Klotz, Otto Julius

Born **Preston, (Cambridge, Ontario, Canada), 31 March 1852**
Died **Ottawa, Ontario, Canada, 28 December 1923**

Otto Klotz pioneered the development of geophysics in Canada. The son of German immigrants Otto and Elisé (*née* Wilhelm) Klotz, Otto studied at the local grammar school and entered the University of Toronto in 1869 but transferred to the University of Michigan the following year. There he studied with James Craig Watson at the Detroit Observatory. After graduating as a civil engineer in 1872, Klotz returned to Preston to establish a private surveying practice. After obtaining the highest qualifications in surveying, he became a contract surveyor for the Department of the Interior (1879), working on the prairie surveys. In 1885, the department gave him the more difficult task of surveying the Canadian Pacific Railway line through the mountains of British Columbia. In 1892, Klotz moved to Ottawa to become a permanent staff member. With the Chief Astronomer, **William King**, Klotz helped to press for, and then design, the future Dominion Observatory, which opened in Ottawa in 1905. Klotz was effectively the assistant director and headed the geophysical work at the observatory. On King's death in 1916, Klotz's appointment as director was held up due to anti-German sentiment. He became chief astronomer and director in 1917, serving till his death.

Klotz was active in the Royal Astronomical Society of Canada, a fellow of the Royal Society of Canada, and recipient of honorary degrees from the universities of Toronto, Michigan, and Pittsburgh. He was Canada's organizing head for entering both the International Union for Geodesy and Geophysics and the International Astronomical Union in 1919–1922. He was also president of the Seismological Society of America. Klotz and his wife Marie Widenmann (married 1873) had four children.

Klotz can be considered Canada's pioneer geophysicist. His division at the Dominion Observatory produced important results for decades after his death. He worked on gravity measurements and magnetic field surveys, but was most interested in the new field of seismology, working on microseisms. At the time of his death, the Dominion Observatory was one of the most important seismological stations in the world.

Klumpke Roberts, Dorothea

Born **San Francisco, California, USA, 9 August 1861**
Died **San Francisco, California, USA, 5 October 1942**

Dorothea Klumpke Roberts headed the Paris Observatory's Bureau of Measurements for the *Carte du Ciel* project, and also published the photographic *Isaac Roberts Atlas of 52 Regions.*

Dorothea Klumpke and her four sisters (all of whom became distinguished in their own fields) were educated in California and then in Paris. She received a BS in mathematics and mathematical astronomy from the University of Paris in 1886, and in 1893 became the first woman to receive the degree Doctor of Science there. Her dissertation was a mathematical study of the rings of Saturn.

In 1887, Klumpke began work at the Paris Observatory, measuring star positions on photographic plates. When the Paris Observatory was assigned a large section of the sky to be photographed for the *Carte du Ciel* project, she was appointed to head the Bureau of Measurements, and from 1891 to 1901 she carried out this task so well that she was awarded the first Prix des Dames of the Société Astronomique de France (1889) and Officier of the Paris Academy of Sciences in 1893.

In 1901 Klumpke married **Isaac Roberts**, an amateur astronomer and pioneer in astronomical photography. They settled in England, and she assisted him in his work. After Roberts' death in 1904, she returned to France and lived with her mother and sister, continuing Roberts' work and publishing results from time to time. In 1929 she published the *Isaac Roberts Atlas of 52 Regions, a Guide to William Herschel's Fields of Nebulosity*, followed by a 1932 supplement; these contained fine enlargements of 50 photographs from Roberts' collection. This earned her the Hélène-Paul Helbronner Prize from the French Academy of Sciences in 1932. In 1934 she was elected Chevalier of the Legion of Honor in recognition of 48 years of service to French astronomy.

About this time, Klumpke Roberts retired from active work, and returned to San Francisco, where she continued her interest in astronomy and young astronomers. She endowed several prizes through the Paris Observatory and the University of California, and gave money to the Astronomical Society of the Pacific for the Klumpke–Roberts Lecture Fund, named in honor of her parents and her husband. This has subsequently become the Klumpke–Roberts Award for those who have excelled in the popularization of astronomy.

Kneller, Andreas

Flourished **(the Netherlands), *circa* 1660**

Other than the fact that he lived in the Netherlands, little is known about Andreas Cellarius. His *Harmonica Macrocosmica*, one of the most beautiful celestial atlases of all time, is a snapshot of 17th-century cosmology: All three major systems (Ptolemaic, Tychonic, and Copernican) are lavishly illustrated by Cellarius.

Alternate name

Cellarius

Knobel, Edward Ball

Born **London, England, 21 October 1841**
Died **probably London, England, 25 July 1930**

After **Christian H. Peters**' death, his editing and republication of **Ptolemy**'s *Almagest* was taken up by English amateur astronomer Edward Knobel. Knobel made significant observations of Mars and Jupiter, and was a cataloger of double stars.

Knobel was instrumental in resolving a major crisis in the Royal Astronomical Society [RAS]. His report on the Sadler–Smyth controversy – see **William Smyth** – was responsible for clearing Smyth's name and for Herbert Sadler's resignation from the RAS Council in disgrace.

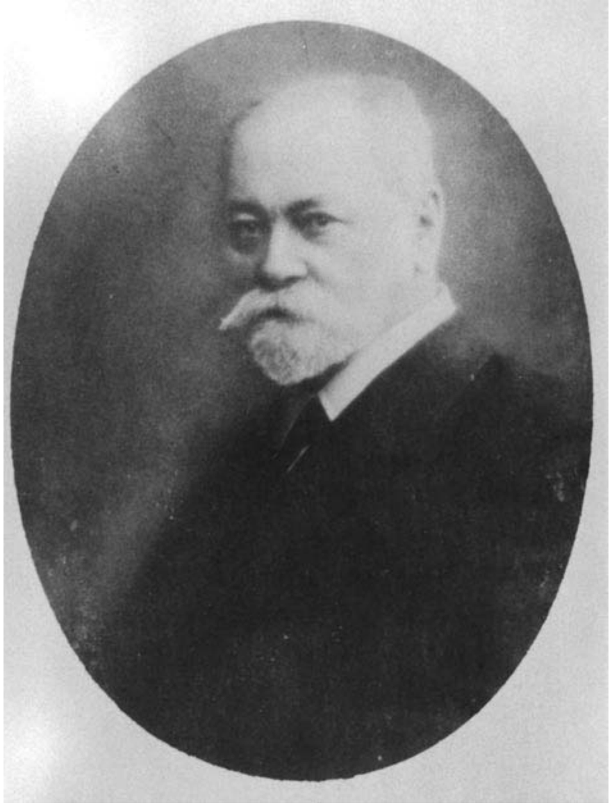
Knorre, Viktor Carl

Born **Nikolajew, (Ukraine), 4 October 1840**
Died **Lichterfelde, (Sachsen-Anhalt), Germany, 25 August 1919**



Viktor Knorre discovered four asteroids and contributed to telescope accessory and mounting improvements. A third-generation astronomer, Knorre was one of the 15 children of Karl Friedrich Knorre (1801–1883), director of the astronomical observatory in Crimea until 1871. Because of the difficult educational situation in Russia, Karl Knorre sent Viktor to school in Fellin, Estonia.

Knorre returned home after he had finished school and helped his father at the observatory for 2 years. In 1862 he left for Berlin, to study astronomy with Wilhelm Förster (1832–1921). After presenting his doctoral thesis Knorre went to Pulkovo Observatory in 1867 as an astronomical calculator. During his time there he traveled with Heinrich Wild (1833–1902) to inspect some meteorological stations and made observations to get the exact location of these stations. He also made magnetic observations.

In 1869 Knorre returned to Nikolajew where he first taught his younger brothers and sisters and then got a post as teacher at the local school. It seems that he earned a lot of praise but received little or no money at all for his work; he left for Berlin again to meet his father who had gone there after retiring from his post in Nikolajew. Knorre soon joined the Berlin Observatory as an observer, where he used the refractor made by **Joseph von Fraunhofer**. His main work involved minor planets, comets, and binary stars. On 4 January 1876 he discovered the minor planet (158) Koronis, followed by (215) Oenone, (238) Hypatia, and (271) Penthesilea in later years. For the observations of minor planets Knorre constructed a micrometer that he described in its various stages of development within the pages of the *Astronomische Nachrichten*.

Knorre also worked on the improvement of other instruments and equatorial telescope mountings. He did not take a post in teaching students at the University in Berlin but was always helpful in introducing new users to the telescopes.

In 1892 Knorre was appointed professor. In 1906 he retired and moved to Lichterfelde, close to Berlin, where he owned a house. Knorre found recreation, away from his ongoing scientific work, while working in the garden or playing chess. In 1909 and 1911 he published works on a new equatorial telescope mounting. A prototype was made by Heele at Knorre's expense.

Knorre died after a short illness.

Kobold, Hermann Albert

Born **Hanover, (Germany), 5 August 1858**
Died **probably Kiel, Germany, 11 June 1942**

Hermann Kobol's more than 200 papers on comets, planets, asteroids, solar motion, eclipses, and the rotation of stellar systems appeared in several journals, including the *Astronomische Nachrichten*, which he edited between 1907 and 1938.

Kobold earned his Ph.D. from Göttingen in 1880; he was a pupil of **Ernst Klinkerfues.** Kobold was first employed as an assistant to **Miklós Konkoly Thege** at O'Gyalla Observatory in Hungary, and then at the University of Strasbourg. He was part of the German team for the 19th-century transits of Venus. In 1902, Kobold got a transfer to Kiel, where he became an "observator" and professor of astronomy at the university. Kobold also wrote a 1906 textbook on stellar astronomy. He retired in 1925.

Köhler, Johann Gottfried

Born **Gauernitz near Meissen, (Sachsen, Germany, 15 December 1745**
Died **Dresden, (Germany), 19 September 1801**

From 1776, Johann Köhler served as *Inspektor* (curator), and from about 1785 until his death as *Oberinspektor* (director), of both the Kunstkammer and the Mathematisch–Physikalischer Salon in Dresden. He published a list of "nebulae" in 1780. The list included several independent discoveries of deep-sky objects that eventually received numbers in **Charles Messier**'s catalog. Köhler's instruments also were apparently used by **Alexander von Humboldt** on his first voyage to South America.

Kohlschütter, Arnold

Born **Halle, Germany, 6 July 1883**
Died **Bonn, (Germany), 28 May 1969**

Arnold Kohlschütter and **Walter Adams** found subtle criteria that could distinguish ordinary giants from dwarf stars.

Kohlschütter was educated at Göttingen University, a student of **Karl Schwarzschild**. He spent 3 years at Mount Wilson Observatory, California, from 1911 to 1914. There he cooperated with Adams in the work that led to a new method for determining the distances to stars.

Kohlschütter and Adams examined the spectra of stars with both large and small parallaxes, but similar apparent magnitudes. The stars with smaller parallaxes were necessarily more luminous. The two Mount Wilson spectroscopists found differences in the absorption-line strength ratios between the two sets of stars – even within the same spectral class. Once calibrated using stars of known distance, these differences could be observed in stars without measured parallax in order to determine their distances. The method refined the technique known as spectroscopic parallax. When coupled with the apparent magnitudes of the stars involved, this method allowed the determination of stellar distances greater than the limit measurable by trigonometric parallax, surpassing the quality of traditional parallax measurements at 25 pc.

In 1897, **Antonia Maury** had identified a few peculiar spectrograms characterized by some of the absorption lines being unusually sharp and others unusually strong for the stellar colors. **Ejnar Hertzprung** recognized in 1905 that these stars were supergiants, the brightest sort known. Kohlschütter and Adams found that differences in line properties arise from the lower gas densities in giant atmospheres, which sharpen those lines whose width is due mostly to Stark effect broadening and strengthen lines produced by ionized atoms, because recombination proceeds more slowly at low density.

In a second Mount Wilson collaboration, Kohlschütter and **Harlow Shapley** concluded that even strong absorption lines typically have a residual flux at their centers that is 20–30% of the continuum, meaning that the region of a stellar atmosphere responsible for the absorption features must be located near an optical depth of 0.2.

In 1918 Kohlschütter was appointed to the staff of Potsdam Observatory, and in 1925 became professor of astronomy at Bonn and director of the observatory there. He undertook the Bonn portion of the *Zweiter Katalog der Astronomischen Gesellschaft*, completed in 1958.

Kohlschütter was coauthor of the *Handbuch der Astrophysik* (1928; with Gustav Eberhard and **Hans Ludendorff**) and of a revised version of **Simon Newcomb**'s *Popular Astronomy* (1926).

Kolhörster, Werner Heinrich Julius Gustav

Born **Schwiebus (Świebodzin, Poland), 28 December 1887**
Died **Munich, Germany, 5 August 1946**

Werner Kolhörster helped bring modern, quantitative methods to the study of cosmic rays.

Kolhörster earned his Ph.D. in physics under the direction of Friedrich Ernst Dorn at the University of Halle in 1911. He then became interested in the discovery of cosmic rays in the Earth's upper atmosphere by Austrian physicist **Victor Hess**, achieved by means of balloon ascensions (up to 5-km altitude) with an electrometer. Kolhörster extended the balloon-borne measurements up to 10-km altitude and fully demonstrated the validity of Hess's conclusions. He remained an assistant at the Physical Institute in Halle until the outbreak of World War I.

After the war, Kolhörster was forced into secondary teaching to support himself, at the Friedrich Werdersche Oberrealschule (*circa* 1920–1924) and the Sophien Realgymnasium, Berlin (*circa* 1924–1928). Nonetheless, Kolhörster became a guest investigator at the Physikalische-Technische Reichsanstalt in Berlin, where he significantly improved the instrumentation used to measure various types of radiation. He frequently tested his equipment in the Alps. In collaboration with physicist Walther Bothe, Kolhörster developed the so called coincidence method of scintillation counting, for which he was awarded the Leibniz Medal of the Prussian Academy of Sciences. Their joint papers in 1928 and 1929 were important in establishing that cosmic rays are very high energy particles, and not very short wavelength photons.

In 1928, Kolhörster was hired as an observer at the Magnetic-Meteorological Observatory at Potsdam. Two years later, he was appointed a *Privatdozent* (lecturer) in geophysics at the University of

Berlin, and concurrently designed the Dahlemer University Institute for High-altitude Radiation Research, the first such facility ever to be established. In 1935, Kolhörster became the laboratory's director and professor of radiation physics. He shared in the discovery of airshowers associated with the production of secondary cosmic rays.

With Leo Tuwim, Kolhörster wrote a leading text, *Physakalische Probleme der Höhenstrahlung* (Physical problems of high-altitude radiation).

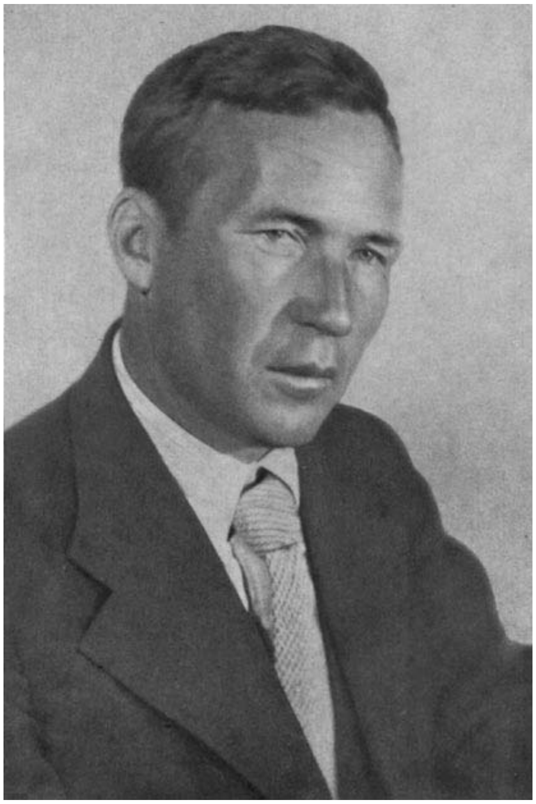
Kolmogorov, Andrei Nikolaevich

Born **Tambov, Russia, 25 April 1903**
Died **Moscow, (Russia), 20 October 1987**



The works of leading Soviet mathematician Andrei Kolmogorov found diverse applications in the treatment of dynamical systems and the study of turbulence or chaos theory as those fields applied to astronomy. The so called Kolmogorov spectrum describes, for instance, the structure of turbulence in the intersteller medium reasonably well. Kolmogorov's father was Nicholas Matveyevich Katayev; his mother, Maria Yakovlevna Katayeva (*née* Kolmogorova), died from complications surrounding his birth. He was then adopted by his aunt, Vera Yakovlevna Kolmogorova, and received her family name. He married Anna Dmitriyevna Kolmogorova (*née* Egorova).

