symbol search subtest requires examinees to match symbols appearing in different groups. Scores on the performance subtests are based on both response speed and correct answers.

Wechsler Intelligence Scale for Children

Definition

The Wechsler Intelligence Scale for Children, often abbreviated as WISC, is an individually administered measure of intelligence intended for children aged six years to 16 years and 11 months.

Purpose

The WISC is designed to measure human intelligence as reflected in both verbal and nonverbal (performance) abilities. David Wechsler, the author of the test, believed that intelligence has a global quality that reflects a variety of measurable skills. He also thought that it should be considered in the context of the person's overall personality.

The WISC is used in schools as part of placement evaluations for programs for gifted children and for children who are developmentally disabled.

In addition to its uses in intelligence assessment, the WISC is used in neuropsychological evaluation, specifically with regard to **brain** dysfunction. Large differences in verbal and nonverbal intelligence may indicate specific types of brain damage.

The WISC is also used for other diagnostic purposes. IQ scores reported by the WISC can be used as part

KEY TERMS

Crystallized intelligence—A type of intelligence that reflects knowledge and skills influenced by a person's sociocultural environment.

Factor analysis—A statistical method for summarizing relationships between variables.

Fluid intelligence—A type of intelligence that involves inductive and deductive reasoning ability.

Intelligence quotient (IQ)—A measurement of intelligence obtained by dividing a person's mental age (determined by level of performance on an age-graded test) by his or her chronological age and multiplying by 100. For example, a ten-year-old with a mental age of thirteen would have an IQ of 130.

Standardization—The administration of a test to a sample group of people for the purpose of establishing scoring norms.

of the diagnostic criteria for **mental retardation** and specific learning disabilities. The test may also serve to better evaluate children with **attention-deficit/hyperactivity disorder** (ADHD) and other behavior disorders.

Precautions

The Wechsler intelligence scales are not considered adequate measures of extreme intelligence (IQ scores below 40 and above 160). The scoring process does not allow for scores outside this range for test takers at particular ages. Wechsler himself was even more conservative, stressing that his scales were not appropriate for people with IQs below 70 or above 130. Despite this restriction, many people use the WISC as a measure of the intelligence of gifted children, who typically score above 130. The age range for the WISC overlaps with that of the **Wechsler Adult Intelligence Scale** (WAIS) for people between 16 and 17 years of age, but experts suggest that the WISC provides a better measure for people in this age range.

Administration and scoring of the WISC require a competent administrator who must be able to interact and communicate with children of different ages and must know test protocol and specifications. WISC administrators must receive training in the proper use of the instrument and demonstrate awareness of all test guidelines.

Description

The Wechsler **intelligence tests**, which include the WISC, the WAIS, and the WPPSI (Wechsler Preschool and Primary Scale of Intelligence), are the most widely used intelligence and neuropsychological assessments. The first version of the WISC was written in 1949 by David Wechsler. The newest version of the WISC is the WISC-III (Wechsler Intelligence Scale for Children-Third Edition, most recently updated in 1991). Since Wechsler's death in 1981, the tests have been revised by their publisher, the Psychological Corporation.

The theoretical basis for the WISC and the other Wechsler scales is Wechsler's belief that human intelligence is a complex ability involving a variety of skills. Because intelligence is multifaceted, Wechsler believed, a test measuring intelligence must reflect this diversity. After dividing intelligence into two major types of skills—verbal and performance—Wechsler used a statistical technique called factor analysis to determine which specific skills fit within these two major domains.

The current version of the WISC (the WISC-III) consists of 13 subtests and takes between 50 and 75 minutes to complete. The test is taken individually, with an administrator present to give instructions. Each subtest is given separately. There is some flexibility in the administration of the WISC—the administrator may end some subtests early if the test taker appears to have reached the limit of his or her capacity. Tasks on the WISC include questions of general knowledge, traditional arithmetic problems, English vocabulary, completion of mazes, and arrangements of blocks and pictures.

Children who take the WISC are scored by comparing their performance to other test takers of the same age. The WISC yields three IQ (intelligence quotient) scores, based on an average of 100, as well as subtest and index scores. WISC subtests measure specific verbal and performance abilities. The Wechsler scales were originally developed and later revised using standardization samples. The samples were meant to be representative of the United States population at the time of standardization.

The WISC is considered to be a valid and reliable measure of general intelligence in children. It is regularly used by researchers in many areas of psychology and child development as a general measure of intelligence. It has also been found to be a good measure of both fluid and crystallized intelligence. Fluid intelligence refers to inductive and deductive reasoning, skills that are thought to be largely influenced by neurological and biological factors. Fluid intelligence is measured by the performance subtests of the WISC. Crystallized intelligence refers to knowledge and skills that are primarily influenced by environmental and sociocultural factors. It is

measured by the verbal subtests of the WISC. Wechsler himself did not divide overall intelligence into these two types. The definition of fluid and crystallized intelligence as two major categories of cognitive ability, however, has been a focus of research for many intelligence theorists.

Verbal IQ

The child's verbal IQ score is derived from scores on six of the subtests: information, digit span, vocabulary, arithmetic, comprehension, and similarities.

The information subtest is a test of general knowledge, including questions about geography and literature. The digit span subtest requires the child to repeat strings of digits recited by the examiner. The vocabulary and arithmetic subtests are general measures of the child's vocabulary and arithmetic skills. The comprehension subtest asks the child to solve practical problems and explain the meaning of simple proverbs. The similarities subtest asks the child to describe the similarities between pairs of items, for example that apples and oranges are both fruits.

Performance IQ

The child's performance IQ is derived from scores on the remaining seven subtests: picture completion, picture arrangement, block design, object assembly, coding, mazes, and symbol search.

In the picture completion subtest, the child is asked to complete pictures with missing elements. The picture arrangement subtest entails arranging pictures in order to tell a story. The block design subtest requires the child to use blocks to make specific designs. The object assembly subtest asks the child to put together pieces in such a way as to construct an entire object. In the coding subtest, the child makes pairs from a series of shapes or numbers. The mazes subtest asks the child to solve maze puzzles of increasing difficulty. The symbol search subtest requires the child to match symbols that appear in different groups. Scores on the performance subtests are based on both the speed of response and the number of correct answers.

Results

WISC scores yield an overall intelligence quotient, called the full scale IQ, as well as a verbal IQ and a performance IQ. The three IQ scores are standardized in such a way that a score of 100 is considered average and serves as a benchmark for higher and lower scores. Verbal and performance IQ scores are based on scores on the 13 subtests.

The full scale IQ is derived from the child's scores on all of the subtests. It reflects both verbal IQ and per-

formance IQ and is considered the single most reliable and valid score obtained by the WISC. When a child's verbal and performance IQ scores are far apart, however, the full scale IQ should be interpreted cautiously.

Wernicke-Korsakoff syndrome

Definition

Wernicke-Korsakoff syndrome is a severe memory disorder usually associated with chronic excessive alcohol consumption, although the direct cause is a deficiency in the B vitamin thiamin.

KEY TERMS

Anterograde amnesia—Amnesia for events that occurred after a physical injury or emotional trauma but before the present moment.

Apathy—Lack of feelings or emotions.

Cognitive—Pertaining to the mental processes of memory, perception, judgment, and reasoning.

Encephalopathy—Brain disease that causes damage or degeneration.

Explicit memory—Consciously recalled memory for facts or events.

Implicit memory—Unconsciously recalled memory for skills, procedures, or associations.

Neurons—Nerve cells in the brain that produce nerve impulses.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Retrograde amnesia—Amnesia for events that occurred before a traumatic injury.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Syndrome—A group of symptoms that together characterize a disease or disorder.

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, the professional handbook that aids clinicians in diagnosing patients' mental disorders, refers to Korsakoff syndrome as alcohol-induced persisting amnestic disorder and includes it under the category of substance-induced persisting **amnestic disorders**.

Description

The disorder was first identified in the late nineteenth century. The first phase of the condition, called Wernicke's encephalopathy, was described by German neurologist and **psychiatrist** Karl Wernicke in 1881. He noted three key symptoms in three patients—two with alcoholism and one who had swallowed sulfuric acid. These patients suffered from mental confusion, eye **movement disorders**, and ataxia (poor motor coordi-

nation). A few years later, S. S. Korsakoff, a Russian psychiatrist, began publishing reports describing a syndrome of anterograde amnesia—an inability to form new memories—and confabulation in individuals with severe alcoholism or certain medical illnesses. (Confabulation refers to the practice of filling in gaps in memory by fabrication.) By 1900, researchers and clinicians studying alcoholism recognized a connection between the two conditions. The typical syndrome begins with acute Wernicke's encephalopathy, with Korsakoff syndrome emerging when the acute phase resolves. The symptoms of Wernicke's encephalopathy appear suddenly. The most prominent symptom initially is mental confusion including memory problems. On examination, patients have difficulty moving their eyes to follow a visual stimulus due to paralysis of the muscles controlling eye movements. For instance, a patient may have trouble looking upward or to the side with one or both eyes. Problems maintaining balance while standing or walking, a condition known as ataxia, are frequently observed as well. If left untreated, most of these symptoms may resolve spontaneously, but the severe memory disorder characteristic of Korsakoff syndrome remains.

The typical person with Korsakoff syndrome appears fairly normal on first impression. Intelligence is intact, and individuals with the syndrome can carry on a conversation quite naturally. They are usually able to recall and talk about incidents that took place before the onset of the disorder and recognize family members and old friends without much difficulty. The ability to form new memories is nearly absent, however. In the course of conversation, people with Korsakoff syndrome may repeat comments or questions several times. They will fail to recognize people they met minutes before or greet a friend with excitement and surprise after a brief trip to another room. These are the characteristics of anterograde **amnesia**. Research shows that anterograde amnesia results from a failure of memory formation and storage. New information is processed normally, but almost immediately forgotten, never making it into the regions of the **brain** where memories of the past are stored. People with Korsakoff syndrome thus have no memories of events that happened after the onset of the illness. Many previously stored memories are still available, however, explaining why individuals with Korsakoff syndrome can usually remember the distant past quite well.

Causes and symptoms

Causes

Wernicke-Korsakoff syndrome is caused by thiamin deficiency. It is most commonly observed in

people with alcoholism since heavy drinkers often eat poorly, and alcoholism interferes with absorption of nutrients from the digestive system. It can also occur in people who are malnourished for other reasons. Thiamin helps produce energy needed to make neurons function properly. Insufficient thiamin can lead to damage or death of neurons.

Thiamin deficiency damages regions of the brain, particularly the thalamus and the mammillary bodies. The thalamus is a structure deep within the brain that serves many important functions. It is often called the major relay station of the brain, and many neurons make connections in the thalamus. The mammillary bodies are part of the hypothalamus, located just below the thalamus. The mammillary bodies receive many neural connections from another part of the brain called the hippocampus, which appears to be the primary part of the brain involved in the formation of memories. Neurons in the mammillary bodies make connections with the thalamus, which in turn makes connections with the cortex of the brain, where long-term memories are stored. This may explain why damage to the mammillary bodies and thalamus can lead to anterograde amnesia. Memories formed in the hippocampus are never stored since connections between hippocampus and cortex are disrupted.

Eye movement disorders observed in the acute phase of the condition are probably due to damage to other nearby brain regions that make connections to the nerves controlling eye muscles. These nerves emerge from the brainstem located right below the thalamus and mammillary bodies. Nerves involved in balance also make connections with other nerves in the brainstem, but a separate part of the brain called the cerebellum may also contribute to ataxia. Reasons why some regions of the brain are selectively affected by thiamin deficiency are not yet fully understood, but selective vulnerability of certain **neurotransmitters** is suspected.

Symptoms

Mental confusion, eye movement disturbances, and ataxia are the primary symptoms of Wernicke's encephalopathy—the first, acute stage of Wernicke-Korsakoff syndrome. At first glance, confusion and ataxia may resemble the effects of severe alcohol intoxication, but they persist after intoxication wears off. Some patients with Wernicke's encephalopathy will recover completely without residual memory deficits, particularly if they are treated quickly with thiamin.

The chronic stage of Wernicke-Korsakoff syndrome, sometimes called Korsakoff **psychosis**, is distinguished by anterograde amnesia, and most untreated patients with

Wernicke's encephalopathy will develop this severe memory disorder, which prevents them from forming lasting memories of events or information encountered after the onset of the initial symptoms. Symptoms of Korsakoff syndrome may also develop spontaneously in many patients who never show signs of Wernicke's encephalopathy. Once patients develop Korsakoff's amnesia, recovery is unlikely.

Loss of memory for past events is called retrograde amnesia. Many people with Korsakoff syndrome have some retrograde amnesia in addition to anterograde amnesia, particularly for events that occurred shortly before the onset of illness, but most can recall the distant past without difficulty.

Immediate memory is not affected. For instance, an individual with Korsakoff syndrome could repeat a sentence or string of numbers immediately after hearing them, although this information would likely be forgotten within half a minute. Preservation of immediate memory allows individuals with Korsakoff syndrome to interact with others and respond to questions. Implicit memory is also preserved, so people with Korsakoff syndrome can learn new motor skills or develop conditioned reactions to stimuli. For example, individuals who play computer games can show improved performance each time they play, even if they cannot explicitly remember having played the game before.

Confabulation is another striking feature of Korsakoff syndrome, although it is not always observed. Confabulation refers to falsification of memory. The individual appears to be making up stories to cover up for inability to remember. Confabulation often seems to involve a confusion of the past and present. For example, if patients with Korsakoff syndrome are asked why they are in the hospital, they may say they just had a baby, are recovering from pneumonia, undergoing medical tests, or even applying for a job.

Patients with Wernicke-Korsakoff syndrome may also show signs of **apathy** and a lack of spontaneous behavior. Emotional expression may be lacking as well.

Interestingly, autopsies often reveal brain lesions characteristic of Wernicke-Korsakoff syndrome in alcoholic patients who showed general cognitive problems like those seen in **dementia**, but who never developed anterograde amnesia. These findings suggest that onset may be gradual in some patients.

Demographics

When **diagnosis** is based on postmortem findings, the estimated prevalence of Wernicke-Korsakoff syndrome is between 1 and 2% of the population. The clas-

sic presentation with acute onset of Wernicke's encephalopathy is fairly rare, about 0.05% of all hospital admissions, although this does not account for patients who do not seek medical attention. Wernicke-Korsakoff syndrome usually follows many years of chronic alcoholism or malnutrition and is seldom seen among people under 20. Most patients are 40 years of age or older. The disorder is apparently more common in alcoholic individuals who are particularly vulnerable to malnutrition such as indigent or homeless people.

Diagnosis

Wernicke's encephalopathy is diagnosed when patients seek medical attention and have the classic trio of signs: mental confusion, eye movement disorders, and ataxia. The diagnosis of Korsakoff syndrome is given when anterograde amnesia is present in an individual with a history of chronic, heavy drinking or malnutrition. When Korsakoff syndrome follows Wernicke's encephalopathy, the entire Wernicke-Korsakoff syndrome diagnosis is appropriate. The diagnosis is supported by neuroimaging or autopsy findings showing degeneration of the thalamus and mammillary bodies and loss of brain volume in the area surrounding the fourth ventricle—a fluid-filled cavity near the brainstem.

Although *DSM-IV-TR* criteria for alcohol-induced persisting amnesic disorder apply to most people with Wernicke-Korsakoff syndrome, there are some differences between the two diagnoses. Despite research findings suggesting that severe amnesia is not a necessary symptom of Wernicke-Korsakoff syndrome, the *DSM-IV-TR* requires the presence of either anterograde or retrograde amnesia for a diagnosis of alcohol-induced persisting amnesic disorder. One additional cognitive symptom is also required. Symptoms listed in the *DSM-IV-TR* include language disturbance (aphasia), inability to carry out motor activities (apraxia), inability to recognize objects (agnosia), or deficits in planning, initiation, organization and abstraction (executive functions). Individuals with Wernicke-Korsakoff syndrome frequently demonstrate problems with executive functions that contribute to the symptoms of confabulation and apathy. Aphasia, apraxia, and agnosia are not common signs of Wernicke-Korsakoff syndrome.

The *DSM-IV-TR* also requires that memory impairment must significantly impair a person's ability to perform normal activities and functions, and it must represent a decline from a previous level of functioning. Amnesia cannot occur exclusively during states of **delirium**, alcohol intoxication, or withdrawal, or be exclusively associated with a dementia. Both of the these

requirements are consistent with the usual presentation of Wernicke-Korsakoff syndrome.

Finally, the *DSM-IV-TR* requires evidence that amnesia is caused by use of alcohol. Such evidence can include an extensive history of heavy drinking; or physical examination or laboratory findings revealing other signs of heavy alcohol use, such as abnormal liver function tests. Despite this *DSM-IV-TR* requirement, Wernicke-Korsakoff's syndrome can occur in the absence of heavy alcohol use. Emergence of the disorder in people without alcoholism is much less common today than it was in the past, however, since vitamins are now added to many foods. In practice, most people who show the hallmark symptoms of Wernicke-Korsakoff syndrome also qualify for the *DSM-IV-TR* diagnosis.

Treatments

Nutritional

Individuals with signs of Wernicke's encephalopathy should be treated with thiamin immediately. In many cases, prompt administration of thiamin reverses the symptoms and prevents amnesia from developing. Thiamin can be administered intravenously or directly into the digestive system. Unfortunately, thiamin is less effective in the chronic phase of the condition. Based on autopsy findings suggesting the presence of Wernicke-Korsakoff syndrome in people with milder cognitive problems who do not show the classic signs of the disorder, researchers have examined the usefulness of thiamin treatment in people with alcohol dependence who are at risk of developing the syndrome. Results suggest that thiamin treatment improves performance on memory tests in this group, and that higher thiamin doses are associated with better performance. These findings suggest that thiamin treatment can help prevent Wernicke-Korsakoff syndrome in heavy drinkers.

Medication

Recent reports suggest that **donepezil** and **rivastigmine**, drugs used to treat **Alzheimer's disease**, may improve memory in patients with Wernicke-Korsakoff syndrome. Both drugs prevent the breakdown of the neurotransmitter acetylcholine, which is important for the formation of memories. Patients treated with these drugs showed improvements on memory tests and were more able to recognize hospital staff and family members. Although improvements appear to be rather modest, these drugs may be useful for patients who do not respond to thiamin. Antidepressants that increase levels of serotonin may also be helpful, although the reasons why are not clear since these drugs are not effective with other memory disorders.

Conditioning

The fact that implicit memory is not affected by Wernicke-Korsakoff syndrome has led some researchers to explore the use of classical conditioning procedures in helping patients to remember specific people. In classical conditioning, animals and people learn to associate a stimulus with an outcome. The most famous example is the pairing of a ringing bell with food. Dogs naturally salivate when given food. In a famous experiment, Ivan Pavlov rang a bell immediately before serving food to dogs. After doing this repeatedly, Pavlov found that the dogs salivated upon hearing the bell ring even when the food was not presented. This form of learning does not rely on the hippocampus and cortex but appears to involve neurons in other parts of the brain. Patients with Wernicke-Korsakoff syndrome who are given specific rewards for correctly choosing a picture of a face that matches a face they have seen previously are more able to choose the correct face than those who do not receive the rewards. Although these individuals do not explicitly remember the face they saw previously, they are still able to make the correct choice. Training patients in this way could enable them to recognize familiar people and differentiate them from strangers.

Prognosis

The prognosis for full recovery from Wernicke-Korsakoff syndrome is poor. Once chronic Korsakoff's amnesia ensues, approximately 80% of patients will never fully recover the ability to learn and remember new information. Because they cannot learn from experience, individuals with Wernicke-Korsakoff syndrome almost always require some form of custodial care. They are usually unable to work, although some can perform simple tasks they learned prior to onset of the condition if closely supervised.

Prevention

Wernicke-Korsakoff syndrome can be prevented with a nutritious diet containing sufficient thiamin. Because severe chronic alcoholism is the most common cause of thiamin deficiency, treatment of alcohol dependence is extremely important. In order to prevent Wernicke-Korsakoff syndrome among people who are unable to stop drinking or among particularly vulnerable individuals like homeless drinkers, some researchers and clinicians have advocated supplementing alcoholic beverages with thiamin.

Wide Range Achievement Test

Definition

Wide Range Achievement Test, 3rd ed. or WRAT-3 is a screening test that can be administered to determine if a more comprehensive achievement test is needed. Achievement tests refer to skills that individuals learn through direct instruction or **intervention**.

Purpose

The WRAT-3 measures basic skills in reading, arithmetic, and spelling. The test covers ages from five to 75 years old and takes approximately 30 minutes to administer.

Precautions

Although screening instruments may save time, these instruments can sometimes have misleading results. For instance, the scores may overestimate or underestimate a person's skills or the test does not measure other important achievement abilities. To obtain a more in-depth result of an examinee's abilities, a more comprehensive achievement test must be administered. For example, the WRAT-3 has no assessment of fundamental skills such as reading comprehension, writing abilities, and applying mathematical concepts to real-life situations. Finally, psychometric testing requires a clinically trained examiner. Therefore, the test should only be administered and interpreted by a trained examiner.

Description

The WRAT-3 has two alternative testing forms (tan and blue). One form is administered with the second form available if needed. Both testing forms (both the tan and blue forms) can be administered. When this is done, a combined score is obtained. Each testing form consists of one reading test, one arithmetic test, and one spelling test. The reading test is administered individually, but the other two tests may be given in groups of up to five people. The reading test consists of 15 letters and 42 individual words that the examinee is asked to name or pronounce. The spelling test consists of writing one's name, 13 letters, and up to 40 words dictated to the examinee and used in a sentence. The spelling items increase with difficulty. Finally, the arithmetic test consists of two parts. Part I requires counting, reading number symbols, and solving simple arithmetic problems that are verbally presented to the examinee. Part II consists of using paper and a pencil to calculate up to 40 arithmetic problems

KEY TERMS

Normal curve equivalents—Standard scores with an average of 100. The normal curve equivalents divide the normal or bell-shaped curve into 100 equal parts. As a result, those scores can be used for statistical analysis because they can be added, subtracted, multiplied and divided.

Percentile ranks—The point at which a given percentage of people fall at or below the individual's test score being calculated. For example, if a person's test score was at the 60th percentile, 40% of other test takers received a higher score, while 60% received a score that was at or below that of the test taker.

Psychometric—Pertaining to testing and measurement of mental or psychological abilities. Psychometric tests convert an individual's psychological traits and attributes into a numerical estimation or evaluation.

within 15 minutes. These arithmetic problems are presented in a test booklet.

Results

Scoring consists of a 1 for a correct answer and a 0 for an incorrect answer. The raw scores are converted to standard scores. These are scores that allow the examiner to compare the individual's score to other people who have taken the test. Additionally, by converting raw scores to standard scores the examiner has uniform scores and can more easily compare an individual's performance on one test with the individual's performance on another test. The average score for each test of the WRAT-3 is 100. An examiner can also obtain grade-equivalent scores, percentile ranks, and normal curve equivalents. A poor performance in any of the three areas assessed by this instrument can indicate the need for further testing.

Yoga

Definition

Yoga is an ancient system of breathing practices, physical exercises and postures, and **meditation** intended to integrate the practitioner's body, mind, and spirit. It originated in India several thousand years ago, and its principles were first written down by a scholar named Patanjali in the second century B.C. The word *yoga* comes from a Sanskrit word, *yukti*, and means "union" or "yoke." The various physical and mental disciplines of yoga were seen as a method for individuals to attain union with the divine.

In the contemporary West, however, yoga is more often regarded as a beneficial form of physical exercise than as a philosophy or total way of life. As of 2002, more than six million people in the United States were practicing some form of yoga, with 1.7 million claiming to practice it regularly.