Before the October 1917 Bolshevik Revolution, Kolmogorov studied in Moscow at the private E. A. Repmann Gymnasium; after the revolution, he attended a high school of the second level. In 1920, he was admitted to Moscow University as a student of the Faculty of Mathematics. There, Kolmogorov began his scientific activities under the guidance of professors P. S. Urysohn, A. K. Vlasov, V. V. Stepanov, and especially N. N. Luzin. In 1922, he acquired experience as a secondary school mathematics teacher, an occupation to which he voluntarily returned after the age of 60. Kolmogorov graduated from Moscow University in 1925 and then enlisted as a postgraduate student. After finishing postgraduate studies, Kolmogorov obtained a position as chair of mathematics at the Moscow Karl-Liebknecht Pedagogical Institute. He also began scientific research at the Mathematical Institute of Moscow University.

Kolmogorov's early research explored the theory of functions of a real variable. He investigated the convergence of trigonometric series, the theory of measure, the theory of functional approximations, set theory, and the theory of integrals. In 1925, working with A. J. Khintchine, he applied methods of the theory of functions to the theory of probabilities. In 1933, Kolmogorov constructed the axiomatic foundations of the theory of probabilities and established the theory of Markovian random processes in continuous time. During the period from 1939 to 1941, he solved extrapolation and interpolation problems concerning stationary processes. He clarified the link between the theories of random processes and that of Hilbert spaces and formulated many problems in terms of functional analysis. Kolmogorov investigated ergodic theorems and formulated the necessary and sufficient conditions of applicability for the law of large numbers. He made significant contributions to constructive logic and topology, having introduced in 1935 the so called upper limit operator (or Nabla-operator) and the topologic invariant of the cohomology ring. Kolmogorov formulated the idea of a topological vector space, and was deeply engaged in the theory of differential equations and in functional analysis. In his works concerning fluid mechanics, Kolmogorov created and developed the concept of local isotropy of turbulence in a viscous, incompressible fluid (at large Reynolds numbers), having established with Alexander M. Obukhov the spectrum of local turbulence (the Kolmogorov–Obukhov law of 2/3).

In celestial mechanics, Kolmogorov's results are especially applicable to the theory of dynamical systems as related to perturbed motions in Hamiltonian systems. These relationships describe, for example, the motion of an asteroid in an elliptical orbit under the perturbing influence of Jupiter. The same equations are pertinent to a wide range of problems addressing the stability of magnetic surfaces in fields with Tokamak geometries (*e. g.*, inside toroidal chambers known as "magnetic traps" and used in thermonuclear fusions experiments) and the stability of rapid rotation of a massive asymmetric rigid body. This work has been continued and expanded by his pupil, Vladimir I. Arnold, who examined the stability of quasi-periodicity in the three-body problem. Generalized methods to construct inverse functions by successive approximations, which overcame difficulties caused by small divisors, were developed by Kolmogorov, Arnold, and Jürgen Moser. The corresponding theory, known as KAM theory, draws its name from the initials of these three men. It plays an important role in investigations of the stability of the Solar System over very long (cosmogonical) timescales.

Kolmogorov was elected a member (academician) of the USSR Academy of Sciences (1939), the academician-secretary of the Department of Mathematics of the USSR Academy of Sciences (1939), a member of the USSR Academy of Pedagogical Sciences (1968), and president of the Moscow Mathematical Society (1964–1966). He received honorary doctoral degrees from the Paris Sorbonne University (1955), Stockholm University (1960), and the Institute of Statistics in India (1962). Kolmogorov was awarded the Stalin Prize (1940), the Eugenio Balzan Prize (1963), and the Lenin Prize (1965). He was declared a "Hero of the Socialist Labor" (1963) and was decorated with many orders and medals from the USSR, Hungary, and the German Democratic Republic.

Konkoly Thege, Miklós [Nikolaus]

Born **Pest (Budapest, Hungary), 20 January 1842**
Died **Budapest, (Hungary), 16 February 1916**

Well respected as an early participant in the evolution of astrophysics, Miklós Konkoly Thege founded an institute for the study of astronomy and astrophysics in Hungary using his own resources. He is rightly thought of as the founder of astronomy in Hungary, although such noteworthy astronomers as **János von Zach** and **Miska Höll** were Hungarian natives practicing astronomy abroad.

The Konkoly Thege family was Hungarian nobility with a considerable landed estate. His parents were Elek and Klára (*née* Földvári) Konkoly Thege. Miklós studied at the universities of Pest (1857–1860) and Berlin (1860–1862), earning a doctor of law degree. While in Berlin, he studied astronomy with **Johann Encke**, J. H. Dove, and H. G. Magnus.

Upon request of his parents he became the subprefect of a Hungarian county for a short time, but Konkoly Thege was much more interested in physics and astronomy. Skillful with his hands, he made his own instruments when becoming an astronomer. In his youth, Konkoly Thege traveled extensively, studied the European observatories, visited the leading optical and precision-mechanical workshops, and made acquaintance with distinguished astronomers of the period.

In 1871, Konkoly Thege built a private observatory on his own estate in Ógyalla (now Hurbanovo, Slovakia). He equipped the observatory with both purchased equipment and instruments he made in his own shops. The largest telescope was a 10.25-in. Browning silver-on-glass Newtonian reflector purchased in England (1874). The most important self-made instruments include a 10-in. refractor (still in use in the Debrecen Heliophysical Observatory), a 6.25-in. astrograph, a 5.25-in. telescope for solar photography, numerous spectrographs, and spectroscopes for observing prominences, meteors, comets, and other celestial objects.

Konkoly Thege's astronomical activity included extensive observational work on various celestial bodies, instrument development, and publication of handbooks on observational astronomy. During his study of sunspots Konkoly Thege drew the projected solar disk and determined the position and shape of the spots. From 1908 on, the sunspots were followed photographically. Sunspot results were reported regularly to Zürich.

Konkoly Thege was one of the first astronomers who carried out spectroscopic observations of meteors, attempting to determine their chemical composition. He studied the spectra of about 30 comets, a pursuit that earned him wide recognition.

At the request of **Hermann Vogel**, Konkoly Thege compiled a catalog describing the spectra of 2,022 stars observed from Ógyalla. Unfortunately, the stellar spectra in this catalog were classified according to the Potsdam Observatory system. Within a few years, after the publication of the Ógyalla catalog, the Harvard system of spectral classification was adopted internationally; in consequence the Ógyalla catalog is less well remembered today.

Konkoly Thege also made drawings of the surface features of the planets Mars and Jupiter. Konkoly Thege's published astronomical and astrophysical work is extensively cited in the contemporary literature, for example, in *A Treatise on Astronomical Spectroscopy*, **Edwin Frost**'s translation, and revision of **Julius Scheiner**'s earlier work.

Konkoly Thege's involvement in the invention and development of instrumentation for astronomy was significant and productive. Two of his inventions that deserve special mention in this regard were several types of a simple, direct vision solar flare telescope, and the blink comparator. One model of the solar flare spectroscope was marketed by Zeiss, though without acknowledging Konkoly Thege's role as the inventor. His blink comparator was eventually manufactured and marketed by G. Heide of Dresden.

One of Konkoly Thege's more lasting contributions to the development of astrophysics was in his publications of detailed instructions on technique. His several books on astrophysics were richly detailed and extensively illustrated with woodcut drawings of equipment. As a result, Konkoly Thege was asked to write the chapter on astrophotography for the influential four-volume compendium, *Handwörterbuch der Astronomie* edited by Karl Wilhelm Friedrich Johannes Valentiner (1845–1913).

As a mentor to other individuals interested in astronomy and astrophysics, Konkoly Thege performed the invaluable role of encouraging the development of other private observatories in Hungary. In addition to the well-equipped and productive observatory of **Jenõ von Gothard** at Herény, and Bishop Haynald's observatory in Kalocsa, Konkoly Thege was also instrumental in the founding of the Kiskartal Observatory of Baron Géza Podmaniczky. The Kiskartal Observatory employed several rising young professional astronomers, and was the site at which the Baroness Berta Dégenfeld-Schomburg made her independent discovery of the extragalactic supernova S Andromedae (SN 1885A). In addition to the scientific contributions of these private observatories, they enriched Hungarian astronomy with extensive collections of instruments and valuable libraries that form the basis for modern institutes in Hungary.

In 1890, Konkoly Thege was appointed director of the National Institute of Meteorology and Geomagnetism. During his directorship the forecast service was created, and the first meteorological maps appeared. The tasks of organization took up his days, leaving little time for astrophysics. Konkoly Thege suggested several times that he wished to transfer ownership of the Ógyalla Observatory to the state, but the problem was complicated by both the political instability and the financial weakness of the Habsburg Austro–Hungarian Empire. Konkoly Thege's highly creative solution to this problem was to invite the Astronomische Gesellschaft [AG] to hold its 17th assembly in Budapest in 1898. He was extremely well known and well-liked by European colleagues like **Willliam Huggins**, many of whom had visited his observatory. As a result the AG ignored a parallel invitation from the Heidelberg Observatory and elected to meet in Budapest. The pressure on Emperor Franz Josef and his cabinet from the resulting international gathering succeeded where other attempts had failed. The emperor himself made the announcement that the state would acquire the Ógyalla Observatory in his address to the assembled astronomers. Therefore in 1899, Konkoly Thege donated the Ógyalla Observatory to the Hungarian state. The observatory's successor is now the Konkoly Observatory of the Hungarian Academy of Sciences, with its headquarters in Budapest.

Konkoly Thege was elected corresponding member (1876), then honorary member (1885) of the Hungarian Academy of Sciences, and a member of the Astronomische Gesellschaft and the Royal Astronomical Society. The minor planet (1445) Konkolya is named for him.

Konkoly Thege retired from his position at the Meteorological Institute in 1911. He was also a talented pianist and qualified maritime engineer and ship captain. In his later years he was again involved in politics as a member of the Hungarian parliament (from 1896 to 1906). Konkoly Thege married Erzsébet Madarassy; their two children died in early childhood.

Kopal, Zdeněk

Born **Litomysl, (Czech Republic), 4 April 1914**
Died **Manchester, England, 23 June 1993**

Czech–American–English astronomer Zdeněk Kopal is most often associated with studies of close binaries and their implications for the interior physics of stars and kinds of systems observed. A youthful enthusiastic amateur astronomer, Kopal joined the Czech Astronomical Society in 1929 and became chair of its section on variable stars in 1931. He received a Ph.D. *summa cum laude* in physics and mathematics at the Charles University of Prague (by then part of Czechoslovakia) in 1937, studied under **Arthur Eddington** in Cambridge, England, in 1938, and took an appointment at **Harlow Shapley**'s Harvard College Observatory at the end of that year. Kopal quickly became an American citizen and worked on ballistics for the United States Navy at the Massachusetts Institute of Technology during World War II, as well as contributing to the mathematics needed for the first generation of computers. In 1951 he became professor and founding chair of the Astronomy Department at the University of Manchester, retiring in 1981 but remaining an active professor emeritus for the rest of his life. His daughter Zdenka married a British astronomer.

Kopal's Ph.D. dissertation already focused on the development of numerical methods for study of close pairs of stars, for instance decomposition of the light curve into Fourier components, and he continued this work in Cambridge, England, and Cambridge, Massachusetts, USA. An early result was that the density distribution of stars must be far more centrally condensed than modelers had supposed for the rotation of the line of apsides of binary orbits to be as slow as it is. **Thomas Cowling** was able to show with **Ludwig Biermann** that Kopal had made a serious error in neglecting the tidal distortion of the shapes of stars, which puts them very nearly into equilibrium, so that they drag on each other very little. With this correction, apsidal motion and other probes of stellar interiors gave concordant results. At Manchester, Kopal produced his classic text, *Close Binary Systems* (1959), in which he summarized the state of the subject just before a three-pronged assault on binary evolution with transfer of material between the stars began in Europe. It is no coincidence that one of the three groups, under Miroslav Plavec, was working at his own Charles University, and Kopal maintained close contact with the Czech astronomical community thereafter.

The concept of mass transfer in binaries can be traced back to **Gerard Kuiper** in 1935, and Kopal 20 years later drew the critical distinction among detached systems (both stars smaller than their Roche lobes), semidetached systems (one star filling its lobe and transferring material to the other), and contact systems, where both stars fill their lobes and material can move back and forth.

With the advent of the space age, Kopal became fascinated by the idea of landing people on the Moon. Realizing that very good Moon maps would be needed, he obtained sponsorship from the United States Air Force to obtain a large number of very high resolution images from the high-altitude observatory at Pic du Midi in the French Pyrenees. The funding was lavish by British standards of the time and enabled Kopal to bring students to Manchester from all over the Middle East. Many of them returned to their home countries to begin astronomy programs there, and the legacy can still be discerned in the relatively large number of papers from these countries published in one of the journals Kopal founded.

By 1962, Kopal recognized that the assortment of journals then being published did not really provide an adequate home for the rapidly increasing literature on Solar System physics and astronomy. He therefore became the founding editor of *Icarus*, published by Academic Press, but turned the editorship over to others (initially Carl Sagan) in 1969. His second foray into publishing came with the recognition that there was also no journal focusing on results obtained from space by scientists in all the countries that hoped to pursue space programs. Thus came into being *Astrophysics and Space Science*, a Reidel journal for which Kopal remained an editor until his death, when it was taken over by his younger colleague at Manchester, John Dyson. Kopal usually maintained a friendly relationship with his authors, sometimes handwriting letters of acceptance. He remained active in space-based research throughout the remainder of his career, writing shortly before his death, for instance, on the shape of the nucleus of comet 1P/Halley as revealed in photographs by the Giotto mission.

Kopal served as an officer of the Royal Astronomical Society and commissions of the International Astronomical Union. He was elected a honorary member of the Czech Astronomical Society in 1967, and minor planet (2628) is named Kopal. Kopal was the author of several popular books as well as many technical publications.

Kopff, August

Born **Heidelberg, Germany, 5 February 1882**
Died **Heidelberg, (Germany), 25 April 1960**

Comet and Trojan asteroid discoverer August Kopff was the son of a master plumber in Heidelberg. From 1900 to 1905 he studied mathematics, physics, and astronomy at the University of Heidelberg, where he got his Ph.D. in 1906 with a paper on "Über die Nebel der Nova Persei." Among his academic teachers were astronomer **Maximilian Wolf**, who founded the Königstuhl Observatory at the University of Heidelberg, mathematician Leo Königsberger (1837–1921), and physicist Georg Quincke (1834–1924). By 1901, Kopff began work with Wolf at the observatory. In 1907 Kopff became *Privatdozent* (lecturer), and in 1912 a professor at the University of Heidelberg. After military service during World War I, Kopff returned to teaching and observing at the University of Heidelberg. In 1924, Kopff became professor of theoretical astronomy at the University of Berlin and simultaneously – as a successor of Fritz Cohn (1866–1921) – director of the Institute for Astronomical Calculation (*Astronomisches* Recheninstitut in Berlin-Dahlem, Germany). (During World War II this institute was evacuated to Saxony, and found a new accommodation in 1945 in Heidelberg.) From 1947 up to his retirement in 1950 Kopff was professor of astronomy at the University of Heidelberg, and besides his directorship of the institute (until 1954) also director of the observatory.

In his time at Königstuhl, Kopff took part in all observation programs of the observatory and published studies on the theory of comets, stellar astronomy, and the theory of relativity. During his time in Berlin he and his co-workers published several catalogs of stars. One of the main projects was the third fundamental catalog of the FK-series (1935), which was adopted as the standard list of fundamental stars by the International Astronomical Union [IAU].

Kopff had memberships to the Academy of Sciences at Berlin (1935), the Deutsche Akademie der Naturforscher Leopoldina (1936), and the American Astronomical Society (honorary, 1949), and was associate of the Royal Astronomical Society (London). He was also actively engaged in the organization of the Astronomische Gesellschaft, to whose council he belonged since 1930. A lunar crater is named for him.

Koppernigk, Nicolaus [Nicholas]

➜ **Copernicus [Coppernig, Copernik], Nicolaus [Nicholas]**

Kordylewski, Kazimierz

Born **Poznan, Poland, 11 October 1903**
Died **Cracow, Poland, 11 March 1981**

A versatile and prolific observer, Kazimierz Kordylewski discovered the "dust clouds" accompanying Lagrangian points L4 and L5 along the Earth's orbit. Son of Wladyslaw and Franciszka (*née* Woroch) Kordylewski, he first attended Poznan University (1922–1924), after which he became an assistant at the Cracow Observatory (1924–1934) and later an adjunct instructor. Kordylewski received his Ph.D. at Jagiellonian University in Cracow (1932). He married Jadwiga Pojak in 1929; the couple had four children.

An accomplished mathematician, Kordylewski calculated the orbits of many comets and minor planets, although his principal work involved the photoelectric photometry of variable stars and the cinematography of solar eclipses. He discovered the nova T Corvi in 1926. Between 1939 and 1951, Kordylewski directed the scientific instruments section of the National Astronomical Copernicus Institute, at Cracow, as well as the institute itself. After 1958, he was chief of the observing station for artificial satellites, and edited the *Eclipsing Binaries Circulars* (1960–). Kordylewski was president of the Cracow branch of the Polish Astronomical Society (1956–).

In 1951, Kordylewski began to hunt for small "Trojan" satellites of the Earth at the L4 and L5 libration points, located 60° ahead of and behind the Moon in its orbit. His initial visual search with a 30-cm refractor proved unsuccessful. Then in 1956, professor Josef Witkowski suggested that Kordylewski stop looking for solid bodies and search instead for faint luminous patches of dust. Following this advice, when observing from the Skalnaté Pleso Observatory in Czechoslovakia's Tatras Mountains in 1956, Kordylewski managed to glimpse with his naked eye an exceedingly faint, diffuse patch of light subtending an apparent angle of 2° at one of the Lagrangian points. He estimated its brightness as only half that of the notoriously difficult Gegenschein. In March and April of 1961, Kordylewski succeeded in capturing images of these transient clouds on film and subjected them to isodensitometry measurements.

Although they were observed as early as January 1964 by the American amateur astronomer John Wesley Simpson (1914–1977) and his colleagues in the Santa Cruz Mountains of California, the reality of the Kordylewski clouds was debated until 1975, when J. R. Roach announced their detection using data acquired over a 15-month period by the Orbiting Solar Observatory 6 [OSO-6] spacecraft. The clouds were subsequently photographed on many occasions by Maciej Winiarski, using batteries of wide-angle cameras at a dark site in Poland's Bieszczady Mountains. Thus, Kordylewski is remembered as the discoverer of these ephemeral natural satellites of the Earth, the culmination of a century-long hunt for a "second Moon."

Korff, Serge Alexander

Born **Helsinki, (Finland), 1906**
Died **New York, New York, USA, 1 December 1989**

Russian–American nuclear and cosmic-ray experimental physicist Serge Korff is known primarily for inventing the class of particle detector called the wire proportional counter and applying it to a range of problems in physics and astronomy. This included the demonstration that cosmic-ray particles carry positive charge, and so must be mostly protons.

Of Russian–American parentage, Korff came to the United States after the October (1917) Revolution deprived his father of his job as lieutenant governor of Finland. Korff received degrees from Princeton (BA: 1928, MA: 1929, Ph.D.: 1931) and held fellowships at Mount Wilson Observatory, the California Institute of Technology, and the Bartol Research Foundation before joining the physics department of New York University in 1941. He retired as professor emeritus in 1973.

Korff participated in expeditions to high-altitude sites to study cosmic rays from 1934 (Mexico) to 1957 (Alaska). The 1934/1935 Peruvian expedition demonstrated beyond doubt the bending of cosmic-ray paths by the Earth's magnetic field and, therefore, the positive charge carried by the particles. His later work on cosmic rays was relevant to radiocarbon dating (*via* the variable production ratio of carbon-14 by cosmic-ray secondary neutrons in the upper atmosphere), radiation hazards of high-altitude flight, and our understanding of the effects of the solar wind on galactic cosmic rays reaching the Earth. Most of the later work was done from balloons and rockets rather than mountain sites, but Korff served for many years on committees devoted to high-altitude research as well as to USA–Latin American scientific cooperation.

Korff received honors from France, Cyprus, Greece, and the United Kingdom, as well as the United States, and was president of the American Geographical Society (1966–1971), the Explorers' Club (1955–1958 and 1961–1963), and the New York Academy of Sciences (1971–1972). His younger colleagues proudly referred to themselves as Korff's balloonatics.

Kovalsky, Marian Albertovich

Born **Dobrzin, Poland, 15/27 August 1821**
Died **Kazan, Russia, 28 May/9 June 1884**

Marian Kovalsky developed new methods in celestial mechanics, composed a zone catalog of northern stars, and studied the motions of stars in the Milky Way. Born into the Polish family of Albert Kovalsky, he matriculated at Saint Petersburg University in 1841 and studied astronomy under **Friedrich Struve** and Aleksei Nikolaevich Savich. Graduating in 1845, Kovalsky spent a year at the Pulkovo Observatory before earning his master's degree (1847) on the motions of comets. Over the next 2 years, he participated in geodetic expeditions conducted by the Russian Geographical Society. In 1849, Kovalsky was made an assistant, and in 1850, a lecturer on astronomy at Kazan University. His doctoral dissertation was awarded in 1852 for his theory of the orbit of Neptune. In that year, Kovalsky was appointed a full professor and in 1855 became director of the university's observatory. He married Henriette Serafimovna Gatsisskaya in 1856; the couple had one son.

Kovalsky's subsequent research elaborated upon the mathematical theory of solar eclipses; he also proposed a simplified method to calculate occultations of stars by the Moon. At the Kazan Observatory, he measured the positions and prepared the zone catalog (published in 1887 for the Astronomische Gesellschaft) of more than 4,200 stars whose declinations lay between 75° and 80°. Kovalsky's most important work, however, concerned his analysis (1860) of the proper motions of stars. Independently of Astronomer Royal **George Airy**, Kovalsky employed data from the star catalog of **James Bradley** to derive improved estimates of the Sun's own motion through space and identified a significant deviation in stellar motions that was not explained for several decades. His work refuted one theory of a "central sun" proposed in 1846 by astronomer **Johann von Mädler** and instead supported contemporary notions of our Galaxy's solid-body rotation.

Kovalsky was appointed a corresponding member of the Saint Petersburg Academy of Sciences (1863), a member of the Royal Astronomical Society (1863), and a founding member of the Astronomische Gesellschaft (1864).

Kozyrev, Nikolai Alexandrovich

Born **Saint Petersburg, Russia, 2 September 1908**
Died **near Leningrad (Saint Petersburg, Russia), 27 February 1983**

Russian astrophysicist Nikolai Kozyrev is best remembered for his claim that he recorded photographically the spectra of emission from gas on the Moon no fewer than four times. This has been widely accepted as evidence that the Moon is not (quite) geologically dead.

Kozyrev graduated from the University of Leningrad in 1928 and, in 1931, was appointed to the staff at Pulkov Astronomical Observatory. He also worked at various times at the observatories in Kharkov, Ukraine, and in the Crimea. Kozyrev was part of the large group of Pulkovo Observatory astronomers (most famously **Boris Gerasimovich**) who were arrested in 1936 and imprisoned or executed. Kozyrev appears briefly in the memoir *The Gulag Archipelago* by Alexander Solzhenitsyn, because the author was deeply impressed by his efforts to continue to carry out work in astrophysics under extraordinarily hostile circumstances. Released in January 1947, Kozyrev set to work to rebuild his shattered career. Despite the unconventionality of his post-World War II work, Kozyrev maintained a formal affiliation with the main astronomical observatory (Pulkovo) of the Soviet Academy of Sciences until the official retirement age.

During the autumn of 1958 Kozyrev began to examine the crater Alphonosus with the Crimean Astrophysical Observatory's 1.3-m Zeiss reflector, which was equipped with a prism spectrograph. On the night of 3 November 1958, when the phase of the Moon was 1 day before last quarter, Kozyrev placed the slit of the spectrograph across the central peak of Alphonsus and opened the shutter of the camera to begin a 30-min exposure. Keeping his eye glued to the eyepiece of a 6-in. auxiliary guidescope, he made frequent manual corrections to keep the slit of the spectrograph centered over the crater's central peak.

While guiding the exposure, Kozyrev noticed that the central peak "appeared brighter and whiter than usual," until "suddenly, in a period of less than a minute, the brightness of the peak dropped to normal." (It was late afternoon in Alphonsus at the time, so these impressions are hardly startling.) He stopped the exposure and inserted a second plate to record the spectrum of the peak, now "in its normal state." This second exposure lasted 10 min. On the first plate, Kozyrev claimed that he could make out a set of faint emission bands centered at 474 nm and 440 nm, but these features were absent on the comparison plate. He attributed them to ionized molecules of diatomic carbon in a rapidly expanding, rarefied cloud of gas released from the central peak and excited to fluorescence by solar ultraviolet radiation. Curiously, the chemical composition of the gas was not similar to terrestrial volcanic emissions, but seemed to resemble the materials found in the nuclei of comets.

Kozyrev's account appeared in the February 1959 issue of *Sky & Telescope*, complete with reproductions of his spectrograms. Expert spectroscopists who examined Kozyrev's images suspected that his "emission bands" were simply artifacts of faulty guiding. Guiding errors would be far less pronounced in the second comparison spectrum, which was exposed with the benefit of the half hour of practice spent guiding the first spectrum and for only one-third the length of time, convincingly accounting for its dearth of supposed emission bands.

At least initially, the report was widely believed and regarded as very significant. Kozyrev received a variety of kinds of recognition, including the statement from Dinsmore Alter that the spectrum was "the most important single lunar observation ever made."

One might expect that witnessing even the rather quiescent emission of gas from a lunar volcano would be a once-in-a-lifetime chance occurrence, so eyebrows were raised in 1960 when Kozyrev announced that he had managed to record a second event in Alphonsus, and this time nothing less than a *bona fide* volcanic eruption. This time there were no "peculiarities in the appearance of the crater," so no comparison spectrum was taken. Kozyrev detected a very slight "uniform increase in contrast" between 530 nm and 660 nm, attributing it to the thermal blackbody radiation emitted by a flow of lava.

This time reaction to Kozyrev's announcement was considerably less ethusiastic. Doubts were further compounded in 1963 when Kozyrev reported that he had repeatedly recorded the emission lines of excited molecular hydrogen in spectra of the crater Aristarchus. In 1969, he announced that new spectra of Aristarchus featured the lines of ionized molecular nitrogen and hydrogen cyanide, but by this time pronouncements elicited few comments.

With the Cold War at its height at this time, direct exchanges between western scientists and their Soviet counterparts were limited. During a visit to the United States, one of Kozyrev's colleagues, the astronomer V. I. Krassovsky, confided to his hosts that not only were Kozyrev's spectra "defective," but that Kozyrev himself was "personally unstable." Few could have imagined the ordeal that may have prompted this appraisal.

Doubts about Kozyrev's lunar spectra are certainly valid when they are considered in the context of some of his other spectrographic "discoveries." In 1954 Kozyrev announced that he had obtained spectrograms of a glow emanating from the night side of Venus. While the reality of the socalled ashen light continues to be debated to this day, even its proponents reacted with incredulity to Kozyrev's claim that the emission he recorded was 50 times brighter than terrestrial "airglow."

The following year Kozyrev published a bizarre claim that the characteristic ruddy color of Mars is an illusion caused by the optical properties of the planet's tenuous atmosphere, which he mistakenly alleged was all but opaque to wavelengths shorter than 500 nm. In 1966 Kozyrev announced the presence of absorption bands in spectra of Saturn's rings that suggested a tenuous atmosphere of ammonia; data from the Voyager space probes have ruled out such a possibility.

During a transit of Mercury in 1973, Kozyrev reported that he was able to detect the emission lines of hydrogen in an atmosphere about 1/100 as dense as the Earth's. The ultraviolet spectrograph aboard the Mariner 10 space probe did detect a hydrogen halo during its flyby of Mercury the following year, but it proved to be 10 trillion times more rarefied than the one postulated by Kozyrev, far beyond the threshold of his instrument.

Even more serious questions are raised by Kozyrev's forays into experimental physics. In 1951 he embarked on a prolonged series of experiments with gyroscopes, torsion balances, and pendulums in the laboratory of the Pulkovo Observatory, inspired by ruminations on the nature of time during his dreary years in captivity. Fifteen years later he published a number of utterly incredible claims: That he had observed quantum effects on a macroscopic scale, that time possesses a variable spatial density and can be shielded against by interposing chiral organic compounds, and that information can be propagated instantaneously through space – seemingly in violation of special relativity. His gyroscope experiments led Kozyrev to infer that the distance from the Equator to the north pole of a rapidly rotating planet should be less than the distance from Equator to its south pole, and he claimed to have confirmed this nonexistent asymmetry by measuring photographs of Jupiter and Saturn. His theory of "causal mechanics" held that the energy source of stars is not thermonuclear but derives from "the flow of time."

Kozyrev's lunar spectra continue to be cited as evidence that the Moon is not quite geologically dead, a tale that is often told in a distorted form and seldom with even a passing reference to the peculiarities of his other work. Yet some of Kozyrev's work is quite praiseworthy, notably his 1974 observations of the azimuthal brightness asymmetry in the rings of Saturn.

Krafft, Johann

➔ **John of Gmunden**

Krebs, Nicholas

Born **Cusa, (Rheinland-Pfalz, Germany), 1401**
Died **(Germany), 1464**

Nicholas Krebs is generally regarded as a key transitional figure between the Middle Ages and the Renaissance. He gave the study of the Universe a legitimacy that would be exploited by the cosmologists of the 17th and 18th centuries.

Krebs's father was a boatman on the Moselle River. In 1413 he joined the Brothers of the Common Life at Deventer in the Lowlands, a group of mystics devoted to experiencing unity with God as inspired by a widely influential book of the time, *Imitatio Christi* (Imitation of Christ). Krebs went on to study philosophy, law, mathematics, the sciences, theology, and the arts at the universities of Heidelberg, Rome, Cologne, and Padua, where he received his doctorate in law. After he was ordained in 1433, he pursued a series of ecclesiastical appointments, culminating in his becoming cardinal in 1448 and Bishop of Brixen in 1450.

Krebs's most important philosophical innovation – the concept of the identity of opposites (*coincidentia oppositorun*), developed in his major philosophical work, *De Docta Ignorantia* (Of learned ignorance, 1440)—is the idea that the distinctions and oppositions among finite beings resolve into unity at the absolute level. His arguments are remarkable for their analytical sophistication. Draw, for instance, a series of bigger and bigger circles, all of which touch a straight line at a point. As the circles get bigger, the more the curve "flattens out" and approaches the straightness of the line, so that if you could thus draw an *infinitely large* circle and place it against the line, there would no longer be any difference between the "curved" line of the circle and the straight line. In this precise way Krebs argues that in the infinite all the opposites become one; thus his oft-misunderstood "mystical" thesis that "everything is everything."

Inspired both by Neoplatonic philosophy and 13th-century mysticism, Krebs's thought developed in marked opposition to scholastic Aristotelianism. Striving for a synthesis of, on the one hand, mathematical and experimental knowledge and, on the other, mysticism and knowledge, Krebs made brilliant and original use of analogies from mathematics. He built a system of epistemology and metaphysics in which the categories of reason, with their opposites and contradictions, give us at best only a limited and inadequate representation of reality that in itself is beyond our direct access and understanding. Krebs's work thereby anticipated the great system of **Immanuel Kant**. Reason is by its very nature discursive, and because our thinking is discursive any conclusions drawn upon it are attained through a series of inferences and not by direct insight. Although it is possible for the intellect to transcend these limitations through intuitive cognitions apprehended all at once, our language cannot adequately express these intuitions because it relies necessarily on categories, oppositions, and contradictions that exist only at the finite, relative level of immediate experience. The unity of opposites in ultimate reality can therefore never be directly or fully attained by us; however, once the mind sees that this cannot be attained, it is then capable of transcending the very linguistic and conceptual limitations once it understands their necessity.

Another fascinating upshot of Krebs' line of thinking is that in studying the Universe we are studying God. This is an idea that reverberated throughout the Renaissance, especially as brought to fruition by scientists like **Galileo Galilei**, who sought to study nature directly rather than through official scriptures to learn about God and the origin of the Universe. The Universe according to Krebs is a theophany, an "appearance of God." In anticipation of the cosmology of **Giordano Bruno** and Baruch Spinoza, Krebs viewed the Universe as endless unfoldings of God; the present "expansion" of existence is, according to his theory, the result of a divine "contraction" from which the unity of God unfolds into multiplicity, an anticipation of 20th-century cyclical cosmological theory. The Universe is therefore itself infinite, which led Krebs to reject the idea of fixed points in space and time in a way that further anticipated 20th-century developments in the relativity of space and time as pioneered by **Albert Einstein**. No place in the Universe – neither on the Earth nor on the Sun – is a privileged position. All judgments about location must therefore be relative. Krebs then even went on to conclude that the geocentric view of the Solar System expressed by the Old Testament is false.

According to Krebs, each individual entity in the Universe is a manifestation of the whole, forming a harmonious system in which each is both unique and part of the whole. His revival of the key phrase from **Anaxagoras**, "everything is in everything," states that everything mirrors the entire Universe, just as conceived in **Gottfried Leibniz's** subsequent theory of monads. The whole of being is in everything, and everything is in the whole. And anticipating both Spinoza and Leibniz still further, he concluded: "all things are what they are, because they could not be otherwise nor better."

The ultimate goal of all inquiry, described in Kreb's final work, *De Visione Dei* (Vision of God, 1453), is the transcendence of the limitations of sensory knowledge to attain through intellectual intuition a vision that goes beyond reason, logic, and language, thereby returning the finite to the infinite and allowing us to achieve a mystical union with the Universe. We are then free to live out the rest of our lives in mystical contemplation of the oneness of all things, a transcendental bridge between the relative, finite world and the absolute, infinite Universe.

Born **Rupelmonde, Flanders (Belgium), 1512**
Died **Duisburg, Nordrhein-Westfalen, Germany, 1594**

Cartographer Gerardus Mercator's map projection is still in use today and has also proved useful for uranography.

Mercator was born in a German family. He studied geography, cartography, and mathematics at the University of Louvain in what is now Belgium, graduating in 1532. He published his first map (of Palestine) in 1537 at the age of 25. From 1537 to 1540 he surveyed and mapped Flanders, and in 1538 he made and published his first world map, based on the **Ptolemy** map. In 1554 Mercator produced a map of Europe. He did cartographical work for Emperor Charles V and was cosmographer to the Duke of Jülich and Cleves. In 1544, he was arrested and prosecuted for heresy, and in 1552 he moved to Duisburg to evade religious persecution because he was a Protestant.