Purpose

Yoga has been recommended as an adjunct to **psychotherapy** and standard medical treatments for a number of reasons. Its integration of the mental, physical, and spiritual dimensions of human life is helpful to patients struggling with distorted cognitions or pain syndromes. The stretching, bending, and balancing involved in the asanas (physical postures that are part of a yoga practice) help to align the head and spinal column; stimulate the circulatory system, endocrine glands, and other organs; and keep muscles and joints strong and flexible. Yoga programs have been shown to reduce the risk of heart disease by lowering blood pressure and anxiety levels. The breath control exercises, known as *pranayama*, emphasize slow and deep abdominal breathing. They benefit the respiratory system, help to induce a sense of relaxation, and are useful in pain management. The meditation that is an integral part of classical yoga practice has been shown to

strengthen the human immune system. Although Western medical researchers have been studying yoga only since the 1970s, clinical trials in the United States have demonstrated its effectiveness in treating asthma, osteoarthritis, heart disease, stress-related illnesses, high blood pressure, anxiety, and mood disorders. Other reports indicate that yoga merits further research in the treatment of **obsessive-compulsive disorder** (OCD) and substance abuse. Studies done in Germany have focused on the psychological benefits of yoga. One clinical trial done in 1994 at the University of Wurzburg found that the volunteer subjects who had practiced yoga scored higher in life satisfaction, with lower levels of irritability and psychosomatic complaints, than the control group.

One of the advantages of yoga as a complementary therapy is its adaptability to patients with a wide variety of physical and psychiatric conditions. There are a number of different schools of yoga—over 40, according to one expert in the field—and even within a particular school or tradition, the asanas and breathing exercises can be tailored to the patient's needs. One can find special yoga courses for children; for people over 50; for people with fibromyalgia, arthritis, or back problems; for cancer patients; and for people struggling with weight. Although most people who take up yoga attend classes, it is possible to learn the basic postures and breathing techniques at home from beginners' manuals or videotapes. Patients who feel self-conscious about exercising in the presence of others may find yoga appealing for this reason. The American Yoga Association has produced a manual and videotape for beginners, as well as a book called *The American Yoga Association's Easy Does It Yoga* for persons with physical limitations. In addition, yoga does not require expensive equipment or special courts, tracks, or playing fields. An area of floor space about 6 ft by 8 ft, a so-called "sticky mat" to keep the feet from slipping, and loose clothing that allows the wearer to move freely are all that is needed.

KEY TERMS

Asana—The Indian term for the poses or postures that are done in sequence during hatha yoga practice.

Hatha yoga—The form of yoga most familiar to Westerners; often practiced as a form of physical therapy.

Pranayama—The breathing exercises that accompany the asanas in hatha yoga.

Yogi (feminine, yogini)—A person who is a respected expert in or teacher of yoga.

Precautions

Patients with a history of heart disease, severe back injuries, inner ear problems or other difficulties with balance, or recent surgery should consult a physician before beginning yoga. Pregnant women are usually advised to modify their yoga practice during the first trimester.

People diagnosed with a dissociative disorder should not attempt advanced forms of pranayama (yogic breathing) without the supervision of an experienced teacher. Some yogic breathing exercises may trigger symptoms of derealization or **depersonalization** in these patients.

Yoga should not be practiced on a full stomach. It is best to wait at least two hours after a meal before beginning one's yoga practice. In addition, while yoga can be practiced outdoors, it should not be done in direct sunlight.

One additional precaution is often necessary for Westerners. Yoga is not a competitive sport, and a "good" practice is defined as whatever one's body and mind are capable of giving on a specific day. Westerners are, however, accustomed to pushing themselves hard, comparing their performances to those of others, and assuming that exercise is not beneficial unless it hurts—an attitude summed up in the phrase "no pain, no gain." Yoga teaches a gentle and accepting attitude toward one's body rather than a punishing or perfectionistic approach. A person should go into the stretches and poses gradually, not forcibly or violently. Stretching should not be done past the point of mild discomfort, which is normal for beginners; frank pain is a warning that the body is not properly aligned in the pose or that the joints are being overstressed. Most people beginning yoga will experience measurable progress in their strength and flexibility after a week or two of daily practice.

Description

There are six major branches of yoga: hatha, raja, karma, bhakti, jnana, and tantra yoga. Hatha yoga, the type most familiar to Westerners, will be discussed more fully in the following paragraph. Raja yoga is a spiritual path of self-renunciation and simplicity; karma yoga emphasizes selfless work as a service to others. Bhakti yoga is the path of cultivating an open heart and single-minded love of God. Jnana yoga is the sage or philosopher's approach; it cultivates wisdom and discernment, and is considered the most difficult type of yoga. Tantra yoga emphasizes transcending the self through religious rituals, including sacred sexuality.

Hatha yoga is the best-known form of yoga in the West because it is often taught as a form of physical therapy. A typical hatha yoga practice consists of a sequence of asanas, or physical poses, designed to exercise all parts of the body in the course of the practice. The asanas incorporate three basic types of movement: forward bends, backward bends, and twists. Practitioners of hatha yoga have over 200 asanas to choose from in creating a sequence for practice. The postures have traditional Indian names, such as Eagle Pose, Half Moon Pose, or Mountain Pose. There are steps for entering and leaving the pose, and the student is taught to concentrate on proper form and alignment. The pose is held for a period of time (usually 10–20 seconds), during which the practitioner concentrates on breathing correctly. Mental focus and discipline is necessary in order to maintain one's poise and balance in the asana. At the close of the practice, most students of yoga rest in a position that allows for a period of meditation. Most yoga practices take about an hour, although some are as short as 20 minutes.

There are a number of different styles of hatha yoga taught in the United States, the best known being Iyengar,

Demonstrations of the tree, cobra, and lotus yoga poses. The tree and triangle are good for balance and coordination. The cobra stretches the pelvic muscles and strengthens the back. Lotus is a meditative pose. (Illustration by Electronic Illustrators Group.)

Bikram, Kripalu, and ashtanga yoga. Iyengar yoga, which was developed by B.K.S. Iyengar, emphasizes attention to the details of a pose and the use of such props as blocks and belts to help students gain flexibility. Bikram yoga, taught on the West Coast by Bikram Choudhury, is practiced in heated rooms intended to make participants sweat freely as they warm and stretch their joints and muscles. Kripalu yoga, sometimes called the yoga of consciousness, emphasizes breathing exercises and the proper coordination of breath and movement. It also teaches awareness of one's psychological and emotional reactions to the various poses and movements of the body. Ashtanga yoga, developed by K. Pattabhi Jois, is the basis of so-called power yoga. Ashtanga yoga is a physically demanding workout that is not suitable for beginners.

Preparation

Good preparation for yoga requires spiritual and mental readiness as well as appropriate clothing and a suitable space. Many practitioners of yoga begin their practice with simple breathing exercises and stretches intended to clear the mind as well as open up the lungs.

Clothing should be comfortable and allow free movement. Some women prefer to practice in a dancer's leotard or similar garment made of stretchy fabric, but a simple tunic or beach cover-up worn over a pair of running shorts works just as well. Brassieres should not be worn during practice because they tend to restrict breathing. Men often practice in swim trunks or running shorts. Both men and women can use an oversize men's cotton T-shirt as a practice garment—these are inexpensive, easy to wash, and nonbinding. The feet are bare.

Aftercare

As was mentioned earlier, traditional hatha yoga practice ends the sequence of asanas with a pose in which meditation is possible, either sitting or lying flat on the back. Other than quiet resting, no particular aftercare is necessary.

Risks

Most reported injuries in yoga result from lack of concentration or attempts to perform difficult poses without working up to them. People who have consulted a physician before starting yoga and practice under the supervision of an experienced teacher are unlikely to suffer serious injury.

Normal results

Normal results following yoga practice are improved posture, lowered blood pressure, increased flexibility in the joints, higher energy levels, and a sense of relaxation.

Abnormal results

Abnormal physical results would include serious injuries to joints or muscles; abnormal psychological results would include dissociative episodes.

Zaleplon

Definition

Zaleplon is classified as a hypnotic drug. These drugs help people sleep. Zaleplon is available in the United States as the brand name drug Sonata.

Purpose

Zaleplon is a drug that is used to treat short-term **insomnia**, and it can be habit-forming.

Description

The United States Food and Drug Administration approved Zaleplon in 1999 to treat short-term problems sleeping. Zaleplon is thought to act by mimicking a chemical in the **brain** that helps to facilitate sleep. It is different from other sleeping pills, because it begins to work almost immediately and its effects are rather short-lived (a few hours). These properties make it beneficial both for people who have troubling falling asleep at bedtime and for people who awaken in the middle of the night and have trouble falling back to sleep. Zaleplon may be taken in the middle of the night so long as the person can sleep at least four more hours before having to awaken.

Zaleplon is available as capsules. The drug is broken down by the liver. It is a controlled substance and can be habit-forming.

Recommended dosage

The usual dose of zaleplon for adults is 5–20 mg. For healthy adults, 10 mg is a common dosage. However, people over age 65, small adults with low body weight, and people with serious health problems (especially liver disease) should take a dose at the low end of this range (usually 5 mg). Zaleplon is taken immediately before bedtime. It usually takes only about 30 minutes for the

sleep-inducing actions of zaleplon to be felt, and sleep-facilitating effects appear to last only a few hours. If zaleplon is taken with a meal, it will take longer to work. For the fastest sleep onset, it should be taken on an empty stomach. The maximum dose for one day is 20 mg. Under no circumstances should a person take more than 20 mg in one day.

Precautions

Zaleplon can be habit-forming and should be taken exactly as directed by a physician. A person who forgets a dose of zaleplon should skip the dose and take the next dose at the regularly scheduled time.

Because zaleplon is used to help people fall asleep, it should not be used with other drugs (over-the-counter or prescription) that also cause drowsiness. Zaleplon should be used only with close physician supervision in people with liver disease and in the elderly, because these individuals are especially sensitive to the sedative properties of zaleplon. Zaleplon should not be used before driving, operating machinery, or performing activities that require mental alertness. People with a history of drug abuse, psychiatric disorders, or depression should be carefully monitored when using zaleplon since zaleplon may worsen symptoms of some psychiatric disorders and can become a drug of abuse.

If zaleplon is needed for more than seven to ten days, patients should be re-evaluated by a physician to determine if another disorder is causing their difficulty sleeping. When zaleplon or other sleeping pills are used every night for more than a few weeks, they begin to lose their effectiveness and/or people may become dependent upon them to fall asleep. Zaleplon can be addictive. People using zaleplon should not stop taking the drug suddenly because withdrawal symptoms, including sleep disturbances, may occur even if zaleplon has been used only for a short time.

KEY TERMS

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy as well as by dissociation.

Antidepressant—A medication used to treat the symptoms of depression.

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

Antipsychotic—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Hypnotic—A type of medication that induces sleep.

Milligram (mg)—One-thousandth of a gram. A gram is the metric measure that equals approximately 0.035 ounces.

Tuberculosis—An infection caused by the bacteria *Mycobacterium tuberculosis* that usually affects the lungs. Individuals with tuberculosis may have nighttime sweating, fever, weight loss, cough, and may spit up blood and mucus.

Side effects

Some sleeping pills such as zaleplon can cause aggressiveness, agitation, **hallucinations**, and **amnesia** (memory problems). A patient experiencing these side effects should call a physician immediately. A physician should also be called immediately if a person taking zaleplon develops a fast or irregular heartbeat, chest pains, skin rash, or itching.

The most common side effects of zaleplon are less serious and include dizziness, drowsiness, impaired coordination, upset stomach, nausea, headache, dry mouth, and muscle aches. Other side effects that may occur include: fever, amnesia, tremor, or eye pain. Many side effects appear worse at higher doses, so it is important to use the lowest dose that will induce sleep.

Interactions

Any drug that causes drowsiness may lead to substantially decreased mental alertness and impaired motor skills when taken with zaleplon. Some examples include alcohol, antidepressants such as **imipramine** or **paroxetine**,

antipsychotics like **thioridazine**, and some antihistamines.

Because zaleplon is broken down by the liver, it may interact with other drugs broken down by the liver. For example, the drug rifampin, which is used to treat tuberculosis, may cause zaleplon to be less effective. Alternatively, cimetidine (Tagamet), a drug commonly used to treat heartburn, may cause people to be more sensitive to zaleplon.

Ziprasidone

Definition

Ziprasidone is a drug used to treat **schizophrenia**. It is available with a prescription under the brand name Geodan.

Purpose

Ziprasidone is in a class of drugs called antipsychotics. It is used to control symptoms of schizophrenia.

Description

The United States Food and Drug Administration approved ziprasidone for treatment of schizophrenia in 2001. Mental well-being is partially related to maintaining a balance between naturally occurring chemicals in the **brain** called **neurotransmitters**. Ziprasidone is thought to modify the actions of several neurotransmitters and in this way restore appropriate function to chemical systems in the brain that are out of balance in people with schizophrenia.

Recommended dosage

The dosage of ziprasidone varies widely from one individual to another. A common initial dosage is 20 mg of ziprasidone taken twice daily. The dosage is gradually increased until symptoms of schizophrenia subside.

Dosages of up to 100 mg may be taken twice daily. Ziprasidone should be taken with food.

Precautions

Ziprasidone may alter the rhythm of the heart. Because of the risk of irregular heartbeats or even death, it should not be taken by people with a history of irregular or prolonged heart rhythms (long QT syndrome), those with heart failure, or individuals who have recently had a heart attack. People with a history of heart disease should discuss the risks and benefits of treatment with their doctor before starting ziprasidone. Ziprasidone may lower blood pressure to dangerously low levels, causing people to faint. It should not be taken by people who have slow heartbeats and those with low levels of potassium or magnesium in their blood.

Individuals with a history of seizure, even seizure brought on by drug or alcohol abuse, should use ziprasidone cautiously and with close physician supervision, because it may increase the tendency to have **seizures**.

Ziprasidone may increase body temperatures to dangerously high levels. People who exercise strenuously, those exposed to extreme heat, individuals taking drugs with anticholinergic effects (this includes many common antidepressants), and persons prone to dehydration, should use the drug cautiously and be alert to dehydration-related side effects. Elderly persons with increased risk of developing pneumonia should be carefully monitored while taking ziprasidone. Because there is a high incidence of **suicide** in all patients with psychotic illnesses, people using ziprasidone should be observed carefully for signs of suicidal behavior. Women who are pregnant or breast-feeding should not take ziprasidone.

Side effects

The most common reason that ziprasidone is stopped is due to development of a rash. Another common side effect is drowsiness. This side effect is usually worse when starting the drug and becomes less severe with continued use. People performing tasks that require mental alertness such as driving or operating machinery should refrain from doing so until they see how the drug affects them. Other side effects that may occur are abnormal, involuntary twitching (5%), and respiratory disorders (8%). Nausea, constipation, indigestion, and dizziness due to low blood pressure occur in more than 5% of people taking ziprasidone.

Other, less common, side effects are rapid heartbeats, low blood pressure, agitation, tremor, confusion,

KEY TERMS

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Milligram (mg)—One-thousandth of a gram. A gram is the metric measure that equals about 0.035 ounces.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

amnesia, dry mouth, increased salivation, joint pains, and abnormal vision.

The incidence of some adverse effects such as low blood pressure, anorexia, abnormal involuntary movements, sleepiness, tremor, cold symptoms, rash, abnormal vision, dry mouth or increased salivation appears to increase at higher dosages.

People taking ziprasidone should alert their health care provider immediately if they develop a rash or hives since this could indicate a potentially serious adverse reaction. Patients should also notify their health care provider immediately if they experience any abnormal involuntary muscle movements. People who think they may be experiencing any side effects from this or any other medication should talk to their physicians.

Interactions

Ziprasidone interacts with many other drugs. It is a good idea to review all medications being taken with a physician or pharmacist before starting this drug. Since ziprasidone may alter the rhythm of the heart, people who are also taking drugs such as quinidine, dofetilide, **pimozide**, sotalol, erythromycin, **thioridazine**, moxifloxacin, and sparfloxacin should not take it. These drugs may also affect properties of the heart and taken with ziprasidone increase the risk of irregular heart rhythms

and other cardiac problems. Because ziprasidone causes sleepiness, it should be used sparingly and with care with other drugs that also have a tendency to make people drowsy such as antidepressants, antihistamines, some pain relievers, and alcohol. Ziprasidone may lower blood pressure to the point at which people feel dizzy or faint. People taking medication to regulate their blood pressure should have their blood pressure monitored and treatment modified as needed. Ziprasidone may also decrease the effects of drugs used to treat Parkinson's disease such as levodopa.

Other drugs taken in combination with ziprasidone may alter the effects of ziprasidone. For example, drugs such as **carbamazepine**, used to treat seizures, increases liver metabolism and may cause ziprasidone to be less effective. Alternatively, drugs such as ketoconazole slow liver metabolism and may increase negative side effects associated with ziprasidone.

Zolpidem

Definition

Zolpidem is classified as a hypnotic drug. These drugs help people sleep. In the United States, zolpidem is available as tablets under the brand name of Ambien.

Purpose

Zolpidem is a drug that is used to treat **insomnia**. Zolpidem is especially helpful for people who have trouble falling asleep. However, once individuals have fallen asleep, zolpidem also helps them continue to sleep restfully. Zolpidem should be used only for short periods, approximately seven to ten days. If sleeping pills are needed for a long period, an evaluation by a physician is recommended to determine if another medical condition is responsible for the insomnia.

Description

Although the way zolpidem helps people sleep is not entirely understood, it is believed to mimic a chemical in the **brain** called gamma-aminobutyric acid (GABA) that naturally helps to facilitate sleep. Zolpidem is a central nervous system depressant. This means that it slows down the nervous system. Unlike some sleeping pills, zolpidem does not interfere with the quality of sleep or usually leave the user feeling sedated in the morning. As a result, most people using zolpidem usually awake feeling refreshed in the morning.

Recommended dosage

The usual dose of zolpidem in adults is 5–10 mg. For healthy adults, 10 mg is commonly recommended. However, people taking other drugs that cause drowsiness, people who have severe health problems, especially liver disease, and older people (over age 65) should take a lower dose, usually 5 mg. Zolpidem should be taken immediately before bedtime and only if the person can count on getting seven or eight hours of uninterrupted sleep. It usually takes only about 30 minutes for the sleep-inducing actions of zolpidem to be felt. Unlike some sleeping pills, the sleep-facilitating effects appear to last six to eight hours.

If zolpidem is taken with a meal, it will take longer to work. For the fastest sleep onset, it should be taken on an empty stomach. The maximum dose for one day is 10 mg. People who miss a dose of zolpidem should skip the missed dose, and take the next dose at the regularly scheduled time. Under no circumstances should a person take more than 10 mg in one day. Zolpidem should be taken exactly as directed by the prescribing physician.

Precautions

Because zolpidem is used to help people fall asleep, it should not be used with other drugs (either over-the-counter, herbal, or prescription) that also cause drowsiness (for example, antihistamines or alcohol). Zolpidem should be used only with close physician supervision in people with liver disease and in the elderly, because these individuals are especially sensitive to the sedative properties of zolpidem. Zolpidem should not be used before driving, operating machinery, or performing activities that require mental alertness. People with a history of drug abuse, psychiatric disorders, or depression should be carefully monitored when using zolpidem since zolpidem may worsen symptoms of some psychiatric disorders.

If zolpidem is needed for more than seven to ten days, patients should be re-evaluated by a physician to determine if another disorder is causing their difficulty

Antidepressant—A medication used to treat the symptoms of depression.

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

sleeping. When zolpidem or other sleeping pills are used every night for more than a few weeks, they begin to lose their effectiveness and/or people may become dependent upon them to fall asleep. Zolpidem can be habit-forming when taken over a long period. People using zolpidem should not stop taking the drug suddenly, but gradually reduce the dose over a few days before quitting, even if zolpidem has been used only a for short time.

Side effects

Some sleeping pills such as zolpidem can cause aggressiveness, agitation, **hallucinations**, and **amnesia**

(memory problems), rapid, racing heartbeat, and chest pains. These side effects are rare, but the patient should call a physician immediately if they occur.

Side effects that occur in more than 5% of patients are headache, nausea, muscle aches, and drowsiness. Although drowsiness is desired when trying to fall asleep, a few people continue to be drowsy the next day. Daytime drowsiness may cause people, especially the elderly, to be less coordinated and more susceptible to falls. Other less common side effects are anxiety, confusion, dizziness, and stomach upset.

Interactions

Any drug that causes drowsiness may lead to substantially decreased mental alertness and impaired motor skills when taken with zolpidem. Some examples include alcohol, antidepressants such as **imipramine** or **paroxetine**, antipsychotics such as **thioridazine**, and antihistamines (commonly found in allergy and cold medications).

The effectiveness of zolpidem may be reduced if taken with rifampin, an antibiotic that is commonly used to treat tuberculosis infections.

GLOSSARY

A

ABSENCE SEIZURE. An epileptic seizure characterized by a sudden, momentary loss of consciousness, occasionally accompanied by some minor, jerky movements in the neck or upper arms, a twitching of the face, or a loss of muscle tone.

ABSTINENCE. Refraining from sexual intercourse for a period of time; may also refer to refraining from use of a substance, such as alcohol.

ABSTRACTION. Ability to think about concepts or ideas separate from specific examples.

ABUSE. Substance abuse is a milder form of addiction than substance dependence. Generally, people who have been diagnosed with substance abuse don't experience the tolerance or withdrawal symptoms—the signs of physiological dependence—that people dependent on a substance experience.

ACETYLCHOLINE. A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

ACETYLCHOLINESTERASE. The chemical responsible for the breakdown of acetylcholine.

ACTIVE COPING STRATEGIES. Ways of handling stress that affect the problem or situation in some way.

ACUTE PSYCHOSIS. A severe mental disorder marked by delusions, hallucinations, and other symptoms that indicate that the patient is not in contact with reality.

ACUTE STRESS DISORDER. Symptoms occurring in an individual following a traumatic event to oneself or surrounding environment. Symptoms include a continued response of intense fear, helplessness, or terror within four

weeks of the event, extreme nervousness, sleep disorders, increased anxiety, poor concentration, absence of emotional response to surroundings, and sometimes a dissociative amnesia—not recalling the significance of the trauma. Symptoms last a minimum of two days and maximum of four weeks. Can become post-traumatic stress disorder.

ADAPTOGEN. A remedy that helps the body adapt to change, and thus lowers the risk of stress-related illnesses.

ADDICTION. A compulsive need for, and use of, a habit-forming substance or behavior.

ADDICTIVE DISORDER. A disorder involving repetitive participation in a certain activity, in spite of negative consequences and despite attempts to stop the behavior. Alcohol abuse is an example.

ADDISON'S DISEASE. Disease caused by malfunctioning adrenal glands that can be treated with cortisol replacement therapy. Symptoms include anemia, low blood pressure, digestive complaints, and diarrhea.

ADENOSINE. A compound that serves to modulate the activities of nerve cells (neurons) and to produce a mild sedative effect when it activates certain types of adenosine receptors. Caffeine is thought to produce its stimulating effect by competing with adenosine for activation of these receptors.

ADJUNCT. A form of treatment that is not strictly necessary to a therapy regimen but is helpful.

ADJUSTMENT DISORDER. A disorder defined by the development of significant emotional or behavioral symptoms in response to a stressful event or series of events. Symptoms may include depressed mood, anxiety, and impairment of social and occupational functioning.

ADRENAL GLAND. A small organ located above each kidney that produces hormones related to the sex drive.

ADRENALINE. Another name for epinephrine, the hormone released by the adrenal glands in response to

stress. It is the principal blood pressure-raising hormone and a bronchial and intestinal smooth muscles relaxant.

AEROSOL. A liquid substance sealed in a metal container under pressure with an inert gas that propels the liquid as a spray or foam through a nozzle.

AFFECT. The expression of emotion displayed to others through facial expressions, hand gestures, tone of voice, etc. Types of affect include: flat (inanimate, no expression), blunted (minimally responsive), inappropriate (incongruous expressions of emotion relative to the content of a conversation), and labile (sudden and abrupt changes in type and intensity of emotion).

AFFECTIVE DISORDER. A disorder involving extreme emotional experience that is not congruent with the environmental circumstances (for example, feeling sad when there is no easily identifiable reason, as in depression).