Mercator solved the problem of depicting a spherical surface on a flat piece of paper in 1568, by using the "cylindrical projection." He used a new way of displaying a map with parallel lines for the latitudes and meridians at 90° to each other. The Mercator projection, using straight lines to indicate latitude and longitude, was a great progress for navigation at sea. Its disadvantage is the disproportion of size: Greenland, for instance, is shown 16 times larger than it is in reality.

Mercator's main work, a three-volume world atlas, was published in several editions from 1585 on, and after his death, by his son. He was the first to use the word "atlas."

Kreutz, Heinrich Carl Friedrich

Born **Siegen (Nordrhein-Westfalen, Germany), 28 September 1854**
Died **Kiel, Germany, 13 July 1907**

Heinrich Kreutz is chiefly remembered for his work on sun-grazing comets and his editorship of the *Astronomische Nachrichten* (1896–1907). He was the son of a superintendent of Siegen. After obtaining his secondary education in Siegen, Kreutz studied astronomy at the University of Bonn under the tutorship of **Eduard Schönfeld** and **Carl Krüger**. He was awarded his Ph.D. in 1880 for a study of the orbit of the great comet C/1861 J1. Afterward, Kreutz spent several months in Vienna with **Edmund Weiss** and **Theodor von Oppolzer**. For roughly a year, he served as a computer at the Recheninstitut in Berlin.

In 1883, Kreutz's former professor, Krüger, was appointed director of the Kiel Observatory. Along with this responsibility, Krüger assumed the editorship of the *Astronomische Nachrichten*, then the world's leading astronomical journal. Kreutz followed Krüger to Kiel, where he accepted a position as computer. From the beginning, however, Kreutz was involved in the editorial work of the *Astronomische Nachrichten*. In 1888, he was also appointed as lecturer at the University of Kiel; by 1891, he was named an associate professor. About that time, Kreutz married Krüger's daughter.

Upon Krüger's death in 1896, Kreutz succeeded him as editor of the *Astronomische Nachrichten*, a position he held for the rest of his life. In that capacity, he produced its volumes 140–175. Kreutz performed these duties with great care and maintained the journal's high standards for publication. When faced with an increasing number of longer papers, he founded the *Astronomische Abhandlungen* (1901), to provide a forum of more comprehensive accounts. Thirteen issues of the *Abhandlungen* were published before his death. Kreutz also directed the headquarters for astronomical telegrams.

Kreutz's most important astronomical research work was his investigation of the orbits of the great sun-grazing comets C/1843 D1, C/1880 C1, and C/1882 R1. Through extensive computational work, he provided evidence that these bodies were all members of a similar group of comets, now called the "Kreutz group," which had their origins in the breakup of a once-larger celestial body.

Krieger, Johann Nepomuk

Born **Unterwiesenbach, (Bavaria, Germany), 1865**
Died **Munich, Germany, February 1902**

Johann Krieger completed less than one-third of a planned lunar atlas that showed great promise before he died, his health ruined by his obsessive commitment to the mapping project. The son of a brewer, Krieger was little more than a boy when he started to observe the Moon with a small refractor from the sleepy mountain hamlet of Unterwiesenbach, where his scanty education ended at the age of 15. Six years later he traveled to Cologne to visit **Hermann Klein**, the foremost German selenographer and popularizer of astronomy of the era. Klein not only warmly encouraged Krieger to make selenography his life's work, but assumed the role of his mentor, directing the young man to study mathematics, physics, photography, and the graphic arts.

Krieger's ensuing academic career faltered because he lacked the mathematical aptitude required for the rigorous curriculum at the University of Munich. Undeterred, he spent his inheritance to establish a private observatory in the Munich suburb of Gern-Nymphenburg. Krieger equipped his observatory with a fine 270-mm refractor and announced his intention to produce an exhaustive lunar atlas. In the quest for a better astronomical climate, he would move his observatory to Trieste on the Adriatic coast several years later.

Klein provided Krieger with photographic prints made from the best lunar negatives taken at the Lick and Paris observatories. The photographs were enlarged to a scale of almost 12 ft. to the Moon's diameter. These grainy, low-contrast prints served as the substrates for Krieger's drawings, ensuring an exceptional level of positional accuracy and proper proportion. At the eyepiece Krieger used different colored pencils on successive nights to sketch the finest details glimpsed in fleeting moments of steady seeing that were far beyond the capability of photography to record. These sketches served as the basis for magnificent shaded drawings executed with India ink, graphite pencil, charcoal, and paper stumps that were almost universally recognized as startlingly superior in their meticulous accuracy, aesthetic appeal, and legibility.

The frantic, monomaniacal pace at which Krieger labored would quickly take its toll, and in only a few short years his health would utterly collapse. He died early, a martyr to selenography. He had completed less than a third of the plates for his atlas, and these would only be published, in rough and fragmentary form, 10 years after his death.

Krieger's work was collected and edited by his friend Rudolf König (1865–1927), an Austrian businessman who was a mathematician and amateur astronomer of rare ability. König published the two lavish volumes of *Johann Nepomuk Kriegers Mond-Atlas*, but only 18 of the 58 plates had been completed by Krieger, the remainder being little more than rough outlines.

Kron, Gerald Edward

Born **Milwaukee, Wisconsin, USA, 6 April 1913**

American photometrist Gerald E. Kron developed a system for measuring colors of stars and other astronomical objects; his system is now called Kron–Cousins (sometimes Kron–Cousins–Johnson) colors. Kron received his BS (1933) and MS (1934) degrees from the University of Wisconsin, and a Ph.D. (1938) from the University of California (Berkeley) for a thesis on the design, construction, and use of a photoelectric photometer for the 36-in. refractor at the Lick Observatory. He joined the staff of the Lick Observatory as a junior astronomer in 1938 and remained there, apart from research associateships at the Massachusetts Institute of Technology and California Institute of Technology, and war work at the United States Naval Ordnance Test Station in California, rising through the ranks until 1965.

With **Joel Stebbins**, a pioneer of photoelectric photometry, Kron applied a new six-color system to variable stars and eclipsing binaries. Other early collaborators were **Joseph Moore** and **Arthur Wyse**.

In 1965, Kron was appointed director of the United States Naval Observatory [USNO] Station in Flagstaff, Arizona, where he developed an electronic camera for its astrometric reflector. He continued to work on photometry of variable stars and globular clusters, reconciling the properties of galaxies as reported in the Zwicky and Shapley–Ames catalogs, and clarifying the nature of the emission from the jets of active galaxies like M87 and the quasar 3C273. He also made major contributions to our understanding of the distribution of interstellar reddening.

Kron has been headquartered at the private Pinecrest Observatory most of the time since his 1973 retirement from USNO. His wife, Katherine C. Gordon (whom he married in 1946) and their son Richard G. Kron are also astronomers.

Krüger, Karl Nicolaus Adalbert

Born **Marienberg, (Saschen, Germany, 3 December 1832**
Died **Kiel, Germany, 21 April 1896**

Stellar astronomer Karl Krüger participated in the development of two great 19th-century stellar catalogs. Krüger was educated at Berlin, and became assistant to **Friedrich Argelander** at Bonn in 1853. Krüger was immediately involved, together with Argelander and Argelander's other assistant, **Eduard Schönfeld**, in the observations that eventually led to the publication of the great *Bonnner Durchmusterung* atlas and catalog for epoch 1855.0. In 1854 Krüger was granted a Ph.D. in astronomy at Bonn. When work on the *Durchmusterung* was completed in 1862, Krüger accepted an assignment at the university observatory in Helsingfors, Russia (now Finland), and in 1876 moved to the Herzogliche Observatory in Gotha, Thuringia, Germany. In 1880, he relocated again, this time to the Kiel Observatory, where he served as professor and observatory director for the remainder of his career. Krüger observed comets and determined a number of stellar parallaxes. His principal work after leaving Bonn, however, appears to have been the zonal observations from Helsingfors and Gotha of all stars in the band +54° 55′ to + 65° 10′ for the Astronomischen Gesellschaft; a catalog of 14,680 stars in that band was published in 1890. In 1893 Krüger published a catalog of 2,153 red stars.

Kūhī: Abū Sahl Wījan ibn Rustam [Wustam] al-Kūhī [al-Qūhī]

Flourished **second half of the 10th century**

Kūhī attained distinction as an astronomer who was skilled in observational instruments, and his work was well known among the astronomers and mathematicians of his age working in the Būyid domains of ʿIrāq and western Iran. Born in Tabaristan, he was supported by three kings of the Būyid Dynasty: ʿAḍud al-Dawla, Ṣamṣām al-Dawla, and Sharaf al-Dawla, whose combined reigns cover the period 962–989. Thus, Kūhī probably did most of his work in the second half of the 10th century.

Ibn al-Haytham and **Bīrūnī** knew of several of Kūhī's works, and later ʿ**Umar al-<u>Khayyām</u>** cites him as one of the "distinguished mathematicians of ʿIrāq" (Sesiano, p. 281). In 969/970 Kūhī assisted in **Ṣūfī**'s observations in Shīrāz to determine the obliquity of the ecliptic, as well as in other observations of the Sun's movement, done on the order of ʿAḍud al-Dawla. And in 988/989 he was director of the observatory that ʿAḍud's son, Sharaf al-Dawla, built in Baghdad, which was intended to observe the Sun, Moon, and the five known planets.

According to Bīrūnī, Kūhī constructed for solar observations a house whose lowest part was in the form of a segment of a sphere of diameter 25 cubits (approximately 13 m) and whose center was in the ceiling of the house. Sunlight was let in through an opening at that center point of the sphere, which was located in the roof.

Three of Kūhī's works deal directly with problems that might be called astronomical. They are: (1) *On What Is Seen of Sky and Sea* (published in Rashed), (2) *On Rising Times* (published in Berggren and Van Brummelen), and (3) *On the Distance from the Center of the Earth to the Shooting Stars* (published in Van Brummelen and Berggren). The first treats the visible horizon and shows how, knowing the height of a lighthouse on an island, one can calculate how far away its light can be seen (and related problems). In the second he shows how one can calculate the rising times and ortive amplitudes of the zodiacal signs by Menelaus's theorem. In the third he uses parallax to show how to calculate the distance to meteors. (Kūhī's technique was rediscovered in 1798 by **Johann Benzenberg** and **Heinrich Brandes** in Germany, who settled the ancient question of whether or not meteors were atmospheric phenomena.) In none of them, however, is any observational data cited, nor are any numerical examples worked. A fourth work, dealing with the astrolabe (published in Berggren), discusses the geometry of that instrument. In particular, it solves problems demanding the construction of certain lines or points of a planispheric astrolabe given other lines and points. A fifth work, applying a method for computing the direction of Mecca, which became common in astronomical works known as *zīj*es, has been ascribed to Kūhī. But the detailed computations carried out are entirely out of character with his other works and so the attribution must, for the present, be regarded as spurious.

Although Kūhī's work was studied by Islamic scholars as late as the 18th century (notably Muḥammad ibn Sirṭāq in the first half of the 14th century and Muṣṭafā Ṣidqī in the 18th century), it – like that of many of his distinguished contemporaries and successors in the eastern regions – was unknown in the west.

Kuiper, Gerard Peter

Born **Harenkarspel, the Netherlands, 7 December 1905**
Died **Mexico City, Mexico, 24 December 1973**

Dutch–American astronomer and planetary scientist Gerard P. Kuiper discovered that the atmosphere of Mars consists largely of carbon dioxide and advocated the importance of Solar System astronomy in the third quarter of the 20th century when it was generally unpopular. Kuiper also participated in the identification of some of the best mountain-top observatory sites, including Mauna Kea (Hawaii) and Cerro Tololo (Chile).

As a teenager, Kuiper was interested in astronomy and had good-enough eyesight to produce a sketch of the Pleiades including stars that are a factor of four fainter than most people can see without a telescope. He earned a B.Sc. in 1927 and a Ph.D. in 1933 from Leiden University, with a thesis on binary stars carried out under **Ejnar Hertzprung**. Among the best known of his own students in turn were Thomas Gehrels, Tobias Owen, and Carl Sagan, all of whom made important contributions to planetary astronomy, especially with the use of infrared observations, another of Kuiper's early interests.

Following his Ph.D., Kuiper became a fellow at Lick Observatory (1933–1935), moved on to Harvard (1935–1936), and was appointed to an assistant professorship at the University of Chicago and Yerkes Observatory in 1936. Kuiper married Sarah Parker Fuller (by whom he had two children) in 1936 and became a US citizen in 1937. He became full professor in 1943 and headed west to the University of Arizona in 1960 as the founder of the Lunar and Planetary Lab [LPL] there, from the directorship of which he resigned a year before his death. His war work was initially as an operations analyst at Eighth Air Force Headquarters in 1944, and he was part of the Alsos debriefing mission to formerly Nazi Europe in 1945.

Kuiper's early work focused on binary stars; he was the first to attempt a statistical description of the distribution of binary orbit periods and mass ratios. He suspected (correctly) an almost uniform distribution over the entire period range, from stars that touch each other (for which he coined the name "contact binaries") to ones almost a parsec apart, and a mass ratio distribution that was a direct reflection of the fact that little stars are much commoner than big ones. Kuiper also did one of the first quantitative estimates of the dependence of star brightness on mass and calculated the relationship (called bolometric correction) between the total brightness of a star and the amount of luminosity in the wavelength band we can see. He and, separately, **Willem Luyten** were responsible for the discovery of most of the white dwarfs found until **Jesse Greenstein** took up the problem in the 1960s; Kuiper was instrumental in recognizing that the white dwarfs, like normal stars, could be classified by the elements whose absorption features appear in their spectra.

During his time at Chicago, Kuiper interacted with **Otto Struve**, **Subrahmanyan Chandrasekhar**, **Gerhard Herzberg**, and **Harold Urey,** and so gradually turned his attention from binary stars to their formation and on to the interdisciplinary topic of the formation of the Solar System. He concluded (probably wrongly) that planet formation is the low-mass extreme of the same process that makes double stars. Kuiper was involved in building the 82-in. reflector at the new McDonald Observatory in west Texas and, with it, discovered methane in the atmosphere of Titan (Saturn's largest satellite) in 1944 and carbon dioxide in the atmosphere of Mars in 1947. He also discovered one satellite each of Neptune (Nereid) and Uranus (Miranda). Many of these accomplishments, and his later survey of minor planets, were undertaken using a Cashman lead sulfide cell (developed during World War II) as an infrared detector.

Kuiper assumed, along with most of his contemporaries, that there would be very few planets or minor planets beyond the orbit of Neptune, while, in contrast, Frederick Leonard, Kenneth Edgeworth, **Fred Whipple**, and A. G. W. Cameron thought that there might be a great many residual planetesimals 30–50 AU from the Sun. Nevertheless, the name Kuiper belt (less often, Kuiper–Edgeworth belt) is invariably attached to these objects and their location.

The LPL, with Whipple's group at Harvard University, became one of the two major planetary science groups in the United States. Increasing friction with his Chicago colleagues over how credit for various discoveries about the Moon and planets should be apportioned was part of the reason Kuiper left the University of Chicago and Yerkes Observatory. He remained the LPL director until a year before his death.

Kuiper and his colleagues investigated planetary atmospheres, prepared an atlas of the Moon (which contributed to the choice of Apollo program landing sites), and pioneered infrared planetary studies from high-altitude aircraft. The American long-lived follow-on mission to these initial studies was called the Kuiper Airborne Observatory. Another of his legacies to later generations of astronomers was the commissioning and overall editing, first, of a four-volume series called *The Solar System* and, later, of a nine-volume (only eight of which were ever completed, shortly after Kuiper's death) compendium covering all of astronomy, from telescopes to cosmology. He was a member of the United States National Academy of Sciences and of the American Academy of Arts and Sciences as well as a foreign associate of the Royal Astronomical Society. Kuiper died of a heart attack while attending an astronomical meeting.

Kulik, Leonid Alexyevich

Born **Tartu, (Estonia), 19 August 1883**
Died **Spas-Demensk near Smolensk, (Russia), 14 April 1942**

Leonid Kulik was a leading Soviet meteoriticist who is best known for his investigations of the 1908 Tunguska, Siberia, impact site. His father was a physician. Kulik's secondary education was completed in 1903 at the Gymnasium in the town of Troitsk, Orenburg Province, in the Ural Mountains, where he won a gold medal. He then pursued an education at the Institute of Forestry in Saint Petersburg until he was inducted into military service in 1904 and sent to Kazan on the Volga River. On his own initiative, he attended lectures at the Faculty of Physics and Mathematics at Kazan University. In 1910, Kulik was arrested for revolutionary activities but, after serving a short time in prison, was sent to the Ilmen region of the Urals. During the next 2 years (1911–1912), he was paroled to work in the Forestry Department on the condition of making frequent reports to the police chief in the town of Zlatoust. In 1912, Kulik married Lidiya Ivanovna; both later served on the scientific staff of the Mineralogical Museum of the Academy of Sciences in Saint Petersburg. In the course of his fieldwork, Kulik had the good fortune to meet and work with a leading scientist, Vladimir Ivanovich Vernadsky, who became known as the father of geochemistry in the USSR. With the outbreak of war, Kulik joined the army and served on the western front.

After the October 1917 Revolution, Kulik's record of arrest under the Czarist regime redounded to his advantage. Early in 1918, he went to the Soviet Academy of Sciences in Petrograd and started working on meteorites. Later that same year, Kulik led an expedition, organized by the academy, to investigate the fall of a stony meteorite on 27 February 1918, near the town of Kashin, in the province of Tver, a short distance north of Moscow. He returned with a 122-kg specimen of the Glasatovo chondrite, named for the village where it fell.

In 1921, the Mineralogical Museum of the Academy of Sciences in Petrograd established a meteorite section with Vernadsky as director. Vernadsky assigned Kulik to lead a 2-year expedition to gather information on the fall of a giant meteorite witnessed in Siberia in June 1908. Reports in provincial newspapers had described a brilliant fireball, visible over a vast area, moving from approximately the south to the north, accompanied by deafening explosions and a great trembling of the ground when it struck the Earth. Using a railroad car designated for the purpose, Kulik visited many places in Siberia and gathered eyewitness accounts. One story implied that the meteorite had landed at Tomsk in western Siberia. Kulik found no meteorite at Tomsk, but learned that the fireball had passed over the Yenesei Province and landed somewhere near the mouth of the Podkamennaya Tunguska River, a site so remote that he could not visit it on that trip.

Throughout his travels, Kulik collected reports of numerous meteorite falls, and sometimes obtained specimens. He made special efforts to educate the people he met about meteorites, and enlisted many volunteers to serve as corresponding observers who would send reports back to the institute on a regular basis. During the 1920s, Kulik issued updated instructions to this network, which grew in membership and in the volume of reports and specimens that were returned to Petrograd each year.

In 1927, Kulik led the first of several expeditions to the Tunguska area to investigate the 1908 fall. From the remote fur-trading station of Vanovara in eastern Siberia, he traveled by horse and reindeer into the deep forest. Kulik was led by local guides, some of whom had witnessed the event at fairly close range. Even after 19 years, the destruction he encountered was awesome beyond all expectations. Kulik found that a vast area of the forest had been uprooted and flattened, with treetops fanning outward. Only on later expeditions did he determine that the fallen trees pointed radially away from the center of an explosion. The tree roots faced a swampy area of low mounds and peat bogs pocked with rounded holes, up to a few dozen meters across, that Kulik believed were the craters made by a swarm of impacting meteorites.

In 1928 and again in 1929/1930, Kulik led two more arduous expeditions to Tunguska in an effort to excavate the water-filled holes and recover the meteorites. He directed the draining and trenching of one large depression, and the boring with hand augers into others. Kulik also conducted geodetic and magnetic surveys of the entire area. But all to no avail; he found no meteorites in the ground or on the surface. However, photographs of the flattened forest, taken on his expeditions, caused a sensation at home and abroad.

Back in Petrograd, Kulik argued for an aerial survey of the Tunguska region. The first attempt, made in 1930, was postponed twice for logistical problems. Faced with delays, Kulik conducted other inquiries. In 1933, he investigated a shower of stony meteorites that occurred on 26 December at Pervomaiskii Poselok in the Vladimir Province of Russia. It was seen over such a wide area that Kulik determined the approximate site of the fall from the reports sent to the Meteorite Institute. He visited the area immediately and obtained about 16 kg of specimens from local citizens. Kulik did not find the strewn field right away, but used a theodolite to calculate the trajectory of the fireball. After the snow melted, he went directly to the strewn field, aided by a group of schoolboys, and collected 97 stones weighing a total of 50 kg. This was the first known instance in which an instrumental calculation revealed the site of a meteorite fall.

In 1937, during an attempted aerial survey of Tunguska, the plane crash-landed but with no harm done to Kulik or the other passengers. Finally, in 1938, the aerial survey successfully revealed that the uprooted trees lay in an elliptical area with a center of devastation some 12 to 15 km across in the northwestern portion of the ellipse. The total affected area was 250 km^2. Kulik returned to the site in the following year to correlate the aerial photographs with geodetic stations he had set up in the region. Further studies, however, were prevented by the onset of World War II.

When Kulik investigated the Tunguska site, only a few scientists favored a meteorite impact as the origin of craters found on the Earth or Moon. However, Kulik's summary of eyewitness accounts of the fireball, together with his photographs of the devastation at the site, provided clear evidence that a large extraterrestrial body had wreaked destruction on the Earth in historic times. This finding prompted many scientists to take a new look at the possibilities of meteorite impacts as *geological processes*.

Kulik found no crater and no meteorites at Tunguska because, like most scientists of the time, he did not understand the explosive potential of meteorites moving through the Earth's atmosphere at cosmic velocities. Today, astronomers and meteoriticists agree that the incoming body exploded in the atmosphere over Tunguska without reaching the ground and without depositing any meteorite fragments. The remaining point of contention is whether that body was a fragment of a comet or a friable asteroid.

By the start of World War II, Kulik held the position of curator of meteorites at the Soviet Academy of Sciences, a well-earned appointment that recognized his leading role in promoting the growth and documentation of the Soviet Union's collection of meteorites. He was the first person to serve as the scientific secretary of the Academy's Committee on Meteorites, which was chaired by Vernadsky. Kulik retained his civilian status because of weak eyesight. Nonetheless, he voluntarily joined the so called minutemen and was captured by the German army and put into a camp. He wrote a series of letters describing his daily life in the camp, where he did some paramedical work. Kulik contracted typhus and died.

Küstner, Karl Friedrich

Born **Görlitz, (Sachsen, Germany), 22 August 1856**
Died **Mehlem, (Nordrhein-Westfalen), Germany, 15 October 1936**

As a meridian observer, Friedrich Küstner achieved an outstanding reputation for the precision and accuracy of his own observations as well as for his careful reconsideration of historical observations. He was the first astronomer to measure the solar parallax using the radial velocities of stars measured at different times of the year. The son of a master bricklayer, Küstner first became familiar with practical astronomy when he was a student at Strassburg University, where he received his Doctor of Philosophy in 1879. While there, he was influenced strongly by **Friedrich Winnecke**. Shortly after finishing school, Küstner began work at the office of the *Berliner Jahrbuch*. There, he mostly worked on computing orbits of minor planets and on the redetermination of the constant of aberration. In 1882, Küstner was selected by **Arthur Auwers** to act as his first assistant on the transit of Venus expedition to Puntas Arenas, Argentina.

In 1884, Küstner was appointed Observator of the Berlin Observatory. During his tenure there, he returned to the problem of determining the constant of aberration. The anomalous data obtained from his observations convinced him that the latitude of the telescope had changed. With further observations over the course of a year, Küstner proved conclusively that the variation of latitude occurred on a different frequency than that predicted by **Leonhard Euler**. Küstner's work allowed **Seth Chandler** to reexamine the entire problem using his own observations, Küstner's, and other zenith observation data sets to determine the correct frequency, later confirmed theoretically by **Simon Newcomb.**

In 1891, Küstner became a Professor of Astronomy and the Director of the Bonn Observatory, succeeding **Eduard Schönfeld**. A couple of years after this, he began work on his catalog of 10,663 stars. This catalog included stars between the celestial equator and declination +51°, using his own observations made with a 6-in. Repsold meridian circle. It was considered the most accurate catalog of its kind at the time of its completion, in part because of his work reducing errors in positions due to stellar magnitude by making all observations reduced to a standard magnitude of 8.5. Using a 12-in. photographic refractor along with a three-prism spectrograph, Küstner also made observations of the radial velocities of stars. This information, combined with his earlier work on fundamental positions of stars and the known velocity of light, length of the year, and radius of the Earth, allowed him to determine the speed of the Earth in its orbit, the aberration constant and the solar parallax.

Küstner received the Gold Medal from the Royal Astronomical Society for his star catalog, his work in the determination of the aberration constant from line-of-sight motions of stars, and for his detection of the variation of latitude. He also received the Bradley Medal of the Prussian Academy of Sciences. At the 1928 International Astronomical Union Meeting in Leiden, the Netherlands, Küstner was conferred an honorary degree. He was a member of the Royal Astronomical Society and the United States National Academy of Science.

In 1887, Küstner married the daughter of a Hamburg sculptor named Börner. They had two children. Their son was a U-boat commander in World War I who was listed as missing. After his retirement, Küstner was cared for by his daughter.

La Caille [Lacaille], Nicolas-Louis de

Born **Rumigny, (Ardennes), France, 15 May 1713**
Died **Paris, France, 21 March 1762**

Nicolas de Lacaille (as he signed his name) was one of the greatest observers of the 18th century and a pioneer in mapping the southern sky. His father served the Duchess of Vendôme as chief huntsman, but he devoted his spare time to the study of natural science and mechanics. After his father died, the young Lacaille put himself under the patronage of the Duke of Bourbon, wishing to study theology to be able to take holy orders. After becoming deacon, however, he forsook the ecclesiastical career and turned all his thoughts to science.

Self-taught in astronomy and mathematics, Lacaille moved to Paris in 1735. There he gained the friendship and the esteem of **Jacques Cassini**, director of the Paris Observatory. In 1736 Lacaille began to work at the observatory, where he was officially engaged 3 years later. This allowed him to meet the most important astronomers of the time. In 1740, Lacaille was appointed professor of mathematics at the prestigious Collège Mazarin, and in 1741 he was admitted to the membership of the Académie royale des sciences. In this period, in order to fulfil his professorial duties, Lacaille wrote several handbooks (entitled *Leçons élémentaires*) that met with a great success and were translated into many languages, even into Latin: They covered mathematics (first edition in 1741), mechanics (1743), geometrical and physical astronomy (1746), and optics (1750). Additionally, beginning in 1745, Lacaille took care of the yearly edition of the *Ephémérides*.

Lacaille's first important astronomical experience was the measurement of the arc of the meridian. In 1739 he had taken part, under the direction of **Giovanni Maraldi**, in the survey of the French southwest coasts, from Nantes to Bayonne. Thanks to the skill he showed on this occasion, he was called to participate in the verification of the Paris meridian, and the results of this work were published in 1743 under the name of Jacques Cassini. Processing all the data he had collected, Lacaille compared several meridian arcs and was able to determine that their extension decreased from the Equator to the poles. This outcome helped to solve definitively the famous question about the Earth's shape, confirming that the Earth is squashed like an orange and not stretched like a lemon. Lacaille was not the only scientist who drew this conclusion, but he was admired since he could do this by considering only 4° of latitude.

From the end of 1750 to June 1754, Lacaille led a scientific expedition to the Cape of Good Hope and drew the first geodetic map of Mauritius. He set up his observatory beneath the slopes of Table Mountain near Cape Town. In only 2 years' time he measured the coordinates of 9,766 stars, probably using a one-half in. diameter telescope. Lacaille drew the first complete map of the southern stars, which would be published by the Académie royale des sciences in 1756: On this map he marked 14 new constellations, which would be rapidly accepted by the astronomers of the entire world and which are still in use in the official constellations list. Besides creating these new constellations, Lacaille broke up the large classical constellation of Argo Navis into its component parts: Carina (Keel), Puppis (Stern), and Vela (Sail).

Lacaille also cataloged 42 nebulae and clusters of the Southern Hemisphere. His list was published in 1755, 16 years before the first installment of **Charles Messier**'s catalog of nebulae and clusters was printed. Lacaille divided his "nebulous stars" into three classes: "Nebulosities not accompanied by stars" (class 1), "Nebulosities due to clusters" (class 2), and "Stars accompanied by nebulosity" (class 3).

At the Cape, Lacaille also turned his attention to the planets. In particular, he made careful observations of the position of the Moon, Venus, and Mars: By comparing his data with the records made in the same time by **Joseph de Lalande** from Berlin, he could calculate, with the parallax method, more accurate values for the distances of these bodies from the Earth.

Additionally, Lacaille occupied himself with the so called longitude problem, which had attracted astronomers' attention for more than two centuries. He polished the "method of the Moon" developed by **John Flamsteed** and thought up some ingenious graphic systems, which allowed him to simplify the toilful calculations required to find the longitude.

After returning to Paris, Lacaille resumed his work at the Collège Mazarin, where he installed a new telescope. His publications were forerunners of modern compilations of stellar catalogs and planetary tables. In 1757, he sent to the press his *Fundamenta Astronomiae*, with a catalog of about 400 bright stars: For the first time star positions were corrected by taking into account aberration and nutation. In 1758, Lacaille published the *Tables solaires*, in which he was the first to mark lunar and planetary perturbations as well as aberration and nutation. These two books would be very important for the increments in accuracy they brought about, and for the inspiration they gave to later astronomers.

Lacaille also edited the *Traité d'optique sur la gradation de la lumière*, whose manuscript was bequeathed him by **Pierre Bouguer**, and took care of a new edition of the *Traité du navire* by the same author. In recognition of his work, many scientific institutions appointed him honorary member: the academies of Saint Petersburg, Berlin, and Stockholm, the Royal Society of London and the Royal Society of Göttingen, and the Institute of Bologna.

In 1761, Lacaille observed the transit of Venus. In the same year, he determined the distance of the Moon, taking into account, for the first time in history, the nonsphericity of the Earth.

A little later, a strong fit of gout took over Lacaille, but he did not stop his work. The illness, however, became worse, and Lacaille died. His friend and colleague Maraldi collected his manuscripts and published them in 1763 under the title of *Coelum australe stelliferum* (Star catalog of the southern sky). In the same year his travel diary, the *Journal historique du voyage fait au Cap de Bonne-Espérance*, was sent to the press. At the time, everybody considered Lacaille's death as a great loss for astronomy and science: Lalande expressed his admiration for the large amount of observations and calculations made by Lacaille, and **Jean Delambre** noted that Lacaille's "astronomical life" lasted only 27 years.

Lacchini, Giovanni Battista

Born **Faenza, (Emilia-Romagna), Italy, 20 May 1884**
Died **Italy, 6 January 1967**

Originally an Italian postal worker, Giovanni Lacchini became a professional astronomer when a special position was legislated just for him. Lacchini's status was due to his enthusiasm for variable stars: He made observations of variables (53,000+) from locations all over Italy – even from moving trains between stations! Lacchini's skill was such that he could estimate the brightness of a star visually to a tenth of a magnitude, using only one comparison star. He was the first international member of the American Association of variable star observers [AAVSO] and was elected vice president of that organization.

Lagrange, Joseph Louis

Born **Turin, (Italy), 25 January 1736**
Died **Paris, France, 10 April 1813**

Joseph Lagrange made numerous, significant contributions to mathematics and to celestial mechanics (Lagrangian points), especially through his invention of the calculus of variations. A particular combination of the variables in a dynamical system is called the Lagrangian. He was the son of Giuseppe Francesco Lodovico Lagrangia and Teresa Grosso. Lagrange found mathematics initially uninteresting but became attracted to it due to **Edmond Halley**'s works. He lived in Turin until 1766, when he moved to Berlin to work at the Academy of Sciences. He stayed there until 1787, when he moved to Paris, where he remained until his death.

Lagrange's mathematical career began in 1754 with a paper submitted to **Leonhard Euler** at the Berlin academy on the calculus of variations. Euler passed copies of Lagrange's work to **Pierre de Maupertuis**, who offered Lagrange a position at the Academy of Sciences at Berlin. Lagrange declined, though he was made an associate foreign member. Meanwhile, with others, Lagrange co–founded the Royal Academy of Sciences in Turin in 1757.

Lagrange applied his considerable talents to many of the unsolved problems in celestial mechanics. For the prize question of 1764, the Paris Academy of Sciences asked for an explanation of why the Moon's rotational and orbital periods coincide, thereby always showing the same face to us. The prize committee awarded the prize to Lagrange, the first of five times he would win a prize competition, a record surpassed only by Euler. Lagrange's winning solution included the first complete mathematical account of the phenomenon of libration.

The 1766 prize question concerned the explanation of the various inequalities in the motions of the four Galilean satellites of Jupiter. If two bodies were alone in the Universe, they would orbit each other along an unchanging elliptical orbit, but the real case is more complex; the gravitational perturbations of the Sun, planets, and satellites mean that orbital parameters constantly vary under changing gravitational influences. These variations or inequalities fall into two categories: periodic, which forever oscillate about a mean value, and secular, which increase without bound. Lagrange's submission won the prize, establishing him as one of the foremost mathematicians in Europe. Shortly afterward, **Jean d'Alembert** offered Euler's position at Berlin to Lagrange when Euler left for the Russian Academy of Sciences. Thus, in October 1766, Lagrange arrived in Berlin.

Jupiter and its satellites are an example of an *n*-body problem. The general method of approach is to solve a corresponding 2-body problem, and then take into account the perturbations caused by the addition of bodies. The motion of the Moon is even more difficult, for the Sun's perturbing effect on the Moon's motion about the Earth is far higher than any other perturbations in the Solar System. In 1770, the academy, dissatisfied with existing tables of the Moon's position, offered a prize for a new theory of the Moon and thus a new method of creating more accurate tables of the Moon's position, which in turn could be used to solve the longitude problem. None of the entries received by the academy were deemed satisfactory, so in 1772 the academy posed the question again, this time with a double prize of 5,000 florins. Both Lagrange and Euler submitted winning papers, and shared the double prize.