AGE-ASSOCIATED MEMORY IMPAIRMENT (AAMI). A condition in which an older person suffers some memory loss and takes longer to learn new information. AAMI is distinguished from dementia in that it is not progressive and does not represent a serious decline from the person's previous level of functioning. Benign senescent forgetfulness is another term for AAMI.

AGITATION. Excessive restlessness or emotional disturbance often associated with anxiety or psychosis. Agitation may be associated with middle-stage Alzheimer's disease.

AGNOSIA. Loss of the ability to recognize familiar people, places, and objects.

AGONIST. A chemical that reproduces the mechanism of action of a neurotransmitter.

AGORAPHOBIA. People with this condition worry that they will not be able to get help or flee a place if they have a panic attack and may refuse to go to places that might trigger a panic attack.

AGRANULOCYTOSIS. A blood disorder characterized by a reduction in the number of circulating white blood cells (granulocytes). White blood cells defend the body against infections. Agranulocytosis is a potential side effect of some of the newer antipsychotic medications used to treat schizophrenia.

AKATHISIA. Agitated or restless movement, usually affecting the legs. Movement is accompanied by a sense of discomfort and an inability to sit, stand still, or remain inactive for periods of time. Akathisia is a common side effect of some neuroleptic (antipsychotic) medications.

AKINESIA. Absence of physical movement.

ALBUMIN. A simple protein that is widely distributed in human blood.

ALLOSTASIS. The process of an organism's adaptation to acute stress.

ALOPECIA. Hair loss (also, loss of feathers or wool in animals).

ALTER. An alternate or secondary personality in a person with dissociative identity disorder. Each alter has a unique way of looking at and interacting with the world.

ALVEOLAR. Pertaining to alveoli, which are tiny air sacs at the ends of the small air passages in the lungs.

ALZHEIMER'S DISEASE. An incurable dementia marked by the loss of cognitive ability and memory over a period of 10–15 years. Usually affects elderly people.

AMBULATION. Ability to walk.

AMENORRHEA. Absence of menstrual periods.

AMINO ACID. A building block of protein.

AMNESIA. A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy, as well as by dissociation.

AMNIOCENTESIS. A test usually done between 16 and 20 weeks of pregnancy to detect any abnormalities in the development of the fetus. A small amount of the fluid surrounding the fetus (amniotic fluid) is drawn out through a needle inserted into the mother's womb. Laboratory analysis of this fluid can detect various genetic defects, such as Down syndrome, or neural tube defects.

AMOTIVATIONAL SYNDROME. Loss of ambition associated with chronic cannabis (marijuana) use.

AMPHETAMINE ABUSE. An amphetamine problem in which the user experiences negative consequences from the use, but has not reached the point of dependence.

AMPHETAMINE DEPENDENCE. The most serious type of amphetamine problem.

AMPHETAMINE INTOXICATION. The effects on the body that develop during or shortly after amphetamine use.

AMPHETAMINE WITHDRAWAL. Symptoms that develop shortly after reducing or stopping heavy amphetamine use.

AMPHETAMINES. A group of powerful and highly addictive substances that stimulate the central nervous system. May be prescribed for various medical conditions, but are often purchased illicitly and abused.

AMYGDALA. An almond-shaped brain structure in the limbic system that is activated in stressful situations to trigger the emotion of fear. It is thought that the emotional overreactions in Alzheimer's patients are related to the destruction of neurons in the amygdala.

AMYLOID. A waxy translucent substance composed mostly of protein, that forms plaques (abnormal deposits) in the brain during the progression of Alzheimer's disease.

ANALEPTIC. A substance that acts as a stimulant of the central nervous system. Caffeine is classified as an analeptic.

ANALGESIC. A substance that provides relief from pain.

ANANDAMIDE. One type of endocannabinoid that appears to help regulate early pregnancy.

ANANKASTIC PERSONALITY DISORDER. The European term for obsessive-compulsive personality disorder.

ANDROGYNY. A way of behaving that includes high levels of both masculinity and femininity.

ANEMIA. Condition that results when there is a deficiency of oxygen in the blood. Can cause fatigue and impair mental functions.

ANEURYSM. A symptomless bulging of a weak arterial wall that can rupture, leading to stroke.

ANGINA. Severe pain and a feeling of constriction around the heart.

ANGIOGRAPHY. A procedure in which a contrast medium is injected into the bloodstream (through an artery in the neck) and its progress through the brain is tracked. This illustrates where a blockage or hemorrhage has occurred.

ANHEDONIA. Loss of the capacity to experience pleasure. Anhedonia is one of the so-called negative symptoms of schizophrenia, and is also a symptom of major depression.

ANOREXIA. Loss of appetite or unwillingness to eat. Can be caused by medications, depression, or many other factors.

ANOREXIA NERVOSA. An eating disorder characterized by an intense fear of weight gain accompanied by a distorted perception of one's own underweight body.

ANOSOGNOSIA. Lack of awareness of the nature of one's illness. The term is usually applied to stroke patients, but is sometimes used to refer to lack of insight on the part of patients with schizophrenia. Anosognosia appears to be caused by the illness itself; it does not

appear to be a form of denial or inappropriate coping mechanism. It is, however, a factor in nonadherence to treatment regimens and the increased risk of relapse.

ANOXIA. Lack of oxygen.

ANTI-ANXIETY AGENT. A medication that is used to treat symptoms of generalized fear that dominates a person's life.

ANTAGONIST. A substance whose actions counteract the effects of or work in the opposite way from another chemical or drug.

ANTECEDENTS. Events that occur immediately before the target behavior.

ANTEROGRADE AMNESIA. Amnesia for events that occurred after a physical injury or emotional trauma but before the present moment.

ANTHELMINTHIC. A type of medication given to expel or eliminate intestinal worms.

ANTICHOLINERGIC. Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

ANTICHOLINERGIC TOXICITY. A poisonous effect brought about by ingestion of medications or other toxins that block acetylcholine receptors. When these receptors are blocked, the person taking the medication may find that he or she gets overheated, has dry mouth, has blurry vision, and his or her body may retain urine.

ANTICIPATION. In medicine, a phenomenon in which certain diseases manifest at earlier ages or in more severe phenotypes in each successive generation of an affected family.

ANTICOAGULANT. A medication (such as warfarin, Coumadin, or Heparin) that decreases the blood's clotting ability, preventing the formation of new clots. Although anticoagulants will not dissolve existing clots, they can stop them from getting larger. These drugs are commonly called blood thinners.

ANTICONVULSANT MEDICATION. A medication that prevents convulsions or seizures; often prescribed in the treatment of epilepsy. Several anticonvulsant medications have been found effective in the treatment of bipolar disorder.

ANTIDEPRESSANT. A medication used to treat the symptoms of depression.

ANTIHISTAMINE. A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

ANTIHYPERTENSIVE. An agent used in the treatment of hypertension (high blood pressure).

ANTIOXIDANT. Substance that protects the body from damaging reactive oxygen molecules in the body. These reactive oxygen molecules can come from inside the body or from environmental pollution and are thought to play a role in the aging process and the development of degenerative disease.

ANTIPSYCHOTIC MEDICATION. A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions, and delirium. May be used to treat symptoms in other disorders, as well.

ANTISOCIAL BEHAVIOR. Behavior characterized by high levels of anger, aggression, manipulation, or violence.

ANTISOCIAL PERSONALITY DISORDER. Disorder characterized by behavior pattern of disregard for others' rights. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy or psychopathy.

ANTISPASMODIC. A medication or preparation given to relieve muscle or digestive cramps.

ANXIETY. A feeling of apprehension and fear characterized by physical symptoms (heart palpitations, sweating, and feelings of stress, for example).

ANXIETY AND ANXIETY DISORDERS. Chronic conditions that can be characterized by an excessive and regular sense of apprehension, with physical symptoms such as sweating, palpitations, and feelings of stress. Anxiety disorders can be caused by biological and environmental events.

ANXIETY-REDUCTION TECHNIQUES. Skills taught by a therapist to help an individual overcome anxiety, stress, and tension, and can include relaxation, visualization and imagery, diaphragmatic breathing, stress inoculation, and meditation.

ANXIOLYTIC. A preparation or substance given to relieve anxiety; a tranquilizer.

APATHY. Lack of feelings or emotions.

APHASIA. Loss of language abilities.

APHONIA. Inability to speak caused by a functional disturbance of the voice box or vocal cords.

APHRODISIAC. A medication or preparation given to stimulate sexual desire.

APLASTIC ANEMIA. A form of anemia in which the bone marrow does not produce adequate amounts of peripheral blood components such as red cells, white cells, and platelets.

APNEA. A brief suspension or interruption of breathing.

APOLIPOPROTEIN E. A protein that transports cholesterol through the body. One form of this protein, apoE4, is associated with a 60% risk of late-onset Alzheimer's disease.

APPERCEPTION. The process of understanding through linkage with previous experience. The term was coined by one of the authors of the Thematic Apperception Test to underscore the fact that people don't "perceive" the story cards in a vacuum; rather, they construct their stories on the basis of past experiences as well as present personality traits.

APPETITE SUPPRESSANTS. Medications that assist in weight loss by reducing appetite or increasing the sensation of fullness.

APRAXIA. Inability to perform purposeful movements that is not caused by paralysis or loss of feeling.

ARRHYTHMIA. Any disturbance in the normal rhythm of the heartbeat.

ARSON. The deliberate setting of fires for criminal purposes, usually to collect insurance money or to cover up evidence of another crime. It is distinguished from pyromania by its connection with planning and forethought rather than failure of impulse control.

ARTERIOSCLEROSIS. A thickening, hardening, and loss of elasticity of the walls of the arteries.

ASANA. The Indian term for the poses or postures that are done in sequence during hatha yoga practice.

ASPERGER'S DISORDER. A condition in which young children experience impaired social interactions and develop limited repetitive patterns of behavior.

ASSAULTIVE. An act with intent of causing harm.

ASSERTIVE. Confidently self-assured; able to express oneself constructively and directly.

ASSESSMENT. In the context of psychological assessment (a structured interview), assessment is information-gathering to diagnose a mental disorder.

ASSISTED SUICIDE. A form of self-inflicted death in which a person voluntarily brings about his or her own

death with the help of another, usually a physician, relative, or friend.

ASSOCIATIONISM. A theory about human learning that explains complex psychological phenomena in terms of coincidental relationships. For example, a person with agoraphobia who is afraid of riding in a car may have had a panic attack in a car on one occasion and has learned to associate cars with the physical symptoms of a panic attack.

ASTRINGENT. A substance or compound that causes contraction or constriction of soft tissue.

ATAQUE DE NERVIOS. A culture-specific anxiety syndrome found among some Latino groups in the United States and in Latin America. It resembles panic disorder in some respects but also includes dissociative symptoms, and frequently occurs in response to a stressful event.

ATHEORETICAL. Unrelated to any specific theoretical approach or conceptual framework. The classification system of *DSM-IV-TR* is atheoretical.

ATHEROSCLEROSIS. Clogging of the arteries, creating a risk factor for stroke.

ATRIAL FIBRILLATION. A disorder in which the upper chambers (atria) of the heart do not completely empty with each contraction (heartbeat). This can allow blood clots to form and is associated with a higher risk of stroke.

ATTENTION DEFICIT DISORDER. A condition that mostly affects children and involves the inability to concentrate on various tasks.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER (ADHD). A learning and behavioral disorder characterized by difficulty in sustaining attention, impulsive behavior, and excessive activity.

ATYPICAL ANTIPSYCHOTICS. A group of newer medications for the treatment of psychotic symptoms that were introduced in the 1990s. The atypical antipsychotics include clozapine, risperidone, quetiapine, ziprasidone, and olanzapine. They are sometimes called serotonin dopamine antagonists, or SDAs.

AUDITORY. Pertaining to the sense of hearing.

AURA. An energy field that is thought to emanate from the human body and to be visible to people with special psychic or spiritual powers.

AUTISM. A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

AUTISTIC PSYCHOPATHY. Hans Asperger's original name for the condition now known as Asperger's disorder. It is still used occasionally as a synonym for the disorder.

AUTONOMIC NERVOUS SYSTEM. The part of the nervous system that governs the heart, involuntary muscles, and glands.

AVERSION. A strong feeling of dislike or disgust. Aversion therapy makes use of this feeling to reduce or eliminate an undesirable behavior.

AVERSION THERAPY. An approach to treatment in which an unpleasant or painful stimulus is linked to an undesirable behavior in order to condition the patient to dislike or avoid the behavior. Chemicals or medications used to produce unpleasant effects are called aversants.

AVOIDANT COPING STRATEGIES. Ways of coping with stress that do not alter the problem in any way, but instead provide temporary relief or distraction.

AYURVEDIC MEDICINE. The traditional medical system of India. Ayurvedic treatments include diet, exercises, herbal treatments, meditation, massage, breathing techniques, and exposure to sunlight.

B

BACK-UP REINFORCER. A desirable item, privilege, or activity that is purchased with tokens and serves as a delayed reward and subsequent motivation for desired behavior.

BARBITURATES. A class of medications (including Seconal and Nembutal) that causes sedation and drowsiness. They may be prescribed legally but may also be used as drugs of abuse.

BASAL GANGLIA. A group of masses of gray matter located in the cerebral hemispheres of the brain that control movement as well as some aspects of emotion and cognition.

BASELINE DATA. Information regarding the frequency and severity of behavior, gathered before treatment begins.

BATTERY. A number of separate items (such as tests) used together. In psychology, a group or series of tests given with a common purpose, such as personality assessment or measurement of intelligence.

BEHAVIOR. A stereotyped motor response to an internal or external stimulus.

BEHAVIOR DISORDERS. Disorders characterized by disruptive behaviors such as conduct disorder, oppositional defiant disorder, and attention-deficit/hyperactivity disorder.

BEHAVIOR MODIFICATION. An approach to therapy based on the principles of operant conditioning. Behavior modification seeks to replace undesirable behaviors with preferable behaviors through the use of positive or negative reinforcement.

BEHAVIOR THERAPIES. Numerous techniques all having their roots in principles of learning.

BEHAVIORAL CONTRACTS. A behavioral contract is a written agreement that defines the behaviors to be performed and the consequences of the specified behaviors.

BEHAVIORAL DEFICIENCY. Failure to engage in a positive, desirable behavior frequently enough.

BEHAVIORAL EXCESS. Engaging in negative, undesirable behavior too often.

BEHAVIORAL INHIBITION. A set of behaviors that appear in early infancy that are displayed when the child is confronted with a new situation or unfamiliar people. These behaviors include moving around, crying, and general irritability, followed by withdrawing and seeking comfort from a familiar person. These behaviors are associated with an increased risk of social phobia and panic disorder in later life. Behavioral inhibition in children appears to be linked to anxiety and mood disorders in their parents.

BEHAVIORAL PHENOTYPE. A term that refers to the greater likelihood that people with a specific genetic syndrome will have certain behavioral or developmental characteristics, compared to people who do not have the syndrome.

BEHAVIORAL THERAPY. An approach to treatment that focuses on extinguishing undesirable behavior and replacing it with desired behavior.

BENIGN PROSTATE HYPERTROPHY. Enlargement of the prostate gland.

BENZODIAZEPINES. A group of central nervous system depressants used to relieve anxiety or to induce sleep.

BEREAVEMENT. The emotional experience of loss after the death of a friend or relative.

BETA AMYLOID PROTEIN. A starchy substance that builds up in the brains of people with Alzheimer's disease to form the plaques that are characteristic of the disease. Beta amyloid is formed when amyloid precursor protein, or APP, is not broken down properly by the body.

BETA BLOCKER. Drugs that block beta-adrenergic receptors on neurons in the central nervous system. When these sites are blocked, heart rate, blood pressure, and anxiety levels decrease.

BEZOAR. A hard ball of hair or vegetable fiber that may develop in the stomach of humans as the result of ingesting nonfood items.

BINGE. An excessive amount of food consumed in a short period of time. Usually, while a person binge-eats, he or she feels disconnected from reality, and feels unable to stop. The bingeing may temporarily relieve depression or anxiety, but after the binge, the person usually feels guilty and depressed.

BINGEING. An excessive amount of food consumed in a short period of time. Usually, while a person binge-eats, he or she feels disconnected from reality, and feels unable to stop. The bingeing may temporarily relieve depression or anxiety, but after the binge, the person usually feels guilty and depressed.

BIOAVAILABILITY. Medication that is available in the body. If the bioavailability of a drug is increased, more is available to the body for use, and if it is decreased, less is available for use.

BIOCHEMICAL. Chemical reactions occurring in living systems.

BIOFEEDBACK. Biofeedback is a technique that uses monitoring instruments to measure and feed back information about muscle tension, heart rate, sweat responses, skin temperature, or brain activity.

BIOFIELD THERAPIES. A subgroup of energy therapies that make use of energy fields (biofields) thought to exist within or emanate from the human body. Biofield therapies include such approaches as Reiki, therapeutic touch, qigong, and polarity balancing.

BIOLOGICAL MARKER. An indicator or characteristic trait of a disease that facilitates differential diagnosis (the process of distinguishing one disorder from other, similar disorders).

BIOPSYCHOSOCIAL HISTORY. A history of significant past and current experiences that influence client behaviors, including medical, educational, employment, and interpersonal experiences. Alcohol or drug use and involvement with the legal system are also assessed in a biopsychosocial history.

BIOPSYCHOSOCIAL MODEL. A hypothetical explanation for why something occurs that includes biological, psychological, and social causes or correlates.

BIOSOCIAL. A biosocial model in psychology asserts that social and biological factors contribute toward the development of personality.

BIPOLAR AFFECTIVE DISORDER. A disorder in which a person alternates manic and depressive episodes.

BIPOLAR DISORDER (FORMERLY MANIC-DEPRESSIVE DISORDER). A mental disorder characterized by dramatic and sometimes rapid mood swings, resulting in both manic and depressive episodes.

BIPOLAR DISORDER NOT OTHERWISE SPECIFIED. Disorder of mood involving mood swings that do not meet criteria for other disorders specified above.

BIPOLAR DISORDERS. Disorders characterized by wide fluctuations in mood.

BIPOLAR I DISORDER. A major mood disorder characterized by full-blown manic episodes, often interspersed with episodes of major depression.

BIPOLAR II DISORDER. Disorder with major depressive episodes and mild manic episodes known as hypomania.

BLACKOUT. A period of loss of consciousness or memory.

BLENDED FAMILY. A family formed by the remarriage of a divorced or widowed parent. It includes the new husband and wife, plus some or all of their children from previous marriages.

BLEOMYCIN HYDROLASE. An enzyme involved in the body's processing of amyloid precursor protein. If the gene that governs production of BH mutates, the APP accumulates, producing the plaques in the brains of patients with Alzheimer's disease.

BLUNTED AFFECT. A term that refers to the loss of emotional expressiveness sometimes found in patients with schizophrenia. It is sometimes called flattened affect.

BODY IMAGE. A term that refers to a person's inner picture of his or her outward appearance. It has two components: perceptions of the appearance of one's body, and emotional responses to those perceptions.

BODY MASS. The quantity of matter in the body (measured by dividing weight by acceleration due to gravity).

BODY MASS INDEX, OR BMI. A measure of body fat, calculated as weight in kilograms over the square of height in meters.

BODYWORK. Any technique involving hands-on massage or manipulation of the body.

BORDERLINE PERSONALITY DISORDER. A severe and usually life-long mental disorder characterized by violent mood swings and severe difficulties in sustaining interpersonal relationships.

BRACHYCARDIA. Slow heartbeat, defined as a rate of less than 60 beats per minute.

BRAIN STEM. The part of the brain that is continuous with the spinal cord and controls most basic life functions. It is the last part of the brain that is destroyed by Alzheimer's disease.

BREEMA. An alternative therapy that originated in California in the 1980s. Breema combines biofield therapy with certain elements of chiropractics and bodywork.

BRUXISM. Habitual, often unconscious, grinding of the teeth.

BULIMIA NERVOSA. An eating disorder characterized by binges in which large amounts of food are consumed, followed by forced vomiting.

BUPRENORPHINE. A medication that blocks some of the withdrawal effects during heroin detoxification.

BURDEN. First described by Treudley in 1946, this term generally refers to the consequences for the family of close contact with a person who is severely mentally ill.

BURNOUT. An emotional condition that interferes with job performance, marked by fatigue, loss of interest, or frustration; usually regarded as the result of prolonged stress.

C

CAFFEINISM. A disorder caused by ingesting very high doses of caffeine (10g or more per day) and characterized by seizures and respiratory failure.

CALORIE. The quantity of heat necessary to raise the temperature of 1kg of water 1°C.

CANCER SCREENING. A procedure designed to detect cancer even though a person has no symptoms, usually performed using an imaging technique.

CANNABIS. The collective name for several varieties of Indian hemp plant. Also known as marijuana.

CANNABIS ABUSE. Periodic use of cannabis, less serious than dependence, but still capable of causing problems for the user.

CANNABIS DEPENDENCE. The compulsive need to use cannabis, leading to problems.

CANNABIS INTOXICATION. The direct effects of acute cannabis use and the reactions that accompany those effects.

CAPITATED PAYMENT SYSTEM. A contract between managed care organizations and health care providers involving a prepaid amount for blocks of services.

CARDIAC TAMPONADE. A condition in which blood leaking into the membrane surrounding the heart puts pressure on the heart muscle, preventing complete filling of the heart's chambers and normal heartbeat.

CARMINATIVE. A substance or preparation that relieves digestive gas.

CARPAL TUNNEL SYNDROME. A disorder of the hand and wrist characterized by pain, weakness, or numbness in the thumb and other fingers. It is caused by pressure on a nerve in the wrist. Carpal tunnel syndrome is frequently associated with heavy use of a computer, typewriter, or musical keyboard.

CARRIER. A vegetable oil such as safflower, olive, grapeseed, or wheatgerm oil used to dilute essential oils for massage.

CARVE-OUT PLANS. Managed care plans that make provision for mental health services by creating subcontracts involving different terms of payment and utilization review from those used for general health care.

CASE MANAGER. A professional who designs and monitors implementation of comprehensive care plans (i.e., services addressing medical, financial, housing, psychiatric, vocational, social needs) for individuals seeking mental health or social services.

CASE RATE. A type of contract between managed care organizations and health care providers involving a prepaid amount for services on a case-by-case basis.

CASTRATION. Desexing a person or animal by surgical removal of the testes (in males) or ovaries (in females). Castration is sometimes offered as a treatment option to violent rapists and pedophiles who are repeat offenders.

CATALEPSY. An abnormal condition characterized by postural rigidity and mental stupor, associated with certain mental disorders.

CATAPLEXY. A symptom of narcolepsy marked by a sudden episode of muscle weakness triggered by strong emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the

patient may become paralyzed for a few seconds to minutes.

CATATONIC BEHAVIOR OR CATATONIA. Term that describes both possible extremes related to movement. Catalepsy is the motionless aspect of catatonia—a person with catalepsy may remain fixed in the same position for hours on end. Rapid or persistently repeated movements, frequent grimacing and strange facial expressions, and unusual gestures are the opposite end of the catatonia phenomenon, involving an excess or distorted extreme of movement.

CATATONIC DISORDER. A severe disturbance of motor behavior characterized by either extreme immobility or stupor, or by random and purposeless activity.

CATATONIC SCHIZOPHRENIA. A subtype of a severe mental disorder that affects thinking, feeling, and behavior, and that is also characterized by catatonic behaviors—either extreme stupor or random, purposeless activity.

CATCHMENT. In mental health, a term that refers to a particular geographical area served by a particular mental health agency.

CATECHOLAMINE. A group of neurotransmitters synthesized from the amino acid tyrosine and released by the hypothalamic-pituitary-adrenal system in the brain in response to acute stress. The catecholamines include dopamine, serotonin, norepinephrine, and epinephrine.

CATHARSIS. A powerful emotional release followed by a feeling of great relief.

CATHETERIZATION. Placing a tube in the bladder so that it can be emptied of urine.

CENTRAL NERVOUS SYSTEM DEPRESSANT. Any drug that lowers the level of stimulation or excitement in the central nervous system.

CENTRAL NERVOUS SYSTEM STIMULANT. Any drug that raises the level of activity in the central nervous system.

CEREBRAL ATERIOGRAPHY. A procedure that allows a wire to be inserted in blood vessels in the brain, which generates an image of diseases in these arteries.

CEREBROVASCULAR. Blood flow in the brain.

CERVIX. The neck or narrow lower end of a woman's uterus.

CHAKRA. One of the seven major energy centers in the body, according to traditional Indian yoga.

CHASING. Betting larger and larger sums of money, or taking greater risks, in order to make up for money previously lost in gambling.

CHELATION. A method of treating lead or mercury poisoning by giving medications that remove heavy metals from the bloodstream. The medications that are used are called chelating agents.

CHOLINESTERASE INHIBITORS. A group of medications given to slow the progression of Alzheimer's disease.

CHOREATHETOID MOVEMENTS. Repetitive dance-like movements that have no rhythm.

CHROMATHERAPY. An alternative form of light therapy in which colored light is directed toward a specific chakra or part of the body in order to heal or correct energy imbalances. Practitioners of chromatherapy are sometimes called chromapaths.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE. Disorder characterized by the decreasing ability of the lungs to ventilate adequately.

CHRYSIN. A flavonoid found in passionflower that may be the source of its anxiolytic properties.

CLASSICAL CONDITIONING. In psychology, a process in which a previously neutral stimulus eventually produces a specific response by being paired repeatedly with another stimulus that produces that response. The best-known example of classical conditioning is Pavlov's dogs, who were conditioned to salivate when they heard a bell ring (the previously neutral stimulus) because the sound had been paired repeatedly with their feeding time.

CLEARINGHOUSE. A centralized organization that is a repository of information and that facilitates access to information.

CLITORIS. The most sensitive area of the female external genitals. Stimulation of the clitoris causes most women to reach orgasm.

CLONIC-TONIC SEIZURE. This is the most common type of seizure among all age groups and is categorized into several phases beginning with vague symptoms hours or days before an attack. These seizures are sometimes called grand mal seizures.

CLOZAPINE. A newer antipsychotic medication that is often given to patients who are developing signs of tardive dyskinesia.

CLUSTER SUICIDE. Refers to the phenomenon of additional suicides being attempted or completed after one suicide has occurred within a small community, such as a group of high school students.

COCA PLANT. The plant that is the source of cocaine.

COCAINE. An illegal drug that increases energy and induces euphoria. It is addictive and is often abused.

CODEINE. A medication that may be prescribed but also may be purchased illegally and is used to reduce pain.

CODON. A three-member nucleotide sequence in messenger RNA that codes for a specific amino acid in synthesizing protein molecules.

COGNITION. The act or process of knowing or perceiving.

COGNITIVE. Pertaining to the mental processes of memory, perception, judgment, and reasoning.

COGNITIVE RESTRUCTURING. An approach to psychotherapy that focuses on helping the patient examine distorted patterns of perceiving and thinking in order to change their emotional responses to people and situations.

COGNITIVE STYLE. A way in which an individual works with and performs cognitive tasks such as reasoning, learning, thinking, understanding, making decisions, and using memory.

COGNITIVE THERAPY. Psychological treatment aimed at changing a person's way of thinking in order to change his or her behavior and emotional state.

COGNITIVE-BEHAVIORAL THERAPY (CBT). An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

COGWHEEL RIGIDITY. An abnormal rigidity in muscles, characterized by jerky movements when the muscle is passively stretched.

COITUS. Sexual intercourse.

COLD TURKEY. A slang term for stopping the use of nicotine (or any other addictive drug) suddenly and completely.

COMA. Unconsciousness.

COMMUNITY MENTAL HEALTH CENTERS. Organizations that manage and deliver a comprehensive range of mental health services, education, and outreach to residents of a given community.

COMMUNITY MENTAL HEALTH CENTERS ACT OF 1963. Federal legislation providing grants for the operation of community mental health centers and related services.

COMORBID. Having another disorder or condition simultaneously.

COMORBID PSYCHOPATHOLOGY. The presence of other mental disorders in a patient together with the disorder that is the immediate focus of therapy.

COMORBIDITY. Association or presence of two or more mental disorders in the same patient. A disorder that is said to have a high degree of comorbidity is likely to occur in patients diagnosed with other disorders that may share or reinforce some of its symptoms.

COMPENSATORY. Counterbalancing or offsetting. A compensatory strategy is one that makes up for or balances a weakness in some area of functioning.

COMPETING BEHAVIORS. Behaviors that interfere with the target behavior because they are preferred by the individual.

COMPLEX ABSENCE SEIZURE. Absence (petit mal) seizures usually begin with a brief loss of consciousness and last between one and 10 seconds. People having a petit mal seizure become very quiet and may blink, stare blankly, roll their eyes, or move their lips. A petit mal seizure lasts 15–20 seconds. When it ends, the individual resumes whatever he or she was doing before the seizure began, and may not realize that anything unusual happened.

COMPLEX SEIZURE. In complex seizures, the person experiences impaired consciousness.

COMPLIANCE. In medicine or psychiatry, cooperation with a treatment plan or schedule of medications.

COMPULSION. A strong impulse to perform an act, particularly one that is irrational or contrary to one's will.

CONDUCT DISORDER. A behavioral and emotional disorder of childhood and adolescence in which children display physical aggression and infringe on or violate the rights of others. Youths diagnosed with conduct disorder may set fires, exhibit cruelty toward animals or other children, sexually assault others, or lie and steal for personal gain.

CONFABULATION. In psychiatry, the filling-in of gaps in memory with false information that the patient believes to be true. It is not deliberate telling of lies.

CONGENITAL. Present at birth.

CONGESTIVE HEART FAILURE. Condition characterized by abdominal pain, swelling in the lower extremities, and weakness caused by a reduced output of blood from the left side of the heart.

CONGRUENCE. A quality of the client-centered therapist, consisting of openness to the client.

CONSEQUENCES. Events that occur immediately after the target behavior.

CONSTIPATION. Difficult bowel movements caused by the infrequent production of hard stools.

CONTINGENCIES. Naturally occurring or artificially designated reinforcers or punishers that follow a behavior.

CONTRAST AGENT, or MEDIUM. A substance injected into the body that illuminates certain structures that would otherwise be hard to see on the radiograph (film).

CONTROLLED BEHAVIOR. The behavior to be changed by self-control strategies; also known as the target behavior.

CONTROLLING BEHAVIORS. Self-control strategies used to change the controlled or target behavior.

CONVERSION. In psychiatry, a process in which a repressed feeling, impulse, thought, or memory emerges in the form of a bodily symptom.

CONVERSION DISORDER. A type of somatoform disorder in which unconscious psychological conflicts or other factors take the form of physical symptoms that are produced unintentionally.

CONVULSION. A violent, involuntary contraction or series of contractions of muscles.

COPING. In psychology, a term that refers to a person's patterns of response to stress.

COPROLALIA. A vocal tic characterized by uttering obscene, hostile, or inappropriate words. A motor tic characterized by obscene gestures is called copropraxia.

CORONARY OCCLUSION. Blockage of the arteries supplying the blood to the heart.

CORPUS CALLOSUM. (plural, corpora callosa) A thick bundle of nerve fibers lying deep in the brain that connects the two cerebral hemispheres and coordinates their functions.

CORTEX. Region in the brain where sensation and perception are processed and integrated into thoughts, memories, and abilities; also where actions are planned and initiated.

CORTICOSTEROIDS. Any one of a number of hormonal steroid compounds that are derived from the adrenal gland.

CORTISOL. A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress.

COVERT. Concealed, hidden, or disguised.

CRACK. A slang term for a form of cocaine that is smokable.

CREUTZFELDT-JAKOB DISEASE. A degenerative disease of the central nervous system caused by a prion, or “slow virus.”

CRITICAL INCIDENT. Also known as a crisis event. An event that is stressful enough to overwhelm the coping skills of a person or group.

CROSS-DRESSING. Wearing clothing and other attire appropriate to the opposite sex.

CRYSTALLIZED INTELLIGENCE. A type of intelligence that reflects knowledge and skills influenced by a person’s sociocultural environment.

CT SCAN. An imaging technique that uses a computer to combine multiple x-ray images into a two-dimensional cross-sectional image. The full name is *computed tomography*.

CUE. Any behavior or event in a person’s environment that serves to stimulate a particular response. For example, the smell of liquor may be a cue for some people to pour themselves a drink.

CUTOFF SCORES. In psychological testing, scores that indicate the borderline between normal and impaired functioning.

CYCLIC AMP. A small molecule of adenosine monophosphate (AMP) that activates enzymes and increases the effects of hormones and other neurotransmitters.

CYCLOTHYMIA. An alternate name for cyclothymic disorder.

CYCLOTHYMIC DISORDER. A relatively mild mood disorder characterized by mood swings between mild depression to mild mania.

CYTOGENETICS. The branch of biology that combines the study of genetic inheritance with the study of cell structure.

D

DAWN SIMULATION. A form of light therapy in which the patient is exposed while asleep to gradually brightening white light over a period of an hour and a half.

DECISION-MAKERS. In some mental health contexts, the term refers to prison or court officials, treatment facility administrators, or family members.

DECONDITIONING. Loss of physical strength or stamina resulting from bed rest or lack of exercise.

DEDUCTIBLE. The amount of money that must be paid out of pocket by health care consumers before the insurance provider will make payments.

DEFENSE. An unconscious mental process that protects the conscious mind from unacceptable or painful thoughts, impulses, or desires. Examples of defenses include denial, rationalization, projection, and repression. Some defenses are considered to represent lower levels of maturation than others; thus, identifying a child’s defenses may be helpful in evaluating his or her level of psychological maturity.

DEFENSE MECHANISMS. Indirect strategies used to reduce anxiety rather than directly facing the issues causing the anxiety.

DEINSTITUTIONALIZATION. The process of moving people out of mental hospitals into treatment programs or halfway houses in local communities. With this movement, the responsibility for care shifted from large (often governmental) agencies to families and community organizations.

DELIRIUM. A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from dementia by its relatively sudden onset and variation in the severity of the symptoms.

DELIRIUM TREMENS. Serious alcohol withdrawal symptoms that must be treated in a hospital and that may include shaking, delirium, and hallucinations.

DELTA-9-TETRAHYDROCANNABINOL(THC). The primary active ingredient in marijuana.

DELUSION. A false belief that is resistant to reason or contrary to actual fact. A patient may be convinced, for example, that someone is trying to poison him or her, or that he or she has a fatal illness despite evidence to the contrary.

DELUSIONAL DISORDER OF THE PERSECUTORY TYPE. A psychotic disorder characterized by a patient’s belief that others are conspiring against him or her.

DEMENCIA. A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person’s ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to

deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

DEMENTIA INFANTILIS. Another term for childhood disintegrative disorder, used more frequently in the European medical literature. The Latin name literally means “early childhood dementia.”

DEMENTIA PRAECOX. A late nineteenth-century term for schizophrenia.

DENIAL. A psychological defense mechanism that reduces anxiety by excluding recognition of an addiction or similar problem from the conscious mind.

DEPENDENCE. The adaptation of neurons and other physical processes to the use of a drug, followed by withdrawal symptoms when the drug is removed; physiological and/or psychological addiction.

DEPENDENT PERSONALITY DISORDER. Personality disorder characterized by a constant, unhealthy need to be liked and appreciated by others at all costs.

DEPERSONALIZATION. A dissociative symptom in which the patient feels that his or her body is unreal, changing, or dissolving.

DEPERSONALIZATION NEUROSIS. Another name for depersonalization disorder.

DEPRESSANT. Something that slows down functioning.

DEPRESSION. A mental state characterized by excessive sadness. Other symptoms include altered sleep patterns, thoughts of suicide, difficulty concentrating, agitation, lack of energy, and loss of enjoyment in activities that are usually pleasurable.

DEREALIZATION. A dissociative symptom in which the external environment is perceived as unreal or dreamlike.

DERVISH. A person who belongs to one of the various mystical and ascetic Muslim orders, such as the Sufis. A whirling dervish meditates by whirling or spinning in an ecstatic dance.

DESENSITIZATION. The reduction or elimination of an overly intense reaction to a cue by controlled, repeated exposures to the cue.

DESIGNER AMPHETAMINES. Substances close in chemical structure to classic amphetamines that provide both stimulant and hallucinogenic effects.

DETOXIFICATION. A process in which the body is allowed to free itself of a drug while the symptoms of withdrawal are treated. It is the primary step in any treatment program for drug or alcohol abuse.

DEVELOPMENTAL DELAY. The failure to meet certain developmental milestones, such as sitting, walking, and talking, at the average age. Developmental delay may indicate a problem in development of the central nervous system.

DEVELOPMENTAL DISABILITIES. Disabilities that are present from birth and delay or prevent normal development, such as mental retardation or autism.

DEXFENFLURAMINE (REDUX). A prescription appetite suppressant for weight loss that was withdrawn from the market due to unacceptable health risks.

DIABETES MELLITUS. A chronic disease affecting the metabolism of carbohydrates that is caused by insufficient production of insulin in the body.

DIABETIC NEUROPATHY. A condition in which the nerve endings, particularly in the legs and feet, become less sensitive. Minor injuries, such as blisters or calluses, are not felt and can thus become infected and become more serious problems.

DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS. A handbook for mental health professionals that includes lists of symptoms that indicate diagnoses of mental disorders.

DIATHESIS. The medical term for predisposition. The stress/diathesis model is a diagram that is used to explain why some people are at greater risk of suicidal behavior than others.

DIETHYLPROPION (TENUATE, TENUATE DOSPAN). A prescription appetite suppressant currently on the market for weight loss.

DIFFERENTIAL DIAGNOSIS. The process of distinguishing one disorder from other, similar disorders.

DIFFERENTIATION. The ability to retain one’s identity within a family system while maintaining emotional connections with the other members.

DIGRAPH. A pair of letters that represents a single speech sound. In English, the *th* in “thumb” and the *ei* in “vein” are examples of digraphs.

DIPLOPIA. A disorder of vision in which a single object appears double. Diplopia is sometimes called double vision.

DISFLUENCY. Disruptions, breakage, or blockages in the forward flow of speech.

DISPLACEMENT. A psychological process in which feelings originating from one source are expressed outwardly in terms of concern or preoccupation with an issue or problem that the patient considers more accept-

able. In some patients with body dysmorphic disorder, obsession about the body includes displaced feelings, often related to a history of childhood abuse.

DISSOCIATED. Feelings of experiencing an altered state of reality, similar to a trance state. During the period of dissociation, the affected person may feel as if he or she is an observer instead of a participant in events, and may feel as if surroundings are unreal or distorted.

DISSOCIATION. A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

DISSOCIATIVE AMNESIA. A dissociative disorder characterized by loss of memory for a period or periods of time in the patient's life. May occur as a result of a traumatic event.

DISSOCIATIVE DISORDERS. A group of disorders marked by the separation (dissociation) of perception, memory, personal identity, and consciousness. Depersonalization disorder is one of five dissociative disorders defined by *DSM-IV-TR*.

DISSOCIATIVE IDENTITY DISORDER (DID). Term that replaced *multiple personality disorder*. A condition in which two or more distinctive identities or personality states alternate in controlling a person's consciousness and behavior.

DISTENSION. The condition of being stretched or expanded, as the abdomen of a pregnant woman.

DISULFIRAM. A medication helps reinforce abstinence from alcohol in people who are recovering from alcohol abuse. If a person taking disulfiram drinks even a small amount of alcohol, he or she experiences facial flushing, headache, nausea, and vomiting.

DIURETIC. A medication or substance given to increase the amount of urine excreted.

DIZYGOTIC. Developed from two fertilized ova. Dizygotic twins are sometimes called fraternal twins.

DOMINANT HAND. The hand that one prefers to use when performing various tasks such as writing or throwing an object.

DOPAMINE. A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

DOUBLE ANXIETY. Acute anxiety from a recent stressful event combined with underlying persistent anxiety associated with generalized anxiety disorder.

DOUBLE-BLIND PLACEBO-CONTROLLED STUDY. A study in which patients are divided into two groups—those who will receive a medication, and those who will receive a placebo (a pill that looks like the medication but has no active ingredients). Neither the patients nor their physicians know which pill any specific patient is receiving.

DOUCHE. A jet or current of water, often with a medication or cleansing agent dissolved in it, applied to a body cavity for medicinal or hygienic purposes.

DOWN SYNDROME. A genetic disorder characterized by an extra chromosome 21 (trisomy 21), mental retardation, and susceptibility to early-onset Alzheimer's disease.

DREAM ANXIETY DISORDER. Another name for nightmare disorder.

DSM. Abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, a handbook for mental health professionals that includes lists of symptoms that indicate specific diagnoses. The text is periodically revised, and the latest version was published in 2000 and is called *DSM-IV-TR*, for Fourth Edition, Text Revised.

DUE PROCESS. A term referring to the regular administration of a system of laws that conform to fundamental legal principles and are applied without favor or prejudice to all citizens. In the context of involuntary commitment or hospitalization, due process means that people diagnosed with a mental illness cannot be deprived of equal protection under the laws of the United States on the basis of their diagnosis.

DYSARTHRIA. A group of speech disorders caused by disturbances in the strength or coordination of the muscles of the speech mechanism as a result of damage to the brain or nerves. Difficulty talking and speaking.

DYSKINESIA. Difficulty in performing voluntary muscular movements.

DYSLEXIA. A type of reading disorder.

DYSMORPHIC. Malformed.

DYSPAREUNIA. Painful sexual intercourse.

DYSPRAXIA. Developmental dyspraxia is an impairment or immaturity of the organization of movement. It is a defect in the way the brain processes information, resulting in messages not being correctly or fully transmitted. The term dyspraxia comes from the word "praxis," meaning "doing" or "acting." Dyspraxia is associated with problems of perception, language, and thought.

DYSSOMNIA. A type of sleep disorder characterized by a problem with the amount, quality, or timing of the patient's sleep.

DYSTHYMIA. Depression of low intensity.

DYSTHYMIC DISORDER. A mood disorder that is less severe than depression but usually more chronic.

DYSTONIA. A neurological disorder characterized by involuntary muscle spasms. The spasms can cause a painful twisting of the body and difficulty walking or moving. Some medications can cause dystonia.

E

ECHOLALIA. Meaningless repetition of words or phrases spoken by another.

ECHOPRAXIA. Imitation of another person's physical movements in a repetitious or senseless manner.

ECSTASY. Best known of the so-called designer amphetamines, also known as MDMA. It produces both stimulant and hallucinogenic effects.

ECT. Electroconvulsive therapy is sometimes used to treat depression or mania when pharmaceutical treatment fails.

ECZEMA. An inflammation of the skin characterized by itching and oozing of a clear fluid.

EDEMA. Abnormal accumulation of fluid in the interstitial spaces of bodily tissue.

EGO. In Freudian psychology, the conscious, rational part of the mind that experiences and reacts to the outside world.

EGOCENTRICITY. Self-centeredness.

EJACULATION. The discharge of semen by the male reproductive organs.

ELECTROACUPUNCTURE. A variation of acupuncture in which the practitioner stimulates the traditional acupuncture points electronically.

ELECTROCARDIOGRAM. (EKG) A test that measures the electrical activity of the heart as it beats. An abnormal EKG can indicate possible cardiac disease.

ELECTROCONVULSIVE THERAPY. Medical treatment that uses electrical currents to cause seizures; sometimes used to treat depression.

ELECTROENCEPHALOGRAM. (EEG) A test that measures the electrical activity of the brain by means of electrodes placed on the scalp or on or in the brain itself.

ELECTROENCEPHALOGRAPH. (EEG) An instrument that measures the normal and abnormal electrical activity in the brain.

ELECTROENCEPHALOGRAPHY. The measurement and recording of the brain's electrical activity.

ELECTROLYTES. Substances or elements that dissociate into electrically charged particles (ions) when dissolved in the blood. The electrolytes in human blood include potassium, magnesium, and chloride.

ELECTRON. One of the small particles that make up an atom. An electron has the same mass and amount of charge as a positron, but the electron has a negative charge.

ELIMINATION. The medical term for expelling wastes from the body.

EMETIC. A medication intended to cause vomiting. Emetics are sometimes used in aversion therapy in place of electric shock. Their most common use in mainstream medicine is in treating accidental poisoning.

EMPATHY. A quality of the client-centered therapist, characterized by the therapist's conveying appreciation and understanding of the client's point of view.

EMPIRICAL. Verified by actual experience or by scientific experimentation.

ENCEPHALITIS. Inflammation of the brain.

ENCEPHALOPATHY. Brain disease that causes damage or degeneration.

ENCOUNTER GROUPS. A term coined by Carl Rogers for therapist-run groups that focus on personal exploration, experiencing in the here-and-now (that is, feelings and interpersonal exchanges occurring in the group setting), and genuine concern and honesty among the members.

ENDOCANNABINOIDS. Cannabis-like compounds produced naturally in the human body.

ENDOGENOUS DEPRESSION. Depression arising from causes within a person, such as chemical or hormonal imbalances.

ENDORPHINS. A group of peptide compounds released by the body in response to stress or traumatic injury. Endorphins react with opiate receptors in the brain to reduce or relieve pain.

ENERGY. The capability of producing force, performing work, or generating heat.

ENFLEURAGE. A technique for extracting essential oils from flower petals by placing them on a layer of purified fat.

ENURESIS. The inability to control urination; bed-wetting.

EPHEBOPHILIA. Sexual desire on the part of an adult for youths in the early stages of puberty, as distinct from prepubertal children.

EPHEDRINE. An amphetamine-like substance used as a nasal decongestant.

EPIDEMIOLOGY. The study of the causes, incidence, transmission, and control of diseases.

EPILEPSY. A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

EPINEPHRINE (ADRENALINE). The principal blood-pressure raising hormone secreted by the adrenal glands in response to stress; a bronchial and intestinal smooth muscles relaxant.

EPISODIC DYSCONTROL. Another term for intermittent explosive disorder.

EROTOMANIC DELUSIONS. Erotomantic delusions involve the mistaken conviction that someone is in love with the delusional person. Often, the love object is a public figure of some prominence, such as an actress, rock star, or political figure. David Letterman and Jodie Foster are celebrities who have both been victimized by persons with erotomantic delusions.

ESSENTIAL FATTY ACIDS (EFAS). a group of polyunsaturated fats that are essential to life and growth but cannot be produced by the body.

ESSENTIAL OIL. The product of special ducts or cells in the tissues of aromatic plants (or the sap of certain trees) that gives the plant its characteristic aroma and therapeutic properties. Essential oils are sometimes called volatile oils because they evaporate readily at room temperature.

ETIOLOGY. The cause or origin of a disease or disorder. The word is also used to refer to the study of the causes of disease.

EUPHORIA. A feeling or state of well-being or elation.

EUSTRESS. A term that is sometimes used to refer to positive stress.

EUTHANASIA. The act of putting a person or animal to death painlessly or allowing them to die by withholding medical services, usually because of a painful and incurable disease. Mercy killing is another term for euthanasia.

EXECUTIVE. Pertaining to supervision, planning, and carrying out duties or actions.

EXECUTIVE FUNCTIONS. A set of cognitive abilities that control and regulate other abilities and behaviors. Necessary for goal-directed behavior, they include the ability to initiate and stop actions, to monitor and change behavior as needed, and to plan future behavior when faced with novel tasks and situations.

EXISTENTIAL FACTORS. Realities of life including death, isolation, freedom, and meaninglessness that must be faced by all individuals.

EXON. A segment of DNA that is transcribed to RNA and encodes information about the protein sequence.

EXPANSION MUTATION. A genetic mutation caused by additional repetitions of a triplet, or trinucleotide sequence, during the process of genetic transmission. In Huntington's disease, the expansion mutation produces more of a toxic gene product.

EXPERIENTIAL KNOWLEDGE. Knowledge gained from experience, often practical, in contrast with theoretical or professional knowledge.

EXPERIENTIAL THERAPY. An approach to therapy that focuses on experiencing inner feelings, rather than talking about problems in a disconnected, intellectual way. Although it is based on person-centered therapy, experiential therapy is more directive because it uses techniques from a variety of therapeutic approaches to draw out a person's inner experiences.