In the first section of this paper, Lagrange made one of his most celebrated contributions to celestial mechanics. He found five points in a 2-body system where a third body, assumed not to gravitationally influence the other two, could be placed so as to remain in a stable position relative to the other two. These five points are today known as the Lagrangian points closely related is the inner Lagrangian Surface for instance, in a binary star systems, on which material can flow freely from one star to the other (also called a Roche lobe).

Despite their success, neither Euler nor Lagrange could explain a phenomenon noted by Halley. Observations from the time of **Ptolemy** could not be reconciled with contemporary observations unless one assumed that the Moon's mean motion was undergoing a steady acceleration. In March 1772, d'Alembert suggested to Lagrange that the lunar acceleration might be the subject of the next prize question. Lagrange's analysis showed that the perturbations caused by the planets were periodic in nature; hence, any variation they caused was also periodic, so they could not produce a secular variation. He concluded that because the secular acceleration could not be accounted for mathematically, then it had to be an observational error. Lagrange won the prize, though it should be pointed out that he was not entirely correct. A later analysis by **Pierre de Laplace** showed that very slow (but periodic) changes in the eccentricity of the Earth's orbit were the source of very long period (hence, apparently secular) variations in the Moon's mean motion.

The next prize question posed by the academy, for 1776, concerned the perturbation of the orbits of the comets. Lagrange began to compose an entry, but shortly afterward withdrew from the contest. The academy found none of the entries worthy of an award, so once again, they repeated the question with a double prize in 1780. This time, Lagrange won the double prize himself.

When Lagrange withdrew from the 1776 contest, he found himself involved in a far more important question: an examination of the orbits of the planets. An elliptical orbit has five main parameters: the inclination of the orbit to the plane of the ecliptic, the eccentricity, the semimajor axis, the position of the nodes, and the position of the aphelion. Gravitational perturbations vary these five parameters. Of the five, two (the position of the nodes and the aphelion positions) could be varied any amount without seriously affecting the constitution of the Solar System, but this was not true of the eccentricity, inclination, or semimajor axis; vary these too greatly, and the orderly march of the planets around the Sun would be disrupted. Hence, the question arose of the long-term stability of the Solar System.

In 1774, Lagrange had shown that the inclinations of the planetary orbits undergo only periodic variations. Lagrange's paper, sent to the Paris academy, was given to Laplace to referee. Laplace applied Lagrange's method and showed that the eccentricities likewise underwent only periodic variations. Moreover, Laplace managed to rush his own work into print *before* Lagrange's (though giving credit to Lagrange for having developed the method he used). Not surprisingly, Lagrange submitted no more papers to the academy.

Lagrange's crowning result thus appeared in the 1776 *Memoirs* for the Berlin Academy of Sciences. Lagrange showed that the semimajor axes of the planetary orbits, like the inclinations and eccentricities, underwent only periodic variations, answering positively the question of the stability of the Solar System.

By 1787, Lagrange's position at Berlin was more of a burden than a joy. He had married his cousin, Vittori Conti, in September 1767, but they had no children. She died in 1783 after some years of poor health. Lagrange's health, too, was far from perfect. Frederick the Great died in 1786, and after his death the prestige and position of Prussia began a long decline. Lagrange accepted an offer from the Paris academy to become a member, particularly since the offer specifically excluded teaching as one of his responsibilities. Lagrange left Berlin on 18 May 1787. In 1792 Lagrange married again, this time to Renée-François-Adélaide le Monnier (daughter of **Pierre le Monnier**). The marriage contract was signed on 3 June by the royal family, one of the last official acts of the doomed Bourbons.

Lagrange himself managed to survive the Revolution, though at times his fate was in doubt. In September 1793, at the height of the Reign of Terror, an order was issued for the arrest of all enemy aliens and the seizure of their property. A special dispensation was arranged for Lagrange at the behest of chemist Antoine Lavoisier, who would himself be executed by the radicals a few months later. Many schools were closed down during the first years of the Revolution, and in an attempt to restore higher learning, the École Polytechnique and École Normale were established; Lagrange taught at both. The École Normale closed down after just 3 months of instruction, but the École Polytechnique survived the revolutions and beyond. Napoleon, who himself was well aware of the prestige associated with top scientists, showered honors on Lagrange and others: Lagrange was made a Senator, then a Grand Officer in the Legion of Honor, and then a Count of the Empire. Finally, on 3 April 1813, Napoleon inducted Lagrange as a Grand Croix of the Order of the Reunion. A week later Lagrange died.

Lalande, Joseph-Jérôme

Born **Bourg-en-Bresse, (Ain), France, 11 July 1732**
Died **Paris, France, 4 April 1807**

Lalande organized and reduced observations from the 1769 French transit-of-Venus expeditions, prepared a great star catalog and important astronomical bibliography, and taught many astronomers.

Lalande's father was Pierre Lefrançois, director of a tobacco warehouse, who married Marie-Anne-Gabrielle Monchinet. Their son was educated by the Jesuits at Bourg and then at Lyons. Sent to Paris to study law, he frequented the observatory of **Joseph Delisle** at the Hôtel de Cluny and attended his lectures and those of **Pierre–Charles Le Monnier** at the Collège royal (now Collège de France). Then he named himself Lalande. A bachelor, in his 50s he adopted his nephew Michel Lefrançois, who married Amélie Harlay, whom he considered both niece and daughter.

In 1751, **Nicolas de La Caille** was at the Cape of Good Hope to measure the lunar parallax, which requires simultaneous measurements. The most advantageous other site being in Berlin, Le Monnier proposed himself as an observer but had his young pupil Lalande carry it out. At Berlin, Lalande was well received by Frederik II. He observed the Moon from 29 November 1751 to 1 September 1752, studied analysis with **Leonhard Euler**, and met the philosophers of the King of Prussia. He became a member of the Berlin Academy of Sciences, and, upon his return to Paris, a member of the Academy of Sciences there as *astronome adjoint* on 4 February 1753. In 1772, Lalande was named *pensionnaire*. He published three memoirs on the lunar parallax in *Mémoires de l'Académie* for 1752, 1753, and 1756.

Delisle sent instructions to his numerous correspondents for observing the transit of Mercury on 6 May 1753. Lalande observed it with Le Monnier at the castle of Meudon (future observatory of **Jules Janssen**) and used a heliometer designed by **Pierre Bouguer**. On Lacaille's return, Lalande adopted his methods rather than those of Le Monnier, leading to a quarrel and a falling out. Lalande remained a friend of Delisle, who offered him in 1754 the dome of the Luxembourg palace where he used his heliometer for determining the diameters of the Moon and the Sun. Lalande observed there for 10 years.

In 1758, **Alexis Clairaut** calculated the date of the return of the comet of 1682 (IP/Halley) with the help of Lalande and **Nicole Lepaute**. Lalande published (1759) a series of tables of Halley's Comet and the history of this comet.

Delisle sent out instructions again for observations of the 6 June 1761 transit of Venus, which Lalande observed at the Luxembourg palace.

Lalande obtained the editorship of the *Connaissance des Temps*, which he transformed, including information useful for navigation. Lalande composed 16 volumes from 1760 to 1775. After becoming a *pensionnaire* of the academy, he left the journal, but he took it up again from 1794 until his death.

In 1762, Delisle, who wished to retire, handed over his astronomy courses at the Collège royal to Lalande, who was named to the chair upon Delisle's death in 1768. In 1764, Lalande published his influential *Astronomie*, which served to instruct astronomers for many years. For his pupils and his own work, he made several observatories available: his own at the Collège Mazarin (now Institut de France) from 1764 to 1806; at his home Palais Royal square from 1770 to 1775; at the Collège Royal, where he settled in 1775; and later at the École militaire.

At the Collège de France, Lalande became a famous teacher, instructing **Jean–Baptiste Delambre**, **Pierre Méchain**, and **Giuseppe Piazzi**. He also taught navigational astronomy, and published (1793) navigational time tables calculated by his niece/daughter. She inspired him to write *Astronomie des Dam*es, published in 1785.

For the transit of Venus on 3 June 1769, Lalande developed Delisle's method of computing solar parallax, and sent instructions and maps. He refused to travel, reserving for himself the analysis of the observations he hoped to receive from his correspondents. In 1770, he deduced a solar parallax of 8.5″ to 8.75″.

With his observations and those of his correspondents and pupils, Lalande established orbits and tables of planets from 1755 to 1796. In 1789, he observed the Sun at the solstice, just as La Caille had done 40 years ago at the same observatory with the same instrument; Lalande calculated that the obliquity of the ecliptic is diminishing by 38′ each century.

In 1783, Lalande started his last great project: to establish a catalog of 50,000 stars down to the ninth magnitude. Observations were made until 1785 at the observatory of the École militaire by his pupil Dagelet, now teacher at this school. After the destruction of this observatory, Lalande achieved its reconstruction in 1788, when his nephew **Michel Lefrançois-Lalande** became its main observer. Lalande published his catalog in *Histoire céleste* (1801), which **Heinrich Olbers** declared one of the most important productions of the 18th century.

Lalande often expressed interest in the history of astronomy. In *Connaissance des Temps*, he published the astronomical history of the past year, and gathered those articles in 1803 in *Bibliographie astronomique avec histoire de l'astronomie de 1781–1802*. This huge volume, the printing of which was funded by the government, is an important bibliographical source.

On 10 August 1792, Lalande saved the lives of several nobles and priests by hiding them in his observatory of the Collège Mazarin. In August 1793, during the Revolution, the academies were suppressed in France. In 1795, after the Terror, the Convention created the Bureau des Longitudes and reestablished the Paris academies gathered in the Institut National. Lalande was the first astronomer named at the Bureau, of which he became the secretary; he was also the delegated director of the Paris Observatory until the return of Mechain. In February 1793, when the Republican calendar was established, Lalande had to adopt it in *Connaissance des Temps*, but by 1801, he publicly wished the return of the Gregorian calendar, which was reestablished in France on 1 January 1806.

Lalande liked to travel. In France, he visited many of his correspondents and spent a few months in Bourg nearly every year. He traveled to England, Switzerland, Holland, Germany, and Italy and published a volume on his travel in Italy. He ascended balloons to study the scintillation of stars and hoped to reach Gotha by such means. In 1798, in Gotha, Lalande presented the newly devised metric system to German astronomers gathered by **János von Zach**.

Lalande became a freemason, probably in Bourg-en-Bresse, around 1770. In 1776, he founded the Lodge of Nine Sisters, which received Voltaire in 1778 and of which Benjamin Franklin was a member. In the 1805 supplement of *Dictionnaire des Athées* of Sylvain Maréchal, Lalande attacked those who bloody the Earth by war. This attracted the attention of Napoleon, who ordered the Academy of Sciences to forbid him from publishing.

Lalande updated the astronomical articles for the new *Encyclopédie méthodique*, published more than 150 memoirs, and helped publish the work of French and foreign scientists, including LaCaille, Bouguer, Jean Montucla, **John Flamsteed**, Jesse Ramsden, and others. He was a member of the academies of London, Berlin, Petersburg, Stockholm, and Bologna.

Lalande was both impatient and generous with correspondents and pupils. He enjoyed attention and glory, receiving it in life and in death; his statue is displayed with one of **Giovanni Cassini** among the 86 illustrious men installed in the middle of the 19th century on the Louvre's façade in the court of Napoléon.

Lalla

Flourished **Lāṭa region, (Gujarat, India), 8th century**

Lalla was a Hindu astronomer who attempted to synthesize two of the principal schools of astronomical thought that were active during the classical period (late 5th to 12th centuries). Despite the significance of Lalla's work, very little is known about his life. According to very brief autobiographical comments, he was a member of a Brāhmaṇa family, the son of Trivikrama Bhaṭṭa, and the grandson of Taladhvaja. Lalla did not record any dates relating to his life or work in his surviving treatises. He is generally placed in the middle of the 8th century on the basis of his borrowings from earlier authors and those of later authors from him. Lalla's geographical location has been assigned to the Lāṭa region on the strength of some allusions in his verses, and a remark by one of his commentators that these probably reflected "regional chauvinism on Lalla's part." Only two of Lalla's works are known to be extant.

The *Śiṣyadhīvṛddhidatantra* (Treatise for increasing the intelligence of students) is one of the first major Sanskrit astronomical treatises known from the period following the 7th-century works of **Brahmagupta** and **Bhāskara I**. It generally treats the same astronomical subject matter and demonstrates the same computational techniques as earlier authors, although there are some significant innovations. Lalla's treatise offers a partial compromise between the rival astronomical schools of his predecessors, **Āryabhaṭa I** and Brahmagupta. Lalla is avowedly a follower of the former, but combines parameters and techniques from both. He borrows the titles from two chapters of the *Āryabhaṭīya* ("Computation" and "The Sphere") and applies them to sections of his own work. The first of these covers standard astronomical tasks, including the mathematical prediction of ominous events such as eclipses and celestial conjunctions.

Lalla's section on "The sphere" is more concerned with general elucidations of the terrestrial and celestial spheres than with the immediate demands of astronomical computation. Nonetheless, Lalla insists on the necessity of understanding the larger mathematical picture as well as the application of formulas: "The learned say that spherics is [essential] for calculation." Both his textual arrangement and arguments were frequently copied by later astronomers. His chapter entitled "False knowledge" contains a defense of cosmology against criticism on physical and scriptural grounds. In the 12th century, **Bhāskara II** wrote a commentary on Lalla's *Śiṣyadhīvṛddhidatantra*.

The *Jyotiṣaratnakośa* (Treasury of Jewels) is Lalla's treatise on catarchic astrology. It represents the earliest known Sanskrit astrological work for determining auspicious and inauspicious times. No edition of that work has been published; the several known manuscripts are incomplete.

Lallemand, André

Born **Cirey, Haute-Saône, France, 29 September 1904**
Died **Paris, France, 24 March 1978**

While he contributed chiefly to the development and application of photomultipliers, André Lallemand also played important roles in the construction and instrumentation of French telescopes.

Lallemand was the son of Louis and Lucie Lallemand; his father was a primary-school teacher. Lallemand's career in astronomy began in 1925 at the Strasbourg Observatory, where he served as an assistant to **Ernest Esclangon**. He qualified as a schoolteacher in the physical sciences in 1927 and taught at a high school in Haguenau, near Strasbourg, for a year. His doctoral research, which examined the magnetic properties of different elements of the iron family, was completed under Pierre Weiss at the Strasbourg Physical Institute. There, Lallemand acquired the experimental techniques that were essential for his later research on electronic detectors and amplifiers. He married Suzanne Ancel in 1928; the couple had two sons.

In 1928, Lallemand returned to the Strasbourg Observatory as *aide-astronome*, the level above an assistant. He devoted his energies to the improvement of astronomical observation methods. His infrared photographs of the solar corona, taken during an eclipse observed at Poulo Condore, Vietnam in 1929, were in accord with the expected diffusion of light by photospheric electrons.

Lallemand's interests then turned to astronomical photometry. In 1934, realization of the first photoelectric imaging devices led him to imagine what he called the "electronic telescope," now known as the "electronic camera." An optical image was first projected onto a photoelectric cell. The emitted electrons were then accelerated and refocused onto a photographic plate. The outbreak of World War II interrupted but also intensified research on these imaging devices. For several years, he and other scientists from the University of Strasbourg were moved to Clermont-Ferrand for defense-related work. In 1943, Lallemand accepted a joint appointment at the Paris Observatory and established a laboratory dedicated to improving photoelectric imaging devices for astrophysical observations.

In the 1950s, Lallemand collaborated on detector developments with Maurice Duchesne. The pair obtained a 100-fold gain in sensitivity as compared to ordinary photography. After 1952, numerous astronomical observations were made with this instrument, especially at the Haute-Provence Observatory. In 1953, Lallemand was named a senior astronomer at the Paris Observatory. In 1959, American astronomer Merle F. Walker invited Lallemand and Duchesne to install their electronic camera at the focus of the 120-in. reflector at the Lick Observatory. There, the trio first measured the differential rotation of the nucleus of M31 (the Andromeda Galaxy).

Many variations of this detector were constructed and utilized at observatories worldwide. In particular, Lallemand developed a wide-field camera with an 8-cm square photocell. Employed on the Canada–France–Hawaii telescope, it provided high-resolution views of the jet seen in the radio galaxy M87. Lallemand was appointed director of the Astrophysical Institute at Paris in 1960. The following year, he was awarded the chair of physical methods of astronomy at the Collège de France.

In the course of his career, Lallemand collected many honors and awards; among them were four prizes of the French Academy of Sciences. Along with his collaborator Duchesne, he received the prize of the French Conseil Supérieur de la Recherche Scientifique (1956). Lallemand was the recipient of the Eddington Medal of the Royal Astronomical Society (1962) and the Paul and Marie Stroobant Prize of the Royal Academy of Belgium (1962). He was made a Commander of the Legion of Honor (1964) and Grand Officer of the National Order of Merit (1968). The universities of Padua and Geneva bestowed honorary doctorates upon him. Lallemand's name is attached to the prize awarded every 2 years to an astronomer by the French Academy of Sciences.