EXPLICIT MEMORY. Consciously recalled memory for facts or events.

EXPOSURE THERAPY. A form of cognitive-behavioral therapy in which patients suffering from phobias are exposed to their feared objects or situations while accompanied by the therapist. The length of exposure is gradually increased until the association between the feared situation and the patient's experienced panic symptoms is no longer present.

EXPRESSIVE THERAPY. An approach to psychotherapy that seeks to relieve the patient's symptoms through exploration of previously unconscious material, leading to greater insight and more adaptive behaviors.

EXTENDED FAMILY FIELD. A person's family of origin plus grandparents, in-laws, and other relatives.

EXTENSIVE SUPPORT. Ongoing daily support required to assist an individual in a specific adaptive area, such as daily help with preparing meals.

EXTERNALIZING DISORDERS. Mental disorders with primary symptoms that involve outward behavior as opposed to inner emotions.

EXTINCTION. The elimination or removal of a person's reaction to a cue as a result of exposure treatment.

EXTRAPYRAMIDAL. Brain structures located outside the pyramidal tracts of the central nervous system.

EXTRAPYRAMIDAL MOVEMENT DISORDERS. Involuntary movements that occur as a side effect of some psychiatric medications.

EXTRAPYRAMIDAL SIDE EFFECTS. A group of neurological side effects including muscle spasms, involuntary movements, and symptoms that resemble Parkinson's disease (also called drug-induced Parkinsonism).

F

FACTITIOUS DISORDER. A type of mental disturbance in which patients intentionally act physically or mentally ill without obvious benefits. It is distinguished from malingering by the absence of an obvious motive, and from conversion disorder by intentional production of symptoms.

FACTOR ANALYSIS. A statistical method for summarizing relationships between variables. For the HAS, factor analysis was utilized to determine the specific sets of symptoms relating to overall anxiety, somatic anxiety, and psychic anxiety.

FADING. Gradually decreasing the amount or frequency of a reinforcer so that the target behavior will begin to occur independent of any rewards.

FAIR HOUSING ACT OF 1968. Federal legislation regarding access to housing that prohibits discrimination based on race, color, national origin, sex, religion, disability, or familial status.

FALSE-POSITIVE. A test result that is positive for a specific condition or disorder, but this result is inaccurate.

FAMILY SYSTEMS THEORY. An approach to treatment that emphasizes the interdependency of family members rather than focusing on individuals in isolation from the family. This theory underlies the most influential forms of contemporary family therapy.

FARADIC. A type of discontinuous alternating electric current sometimes used in aversion therapy. It is named for Michael Faraday, an eminent British physicist.

FASCIA (PLURAL, FASCIAE). A band or sheath of connective tissue that covers, supports, or connects the muscles and the internal organs.

FECES. Waste products eliminated from the large intestine; excrement.

FEEDBACK. A reaction or response from others to a particular behavior or activity.

FEEDBACK LOOP. A naturally occurring process whereby individuals control their behavior by self-monitoring, self-evaluation, and self-reinforcement.

FEEDBACK LOOPS. Chains of biochemical reactions in which the products of reactions limit or enhance the subsequent reactions, and in which the chain ends up back at the first reaction, either limiting or enhancing it.

FEMININITY. Prescribed behavior for females, characterized by interpersonal warmth, passivity, and lack of aggression.

FENFLURAMINE (PONDIMIN). A prescription appetite suppressant for weight loss that was withdrawn from the market due to unacceptable health risks.

FETISHISM. A paraphilia in which a person requires a nonliving object (or occasionally a nongenital part of the body, such as the partner's feet) in order to achieve sexual arousal and satisfaction.

FIRST-RANK SYMPTOMS. A list of symptoms that have been considered to be diagnostic of schizophrenia. They include, delusions, somatic hallucinations, hearing voices commenting on one's behavior, and thought insertion or withdrawal. First-rank symptoms are sometimes called Schneiderian symptoms, after the name of Kurt Schneider, the German psychiatrist who listed them in 1959.

FLASHBACK. The re-emergence of a traumatic memory as a vivid recollection of sounds, images, and sensations associated with the trauma. The person having the flashback typically feels as if he or she is reliving the event.

FLAVONOIDS. Plant pigments that have a variety of effects on human physiology. Some of these pigments have anti-inflammatory, anti-carcinogenic, and antioxidant effects, for example.

FLOODING. A type of exposure treatment in which the patient is exposed to an anxiety-provoking or feared situation all at once and kept in it until the anxiety and fear subside.

FLUID INTELLIGENCE. A type of intelligence that involves inductive and deductive reasoning ability.

FOLIC ACID. An essential B-vitamin that humans obtain through diet.

FOOD FREQUENCY QUESTIONNAIRE. A listing of how often a person consumes foods from certain food groups in a given period of time.

FORENSIC. Pertaining to courtroom procedure or evidence used in courts of law.

FORMICATION. The sensation of bugs creeping on the skin.

FREE-FLOATING. A term used in psychiatry to describe anxiety that is unfocused or lacking an apparent cause or object.

FREQUENCY DISTRIBUTION. In statistics, the correspondence between a set of frequencies and the set of categories used to classify the group being tested.

FRONTAL CORTEX. The part of the human brain associated with aggressiveness and impulse control. Abnormalities in the frontal cortex are associated with an increased risk of suicide.

FRONTAL LOBE DEMENTIA. Dementia caused by a disorder, usually genetic, that affects the front portion of the brain.

FRONTAL LOBES. A region of the brain that influences higher mental functions often associated with intelligence, such as the ability to foresee the consequences of actions, planning, comprehension, and mood.

FROTTAGE. The act of touching or rubbing against the body or genitals of a non-consenting individual.

FUGUE. A dissociative experience during which a person travels away from home, has amnesia for their past, and may be confused about their identity but otherwise appears normal.

FUGUE STATE. A form of amnesia in which the person appears to be conscious and to make rational decisions, but upon recovery, the period is not remembered. Fugue states represent one type of reaction to traumatic experiences.

G

GABA. Gamma-aminobutyric acid, an inhibitory neurotransmitter in the brain.

GADOLINIUM. A very rare metallic element useful for its sensitivity to electromagnetic resonance, among

other things. Traces of it can be injected into the body to enhance MRI pictures.

GALACTORRHEA. Lactation occurring in the absence of pregnancy.

GAMMA RAY. A high-energy photon emitted by radioactive substances.

GAMMA-AMINOBUTYRIC ACID (GABA). A neurotransmitter that helps to lower or reduce the level of excitement in the nerves, leading to muscle relaxation, calmness, sleep, and prevention of seizures.

GANSER SYNDROME. A rare subtype of factitious disorder accompanied by dissociative symptoms. It is most often seen in male patients under severe stress in prison or courtroom settings.

GANTRY. A name for the couch or table used in a CT scan. The patient lies on the gantry while it slides into the x-ray scanner.

GAS CHROMATOGRAPHY/MASS SPECTROMETRY (GC/MS). A definitive method of testing for specific drugs, used to confirm immunoassay results indicating drug use. GC/MS separates the substances present in the urine sample, then breaks them into unique molecular fragments, which are matched against a database of known substances.

GASTRITIS. Inflammation of the lining of the stomach.

GATEWAY DRUG. A mood-altering drug or substance, typically used by younger or new drug users, that may lead to the use of more dangerous drugs.

GENDER DYSPHORIA. A state of persistent discomfort or depression associated with one's gender role or biological sex.

GENDER ROLE CONFLICT OR STRESS. A negative psychological state resulting from a discrepancy between gender role expectations and how one actually thinks, feels, or behaves.

GENDER ROLES. Stereotypical expectations regarding how one should think, behave, and feel depending on whether one is male or female.

GENERALIZATION. A person's ongoing use of new behaviors that were previously modeled for him or her. Generalization is also called transfer of training or maintenance.

GENERALIZED ANXIETY DISORDER. A general form of fear that can dominate a person's life.

GENERIC. A term that refers to a medication that is not protected by a registered trademark.

GENETIC POOL. The genetic material of an entire population.

GENOGRAM. A family tree diagram that represents the names, birth order, sex, and relationships of the members of a family. Therapists use genograms to detect recurrent patterns in the family history and to help the members understand their problem(s).

GENOME. The total genetic makeup of a cell or organism. The human genome is the complete genetic constitution of a human being.

GENOMIC IMPRINTING. The process in which specific genes or DNA segments are modified during the development of sperm or egg cells in a parent-specific fashion. The modification is reversible and appears to include the addition or removal of methyl groups to specific areas within the DNA sequence.

GENOTYPE. The genetic makeup of an organism or a set of organisms.

GESTALT. A German word that means “form” or “structure.” The Gestalt Closure subtest on the K-SNAP measures a person’s ability to identify a whole object from a partially completed drawing of its form.

GESTALT THERAPY. A therapeutic approach that focuses on increasing awareness of feelings and impulses in the present.

GHB. GHB, or gamma hydroxybutyrate, is a central nervous system depressant that has been abused in the United States for euphoric, sedative, body-building, and date-rape purposes.

GILLBERG’S CRITERIA. A six-item checklist for AS developed by Christopher Gillberg, a Swedish researcher. It is widely used in Europe as a diagnostic tool.

GINGKO BILOBA. A shade tree native to China with fan-shaped leaves and fleshy seeds with edible kernels. Ginkgo extract is being studied as a possible complementary or adjunctive treatment for Alzheimer’s.

GINSENG ABUSE SYNDROME. A group of symptoms recognized by Chinese physicians as the result of excessive use of ginseng. The symptoms include dizziness, high blood pressure, restlessness, nausea, possible bleeding from the digestive tract, and skin rashes.

GLANS. The tip of the penis.

GLAUCOMA. A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

GRAND MAL SEIZURE. A seizure characterized by a sudden loss of consciousness that is immediately followed by generalized convulsions. Such a seizure is usually preceded by a sensory experience, called an aura, which provides a warning as to an impending convulsion.

GRANDIOSE. Having an exaggerated belief in one’s importance or status. In some people, grandiosity may be so extreme as to be delusional.

GRANDIOSE DELUSIONS. Grandiose delusions magnify the person’s importance; the delusional person may believe himself or herself to be a famous person, to have magical superpowers, or to be someone in a position of enormous power (such as being the Prime Minister or President).

GRANDIOSITY. Exaggerated and unrealistic self-importance; inflated self-assessment. Grandiosity is considered one of the core characteristics of persons diagnosed with narcissistic personality disorder.

GRIDIRON ABDOMEN. An abdomen with a network of parallel scars from repeated surgical operations.

GROUP COHESIVENESS. The degree to which a group functions well in its assigned task.

GROUP PSYCHOTHERAPY; GROUP THERAPY. A form of therapy in which a small, carefully selected group of individuals meets regularly with a therapist to assist each individual in emotional growth and personal problem-solving. The group provides support and correction through feedback, constructive criticism, and a forum for consultation and reference.

GUANETHIDINE. A medication used to treat high blood pressure.

GUIDED IMAGERY. Techniques in which individuals actively imagine themselves in a scene (usually a different location, such as a relaxing beach, or a trigger situation where one handles the situation successfully), typically guided by another person describing the scene.

H

HABITUATION. The reduction of a person’s emotional or behavioral reaction to a cue by repeated or prolonged exposure.

HALF-LIFE. The time required for half of the atoms in a radioactive substance to disintegrate.

HALLUCINATIONS. False sensory perceptions. A person experiencing a hallucination may “hear” sounds or “see” people or objects that are not really present.

Hallucinations can also affect the senses of smell, touch, and taste.

HALLUCINOGENS. Substances that cause hallucinations.

HASHISH. The dark, blackish resinous material that exudes from the leaves of the Indian hemp plant.

HATHA YOGA. The form of yoga most familiar to Westerners; often practiced as a form of physical therapy.

HEALTH MAINTENANCE ORGANIZATION (HMO). A type of managed care system that involves payment contracts with a group or panel of health care providers.

HEALTH MAINTENANCE ORGANIZATION ACT OF 1973. Federal legislation that provided aid to develop HMOs.

HEBEPHRENIC SCHIZOPHRENIA. An older term for what is now known as the disorganized subtype of schizophrenia.

HEMATEMESIS. Vomiting blood. Hematemesis is a symptom that sometimes occurs with gastrointestinal ulcers made worse by high levels of caffeine consumption.

HEMATOMA. An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

HEMISPHERE. One side of the brain, right or left.

HEPATITIS. An inflammation of the liver that can be caused by a variety of factors.

HIB DISEASE. An infection caused by *Haemophilus influenzae*, type b (Hib). This disease mainly affects children under the age of five. In that age group, it is the leading cause of bacterial meningitis, pneumonia, joint and bone infections, and throat inflammations.

HIERARCHY. In exposure therapy, a list of feared items or situations, ranked from least fearsome to most fearsome.

HIGH-DENSITY SEX OFFENSES. Several offenses within a short period of time.

HIGH-FUNCTIONING AUTISM (HFA). A subcategory of autistic disorder consisting of children diagnosed with IQs of 70 or higher.

HIPPOCAMPUS. A part of the brain that is involved in memory formation and learning. The hippocampus is shaped like a curved ridge and belongs to an organ system called the limbic system.

HISTAMINE. Substance released during allergic reactions.

HISTRIONIC. Theatrical.

HOLDING THERAPY. A controversial treatment for autism, reactive attachment disorder, and other problems of children in which an adult holds a child despite any resistance from the child until the child submits and experiences an emotional release.

HOLISTIC. An approach to health care that emphasizes the totality of an individual's spiritual, psychological, and physical, well-being, and that situates a disease or disorder within that totality.

HOMEOSTASIS. The tendency of a family system to maintain internal stability and resist change.

HOMOCYSTEINE. A chemical that builds up in the blood when methionine is not properly processed. High blood levels of homocysteine increase risk of heart disease and stroke.

HOST. The dominant or main alter in a person with dissociative identity disorder.

HUMAN POTENTIAL MOVEMENT. A movement dating back to the beginning of the 1900s that reflected an altered perspective of human nature from inherently corrupt to inherently good.

HUMANISTIC AND EXISTENTIAL THERAPIES. Therapies that focus on achieving one's full potential, guided by subjective experience.

HUMOR. In ancient medicine, one of four body fluids (blood, phlegm, yellow bile, and black bile) that were thought to determine a person's basic constitution and personality.

HUMORAL. A term describing a hormonal substance secreted by an endocrine gland (such as the thyroid).

HUNTINGTON'S DISEASE. A hereditary disorder that appears in middle age and is characterized by gradual brain deterioration, progressive dementia, and loss of voluntary movement. It is sometimes called Huntington's chorea.

HYDRATED. Combining a substance with water.

HYDROCEPHALUS. The accumulation of cerebrospinal fluid (CSF) in the ventricles of the brain.

HYDROGEN. The simplest, most common element known in the universe. It is composed of a single electron (negatively charged particle). It is the nuclear proton of hydrogen that makes MRI possible by reacting resonantly to radio waves while aligned in a magnetic field.

HYDROMORPHONE. A prescribed opiate (Dilaudid) used to treat severe pain; also abused illegally.

HYPERACTIVE. Behavior disturbances, usually in children and adolescents, that involves impulsiveness, low levels of concentration, and distractibility.

HYPERAROUSAL. A symptom of traumatic stress characterized by abnormally intense reactions to stimuli. A heightened startle response is one sign of hyperarousal.

HYPEREMESIS GRAVIDARUM. Uncontrollable nausea and vomiting associated with pregnancy. Acupuncture appears to be an effective treatment for this condition.

HYPERPHAGIA. An abnormally large appetite for food. Hyperphagia is one of the symptoms of Prader-Willi syndrome.

HYPERSENSITIVE INTERNAL SUFFOCATION ALARM. A sensitive alarm goes off and the affected person's brain sends the body false signals that not enough oxygen is being received, which causes an increase in their breathing rate.

HYPERTENSION. High blood pressure, often brought on by smoking, obesity, or other causes; one of the major causes of strokes.

HYPERTHERMIA. Elevated body temperature resulting from ingestion of amphetamines.

HYPERTHYROIDISM. Condition resulting from the thyroid glands secreting excessive thyroid hormone, causing increased basal metabolic rate, and causing an increased need for food to meet the demand of the metabolic activity; generally, however, weight loss results.

HYPERVENTILATION. A pattern of rapid, shallow breathing that is frequently found in patients with Rett's disorder.

HYPERVIGILANCE. A state of abnormally intense wariness or watchfulness that is found in survivors of trauma or long-term abuse. Hypervigilance is sometimes described as "being on red alert all the time."

HYPERVIGILANT. Extreme attention to both internal and external stimuli.

HYPNAGOGIC HALLUCINATIONS. Dream-like auditory or visual hallucinations that occur while a person is falling asleep.

HYPNOSIS. The means by which a state of extreme relaxation and suggestibility is induced; used to treat amnesia and identity disturbances that occur in dissociative disorders.

HYPNOTHERAPY. The use of an induced trance state, or hypnosis, as a therapy.

HYPNOTIC. A type of medication that induces sleep.

HYPOCHONDRIASIS. A mental condition in which the affected person perceives illness or symptoms of illness when none exist.

HYPOGONADISM. Abnormally decreased gonad function with retardation of sexual development.

HYPOKALEMIA. Abnormally low levels of potassium in the blood. Hypokalemia is a potential medical emergency, as it can lead to disturbances of the heart rhythm. Muscle cramps and pain are a common symptom of hypokalemia in bulimic patients.

HYPOKINESIA. A condition of abnormally diminished motor activity.

HYPOMANIA. A milder form of mania which is characteristic of bipolar II disorder.

HYPONATREMIA. A condition characterized by an abnormally low concentration of sodium in the blood.

HYPOPNEA. Breathing that is too shallow to maintain adequate levels of oxygen in the blood.

HYPOTENSION. Low blood pressure.

HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) SYSTEM. A part of the brain involved in the human stress response. The HPA system releases cortisol, the primary human stress hormone, and neurotransmitters that activate other brain structures associated with the "fight-or-flight" reaction. The HPA system appears to function in abnormal ways in patients diagnosed with depersonalization disorder. It is sometimes called the HPA axis.

HYPOTHALAMUS. A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, blood pressure, blood sugar levels, and other functions.

HYPOTHESIS. An assumption, proposition, or educated guess that can be tested empirically.

HYPOTHYROIDISM. Thyroid gland that is abnormally low-functioning. A lowered metabolic rate results.

HYPOVENTILATION. An abnormally low level of blood oxygenation in the lungs.

HYSTERIA. In nineteenth-century psychiatric use, a neurotic disorder characterized by violent emotional outbursts and disturbances of the sensory and motor (movement-related) functions. The term "hysterical neurosis" is still used by some psychiatrists as a synonym for conversion disorder.

ID. A construct in Freudian psycho dynamic theory that represents the irrational, self-centered aspects of human thought.

IDEAL WEIGHT. A range of body weights recommended for generally healthy adults.

IDENTIFIED PATIENT (IP). The family member in whom the family's symptom has emerged or is most obvious.

IDENTITY DIFFUSION. A character formation that is scattered or spread around rather than an identity that becomes solidified or consolidated.

IDIOGRAPHIC. An approach to interpreting the results of a projective test within the context of the individual subject's record.

IEP. See Individualized Education Plan

ILLUSION. A misperception or misinterpretation in the presence of a real external stimulus.

IMITATIVE BEHAVIOR. Behaviors of a therapist or group member that are imitated, consciously or unconsciously, by other group members.

IMMUNOASSAY. The method used in routine or preliminary urine drug screening.

IMMUNOSUPPRESSANT. Medications that suppress or lower the body's immune system, primarily used to help the body accept a transplanted organ.

IMPLICIT. Implied or suggested without being clearly stated. Some critics of *DSM-IV-TR* maintain that its contributors based the criteria sets for certain disorders on an implicit notion of a mentally healthy human being.

IMPLICIT MEMORY. Unconsciously recalled memory for skills, procedures, or associations.

IMPULSE CONTROL DISORDERS. Group of disorders characterized by impulsive behavior, such as stealing.

IN VIVO. A Latin phrase that means "in life." In modeling and exposure therapies, it refers to practicing new behaviors in a real setting, as distinct from using imagery or imagined settings.

INBORN ERROR OF METABOLISM. A rare enzyme deficiency; children with inborn errors of metabolism do not have certain enzymes that the body requires to maintain organ functions. Inborn errors of metabolism can cause brain damage and mental retardation if left untreated. Phenylketonuria is an inborn error of metabolism.

INCEST. Unlawful sexual contact between persons who are biologically related. Many therapists, however, use the term to refer to inappropriate sexual contact between any members of a family, including stepparents and stepsiblings.

INCISORS. The four teeth in the front of each jaw in humans. The incisors of patients with bulimia frequently show signs of erosion from stomach acid.

INCONTINENCE. Inability to control the release of urine or feces.

INDEMNITY INSURANCE. Insurance plans that pay on a fee-for-service basis in the event of illness or injury.

INDICES. Scores based on performance in more than one area. On the WAIS, there are four index scores, each based on an individual's performance in more than one subtest.

INDIVIDUALIZED EDUCATION PLAN (IEP). A plan of instruction drawn up for an individual student who is having specific difficulties with mathematics, reading, or other skills necessary to progress beyond elementary school.

INDIVIDUAL PSYCHOTHERAPY. A relationship between therapist and patient designed to foster the patient's emotional growth and personal problem-solving skills.

INFORMATION GIVING. Imparting of information about a disease or condition as part of the therapeutic process.

INFORMED CONSENT. A person's agreement to undergo a medical or surgical procedure, or to participate in a clinical study, after being properly advised of the medical facts related to the procedure or study and the risks involved.

INFUSION. The most potent form of extraction of an herb into water. Infusions are steeped for a longer period of time than teas.

INHALANTS. A class of drugs that are inhaled in order for the user to experience a temporary "high." These chemicals include volatile solvents (liquids that vaporize at room temperature) and aerosols (sprays that contain solvents and propellants), and include glue, gasoline, paint thinner, hair spray, and others. They are dangerous because they can cause hallucinations, delusions, difficulty breathing, headache, nausea, vomiting, and even "sudden sniffing death." Inhalants can also cause permanent damage to the brain, lung, kidney, muscle, and heart.

INSIDIOUS. Proceeding gradually and inconspicuously but with serious effect.

INSOMNIA. A chronic inability to sleep or to remain asleep throughout the night.

INSULIN RESISTANCE. The body's inability to utilize blood sugar, at times leading to diabetes.

INSULT. In medicine, an injury or trauma to the brain or other part of the body.

INTEGRATED SETTING. Placing individuals in typical employment situations rather than making placements into sheltered workshops or other segregated settings.

INTELLIGENCE QUOTIENT (IQ). A measurement of intelligence obtained by dividing a person's mental age (determined by level of performance on an age-graded test) by his or her chronological age and multiplying by 100. For example, a ten-year-old with a mental age of thirteen would have an IQ of 130.

INTER-RATER RELIABILITY. The degree to which judgments about a person are consistent among raters or diagnosticians.

INTERMEDIATE CARE FACILITY. An inpatient facility that provides periodic nursing care.

INTERNALIZING DISORDERS. Mental disorders with primary symptoms that involve inner emotions as opposed to outward behavior.

INTEROCEPTIVE. Referring to stimuli or sensations that arise inside the body. In interoceptive exposure treatment, the patient is asked to exercise or perform other actions that produce feared internal physical sensations.

INTERPERSONAL LEARNING. Learning that takes place via feedback from others.

INTERPERSONAL THERAPY. An approach that includes psychoeducation about the sick role, and emphasis on the present and improving interpersonal dynamics and relationships. Interpersonal therapy is effective in treating adjustment disorders related to physical illness.

INTOXICATION. The condition of being drunk.

INTRAMUSCULAR. An injection that is given into a muscle.

INTRAPSYCHIC. Occurring inside a person's mind or psyche.

INTRON. A segment of DNA that interrupts an exon and that does not encode any information about the protein sequence.

IONIZING RADIATION. Electromagnetic radiation that can damage living tissue by disrupting and destroying individual cells. All types of nuclear decay radiation

(including x rays) are potentially ionizing. Radio waves do not damage organic tissues they pass through.

IPECAC. The dried root of *Caephalis ipecacuanha*, a South American plant. Given in syrup form, ipecac is most commonly used to induce vomiting in cases of accidental poisoning.

IRRITABLE BOWEL SYNDROME (IBS). A condition affecting the small and large intestine, usually associated with emotional stress. There may be complaints of diarrhea and pain in the lower abdomen.

ISCHEMIA. Localized anemia of tissues due to obstructed inflow of blood.

J

JAUNDICE. A yellowing of the skin caused by excess bilirubin in the blood; a liver disorder.

JOURNALING. Involves writing out thoughts and feelings in an unstructured format. A "stream of consciousness" approach (writing whatever comes to mind) is suggested for greatest effectiveness.

K

KAVALACTONES. Medically active compounds in kava root that act as local anesthetics in the mouth and as minor tranquilizers.

KAVAPYRONES. Compounds in kava root that act as muscle relaxants and anticonvulsants.

KETAMINE. An anesthetic, used predominantly by veterinarians to treat animals, that can be used as a date-rape drug.

KI. The Japanese spelling of qi, the traditional Chinese term for vital energy or the life force.

KILOGRAM. A metric unit of weight. It equals 2.2 lb.

KLEPTOMANIA. A disorder of impulse control characterized by repeated stealing or shoplifting of items that the person does not need.

KLINEFELTER'S SYNDROME. A genetic disorder in males characterized by the presence of an extra X chromosome in addition to the normal XY. Most men with Klinefelter's syndrome have learning problems, are sterile, and have a shortened life expectancy.

KORSAKOFF'S SYNDROME. A disorder of the central nervous system resulting from long-term thiamine deficiency. It is characterized by amnesia, confusion, con-

fabulation, and unsteady gait, and is most commonly seen in alcoholics.

KUNDALINI. In Indian yoga, a vital force or energy at the base of the spine that is activated or released by certain yoga postures or breathing techniques. This release is called the “awakening” of the kundalini. Some Westerners have had kundalini experiences that were diagnosed as psychotic episodes or symptoms of schizophrenia.

L

(LA) BELLE INDIFFÉRENCE. A psychiatric symptom sometimes found in patients with conversion disorder, in which the patient shows a surprising lack of concern about the nature or implications of his/her physical symptom.

LABIA. The outside folds of tissue that surround the clitoris and the opening of the urethra in women.

LABILE. Subject to frequent change, particularly in reference to mood.

LANUGO. Downy hair, usually associated with infants, that sometimes develops on the face and back of people affected by anorexia nervosa.

LAPSE. A single, isolated occurrence of a symptom or negative behavior.

LARYNGOSPASM. Spasms that close the vocal apparatus of the larynx (the organ of voice production).

LATERALIZATION. The control of specific neurological functions by one side of the brain or the other; for example, in most right-handed people, language functions are controlled by the left side of the brain and spatial and visual functions are controlled by the right side of the brain.

LAXATIVE. Substance or medication that encourages a bowel movement.

LEAST RESTRICTIVE ENVIRONMENT. Refers to care options that involve the least amount of restraint and the greatest degree of independence possible, while still meeting the individual’s needs and maintaining safety.

LEUCOTOMY OR LEUKOTOMY. White matter cutting—severing the white matter of the frontal lobe of the brain.

LEUKODYSTROPHY. A disturbance of the white matter of the brain.

LEWY BODIES. Areas of injury found on damaged nerve cells in certain parts of the brain associated with

dementia. Lewy body dementia was first recognized in the 1980s and is now distinguished from Alzheimer’s disease.

LEWY-BODY DISEASE. A type of dementia that resembles Alzheimer’s disease, but progresses more rapidly. Common symptoms include fluctuations in confusion and recurring visual hallucinations. In this disease, abnormal brain cells are distributed throughout the brain.

LIBIDO. Psychic energy or instinctual drive associated with sexual desire, pleasure, or creativity.

LIMBIC SYSTEM. A group of structures in the brain that includes the amygdala, hippocampus, olfactory bulbs, and hypothalamus. The limbic system is associated with homeostasis and the regulation and arousal of emotions.

LIMITED SUPPORT. A predetermined period of assistance required to deal with a specific event, such as training for a new job.

LOBOTOMY. A surgical procedure involving the cutting of nerve fiber bundles in the brain.

LOCALIZATION. The control of specific neurological functions by specific areas in the brain.

LOCUS CERULEUS. A part of the brain where the neurotransmitter causes excitation.

LOFEXIDINE. A medication approved for use in England to aid the opioid detoxification process.

LOW AFFECT. Severe lack of interest and emotions; emotional numbness.

LUX. The International System unit for measuring illumination, equal to one lumen per square meter.

M

MACERATION. A technique for extracting essential oils from plant leaves and stems by crushing the plant parts and soaking them in warm vegetable oil.

MACHISMO. The exaggerated image of extreme masculinity that includes such qualities as concern for personal honor, virility, physical strength, heavy drinking, toughness, aggression, risk taking, authoritarianism, and self-centeredness.

MACROSOCIAL. Pertaining to the wider society, as distinct from such smaller social groupings as families, neighborhoods, etc.

MAGNETIC FIELD. The three-dimensional area surrounding a magnet, in which its force is active. During

MRI, the patient's body is permeated by the force field of a superconducting magnet.

MAINTENANCE TREATMENT. The period of treatment beginning after the initial introduction of the treatment medication. During this period, the dose of medication can be either increased or decreased, depending on the program and needs of the patient.

MALADROITNESS. Another word for awkwardness or clumsiness.

MALAISE. The medical term for a general condition of unease, discomfort, or weakness.

MALINGERING. Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

MANIA. An elevated or euphoric mood or irritable state that is characteristic of bipolar I disorder. This state is characterized by mental and physical hyperactivity, disorganization of behavior, and inappropriate elevation of mood.

MANIC. Referring to mania.

MANTRA. Originally, a sacred word or phrase repeated over and over to help focus the mind during meditation; in the Western world, this may refer to any repeated syllable, word, or phrase used to meditate.

MAO INHIBITORS. A group of antidepressant drugs that decrease the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

MARIJUANA. The dried and shredded or chopped leaves of the Indian hemp plant.

MASCULINITY. Prescribed behavior for males, characterized by independence, strength, control, and avoidance of emotional expressiveness.

MASOCHISM. A mental disorder in which a person obtains sexual satisfaction through pain or humiliation inflicted by the self or by another person. The term is sometimes used more generally to refer to a tendency to find pleasure in submissiveness or self-denial.

MASOCHISTIC TENDENCIES. Tendencies to direct harm or hatred toward oneself.

MAZINDOL (SANOREX, MAZANOR). A prescription medication for weight loss currently on the market.

MEAN. The mathematical average of all scores in a set of scores.

MEDICAID. A program jointly funded by state and federal governments that reimburses hospitals and physicians for the care of individuals who cannot pay for their

own medical expenses. These individuals may be in low-income households or may have chronic disabilities.

MEDICAID HOME AND COMMUNITY-BASED WAIVER. Legislation regarding the use of Medicaid funds for care services; allows certain federal requirements to be bypassed so that states can use the funds more flexibly for accessing home- and community-based services rather than using hospitals or intermediate-care facilities.

MEDICAL MODEL. The basic conceptual framework in the West since the nineteenth century for understanding, researching, and classifying mental disorders.

MEDICARE. A federally funded health insurance program for individuals age 65 and older or certain categories of younger persons with disabilities.

MEDROXYPROGESTERONE. A progestin, a female hormone.

MEDROXYPROGESTERONE ACETATE (MPA). A female hormone that may be prescribed for male patients with sexual sadism or other paraphilias. MPA helps to control sexual urges in men by speeding up the clearance of testosterone from the bloodstream.

MELANCHOLIA. A form of severe depression characterized by weight loss, insomnia, and an inability to experience pleasure.

MENINGES. A membrane covering the brain and spinal cord that consists of three layers: the *pia mater*, the innermost layer; the *arachnoid*, in the middle; and the *dura mater*, the outermost layer.

MENOPAUSE. A period of decreasing hormonal activity in women, when ovulation stops and conception is no longer possible.

MERIDIANS. In traditional Chinese medicine, a network of pathways or channels that convey qi (also sometimes spelled "ki"), or vital energy, through the body.

MERYCISM. Another name for rumination disorder.

META-ANALYSIS. The statistical analysis of a large collection of analyses from individual studies for the purpose of integrating the findings.

METABOLISM. The group of biochemical processes within the body that release energy in support of life.

METHADONE. A drug often prescribed legally as a replacement for heroin. It induces a slight high but blocks heroin from producing a more powerful euphoric effect. It may be used in heroin detoxification to ease the process, or it may be used daily after detoxification as maintenance therapy. Methadone maintenance therapy is controversial.

METHAMPHETAMINE. The most common illegally produced amphetamine.

METHIONINE. An amino acid that, when not metabolized properly, allows homocysteine to build up in the blood. Folic acid aids methionine metabolism.

METHYLPHENIDATE. A mild central nervous system stimulant that is used to treat hyperactivity.

MIDDLE NOTE. A term used in perfumery and aromatherapy to designate essential oils whose odors emerge later than top notes but evaporate more rapidly than bottom notes. Chamomile is considered a middle note in aromatherapy.

MILD COGNITIVE IMPAIRMENT (MCI). A transitional phase of memory loss in older people that precedes dementia or Alzheimer's disease.

MILLIGRAM (MG). One-thousandth of a gram. A gram is the metric measure that equals about 0.035 ounces.

MILLON CLINICAL MULTIAXIAL INVENTORY (MCMI-II). A self-report instrument designed to help the clinician assess DSM-IV-related personality disorders and clinical syndromes. It provides insight into 14 personality disorders and 10 clinical syndromes.

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY (MMPI-2). A comprehensive assessment tool widely used to diagnosed personality disorders.

MIXED MANIA/MIXED STATE. A mental state in which symptoms of both depression and mania occur simultaneously.

MODALITY. One of the primary forms of sensation, such as vision, touch, or hearing.

MODELING. A type of teaching method used in social skills training. Therapists who use this method may offer positive and negative examples of the behaviors that make up a social skill.

MONOAMINE OXIDASE INHIBITORS (MAOIS). A group of antidepressant drugs that decrease the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

MONOGENIC. Determined or controlled by a single gene. Huntington's disease is one of the few psychiatric disorders that is monogenic.

MONOMANIA. A nineteenth-century term for a pathological obsession with one idea or one social cause. Nineteenth-century psychiatrists often associated explosive behavior with monomania. The word is no longer used as a technical term.

MONOZYGOTIC. Developed from a single fertilized ovum. Monozygotic twins are sometimes called identical twins.

MORBIDITY. The unhealthiness or disease characteristics associated with a mental disorder.

MOSAICISM. A genetic condition in which some cells in an organism have one set of chromosomes and other cells have a different set.

MOTIVATIONAL ENHANCEMENT THERAPY. Therapy that focuses on increasing motivation for change by empathically comparing and contrasting the consequences and benefits of changing or not changing.

MOTOR. Involving muscle movement.

MOTOR SKILLS. Skills pertaining to or involving muscular movement.

MOVEMENT EDUCATION. A term that refers to the active phase of bodywork, in which clients learn to move with greater freedom and to maintain the proper alignment of their bodies.

MOXIBUSTION. A technique in traditional Chinese medicine that involves burning a *Moxa*, or cone of dried wormwood leaves, close to the skin to relieve pain. When used with acupuncture, the cone is placed on top of the needle at an acupuncture point and burned.

MRI. Magnetic resonance imaging. A special imaging technique used to image internal parts of the body, especially soft tissues.

MULTI-INFARCT DEMENTIA. Dementia caused by damage to brain tissue resulting from a series of blood clots or clogs in the blood vessels. It is also called vascular dementia.

MULTIAXIAL. Refers to a type of classification system that involves numeric measurement along more than one dimension and is not based on assignment to mutually exclusive categories.

MULTIMODAL. Involving several types of therapeutic interventions such as heat or ice packs, electrical stimulation, and ultrasound; sometimes refers to a mix of physical and psychological therapies.

MULTIPLE PERSONALITY DISORDER (MPD). An older term for dissociative identity disorder (DID).

MULTIPLE SCLEROSIS. A disease characterized by patches of hardened tissue in the brain or spinal cord, paralysis, and/or muscle tremors.

MUSCLE DYSMORPHIA. A subtype of BDD, described as excessive preoccupation with muscularity

and bodybuilding to the point of interference with social, educational, or occupational functioning.

MUTATION. A spontaneous change in the sequence of nucleotides in a chromosome or gene. Mutations may affect the number and structure of chromosomes or cause deletions of part of a chromosome. Rett's disorder is caused by a mutation on the long arm of the X chromosome.

MUTISM. Inability to speak due to conscious refusal or psychological inhibition.

MYASTHENIA GRAVIS. A disease characterized by weakness of the muscles caused by an autoimmune reaction.

MYELIN SHEATHS. A fatty layer around nerve cells that aids the transmission of nerve impulses.

MYOCARDIAL DISEASE. Disease of the muscular layer of the heart wall.

MYOCLONUS. An abrupt spasm or twitching in a muscle or group of muscles. It is more common in early-onset AD than in late-onset Alzheimer's.

N

NARCISSISTIC PERSONALITY DISORDER. Personality characterized by continually exaggerating one's own positive qualities and refusing to recognize personal defects or flaws.

NARCISSISTIC PERSONALITY INVENTORY (NPI). The most widely used English-language diagnostic instrument for narcissistic personality disorder. Based on the *DSM-III* criteria for NPD, the NPI is frequently used in research studies as well as patient assessment.

NARCOLEPSY. A disorder characterized by frequent and uncontrollable attacks of deep sleep.

NARCOTHERAPY. A form of psychotherapy that involves the administration of a drug that makes the patient drowsy.

NALOXONE. A drug that combines competitively with opiate receptors on the nerve cells and blocks or reverses the action of narcotic analgesics.

NARROW-ANGLE GLAUCOMA. An eye disorder caused by a buildup of fluid pressure inside the eyeball due to an abnormally small angle between the iris (the colored portion of the eye) and the cornea (the transparent front part of the eye).

NATURAL SUPPORTS. Using a person's already existing support network to help the person reach a goal, such as the employment of their choice.

NEGATIVE SYMPTOMS. Symptoms of schizophrenia that represent a loss or reduction of normal functioning.

NEPHRITIS. Inflammation of the kidney.

NERVOUS TIC. A repetitive, involuntary action, such as the twitching of a muscle or repeated blinking.

NEUROFIBRILLARY TANGLES. Accumulations of twisted protein fragments found inside the nerve cells in the brains of Alzheimer's patients.

NEUROLEPTIC. Another name for the older antipsychotic medications, such as haloperidol (Haldol) and chlorpromazine (Thorazine).

NEUROLEPTIC MALIGNANT SYNDROME (NMS). An unusual but potentially serious complication that develops in some patients who have been treated with antipsychotic medications. NMS is characterized by changes in blood pressure, altered states of consciousness, rigid muscles, and fever. Untreated NMS can result in coma and death.

NEUROLEPTIC-INDUCED ACUTE DYSTONIA. A severe form of dystonia, a neurological movement disorder, caused by the use of neuroleptic drugs.

NEUROLEPTIC-INDUCED AKATHISIA. Refers to the disorder characterized by a physical restlessness (the inability to sit still, for example), and excessive voluntary movements, as a result of the use of neuroleptic drugs; research indicates it is likely the most common of neuroleptic-induced movement disorders.

NEUROLEPTIC-INDUCED PARKINSONISM. Symptoms similar to Parkinson's disease that may appear in people taking neuroleptic (antipsychotic) medications. These symptoms include tremors in muscles and a shuffling gait.

NEUROLEPTIC-INDUCED TARDIVE DYSKINESIA. A potentially irreversible neurological disorder caused by the use of antipsychotic/neuroleptic medications, with symptoms involving uncontrollable movement of various body parts. Some of these movements include involuntary movements of the tongue and mouth, grimacing, and lip-smacking.

NEUROLOGIC. Pertaining to the nervous system (brain and nerve cells).

NEURONS. Nerve cells in the brain that produce nerve impulses.

NEUROPATHIC. Relating to neural damage.

NEUROPSYCHOLOGICAL FUNCTIONING. The ability of the nervous system and brain to process and interpret information received through the senses.

NEUROTRANSMISSION. The conduction of a nerve impulse along a chain of nerve cells, which occurs when a cell in the chain secretes a chemical substance, called a neurotransmitter, onto a subsequent cell.

NEUROTRANSMITTER. A chemical in the brain that transmits messages between neurons, or nerve cells.

NEUROTRANSMITTERS. Chemicals that carry nerve impulses from one nerve cell to another. Alzheimer's disease causes a drop in the production of several important neurotransmitters.

NIMBY PHENOMENON. Acronym for Not In My Backyard, describing the common opposition displayed by citizens toward the placement of group homes or other social service facilities in their neighborhoods.

NOMOTHEIC. An approach to interpreting the results of a projective test in which the subject's answers are measured against a normative comparison sample.

NON-AMBULATORY. Unable to walk.

NON-DOMINANT HAND. The hand that one does not typically use when performing various tasks, such as writing or throwing an object.

NONDIRECTIVE THERAPY. An approach to therapy in which the therapist actively attempts to avoid giving advice, making interpretations, or otherwise influencing the focus of the individual's thoughts or statements.

NONENDOGENOUS. A factor that arises or is produced outside of the organism.

NORADRENERGIC. Acts similarly to norepinephrine or noradrenaline.

NOREPINEPHRINE. A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

NOREPINEPHRINE (NORADRENALINE). A hormone with similar stimulatory effects to epinephrine but, in contrast to epinephrine, has little effect on cardiac (heart) output and in relaxing smooth muscles.

NORMAL CURVE EQUIVALENTS. Standard scores with an average of 100. The normal curve equivalents divide the normal or bell-shaped curve into 100 equal parts. As a result, those scores can be used for statistical analysis because they can be added, subtracted, multiplied, and divided.

NORMED. Describes a process used in the developmental stages of a test instrument. The new test is first given to a cross-section of a population for which it is designed. The scores, placements, rankings, etc., of these persons then become the source for all future comparisons

(norm group). When a new subject takes the test, his/her score, placement, ranking, etc., is determined based upon comparison with or deviation from the norm group.

NOSOLOGY. The branch of medicine that deals with the systematic classification of diseases and disorders.

NUCLEAR FAMILY. The basic family unit, consisting of father, mother, and their biological children.

NUCLEOTIDE. One of the molecules that form the building blocks of DNA or RNA. The nucleotides of DNA include a phosphate group, four chemical bases (adenine, cytosine, guanine, and thymine), and a sugar containing five carbon atoms. In RNA, the thymine base is replaced by uracil.

NYSTAGMUS. A persistent involuntary movement of the eyes from side to side. It is one of the symptoms of inhalant intoxication syndrome.

O

OBJECT RELATIONS. In psychology, a phrase that refers to the way in which a subject describes relationships with other people in their environment, and the ways in which he or she has internalized interpersonal relationships.

OBJECT-RELATIONS THEORY. An approach to psychological development that includes Nancy Chodorow's stating that children develop according to interactions with their primary caregivers.

OBSESSION. A persistent image, idea, or desire that dominates a person's thoughts or feelings.

OBSESSIVE-COMPULSIVE. Characterized by obsessive and compulsive behaviors.

OBSESSIVE-COMPULSIVE DISORDER. Disorder in which the affected individual has an obsession (such as a fear of contamination, or thoughts he or she doesn't like to have and can't control) and feels compelled to perform a certain act to neutralize the obsession (such as repeated handwashing).

OCCIPITAL. The occipital bone forms the back part of the skull.

OEDIPAL CONFLICT. A developmental conflict that emerges during the third or oedipal stage of Freud's psychosexual development stages. During this stage, a conflict emerges with regard to the triad of father, mother, and child. The conflict concerns the sexual impulses that the child has toward the parent of the opposite gender and the hostile impulses that the child has towards the

parent of the same gender. During this stage, the developmental conflict concerns a resolution of oedipal issues.

OLFACTORY NERVE. The cranial nerve that regulates the sense of smell.

ONSET. The point in time at which the symptoms of a disorder first became apparent.

OPERANT. Conditioning in which the desired response is reinforced by an introduced stimulus.

OPIATES. A class of drugs that is either derived from opium (i.e. morphine, hydromorphone, oxymorphone, heroin, codeine, hydrocodone, oxycodone) or resembles these opium derivatives (such as meperidine) and is commonly referred to as narcotics.

OPIOIDS. Substances that reduce pain and may induce sleep. Some opioids are endogenous, which means that they are produced within the human body. Other opioids are produced by plants or formulated synthetically in the laboratory.

OPPOSITIONAL DEFIANT DISORDER. An emotional and behavioral problem of children and adolescents characterized by defiant, hostile, or disobedient behavior that has lasted for longer than six months.

ORAL PHASE. The first of Freud's psychosexual stages of development in which satisfaction is focused on the mouth and lips. During this stage sucking and eating are the primary means of gratification.

ORGANIC BRAIN SYNDROME. A class of disorders characterized by progressive deterioration of mental processes caused by temporary brain dysfunction or permanent brain damage. Symptoms include delusions, dementia, amnesia, and delirium that are not caused by drugs, alcohol, or as a side effect of medication.

ORGASM. Another word for sexual climax.

ORIENTATION. In psychiatry, the ability to locate oneself in one's environment with respect to time, place and people.

ORLISTAT (XENICAL). A prescription medication for weight loss currently on the market.

ORTHOSTATIC HYPOTENSION. A sudden decrease in blood pressure due to a change in body position, as when moving from a sitting to standing position.

OSTEOPOROSIS. A loss of bone minerals.

OUTCOME EXPECTANCIES. What one believes will happen as a result of engaging in a certain behavior.

OVERCOMPENSATION. An attempt to overcome or correct a behavior by going too far in the opposite direction.

OVERVALUED IDEA. An unreasonable, sustained belief that is held with less than delusional intensity (i.e., the person can acknowledge, to some degree, that the belief may be false). The belief is not accounted for by the individual's cultural or religious background.

OXIMETRY. The measurement of blood oxygen levels.

P

PAIN DISORDER. One of several somatoform disorders described in the revised, fourth edition of the mental health professional's handbook, the *Diagnostic and Statistical Manual of Mental Disorders*. The term "somatoform" means that symptoms are physical but are not entirely understood as a consequence of a general medical condition or as a direct effect of a substance, such as a drug.

PAINSTATES. Refers to the four-way classification of pain disorder as being (1) acute with psychological factors, (2) acute with psychological factors and a general medical condition, (3) chronic with psychological factors, and (4) chronic with psychological factors and a general medical condition.

PANACEA. A medicine or other substance regarded as a cure for all ills.

PANIC ATTACK. Specific periods of time when a person has a feeling that s/he is dying or having a heart attack with chest pain, a feeling as though s/he could pass out, and fear that s/he is going insane.

PANIC DISORDER. An anxiety disorder in which an individual experiences sudden, debilitating attacks of intense fear.

PANIC DISORDER WITH AGORAPHOBIA. Repeated panic attacks in which the patient is worried about the attacks enough that the worry restricts their activity.

PANIC DISORDER WITHOUT AGORAPHOBIA. Repeated panic attacks without symptoms of agoraphobia.

PARAMETER. A characteristic or factor that is measured during a test of a complex process or activity like sleep.

PARANOIA. A mental disorder characterized by baseless suspicions or distrust of others, often delusional in intensity.

PARANOID. A mental attitude characterized by unjustified or excessive distrust of other people, usually combined with anger.

PARANOID PERSONALITY. A personality disorder characterized by unwarranted suspicion, jealousy, hypersensitivity, social isolation and a tendency to detect malicious intent in the words and actions of others.

PARAPHILIAS. A group of mental disorders that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

PARASOMNIA. A type of sleep disorder characterized by abnormal changes in behavior or body functions during sleep, specific stages of sleep, or the transition between sleeping and waking.