Lallemand was an officer of many important associations and committees. He served as president of the French National Committee on Astronomy (1963–1967), president of the French Society of Physics (1964), and president of the Bureau of Longitudes (1964). He likewise participated in the council to the European Southern

Observatory [ESO] and the management of the Haute-Provence Observatory. Lallemand retired in 1974.

Lambert, Johann Heinrich [Jean Henry]

Born **Mülhausen, (Mulhouse, Haut-Rhin), France, 26 August 1728**
Died **Berlin, (Germany), 25 September 1777**

Johann Lambert was a physicist known for pioneering work in photometry and in astronomy for his ideas of the nature of the Milky Way. In physics, Lambert is remembered by the unit for illumination density and a number of laws that bear his name.

Lambert was born the son of Lukas Lambert, a tailor, and Elisabeth Schmerber. The family lived in very modest if not poor conditions. He had to help his father and at the age of 12 was taken out of school to learn the trade. Instead, his younger brother became a tailor, leaving Lambert time for private study of literature, the Latin and French languages, calculus, and elementary sciences. About this time, he became interested in astronomy and started to observe the sky.

Lambert gained employment from the Mulhouse town chronicler named Reber for a modest income, and in 1743 he became a bookkeeper for an ironworks at Seppois. He observed the bright comet C/1743 X1 (Klinkenberg-de Chéseaux) and attempted to calculate its orbit. In 1745, Lambert went to Basle to act as a science writer for professor Johann Rudolf Iselin and to continue his studies in science and philosophy.

In 1748, Lambert accepted a position as teacher in the home of Reichsgraf Peter von Salis, in Chur, Switzerland, where he stayed for 8 years. During this time he undertook many investigations that became the foundation of his later scientific and philosophical work, including the 1749 idea of a disk-shaped Milky Way. In 1753, Lambert became a member of the Helvetische Gesellschaft and in 1754 of the Physikalisch–mathematische Gesellschaft in Basle, for which he published his first paper, the results of meteorological observations in 1755.

In 1756, Lambert left Chur to travel through western Europe, together with two students. Their first destination was Göttingen where they made academic contacts: In 1757, Lambert was elected a member of the Göttingingische Sozietät. In the following 2 years, they were based in Utrecht, the Netherlands, and from there visited academics throughout the country. After further journeys to France and Italy, Lambert returned to the Salis family in late 1758.

In May 1759, Lambert visited Zürich, where he worked with Johannes Gessner and published his *Freye Perspektive* (Free perspective). From there he returned to Mülhausen to stay with his mother, sisters, and brothers. When his mother died soon afterward, Lambert moved to Augsburg, where he published some of his most important works: *Photometria* (1760), a foundation of photometry, *Eigenschaften über Kometenbahnen* (1761), a geometrical method to determine cometary orbits, and *Cosmologische Briefe* (1761), a theoretic–philosophical discussion of the Universe and, in particular, the Milky Way.

Lambert was among the scientists who tried to establish a Churbairische Akademie der Wissenschaften. His work at this academy included fundamental theory of cartography. In 1762, because of trouble over the nomination of a professor, Lambert left the academy but remained a correspondent. He returned to Chur where he stayed till autumn 1763 and completed his philosophical work, *Neues Organon*, then traveled *via* Augsburg to Leipzig, where he found a publisher for this work.

In January 1764, Lambert arrived in Berlin. On the recommendation of his Swiss compatriots Sulzer and **Leonhard Euler**, he was introduced to King Frederick II, but it took about a year until the king became convinced of his abilities and made him a member of the Berlin Academy of Sciences in January 1765. At the Berlin Academy, Lambert busily continued his work in philosophy, mathematics, and physical sciences, including astronomy, and published numerous papers. In philosophy, he was a representative of rationalism, and contributed to the theory of knowledge. In mathematics, he worked on the theory of conic sections, trigonometric functions for complex variables (Demoivre's theorem), and hyperbolic functions. In 1765 he found a proof for the irrationality of the numbers π and e.

Lambert continued his meteorological studies and, in 1771, proposed a meteorological world organization. He included the winds in his considerations, and in 1775, published *Hygrometrie*, a treatise of air humidity. In 1774, he founded the *Astronomisches Jahrbuch* together with **Johann Bode**. In 1775, Lambert became ill, but refused medical treatment. Despite increasing health problems, in May 1777 he finally completed his *Pyrometrie*, a treatise of the theory of heat.

In astronomy, Lambert's early observations and calculations on the comet of 1744 led to a geometrical method for their orbital determination (*Eigenschaften über Kometenbahnen*, 1761). He calculated orbits for the comets Messier (C/1769 P1), Lexell (D/1770 L1), and Messier (C/1773 T1). In 1773 he noted that the changes to some cometary orbits differ slightly from what is expected from gravity alone (Lambert's theorem of cometary motion).

In his *Cosmologische Briefe*, Lambert gives a theoretical description of the Universe as it was known at his time. He wished to extend Newtonian physics, well established for the planets, to comets and stellar universe. Moreover, Lambert gives a hierarchical theory of cosmology. Like his contemporaries, he had a "teleological" view of the Universe, assuming *somebody* who defines a *purpose* of everything. Perhaps the most important part of this work, based on his

1749 idea, is the theory of the Milky Way as a disk, a system formed by thousands of stars surrounding the Sun, with the Milky Way plane resembling the "ecliptic for the stars." Lambert thought that every star is a sun with a planetary system. Also, he assumed that there may be other Milky Way systems, potentially forming a higher-order system. When he published his theory in 1761, Lambert was unaware of similar ideas by **Thomas Wright** (1750) and **Immanuel Kant** (1755), of which he learned only after his publication. There are some differences though: Lambert was inconclusive on the nature of the "nebulae," once viewing them as extragalactic stellar systems (as Kant always did), and another time as central bodies for galactic substructures. Also in difference to Kant, Lambert argued for a finite cosmos. But like Kant and Wright, he assumed that all celestial bodies, even the Sun and comets, are inhabited. Lambert's theory of diffuse reflection, developed in *Photometria*, introduced the important term *albedo* for the fraction of diffusely reflected light by surfaces. He also wrote on aurorae, zodiacal light, lunar topography, and the (nonexistent) satellite of Venus. The *Astronomisches Jahrbuch* he founded in 1774 became an important periodical under the direction of Bode. Lambert died unmarried.

Lamech, Felix

➔ **Chemla-Lameche, Felix**

Lamont, John [Johann Von]

Born **Corriemulzie near Braemar, (Highland), Scotland, 13 December 1805**
Died **Munich, Germany, 6 August 1879**

John Lamont's principal work was in practical astronomy, chiefly the measurement of the positions of stars, particularly in clusters such as *h* and χ Persei.

Lamont was born of Roman Catholic parents; his father died in 1816. Too poor to obtain advanced schooling at home, at the age of 12 Lamont was given a scholarship to attend a Benedictine monastery college at Ratisbon, Bavaria. He did so, with a view to the priesthood, but abandoned this project and studied astronomy at Munich.

Lamont joined the staff (assistant astronomer) of the Royal Observatory at Bogenhausen (Munich Observatory) in 1830, and was appointed director in 1835. He succeeded **Johann Soldner**. (This post was equal to that of Astronomer Royal for Bavaria; later he became professor of astronomy at Munich University.)

Lamont now controlled the second largest refracting telescope in existence. On at least two occasions he made prediscovery observations of Neptune, though did not recognize it as a planet. Lamont's orbital calculations for Saturn's and Uranus's satellites resulted in masses for those two planets. He also observed comet 1P/Halley in 1836.

In astrophysics, Lamont made early sketches of stellar spectra (1838). In geophysics, for which he is most famous, Lamont made the 1850 discovery of the Earth's 11-year magnetic period.

Lamont was a member of the English Royal Society and the Royal Astronomical Society. He never married, and after his death, he left his money and property to establish scholarships for young students of science.

Lampland, Carl Otto

Born **near Hayfield, Minnesota, USA, 29 December 1873**
Died **Flagstaff, Arizona, USA, 14 December 1951**

Carl Lampland was involved with both of the Solar System projects for which the Lowell Observatory became famous: observations of Mars and the search for "Planet X." He also accumulated a massive collection of fine photographs of nebulae, including galaxies and gaseous nebulae, and made accurate estimates of the temperatures and temperature balances for various objects in the Solar System.

Lampland was the third of 11 children born to Norwegian parents. He received a B.S. degree in 1899 from Valparaiso Normal School at Valparaiso, Indiana. Lampland then graduated with a B.A. degree in astronomy from Indiana University in 1902. He accepted a position as astronomer at the invitation of **Percival Lowell** from the Lowell Observatory in 1902. Lampland also received an M.A. degree in 1906 and an honorary L.L.D. in 1930 from Indiana University.

In the early years at Flagstaff, Lampland was closely associated with Lowell in observing the planets, particularly Mars. He designed the planetary cameras used on the 24-in. Clark refractor, for which he received the medal of the Royal Photographical Society of Great Britain. In 1905, Lampland initiated the first photographic search for the trans-Neptunian planet postulated by Lowell. After Lowell added a 42-in. reflector to the observatory's telescopes in 1909, Lampland served as the principal observer with that instrument for the next 42 years. With it, he made over 10,000 photographs of nebulae, star clusters, variable stars, novae, and planets. He studied these photographs and published interpretations of the changes they revealed. For example, Lampland conducted an extensive campaign to record changes in NGC 2261, after changes in that nebula were noted by **John Mellish** and documented by **Edwin Hubble**. Lampland was responsible for the recognition of the second truly variable nebular phenomenon, the expansion of the Crab Nebula supernova remnant, showing that it must have formed about the time of the 1054 supernova. Unfortunately, Lampland was extremely reluctant to publish the results of his photographic work, so much so that in 1948 the International Astronomical Union passed a resolution pointing out the desirability of having the photographs published. Sadly, he died within a few years after the resolution added importance to his work; thousands of his excellent photographs remain unpublished.

In collaboration with **William Coblentz** of the National Bureau of Standards, Lampland measured the temperatures of the planets with thermocouples that he constructed. Based on those measurements, and in collaboration with **Donald Menzel**, they concluded that the energy reflected, and reradiated, from the planets was very nearly that which each planet received from the Sun.

Lampland was a member of several professional societies, including the American Academy of Arts and Sciences. He married Verna B. Darby, a classmate from Indiana University, in 1911. She frequently worked with him as an assistant on the 42-in. telescope.

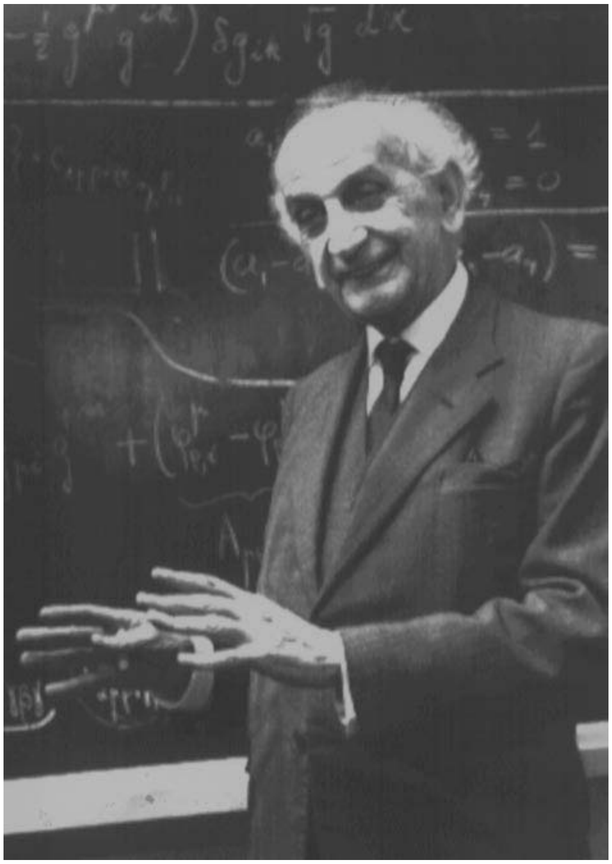
Lanczos, Cornelius

Born **Székesfehérvár, (Hungary), 2 February 1893**
Died **Budapest, Hungary, 25 June 1974**

Hungarian mathematical physicist Cornelius Lanczos explored some of the consequences of **Albert Einstein**'s general theory of relativity pertinent to cosmology, for instance, how the variables expressing measurable quantities must connect across discontinuities in curved space.

Born Kornel Löwy in Hungary, Lanczos changed his name to conceal his German origins. His father, Carolus Löwy, a lawyer, provided for his broad education. He attended a Jewish elementary school, learning several foreign languages, and the local gymnasium, run by the Catholic Cistercians. Graduating from the Gymnasium in 1910, Lanczos entered the University of Budapest in the fall of that year. His teachers in physics, Loránd (Roland) Eötvös, and in mathematics, Lipot (Leopold) Fejér, inspired him to excel in these fields.



Upon graduation in 1915, Lanczos received an appointment as assistant at the Technical University of Budapest, where he worked on relativity theory, dedicating his dissertation, with permission, to Einstein. After receiving his doctorate in 1921, he left Hungary because of its increasing hostility to Jews, and took a position as assistant to the physicist Franz Himstadt at the University of Freiburg in Germany.

In 1924 Lanczos moved to Frankfurt am Main, becoming a colleague of Paul Epstein. During 1928/1929 he was Einstein's assistant in Berlin, returning to Frankfurt at the end of that year. During the 1920s Lanczos joined the German Physical Society and published papers on the general theory of relativity, on a simplified coordinate system for Einstein's gravitation equations, on the expected red shift in a De Sitter universe, and on cosmology. In this period he independently discovered the mathematical equivalence of Werner Heisenberg's discrete matrix representation and **Erwin Schrödinger**'s continuous wave representation of the formal expressions of quantum mechanics expressible as integral equations.

In 1931 Lanczos spent a year as visiting professor at Purdue University in Lafayette, Indiana, USA, returning briefly to Germany during 1932. Recognizing that overt discrimination made continued work there impossible for a person of Jewish origins, he returned to Purdue as a professor that same year. Lanczos' work focused on mathematical physics and numerical analysis, and he had an extensive correspondence with Einstein. Extending his interest in relativity, he published several fundamental papers in this area.

During 1944 Lanczos took a position at Boeing Aircraft Company where he worked on applications of mathematics to aircraft design, developing numerical methods to solve certain problems. He resigned his position at Purdue in 1946 to take a permanent position at Boeing, but in 1949 he moved to the Institute for Numerical Analysis of the National Bureau of Standards in Los Angeles, California, working on digital computers and numerical methods.

For political reasons connected with the investigations of Joseph R. McCarthy in the United States Senate, Lanczos became uncomfortable in the USA, and was delighted to receive an offer from Schrödinger to head the Theoretical Physics Department at the Dublin Institute for Advanced Study in Ireland, which post he accepted in 1952. (He also held visiting professorships at North Carolina State University, Raleigh, North Carolina, USA, and received the Chauvenet prize of the mathematical Association of America during the 1960s.) At the Dublin Institute, Lanczos happily returned to science and over the next few years he published more than a hundred papers on topics primarily related to the theory of relativity. Late in life he returned to Hungary.

Landgrave of Hessen-Kassel

➲ **Wilhelm IV**

Lane, Jonathan Homer

Born **Genesee, New York, USA, 9 August 1819**
Died **Washington, District of Columbia, USA, 3 May 1880**

Mathematical physicist J. Homer Lane produced the earliest theoretical treatment of the Sun's internal structure (1870) by applying known physical laws to the behavior of a gaseous sphere (under certain assumptions). Lane's solar studies were well informed by contemporary research in thermodynamics and represented an outgrowth of his laboratory investigations into the behavior of gases at very low temperatures.

Lane was the son of farmers Mark and Henrietta (*née* Tenny) Lane. First educated at home, Lane was admitted to Phillips Academy, Exeter, New Hampshire in 1839, where he developed a lifelong preoccupation with the determination of absolute zero, the theoretically lowest possible temperature. Lane then entered Yale College as a sophomore from which he graduated in 1846. There, he was influenced by the astronomical and meteorological research of **Denison Olmsted**.

After teaching for one year and working briefly for the United States Coast Survey, Lane obtained a position in 1848 as assistant examiner at the United States Patent Office in Washington, DC. He was promoted to principal examiner in 1851. Through his position, Lane became acquainted with the nation's leading physical scientists and astronomers, including **Joseph Henry**, **Simon Newcomb**, and **Benjamin Peirce**. Through their encouragement and occasional support, Lane pursued the construction of his "cold apparatus" for reducing gases to very low temperatures. Although these experiments were judged to be generally successful, Lane never published an account of his cryogenic investigations. He never married.

A change of administration forced Lane out of the Patent Office in 1857, and for the next decade or so, he pursued research at the home of his brother in rural Franklin, Pennsylvania. After the Civil War, Lane returned to Washington (1866), resumed his experiments on gases, and turned his thoughts toward an understanding of the Sun's temperature, density, and pressure. In 1869, he obtained a position at the Office of Weights and Measures, forerunner of the National Bureau of Standards, where he remained for the rest of his life.