PARESTHESIAS. Abnormal sensations of tingling or "pins and needles." Paresthesias are a common panic-like symptom associated with agoraphobia.

PARKINSON'S DISEASE. A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness. It may be related in some way to Lewy body dementia.

PARKINSONIAN. Related to symptoms associated with Parkinson's disease. These symptoms may be induced by certain medications, and, in these cases, the person does not have Parkinson's disease—they have Parkinson-like or Parkinsonian symptoms.

PASSIVE-AGGRESSIVE BEHAVIORS. Behaviors that represent covert expressions of hostile or negative feelings that the person is unable or unwilling to express directly.

PATHOGNOMONIC. Describing symptoms characteristic of a particular disease.

PATIENT CARE EPISODES. A specific measure of the volume of care provided by an organization or system. It begins with a treatment visit to a health care facility (a hospital or residential treatment center, for example) and ends when a person leaves the facility, so it may vary by patient and visit. Over time, the volume of patient care episodes indicates the degree to which a population uses certain health care capacities. Other measures that may be used to measure volume of care include number of beds or bed-days, total number of patients served, and also more specific measures like patient-contact hours.

PAVOR NOCTURNUS. The Latin medical term for sleep terror disorder.

PELVIS. The basin-like cavity in the human body below the abdomen, enclosed by a framework of four bones.

PENETRANCE. In genetics, the frequency with which a specific gene produces its effects in a group of people or other organisms. Penetrance is expressed as a percentage.

PENIS. The external male sex organ.

PERCENTILE RANK. The point at which a given percentage of people fall at or below the individual's test score being calculated. For example, if a person's test score was at the 60th percentile, 40% of other test takers received a higher score, while 60% received a score that was at or below that of the test taker.

PERFORMANCE ANXIETY. A subcategory of circumscribed social phobia in which the patient's fear is limited to performing certain activities or tasks in public. Common areas of performance anxiety include public speaking, acting on stage, solo singing, and playing instrumental solos.

PERINEAL. An anatomical area located between the external genitals and the anus.

PERIPHERAL NERVE. A nerve in a distant location from the brain that receives information in the form of an impulse from the brain and spinal cord.

PERSECUTORY DELUSIONS. Unrealistic conviction of being harassed, tormented, and persecuted.

PERSON-CENTERED PLANNING. A technique in which a plan for a person's future is developed by a team consisting of the person, family members, service providers and friends (natural supports). The team develops a practical plan based on the person's wishes and dreams. Each team member agrees to perform certain tasks identified in the plan to help the person reach goals.

PERSON-CENTERED THERAPY. A therapeutic approach that believes the client's own drive towards growth and development is the most important factor in healing.

PERSONALITY DISORDER. A personality disorder is a maladaptive pattern of behavior, affect, and/or cognitive style displayed in a broad range of settings. The pattern deviates from the accepted norms of the individual's culture and can occur over a lifetime.

PERSONALITY INVENTORY. A type of psychological test that is designed to assess a client's major personality traits, behavioral patterns, coping styles, and similar characteristics. The Minnesota Multiphasic Personality Inventory is an example of a personality inventory.

PERSONALIZATION. The tendency to refer large-scale events or general patterns of events to the self in inappro-

appropriate ways. For example, a person who regards the loss of a friend or relative in an accident as punishment for having quarreled with them before the accident is said to be personalizing the event. Personalization increases a person's risk of developing acute stress disorder or post-traumatic stress disorder after a traumatic event.

PERVASIVE DEVELOPMENTAL DISORDERS (PDDs). A category of childhood disorders that includes Asperger's syndrome and Rett's disorder. The PDDs are sometimes referred to collectively as autistic spectrum disorders.

PET. Abbreviation for positron emission tomography, a highly specialized imaging technique using radioactive substances to identify active tumors, as well as neurological disease progression.

PETECHIAE. Pinpoint-sized hemorrhages in the skin or a mucous membrane. In bulimia, petechiae may appear in the skin around the eyes as a result of increased pressure in the capillaries caused by vomiting.

PHENCYCLIDINE. The full name of the drug commonly called PCP that is often abused to induce hallucinations.

PHENOL. A white crystalline water-soluble substance used chiefly as an antiseptic and disinfectant.

PHENOMENOLOGICAL THERAPY. A therapeutic approach that focuses on the interpretations individuals place on their experiences.

PHENOTHIAZINES. A class of drugs widely used in the treatment of psychosis.

PHENOTYPE. The observable signs, symptoms, and other aspects of the makeup of an organism. The term is also used sometimes to refer to the appearance of an organism resulting from the interaction between its genotype and its environment.

PHENYLKETONURIA. (PKU) An inherited disease in which the body cannot metabolize the amino acid phenylalanine properly. If untreated, phenylketonuria can cause mental retardation.

PHOBIA. Irrational fear of places, things, or situations that leads to avoidance.

PHONICS. A method of teaching reading and spelling based on the phonetic interpretation of ordinary spelling.

PHONOLOGICAL DISORDER. A developmental disorder of childhood in which the child fails to use speech sounds that are appropriate for his or her age level and native language or dialect.

PHOTON. A light particle.

PHOTOTHERAPY. Another name for light therapy in mainstream medical practice.

PHYSICAL DEPENDENCE. A maladaptive behavior that over a three-month period has caused the individual to experience tolerance and withdrawal symptoms.

PHYSIOLOGY. The branch of medicine concerned with biological processes or functions in the human body or any of its parts.

PHYSOSTIGMINE. A short-acting drug that enhances levels of a substance (acetylcholine) between neurons in the brain.

PICK'S DISEASE. A rare type of primary dementia that affects the frontal lobes of the brain. It is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.

PLACEBO. An inactive substance or preparation used as a control in experiments with human subjects to test the effectiveness of a drug or herbal preparation. Some patients may experience a medicinal response or experience side effects to a placebo simply because they have faith in its powers even though it contains no medicine.

PLAQUE. A sticky cholesterol-containing substance that builds up on the walls of blood vessels, reducing or blocking blood flow.

PLAQUES. Clumps or clusters of beta amyloid fragments, dead or dying nerve cells, and other cellular debris, found in the brains of patients with Alzheimer's disease.

PLAY THERAPY. A type of psychotherapy for young children involving the use of toys and games to build a therapeutic relationship and encourage the child's self-expression.

PNEUMOTHORAX. A condition in which air or gas is present in the chest cavity.

POLARITY THERAPY. A form of energy therapy influenced by Ayurvedic medicine that integrates bodywork with diet, home exercises, and self-awareness techniques. It is sometimes called polarity balancing.

POLYGENIC. A trait or disorder that is determined by a group of genes acting together. Most human characteristics, including height, weight, and general body build, are polygenic. Schizophrenia and late-onset Alzheimer's disease are considered polygenic disorders.

POLYSOMNOGRAM. A machine that is used to diagnose sleep disorders by measuring and recording a variety of body functions related to sleep, including heart rate, eye movements, brain waves, muscle activity,

breathing, changes in blood oxygen concentration, and body position.

PORPHYRIA. A group of disorders that arise from changes in the metabolism of porphyrin, a naturally occurring compound in the body. The disorders are characterized by acute abdominal pain and neurological problems.

PORPHYRIN. Any iron- or magnesium-free pyrrole derivative occurring in many plant or animal tissues.

POSITIVE AFFIRMATION STATEMENTS. Statements repeated to oneself, either aloud or mentally, that reflect attitudes of self-worth.

POSITIVE REINFORCEMENT. A procedure or response that rewards a desired behavior.

POSITIVE SYMPTOMS. Symptoms of schizophrenia that represent excesses or distortions of normal mental functions.

POSITRON. One of the small particles that make up an atom. A positron has the same mass and amount of charge as an electron, but the positron has a positive charge.

POST MORTEM. After death. The definitive diagnosis of Alzheimer's disease can be made only after the patient's death.

POST-TRAUMATIC STRESS DISORDER. A disorder caused by an extremely stressful or traumatic event (such as rape, act of war, or natural disaster) in which the trauma victim is haunted by flashbacks. In the flashbacks, the event is re-experienced in the present. Other symptoms include nightmares and feelings of anxiety.

POSTURAL TREMOR. A continuous quiver that affects body posture and movement.

PRADER-WILLI SYNDROME. A developmental disorder of childhood characterized by mental retardation, poor muscle tone, delayed growth and sexual maturation, and childhood onset of an abnormally large appetite for food.

PRANA. The Sanskrit word for vital energy, roughly equivalent to qi in traditional Chinese medicine.

PRANAYAMA. The breathing exercises that accompany the asanas in hatha yoga.

PRE-MENSTRUAL SYNDROME. A severe change in mood that occurs in women immediately prior to, and during, their menstrual period.

PREECLAMPSIA. A complication of pregnancy characterized by high blood pressure, fluid retention, and

protein in the urine. If the patient develops convulsions, the condition is called eclampsia.

PREFERRED PROVIDER ORGANIZATION (PPO). A type of managed care system involving payment contracts with a group or panel of health care providers.

PREMIUM. The cost of enrollment in a health insurance plan. Premiums are usually paid on a monthly basis.

PRESENILE DEMENTIA. An older name for Alzheimer's disease.

PRESSURE ULCERS. Also known as pressure sores or bed sores, these can develop in stroke patients who are unable to move. If not treated properly, they can become infected.

PREVALENCE. Occurrence in a population.

PRIAPISM. Persistent abnormal erection of the penis, usually without sexual desire, and accompanied by pain and tenderness.

PRIMARY ENURESIS. Bed-wetting in a child who has not yet developed bladder control.

PRIMARY GAIN. In psychiatry, the principal psychological reason for the development of a patient's symptoms. In conversion disorder, the primary gain from the symptom is the reduction of anxiety and the exclusion of an inner conflict from conscious awareness.

PRIMARY NARCISSISM. Sigmund Freud's term for a normal phase in early childhood development in which the infant has not yet learned to distinguish between itself and its world, and sees other people and things in its environment as extensions of itself.

PRIMARY PERSONALITY. The core personality of a patient with dissociative identity disorder. In women, the primary personality is often timid and passive, and may be diagnosed as depressed.

PRIMARY PULMONARY HYPERTENSION (PPH). A rare but potentially fatal disorder that affects the blood vessels in the lungs.

PRION. A protein particle that lacks nucleic acid.

PROCESS ADDICTION. An addiction to a mood-altering behavior or series of behaviors rather than a substance.

PROCESS-EXPERIENTIAL THERAPIES. A group of therapies based on a person-centered approach that incorporates elements of cognitive and Gestalt therapies.

PRODROMAL. Premonitory; having the character of a warning. The first psychotic episode in schizophrenia is often preceded by a prodromal phase.

PROGRESSIVE RELAXATION. A technique for managing stress in which the person relaxes major muscle groups in a fixed sequence, often beginning with the feet and moving towards the head.

PROJECTION. A psychological process in which a person unconsciously attributes unacceptable feelings to someone else. Narcissists often project their envy onto other people, claiming that the person in question is envious of them.

PROJECTIVE TEST. A psychological test in which the test taker responds to or provides ambiguous, abstract, or unstructured stimuli, often in the form of pictures or drawings. A projective test may assess a person's thinking patterns, observational ability, feelings, and attitudes.

PROLACTIN. A hormone that stimulates milk production and breast development.

PROSTAGLANDINS. A group of unsaturated fatty acids involved in the contraction of smooth muscle, control of inflammation, and many other body processes.

PROSTATE GLAND. The gland at the base of a male's urethra that produces a component of semen.

PROTOCOL. A plan for carrying out a scientific study or a patient's course of treatment.

PSEUDODEMENTIA. A term for a depression with symptoms resembling those of dementia. The term "dementia of depression" is now preferred.

PSEUDOSEIZURE. An attack that resembles an epileptic seizure but is not associated with abnormal electrical discharges in the patient's brain.

PSYCHIATRIC EPIDEMIOLOGY. A field of research for establishing the incidence, distribution or prevalence, and control of mental disorders in a population, including the sum of the factors controlling the presence of mental disorders.

PSYCHIC NUMBING. An inability to respond emotionally with normal intensity to people or situations; this affects positive emotions as well as fear or anger.

PSYCHOACTIVE SUBSTANCE. A drug that produces mood changes and distorted perceptions; a mind-altering drug.

PSYCHOANALYTIC THEORY. A psychological theory proposed by Sigmund Freud involving unconscious conflicts and specific stages of development; central themes include sexuality and male superiority.

PSYCHODRAMA. A specific form of role play that focuses on acting out "scripts" of unresolved issues with-

in the family, or helping family members adopt new approaches and understanding of one another.

PSYCHODYNAMIC. Referring to the motivational forces, unconscious as well as conscious, that form human attitudes and behavior.

PSYCHODYNAMIC GROUPS. Psychotherapy groups that utilize the principles of unconscious needs and motivations developed by Sigmund Freud.

PSYCHODYNAMIC THEORISTS. Therapists who believe that the origins of mental problems lie in a person's internal conflicts and complexes.

PSYCHOEDUCATION. An approach to treatment that combines instruction with various therapeutic techniques.

PSYCHOGENIC. Originating in the mind, or in a mental process or condition. The term "psychogenic" is sometimes used as a synonym for "conversion."

PSYCHOLOGICAL ASSESSMENT. A process of gathering and synthesizing information about a person's psychological makeup and history for a specific purpose, which may be educational, diagnostic, or forensic.

PSYCHOMETRIC. Pertaining to testing and measurement of mental or psychological abilities. Psychometric tests convert an individual's psychological traits and attributes into a numerical estimation or evaluation.

PSYCHOMOTOR. Referring to a response or reaction that involves both the brain and muscular movements.

PSYCHOMOTOR RETARDATION. Slowed mental and physical processes characteristic of a bipolar depressive episode.

PSYCHOMOTOR SEIZURE. A seizure characterized by electrical activity that is characterized by variable degrees of loss of consciousness and often accompanied by bizarre behavior.

PSYCHONEUROTIC. Pertaining to a neurosis or disorder of the brain; emotionally unstable.

PSYCHOPATH. A person who ruthlessly preys on others, using charm, deceit, violence or other methods that allows him or her to get what they want. Another word that is sometimes used for psychopath is sociopath.

PSYCHOPATHY. A psychological syndrome that includes lack of a conscience or sense of guilt, lack of empathy, egocentricity, pathological lying, repeated violations of social norms, disregard of the law, shallow emotions, and a history of victimizing others.

PSYCHOSEXUAL CONFLICTS. In Freudian categories, internal conflicts related to problems at a particular stage

of childhood development. Freud associated each developmental stage with a particular part of the human body, such as the mouth or the phallus.

PSYCHOSIS. (Plural: psychoses) Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an overarching disorder, not a disorder in itself. Psychotic symptoms include delusions and hallucinations.

PSYCHOSOCIAL. A term that refers to the emotional and social aspects of psychological disorders.

PSYCHOSOMATIC. Physical disorder originating in, or aggravated by, the psychic or emotional processes of the individual.

PSYCHOTIC. Mental disorder characterized by disturbances of personality and a loss of normal association with reality.

PSYCHOTROPIC. Having an effect on the mind, brain, behavior, perceptions, or emotions. Psychotropic medications are used to treat mental illnesses because they affect a patient's moods and perceptions.

PTOSIS. Drooping of the upper eyelid.

PUNISHER. Anything that causes a decrease of a particular behavior.

PUNITIVE. Concerned with, or directed toward, punishment.

PURGING. Inappropriate actions taken to prevent weight gain, often after bingeing, including self-induced vomiting or the misuse of laxatives, diuretics, enemas, or other medications.

Q

QI. The Chinese term for energy, life force, or vital force.

QIGONG. A traditional form of Chinese energy therapy that includes physical exercises, breathing techniques, postures, and mental discipline. Internal qigong refers to exercises practiced to maintain one's own health and vitality; external qigong refers to the transfer of energy from a qigong master to another person for healing purposes. External qigong is also known as medical qigong.

QUICKENING. A term that refers to the movements or other signs of life of a fetus in the womb.

R

RADIO WAVES. Electromagnetic energy of the frequency range corresponding to that used in radio communications, usually 10,000 cycles per second to 300 billion cycles per second. Radio waves are the same as visible light, x rays, and all other types of electromagnetic radiation, but are of a higher frequency.

RADIOLOGIST. A medical doctor specially trained in radiology (x ray) interpretation and its use in the diagnosis of disease and injury.

RAPID EYE MOVEMENT (REM) SLEEP. A type of sleep during which the person's eyes move back and forth rapidly underneath their closed eyelids. REM sleep is associated with dreaming.

RAPPORT. A relation of empathy and trust between a therapist and patient.

RATIONAL EMOTIVE THERAPY. A form of psychotherapy developed by Albert Ellis and other psychotherapists based on the theory that emotional response is based on the subjective interpretation of events, not on the events themselves.

RAYNAUD'S SYNDROME. A disorder of the circulatory or vascular system characterized by abnormally cold hands and feet because of constricted blood vessels in these areas.

REALITY TESTING. A phrase that refers to a person's ability to distinguish between subjective feelings and objective reality. A person who knows that their body is real even though they may be experiencing it as unreal, for example, is said to have intact reality testing.

REBOUND EFFECT. A physical reaction to stopping a medication characterized by the reappearance of the symptom that the medication was given to suppress. For example, people who stop taking a sedative may experience rebound insomnia.

RECIDIVISM. A tendency to return to a previously treated activity, or repeated relapse into criminal or deviant behavior.

REFERENTIAL. A type of delusion in which the person misinterprets items, minor occurrences, or other people's behavior as referring to them. Misinterpretations of this sort that are not as resistant to reality as a delusion are sometimes called ideas of reference.

REFOCUSING TECHNIQUES. Techniques that direct one's attention away from overwhelming, negative thoughts and emotions by focusing on inner peace and managing one issue at a time.

REGIMEN. A regulated course of treatment for a medical or mental disorder.

REGISTERED DIETITIAN. A person who has met certain education and experience standards and is well-qualified to provide nutrition counseling.

REGURGITATION. The return of partly digested food from the stomach to the mouth. Regurgitation may be either an intentional act or an involuntary physical reaction.

REHABILITATIVE. To restore; to put back into good condition.

REIKI. A form of energy therapy that originated in Japan. Reiki practitioners hold their hands on or slightly above specific points on the patient's body in order to convey universal life energy to that area for healing.

REINFORCEMENT. Praise or criticism (or, in substance use, physical consequences) that make a behavior more or less likely in the future. Positive reinforcement (like praise or rewards) increase the likelihood of the behavior, and negative reinforcement (such as criticism or withholding of rewards) decrease the likelihood of the behavior.

REINFORCEMENT SCHEDULE. The frequency and amount of reinforcers administered.

REINFORCER. Anything that causes an increase of a particular behavior.

RELAPSE. A person experiences a relapse when he or she re-engages in a behavior that is harmful and that he or she was trying to change or eliminate. Relapse is a common occurrence after treatment for many disorders, including addictions and eating disorders.

RELAXATION RESPONSE. The body's inactivation of stress responses and return of stress hormone levels to normal after a threat has passed.

RELIABILITY. The ability of a test to yield consistent, repeatable results.

REMISSION. In the course of an illness or disorder, a period of time when symptoms are absent.

REPETITIVE STRESS INJURY (RSI). A type of injury to the musculoskeletal and nervous systems associated with occupational strain or overuse of a specific part of the body.

RESPIRATORY DEPRESSION. Significant impairment of the respiratory system.

RESPONSE COST. A behavioral technique that involves removing a stimulus from an individual's environment so that the response that directly precedes the removal is

weakened. In a token economy system, response cost is a form of punishment involving loss of tokens due to inappropriate behavior, which consequently results in decreased ability to purchase back-up reinforcers.

RESPONSE-CONTINGENT. An approach to treatment in which rewards or punishments are given in response to a particular behavior to be encouraged or corrected.

RESPONSE-CONTINGENT LEARNING. A principle that posits that the consequences of a behavior determine whether it will increase or decrease in frequency. Behaviors that bring about desired responses tend to increase, while those that either remove the chance to obtain a desirable outcome, or those that cause some unpleasant or painful consequence, tend to decrease.

RETROGRADE AMNESIA. Amnesia for events that occurred before a traumatic injury.

RETROPERITONEAL. The anatomical area between the peritoneum (lining of the abdominal cavity) and the muscular and connective tissues of the abdominal wall.

RHIZOME. The fleshy underground horizontal root of certain plants. Valerian preparations are made from dried rhizomes as well as from roots of the valerian plant.

RISK ASSESSMENT. The process of gathering and interpreting data useful in estimating the probability that an individual will demonstrate violence.

RISK MANAGEMENT PLAN. Using the results of a risk assessment to tailor intervention strategies intended to reduce the probability that an individual will demonstrate violence.

ROLE. The set of customary or expected behavior patterns associated with a particular position or function in society. For example, a person's role as mother is associated with one set of expected behaviors, and her role as a worker with a very different set.

ROLE TRANSITION. Life changes that require an alteration in one's social or occupational status or self-image.

ROLE-PLAYING. A technique used in assertiveness training and other forms of therapy in which participants act out roles relevant to real-life situations in order to change their attitudes and behaviors.

RORSCHACH TEST. Also known as the Rorschach Psychodiagnostic Test. A commonly administered projective measure in which subjects are asked to describe a series of black or colored inkblots. The inkblots allow the patient to project his or her interpretations, which can be used to diagnose particular disorders.

RUMINATE. To chew or rechew regurgitated food.

RUMINATION. A tendency to dwell on certain thoughts, particularly negative ones, repeatedly or obsessively.

RUSH. The initial intensely pleasurable sensation experienced from injecting a narcotic or stimulant drug. The term has also been applied to the feeling of excitement experienced from the behaviors involved in process addictions.

S

SADISM. A mental disorder in which sexual arousal and gratification are obtained by inflicting pain or humiliation on another person.

SCALE. A subset of test items from a multi-item test.

SCAPEGOATING. the emergence of behavioral problems in one family member, usually the identified patient, who is often punished for problems within the entire family.

SCHILDER'S DISEASE. A disturbance of the white matter of the brain that causes blindness, deafness, and mental deterioration

SCHIZOAFFECTIVE DISORDER. A mental disorder that shows a combination of symptoms of mania and schizophrenia.

SCHIZOPHRENIA. A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

SCHNEIDERIAN SYMPTOMS. Another name for first-rank symptoms of schizophrenia.

SCOLIOSIS. An abnormal lateral (sidewise) curvature of the spine.

SCREENING TEST. A test given as a preliminary tool, that helps to later target a more thorough analysis.

SEASONAL AFFECTIVE DISORDER (SAD). A mood disorder characterized by depression, weight gain, and sleepiness during the winter months. An estimated 4–6% of the population of Canada and the northern United States suffers from SAD.

SECONDARY BEHAVIORS. Negative behavioral, emotional, or cognitive reactions to stuttering.

SECONDARY ENURESIS. Bed-wetting in a child who has established bladder control but has begun to wet the bed again, usually as the result of emotional stress.

SECONDARY GAIN. A term that refers to other benefits that a patient obtains from a conversion symptom. For example, a patient's loss of function in an arm might require other family members to do the patient's share of household chores; or they might give the patient more attention and sympathy than he or she usually receives.

SECTION 504. This section of the Rehabilitation Act of 1973 provides that no person may be discriminated against because of a physical disability.

SEDATION. A state of emotional or physical relaxation. The term is usually used to refer to this condition when it is produced by a medication.

SEDATIVE. A medication that induces relaxation and sleep.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIS). Commonly prescribed drugs for treating depression. SSRIs affect the chemicals that nerves in the brain use to send messages to one another. These chemical messengers (neurotransmitters) are released by one nerve cell and taken up by others. Neurotransmitters not taken up by other nerve cells are taken up by the same cells that released them. This process is termed "reuptake." SSRIs work by inhibiting the reuptake of serotonin, an action which allows more serotonin to be taken up by other nerve cells.

SELF-ACTUALIZATION. The belief that all human beings have an inborn tendency toward growth and self-improvement.

SELF-CONCEPT. Attitudes about oneself.

SELF-EFFICACY. One's belief about how well he or she can perform a given task, regardless of that person's actual ability.

SELF-HELP GROUPS. Groups that fall outside the realm of psychotherapy groups, but that offer help to individuals around a particular problem or concern. These groups typically are not professionally led.

SELF-INSTRUCTIONAL TRAINING. Teaches individuals to become aware of their self-statements, evaluate whether these self-statements are helpful or hindering, and replace maladaptive self-statements with adaptive ones.

SELF-RATED. A term in psychological testing that means that the person taking the test is the one who decides whether a question applies to them and records the answer, as distinct from an examiner's evaluating and recording answers.

SEMANTIC-PRAGMATIC DISORDER. A term that refers to the difficulty that some children with pervasive developmental disorders have with pragmatic language

skills. Pragmatic language skills include knowing the proper tone of voice for a given context, using humor appropriately, making eye contact with a conversation partner, maintaining the appropriate volume of one's voice, etc.

SEMEN. A thick whitish fluid containing sperm, produced by the male reproductive organs.

SEMINAL VESICLES. Sac-like structures bordering the male urethra and serving as storage depots for seminal fluid.

SENSITIVITY TRAINING. Training conducted in T-groups to reduce tensions and racial prejudice among the public.

SENSITIZATION. To make sensitive or susceptible.

SENSORY INTEGRATION THERAPY. A treatment that was originally designed for children with autism. Sensory integration therapy is often performed by occupational or physical therapists; its goal is to help the child with autism process information acquired through the senses (hearing, touch, taste, and smell as well as sight) more effectively.

SEQUELA (PLURAL, SEQUELAE). An abnormal condition resulting from a previous disease or disorder. An episode of depression is a common sequela of acute stress disorder.

SEROTONERGIC. Containing, activating, or otherwise involving serotonin, which is a chemical that aids in the transmission of nerve impulses.

SEROTONIN. A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

SEROTONIN SYNDROME. A condition characterized by at least three of the following symptoms: diarrhea, fever, extreme perspiration, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking. It is a result of too much serotonin in the body.

SEXUAL VIOLENCE. Actual, attempted or threatened sexual contact with a person who is non-consenting or unable to give consent.

SHAMAN. In certain indigenous tribes or groups, a person who acts as an intermediary between the natural and supernatural worlds. Shamans are regarded as having the power or ability to cure illnesses.

SHAPING. A technique used in teaching social skills by prompting and reinforcing behaviors that come close to the desired behavior.

SHIFT. The transition of control from one alter to another in a person with dissociative identity disorder. Usually shifts occur rapidly, within seconds but in some cases a more gradual change over is observed. Also referred to as a switch.

SHORT-CIRCUITING OF CONTINGENCIES. The proper reinforcer or punisher for a given behavior is not administered.

SIBLING RIVALRY. Competition among brothers and sisters in a nuclear family. It is considered to be an important influence in shaping the personalities of children who grow up in middle-class Western societies but less relevant in traditional African and Asian cultures.

SIMPLE PHOBIA. An older term for specific phobia.

SKILLED NURSING FACILITY. An inpatient facility that provides 24-hour nursing services to individuals in need of extended care.

SLE (SYSTEMIC LUPUS ERYTHEMATOSUS). An autoimmune disease that leads to inflammation and damage to various body tissues and parts, including joints, skin, kidneys, heart, lungs, blood vessels, and brain.

SLEEP APNEA. Short periods in which a person stops breathing during sleep. Breathing re-starts spontaneously; however, this condition can lead a lack of oxygen in the body.

SLEEP PARALYSIS. An abnormal episode of sleep in which the patient cannot move for a few minutes, usually occurring while falling asleep or waking up. Sleep paralysis is often found in patients with narcolepsy.

SLEEP TERROR DISORDER. A sleep disorder that is distinguished from nightmare disorder by the intensity of associated anxiety symptoms, the absence of complete wakefulness, and the person's difficulty recalling the episode.

SLOW SUICIDE. A term used to refer to lifestyle behaviors known to shorten life expectancy, such as smoking, drinking heavily, having unsafe sex, etc.

SOCIAL COGNITIVE THEORY. The theory that behavior is determined by an interaction between cognitive, behavioral, and environmental factors.

SOCIAL LEARNING. Learning by observing others' responses and acquiring those responses through imitation of the role model(s).

SOCIAL LEARNING THEORY. A subset of learning theories based on the concept that human behavior originates in and is affected by the interplay among the person's learned experiences, previous behaviors, and environmental influences.

SOCIAL MODELING. A process of learning behavioral and emotional response patterns from observing one's parents or other adults. Some researchers think that social modeling plays a part in the development of conversion disorder in children.

SOCIAL PERSPECTIVE-TAKING. A skill that involves a person's capacity to perceive or recognize other people's thoughts and feelings.

SOCIALIZATION. An ongoing process in which a person learns and internalizes the values and behavior patterns of his or her culture and social group.

SOLUTION-FOCUSED THERAPY. A type of therapy that involves concrete goals and an emphasis on future direction rather than past experiences.

SOMATIC. Relating to the body or to the physical.

SOMATIC CONCERN. Excessive concern about the body, particularly in relation to illness.

SOMATIC EDUCATION. A term used in both Hellerwork and the Feldenkrais method to describe the integration of bodywork with self-awareness, intelligence, and imagination.

SOMATIZATION. When mental or emotional distress is expressed physically in a way that disrupts body function.

SOMATIZATION DISORDER. A type of mental disorder in which the patient suffers from physical complaints that serve as coping strategies for emotional distress.

SOMATOFORM. Referring to physical symptoms with a psychological origin.

SOMATOFORM DISORDERS. A group of psychiatric disorders that are characterized by external physical symptoms or complaints.

SPECIFIC PHOBIA. A type of phobia in which the object or situation that arouses fear is clearly identifiable and limited. An older term for specific phobia is simple phobia.

SPECT. Abbreviation for single photon emission computerized tomography, a highly specialized imaging technique using radioactive substances used in research, and to identify neurological disorder/disease progression.

SPEECH-LANGUAGE PATHOLOGIST. Specialist trained in assessment and diagnosis of communication disorders.

SPIRAL CT. Also referred to as helical CT, this method allows for continuous 360-degree x-ray image capture.

SPLITTING. A psychological process that occurs during the childhood of a person with NPD, in which the child separates aspects of him- or herself that the parents value from those that they disregard.

SPONTANEOUS REMISSION. Recovery from a disease or disorder that cannot be attributed to medical or psychiatric treatments.

STALKING. The intentional pursuit or surveillance of another person, usually with the intent of forcing that person into a dating or marriage relationship. Stalking is now punishable as a crime in all 50 states.

STANDARD DEVIATION. A measure of variability in a set of scores. The standard deviations are based on a comparison to others in the same age group.

STANDARDIZATION. The administration of a test to a sample group of people for the purpose of establishing test norms.

STANDARDIZED TEST. A test that follows a regimented structure, and each individual's scores may be compared with those of groups of people.

STIGMA. A mark or characteristic trait of a disease or defect; by extension, a cause for reproach or a stain on one's reputation. Such sexually transmitted diseases as HIV infection carry a severe social stigma.

STIMULUS. Something that incites or moves a person to thought, emotion, or action. In mainstream psychotherapy, a stimulus can be anything from a certain picture or image to a smell, a sound, or a word or idea. In aversion therapy, the stimulus is typically a mild electric shock or a medication that produces unpleasant results.

STIMULUS FADING. A form of behavior modification used to treat children with selective mutism, in which goals of gradually increasing difficulty are set for the child.

STOOLS. Feces, bowel movements.

STREPTOCOCCUS (PLURAL, STREPTOCOCCI). A type of bacterium that is spherical in shape and occurs in chains or pairs. Some diseases that are caused by streptococci appear to be related to obsessive-compulsive disorder.

STRESS. A physical and psychological response that results from being exposed to a demand or pressure.

STRESS MANAGEMENT. A set of techniques and programs intended to help people cope more effectively with stress in their lives by analyzing the specific stressors and taking positive actions to minimize their effects. Most stress management programs deal with job stress and workplace issues.

STRESSOR. A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

STRIATUM. A part of the basal ganglia, a deep structure in the cerebral hemisphere of the brain. Abnormally high levels of dopamine in the striatum are thought to be related to the delusions and hallucinations of schizophrenia.

STRUCTURAL INTEGRATION. The term used to describe the method and philosophy of life associated with Rolfing. Its fundamental concept is the vertical line.

STUPOR. A trance-like state that causes a person to appear numb to their environment.

SUBDURAL HEMATOMA. Active bleeding or a blood clot inside the dura (leathery covering of the brain). This bleeding or clot causes swelling of the brain, and, untreated, the condition can cause death.

SUBJECTIVE. Referring to a person's unique internal thoughts and feelings, as distinct from the objects of those thoughts and feelings in the external world.

SUBJECTIVE UNITS OF DISTRESS (SUDS) SCALE. A scale used by patients during exposure treatment to rate their levels of fear and anxiety with numbers from zero to 100.

SUBSTANCE ABUSE DISORDER. Disorder that is characterized by: an individual's need for more of a drug or alcohol than intended, an inability to stop using by choice, and an ongoing difficulty in recovering from the effects of the substance.

SUBSTANTIA NIGRA. Dark-colored matter located in a section of the crus cerebri area of the brain.

SUDDEN SNIFFING DEATH. Death resulting from heart failure caused by heavy use of inhalants in a single lengthy session.

SUICIDE GESTURE. Attempted suicide characterized by a low-lethality method, low level of intent or planning, and little physical damage. Pseudocide is another term for a suicide gesture.

SUPEREGO. According to Freud, the part of the mind that represents traditional parental and societal values. The superego is the source of guilt feelings.

SUPPLEMENTAL SECURITY INCOME. A federal program that provides cash to meet basic needs for food, shelter and clothing for aged, blind, and disabled individuals who have little or no income.

SUPPORT GROUP. A group whose primary purpose is the provision of empathy and emotional support for its members. Support groups are less formal and less goal-directed than group therapy.

SUPPORTIVE THERAPY. An approach to psychotherapy that seeks to encourage the patient or offer emotional support to him or her, as distinct from insight-oriented or educational approaches to treatment.

SURVIVOR'S GUILT. A psychological reaction in trauma survivors that takes the form of guilt feelings for having survived or escaped a trauma without serious injury when others did not.

SYDENHAM'S CHOREA. A serious manifestation of acute rheumatic fever that commonly occurs in children ages seven through 14, peaking at age eight. This disease of the central nervous system is characterized by emotional instability, purposeless movements, and muscular weakness. At its peak in the 1950s it occurred in nearly 50% of the acute rheumatic fever cases, but by 2002 had subsided to a degree of less than 10% of the acute cases.

SYNAPTIC CLEFT. An area between nerve cells that can contain neurotransmitters.

SYNCOPE. A brief lapse of consciousness caused by a temporarily insufficient flow of blood to the brain.

SYNDROME. A group of symptoms that together characterize a disease or disorder.

SYSTOLIC. Referring to the rhythmic contraction of the heart (systole), when the blood in the chambers of the heart is forced out. Systolic blood pressure is blood pressure measured during this phase.

T

T-GROUPS. Short for "basic skills training groups" that are focused on education and discussion regarding social issues, personal problems experienced outside the group setting, and problems from one's past.

TACHYCARDIA. A pulse rate above 100 beats per minute.

TACTILE/TACTUAL. Perceptible by touch.

TANNIN. An astringent compound found in chamomile, oak bark, and certain other plants. Tannin in large quantities can interfere with iron absorption.

TARDIVE DYSKINESIA. A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

TARGET BEHAVIOR. The specific behavior to be increased or decreased during treatment.

TAU PROTEIN. A protein that is involved in maintaining the internal structure of nerve cells. The tau protein is damaged in Alzheimer's disease and ends up forming the neurofibrillary tangles.

TEMPERAMENT. A person's natural disposition or inborn combination of mental and emotional traits.

TEMPORAL LOBE. Large lobe of each side of the brain that contains a sensory area associated with hearing.

TEMPOROMANDIBULAR JOINT DISORDER (TMJ). Inflammation, irritation, pain, limited range of motion, and clicking sounds in the jaw caused by improper opening and closing of the joint.

TEMPOROMANDIBULAR JOINT DYSFUNCTION. Condition resulting in pain in the head, face, and jaw. Muscle tension or abnormalities of the bones in the area of the hinged joint (the temporomandibular joint) between the lower jaw and the temporal bone are usually the cause.

TERMINATION. The important process of ending a therapy group.

TETRAHYDRACANNABINOL (THC). The active substance in marijuana.

THALAMUS. The middle part of the diencephalon (a part of the human forebrain), responsible for transmitting and integrating information from the senses.

THEMATIC APPERCEPTION TEST (TAT). A projective test using stories and descriptions of pictures to reveal some of the dominant drives, emotions, sentiments, conflicts, and complexes of a personality.

THEMATIC DREAM MATERIAL. Psychoanalysts use the technique of dream interpretation to offer patients insight into their unconscious conflicts. The dreams of patients include themes, notions, or underlying ideas about specific objects, situations, or issues. When patients begin to understand the content or themes of their dreams, they may gain insight into their unconscious motives.

THERAPEUTIC ALLIANCE. The technical term for the cooperative relationship between therapist and patient that is considered essential for successful psychotherapy.

THERAPEUTIC DYAD. A term that refers to the two people involved in a psychotherapeutic relationship, namely the therapist and the person seeking treatment.

THERAPEUTIC LETTER. A letter written to the deceased in order to help the survivors express feelings and thoughts they may not have been able to before the loss.

THERAPEUTIC TOUCH (TT). An American form of energy therapy based on the ancient tradition of the laying-on of hands. TT is thought to work by removing energy blockages or disturbances from the patient's aura.

THERAPEUTIC VALUE. The potential benefit of an object or situation, in terms of its ability to enhance functioning (social, emotional, intellectual, occupational, etc.) in an individual.

THERAPEUTIC WRITING. A treatment technique in which patients are asked to set down in writing an account of the traumatic event and their emotional responses to it.

THERMISTOR. An electrical device whose resistance decreases with rises in temperature.

THIAMIN. A B-vitamin that is essential to normal metabolism and nerve function, and whose absorption is affected by alcoholism.

THORACIC. Refers to the chest area. The thorax runs between the abdomen and neck and is encased in the ribs.

THOUGHT INSERTION/WITHDRAWAL. The notion that an outside force (space aliens, evil people, etc.) can put thoughts or ideas into one's mind or remove them. It is considered one of the first-rank symptoms of schizophrenia.

THROMBOCYTOPENIA. A condition involving abnormally low numbers of platelets (blood-clotting agents) in the blood; usually associated with hemorrhaging (bleeding).

THYROID. A gland in the neck that produces the hormone thyroxin, which is responsible for regulating metabolic activity in the body. Supplemental synthetic thyroid hormone is available as pills taken daily when the thyroid fails to produce enough hormone.

THYROID HORMONE. A complex hormone that regulates metabolic rate of all cells.

THYROTOXICOSIS. A disease characterized by an enlarged thyroid gland and speeded-up body metabolism

caused by excessive thyroid secretion. It is also known as Graves' disease.

TIC. A sudden involuntary behavior that is difficult or impossible for the person to suppress. Tics may be either motor (related to movement) or vocal, and may become more pronounced under stress.

TINCTURE. An alcohol-based herbal extract prepared by soaking parts of the plant in a mixture of alcohol and water. Established ratios and dilutions are followed.

TISSUE PLASMINOGEN ACTIVATOR (TPA). A drug that is sometimes given to patients within three hours of a stroke to dissolve blood clots within the brain; also used to treat heart attack victims.

TOKEN. Any item that can be seen and collected (such as stickers or points in a point tally) that has no value of its own, but is used as an immediate reward for desirable behavior that is later exchanged for back-up reinforcers.

TOLERANCE. Progressive decrease in the effectiveness of a drug with long-term use.

TONIC-CLONIC (GRAND MAL) SEIZURE. This is the most common type of seizure and is categorized into several phases beginning with vague symptoms hours or days before an attack. During the seizure, there is abnormal muscle contraction and relaxation and the individual may lose consciousness.

TOPICAL. A type of medication or preparation intended for use on the skin or external surface of the body.

TORPOR. Sluggishness or inactivity.

TOURETTE SYNDROME. Neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics that come and go over years, usually beginning in childhood and becoming chronic. Sometimes the tics include inappropriate language.

TOURNIQUET. A rubber tube or length of cloth that is used to compress a blood vessel in order to stop bleeding or to shut off circulation in a part of the body. The tourniquet is wrapped around the arm (or other limb) and tightened by twisting.

TOXICOLOGY SCREEN. A blood or urine test that detects the presence of toxic chemicals, alcohol, or drugs in body fluids.

TOXOCARIASIS. Infection with roundworm larvae, commonly transmitted by the feces of dogs and cats.

TOXOPLASMOSIS. A parasitic infection caused by the intracellular protozoan *Toxoplasmosis gondii*. Humans are most commonly infected by swallowing the oocyte form of the parasite in soil (or kitty litter) contaminated by feces from an infected cat; or by swallowing the cyst form of the parasite in raw or undercooked meat.

TRACE MINERAL. An element essential to nutrition or bodily processes that is found in minute quantities.

TRACHEOSTOMY. A surgical procedure in which an artificial opening is made in the patient's windpipe to relieve airway obstruction.

TRAIT ANXIETY. A type of persistent anxiety found in some patients with generalized anxiety disorder. Trait anxiety is regarded as a feature (trait) of a person's temperament.

TRANQUILIZER. A medication that induces a feeling of calm and relaxation.

TRANSCENDENTAL MEDITATION (TM). A meditation technique based on Hindu practices that involves the repetition of a mantra.

TRANSSEXUAL. A person whose gender identity is opposite his or her biologic sex.

TRANSVESTITE. A person who derives sexual pleasure or gratification from dressing in clothing of the opposite sex.

TRAUMA. A disastrous or life-threatening event that can cause severe emotional distress, including dissociative symptoms and disorders.

TREMOR. Involuntary shaking of the hands and arms.

TREPANATION OR TREPANNING. Surgical removal of a piece of the skull to expose the brain.

TRIANGLING. A process in which two family members diminish the tension between them by drawing in a third member.

TRICHOBEZOAR. A hairball that results from a buildup of swallowed hairs becoming lodged in the digestive system.

TRICHOPHAGIA. Eating hair.

TRICHOPHAGY. Biting hair.

TRICHOTILLOMANIA. A disorder marked by repeated pulling and tugging of one's hair, usually resulting in noticeable hair loss on the scalp or elsewhere on the body.

TRICHURIASIS. Infection with the larvae of roundworms. These parasites may live for 10–20 years in humans.

TRICYCLIC ANTIDEPRESSANTS (TCAS). Antidepressant medications that have the common characteristic of a three-ring nucleus in their chemical structure. Imipramine and amitriptyline are examples of tricyclic antidepressants.

TRIGGER. Any situation (people, places, times, events, etc.) that causes one to experience a negative emotional reaction, which is often accompanied by a display of symptoms or problematic behavior.

TRIGLYCERIDES. Fats in the blood.

TRISOMY. An abnormality in chromosomal development. Chromosomes are the structures within a cell that carry its genetic information. They are organized in pairs. Humans have 23 pairs of chromosomes. In a trisomy syndrome, an extra chromosome is present so that the individual has three of a particular chromosome instead of the normal pair. An extra chromosome 18 (trisomy 18) causes mental retardation.

TRYPTOPHAN. An essential amino acid released from proteins during the process of digestion. Tryptophan is an important ingredient in the body's production of serotonin.

TSUBO. In shiatsu, a center of high energy located along one of the body's meridians. Stimulation of the tsubos during a shiatsu treatment is thought to rebalance the flow of vital energy in the body.

TUBERCULOSIS. An infection caused by the bacteria *Mycobacterium tuberculosis* that usually affects the lungs. Individuals with tuberculosis may have nighttime sweating, fever, weight loss, cough, and may spit up blood and mucus.

TYPE II DIABETES. Resistance to the effects of insulin in the presence of normal or elevated insulin levels, resulting in failure of glucose to enter cells and in a cascade of other abnormal physiologic reactions.

TYRAMINE. Intermediate product between the chemicals tyrosine and epinephrine in the body and a substance normally found in many foods. Found especially in protein-rich foods that have been aged or fermented, pickled, or bacterially contaminated, such as cheese, beer, yeast, wine, and chicken liver.

U

ULTRASONOGRAPHY. A process that uses the reflection of high-frequency sound waves to make an image of structures deep within the body. Ultrasonography is routinely used to detect fetal abnormalities. In stroke victims, a cardiac ultrasound, or echocardiogram, allows the beating heart to be examined.

UNCONDITIONAL POSITIVE REGARD. A quality of the client-centered therapist, characterized by the therapist's acceptance of the client without judgment.

UNIVERSALITY. The feeling of being isolated, unique, and separate from others, often experienced by therapy group members.

URETHRA. The tubular passage conducting urine from the bladder to the exterior. In the male, the urethra traverses the penis.

URETHRITIS. Inflammation of the urethra, which is the duct that carries urine and (in males) semen to the outside of the body.

URINARY INCONTINENCE. A term that is sometimes used for enuresis in adults. Urinary incontinence is often found in patients with late-stage Alzheimer's disease or other adult-onset dementias.

URINARY RETENTION. Excessive storage of urine in the body.

URINARY SYSTEM. The kidney, urethra, bladder, and associated organs that process urine and eliminate it from the body.

UTERUS. The hollow muscular sac in which a fetus develops; sometimes called the womb.

UTILIZATION REVIEW. A process used by managed care organizations involving scrutiny of service care delivery to determine whether services are necessary.

V

VAGINA. The part of the female reproductive system that opens to the exterior of the body and into which the penis is inserted during sexual intercourse.

VAGINISMUS. An involuntary tightening of the vaginal muscles that makes sexual intercourse painful, difficult, or impossible.

VALERENIC ACID. The primary medicinal component in valerian preparations.

VALIDITY. The ability of a test to measure accurately what it claims to measure.

VASCULAR. Pertaining to the bloodstream (arteries, veins, and blood vessels).

VETERAN'S ADMINISTRATION HOSPITALS. Medical facilities operated by the federal government explicitly for veterans of the United States military.

VICARIOUS. Acquired through imagined participation in the experience of others. Modeling is a form of vicarious learning.

VIRTUAL REALITY. A realistic simulation of an environment, produced by a computer system using interactive hardware and software.

VOLATILE SOLVENT. A solvent (substance that will dissolve another substance) that evaporates at room temperature.

VOYEUR. A person who engages in the behavior of voyeurism.

VOYEURISM. A paraphilia that involves watching unsuspecting people, usually strangers, undress or engage in sexual activity.

VULVAR VESTIBULITIS SYNDROME (VVS). Vulvar vestibulitis syndrome is thought to be the most frequent cause of dyspareunia in premenopausal women. A chronic, persistent clinical syndrome, vulvar vestibulitis is characterized by severe pain on vestibular touch or attempted vaginal entry.

W

WAXY FLEXIBILITY. A condition in which a person can be molded into a strange position and hold that position for a long period of time.

WERNICKE'S SYNDROME. A group of symptoms that appears in some people who are dependent on alcohol. Due to low levels of thiamin, the syndrome results in disordered eye movements, very poor balance and difficulty walking.

WERNICKE-KORSAKOFF SYNDROME. Group of symptoms that appears in people who are dependent on alcohol. The syndrome is due to a thiamin deficiency, and severely affects one's memory, preventing new learning from taking place.

WITHDRAWAL. Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

WRAPAROUND. A relatively new form of mental health service delivery that strives to accommodate all family members based on self-defined needs, flexibly incorporating both formal and informal community services.

X

XANTHINE. A class of crystalline nitrogenous compounds that includes caffeine.

Y

YIN AND YANG. In traditional Chinese medicine and philosophy, a pair of opposing forces whose harmonious balance in the body is necessary to good health.

YOGA. A system of exercises for achieving bodily or mental control and well-being.

YOGI (FEMININE, YOGINI). A person who is a respected expert in or teacher of yoga.