In 1869, Lane delivered a paper, "On the Theoretical Temperature of the Sun," before the National Academy of Sciences. It was published the following year in the *American Journal of Science*. Lane was the first to derive a mathematical relation between the temperature, pressure, and density of a gaseous sphere, under the assumed conditions of hydrostatic equilibrium and thermal or convective equilibrium. These yielded a single differential equation that Lane solved for the surface temperature of the Sun (under an assumed range of specific heats). Had he carried the analysis further, Lane might also have calculated the central temperature of the Sun. Implicit in Lane's results was his recognition that the internal temperature would vary inversely with the radius of the sphere. This mathematical relationship, later dubbed Lane's law (or more properly the Lane–Emden equation), was not demonstrated explicitly until 1887 by **William Thomson** (Lord Kelvin). Independently of Lane, **Georg Ritter** derived the same mathematical equations in a series of papers published between 1878 and 1883.

Lane's paper garnered him election to the National Academy of Sciences in 1872. But in spite of this recognition, Lane remained an astronomical outsider. He did not pay attention to the rapidly emerging field of observational astrophysics, and the spectacular findings derived from spectroscopic studies of the Sun. His contribution is viewed not as a remarkable fluke, but instead as the successful application of known physical laws to the construction of a theoretical model of the Sun (and other stars), whose fuller development awaited the next generation of astronomers and physicists.

Langley, Samuel Pierpont

Born **Roxbury, Massachusetts, USA, 22 August 1834**
Died **Aiken, South Carolina, USA, 27 February 1906**

Samuel Langley was a pioneer solar astrophysicist and founder of the Smithsonian Astrophysical Observatory. He was the son of Samuel Langley, a Boston wholesale merchant, and Mary Sumner Williams. He was a descendent of the prominent Mather family. Langley was educated in several private schools, the Boston Latin School, and the Boston High School, from which he graduated in 1851. He never married. In his youth Langley used his father's small telescope; at 20, he and his only brother John started building small telescopes.

With few employment opportunities in astronomy, Langley aimed to become an architect or civil engineer. Instead of attending college, he decided to go to work immediately to learn these crafts, working some time in a Boston architectural firm; he obtained similar work in Saint Louis, Missouri, then in Chicago, Illinois. Through this experience, Langley developed superb mechanical and freehand drawing skills, as well as learning sound business procedures. But he became disinterested in architecture and returned home in 1864. His brother had just been discharged from the Union Navy, after 3 years in the Civil War. In 1865, the Langley brothers toured the centers of culture and learning in Europe; this included many of Europe's observatories. On his return, Langley learned that Harvard College Observatory was expanding. Impressed with Langley's enthusiasm and experience in telescope construction, professor **Joseph Winlock** hired him as an observatory assistant. He remained at Harvard College Observatory less than a year. In 1866, Langley was offered the professorship of mathematics at the United States Naval Academy with the understanding that his primary duty would be to restore their small astronomical observatory; it had been unused while the Naval Academy spent the Civil War in Newport, Rhode Island.

At the invitation of Western University of Pennsylvania (later Pittsburgh) trustee William Thaw, Langley agreed to take charge of the newly acquired Allegheny Observatory as professor of astronomy and physics in 1867. Thaw and two other wealthy Pennsylvanians had conceived the observatory in 1859, shortly after the appearance of comet C/1858 L1 (Donati). The observatory opened on 27 November 1861 with a 13-in. Fitz refractor telescope, then the third largest in the world. In the first years, it was used strictly for the entertainment of the members of the Allegheny Telescope Association. As interest waned, the observatory went into debt. In May 1867, the club donated the observatory to the university.

Langley developed what he termed the New Astronomy, which concentrated on measuring the celestial bodies and analyzing their physical composition, structure, and other properties. This later developed into astrophysics. His greatest astrophysical achievement was measuring the distribution of heat in the spectrum of the Sun. Given the lack of precision of instruments, he invented the bolometer in December of 1880, used to measure the amount of radiation coming from celestial bodies with very great accuracy. It electrically measures a slight difference in resistance between two thin, blackened strips of tape, when one strip receives radiation while the other does not; the difference indicates the amount of radiation received.

Langley spent years studying the selective absorption of solar radiation by the Earth's atmosphere. Up until 1881, this study had been limited to the relatively low altitudes of Pennsylvania. With funding from Thaw and the United States Army Signal Service (responsible for much of the weather forecasting of that era), Langley led an expedition to Mount Whitney (14,494 ft.). The result was a 240-page technical report, "Researches on Solar Heat and Its Absorption by the Earth's Atmosphere: A Report on the Mount Whitney Expedition," published in 1884.

Using these data, Langley attempted to measure the solar constant, the quantity of solar radiation striking the top of the Earth's atmosphere. He judged it to be 3 cal cm^{-2} min^{-1}. Unfortunately, Langley miscalculated the absorption of the Sun's energy by the air. Although the reductions of his own data were in error, this value of the solar constant was accepted by scientists for about 20 years, thanks to his reputation.

During the Mount Whitney expedition, Langley discovered a previously unobserved extension of the infrared region of the spectrum. At the Allegheny Observatory, he was able to start mapping this new region of the spectrum. He also used the bolometer to obtain a good approximation of the temperature of the Moon.

Langley observed several solar eclipses to study the Sun's corona. His classic 1873 illustration of a sunspot became standard in textbooks of the time.

As a science popularizer, Langley contributed occasional items to the *Pittsburgh Gazette* and lectured throughout the Pittsburgh area.

To help fund his research, Langley found a way that the Allegheny Observatory could generate revenue by selling accurate time. In 1869, he obtained a transit telescope to determine the exact time by the stars, and he assembled a special telegraph system connected to his master clock. Langley solved the problems of the railroads by creating his own precise time, known as the Allegheny system, which he transmitted to the railroads, twice daily, over the telegraph. Although he had originally designed the system to provide time to the city clocks of Allegheny City and Pittsburgh, his railroad customers became much more important. Within the first 4 years, the time service brought in $60,000, which helped pay for the observatory's research and the purchase of instruments. Originally, the university's trustees had thought that Langley's $2,000 a year salary would be the observatory's largest expense. Langley's time service also inspired the eventual time zone system we have today. With the Allegheny system as an example, Charles Ferdinand Dowd and Sandford Fleming started lobbying and promoting a time zone system. Consequently, the great railroad conference of 1883 set up four American time zones; this idea was accepted internationally in 1884.

Langley was appointed assistant secretary of the Smithsonian Institution on 12 January 1887. After naturalist Spencer F. Baird died later that year, Langley succeeded him as the third secretary of the institution on 18 November. This was the most powerful scientific position in America. Until 1891, Langley continued his solar and aerodynamic research half the time at Allegheny until **James Keeler** became director there. In the spring of 1890 he founded the Smithsonian Astrophysical Observatory. Supported only minimally by Congress, the observatory lacked sufficient facilities for many years, but Langley was able to turn it into a valuable research facility.

Langley is also an important pioneer of flight and scientific research into aerodynamics. His greatest successes came in 1896, when two "aerodromes" were catapulted from a houseboat on the Potomac River for flights of 3,000 ft. and 4,200 ft. Although both were unmanned vehicles, they were the first sustained free flights of power-propelled heavier-than-air machines.

Langley was president of the American Association for the Advancement of Science (1888), a member of the National Academy of Science, fellow of the Royal Society of London and the Royal Society of Edinburgh, and awarded a Draper Medal, a Rumford Medal, and a Janssen Medal. He received honorary degrees from Oxford, Cambridge, Harvard, Princeton, Michigan, and Wisconsin universities. The international unit of radiant energy was named the langley, in 1947.

Langren, Michael Florent van

Born **Amsterdam, the Netherlands or Mechlin or Antwerp, (Belgium), *circa* 1600**
Died **Brussels, (Belgium), May 1675**

Michael van Langren was active in cartography, navigation, and engineering, but his principal significance for the history of astronomy is in his mapping of the lunar surface. Not only were his maps as good as or better than those of his contemporaries **Giovanni Riccioli** and **Johannes Hevel**, but his nomenclature for lunar features also established the pattern that is still followed today. He also published a treatise on the comet of 1652 (C/1652 Y1).

Langren's mother and father (Arnold Florent, also a cartographer) were Catholics and immigrated to Brussels, then under Spanish rule. The patronage of Catholic rulers, or the quest for it, was an important factor in Langren's career.

By 1625, Langren was attempting to solve the problem of longitude determination at sea by using the Moon as a universal time finder. Equipped with an ephemeris predicting the times of appearances and disappearances (at sunrises and sunsets in the waxing and waning moon respectively) of lunar features, a navigator could, in principle, know the time at the longitude of the ephemeris by observing the events themselves. Comparing the predicted time with local time would yield the longitude difference. Such a system required detailed and accurate maps of the Moon at each phase using a coherent coordinate system and libration theory.

Langren had plans to create this apparatus by the early 1630s, but the death of his prospective Spanish patroness, Princess Isabella, delayed the appearance of his first manuscript map of the Moon until early 1645. After receiving a privilege in Brussels for his lunar map, he printed his own engraving of it entitled *Plenilunii Lumina Austriaca Philippica* shortly after March 1645. This map, as the title indicates, was of the Full Moon; the entire series of phases, though drafted in manuscript, was never published.

Langren's map of the Full Moon introduced a rich nomenclature for lunar features. His scheme named prominent craters and mountains after illustrious scientists and rulers. He identified seemingly aquatic features with standard Latin terms such as *mare, sinus, oceanus, lacus, flumen* (sea, bay, ocean, lake, river), and others. His terms for highlands were also Latin and included *terra*, *littus*, *promontorium*, and *montes* (land, shore, cape, and mountain range). Most of the specific names Langren assigned have been changed, but his general scheme is recognizable today, and the crater he named Langrenus still bears that name.

Lansbergen, Jacob

Born **Goes, The Netherlands, 1590**
Died **Middelburg, The Netherlands, 1657**

Physician Jacob Lansbergen was important in the Copernican debate within the Low Countries. His *Apologia* (1663) defended the author's late father, Copernican **Philip Lansbergen**, against polemical attacks from anti-Copernicans **Libertus Fromondus** and **Marin Mersenne**.

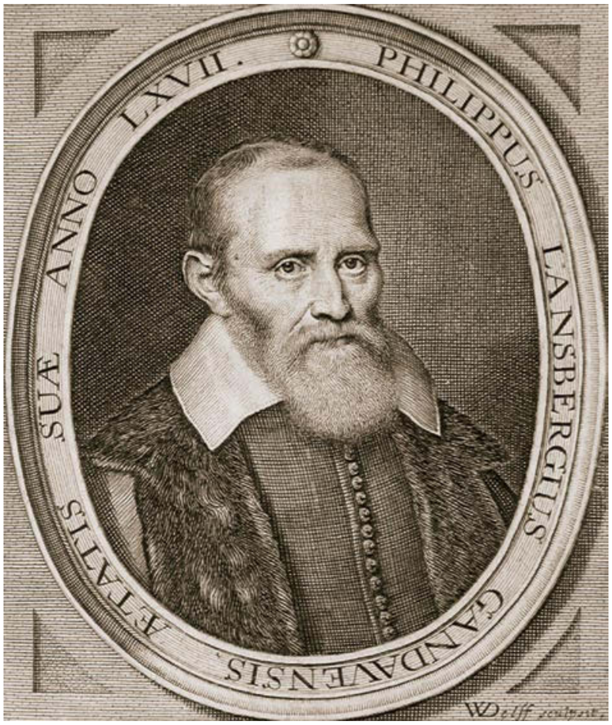
Lansbergen, Philip

Born **Ghent, (Belgium), 25 August 1561**
Died **Middelburg, The Netherlands, 8 December 1632**

Philip Lansbergen was an early advocate of a moving Earth and Sun-centered system.

Born of Protestant parents who left the Netherlands for religious reasons in 1566, young Philip Lansbergen grew up in France and England, where he was educated in mathematics and theology. Upon his return to the Netherlands without a degree in 1579, he accepted employment as a minister in Antwerp, but when this city was conquered by the Spanish in 1585, Lansbergen went to Leiden to apply himself to theology. Shortly after he married Sara Lievaerts in 1586, Lansbergen moved to Goes to be a minister again. Here, alongside his religious acts, he developed his liberal views on astronomy, was engaged in politics, and practiced medicine.



In 1613, after a series of minor incidents, Lansbergen ran into serious problems. The death of one of his patients caused a protracted medical controversy, and his opposition to the appointment of a new mayor ended in his dismissal. Thereupon, he moved to Middelburg and, provided with an annuity of "the Staten van Zeeland," Lansbergen addressed himself mainly to astronomy, mathematics, and medicine until his death in 1632. His wife died in 1625; he left six sons and four daughters.

A follower of **Nicolaus Copernicus**, Lansbergen spoke out for a moving Earth in his writings. Especially his *De motus solis* (1619) and *Bedenckinghen op den daghelijckschen ende jaerlijckschen loop vanden aerdt-cloot* (1629) presented further proof supporting Copernicus's system. However, although being modern-minded on astronomy, he refused to accept **Johannes Kepler**'s theory on the elliptical motion of the planets. Sharp attacks and fierce criticism of Kepler by Lansbergen culminated in the publication of his own astronomical tables based on circular planetary motion instead. Lansbergen thought these *Tabulae motuum coelestium perpetuae* (1632) could rival Kepler's *Tabulae Rudolphinae* (1627). Initially these tables found a ready market, but interest soon waned when their accuracy proved to be not comparable to those of Kepler.

Lansbergen's further works on astronomy and mathematics comprised studies on the use of the astronomical quadrant and astrolabe, the sizes and distances of celestial bodies, the design of planar sundials, and problems in spherical trigonometry. In the Netherlands Lansbergen was one of the first to defend openly Copernicus's theory, and for a long time he was the sole Dutch theologian holding his notion of a moving Earth.

Laplace, Pierre-Simon de

Born **Beaumont-en-Auge, (Calvados), France, 23 March 1749**
Died **Paris, France, 5 March 1827**

Pierre-Simon de Laplace developed numerous mathematical techniques, played an important role in the development of the metric system, and made significant contributions to celestial mechanics. His name is remembered in the Kant–Laplace hypothesis for the origin of the Solar System and is a mathematical operator called the Laplacian. His father, Pierre, was a cider merchant, and his mother Marie-Anne Sochon came from a landowning family; he had a sister, Marie-Anne, born in 1745. Laplace married Marie Charlotte de Courty de Romanges on 15 May 1788. They had a daughter, Sophie-Suzanne, who died giving birth to a daughter, and a son, Charles-Émile, who died in 1874.

His father expected Laplace to make a career in the Church, so he entered the local Benedictine school; at 16, he entered the College of Arts at Caen, a Jesuit school, still intending to study theology, but his interest in mathematics was piqued by two of his teachers, Christopher Gadbled and Pierre le Canu.

Le Canu was acquainted with **Jean d'Alembert**; when Laplace left the College of Arts without taking his degree, he went to Paris with a letter of recommendation from le Canu. According to legend, d'Alembert sent Laplace away after giving him some mathematical problems, which Laplace solved overnight. In the event, d'Alembert became one of Laplace's great supporters, and obtained for him a position at the Military School in Paris.

The position meant Laplace could afford to stay in Paris, and he began to bombard the *Académie royale des sciences* with papers, the first one presented on 28 March 1770. Within 2 years, he presented 13 papers to the *academy*, of which four were eventually published.

Laplace's brilliance was clear to everyone, including himself. In 1771 and 1772, the *academy* elected to membership two scientists, older but less capable. Laplace threatened to leave Paris; d'Alembert wrote to **Joseph Lagrange**, asking on Laplace's behalf if there were any positions available at the Academy of Sciences in Berlin. In the end, Laplace was elected to membership in the *academy* on 1 January 1773, and stayed in Paris.

Laplace developed many important mathematical techniques that informed probability theory, physical science (especially the analysis of heat and sound), cosmology, and celestial mechanics. He was able at last to provide an answer to a query raised by **Isaac Newton** in his *Opticks* about the long-term stability of the planetary orbits. The mutual gravitation of the planets causes their five orbital parameters to vary; finding the exact nature of these variations (called inequalities) was an important part of celestial mechanics in the years following the triumph of Newton. There are two types of variation: first, a periodic variation, whereby an orbital parameter stays close to or oscillates about a mean value, and second, a secular variation, whereby an orbital parameter increases (or decreases) without bound. Determination of the periodic or secular nature of a planet's semimajor axis *a*, eccentricity *e*, or orbital inclination *i* would shed light on the long-term stability of the Solar System.

On 10 February 1773, only a month after his election to the academy, Laplace read the first part of a paper on the secular inequalities of the planets; the second part, probably read before 27 April 1774, examined the secular variations of the semimajor axis, and through a variety of *ad hoc* methods, Laplace claimed to show that the variations were purely periodic. Shortly afterward, Lagrange submitted a paper concerning variations in the line of nodes and the orbital inclination, showing that the latter were periodic, not secular. Lagrange's paper was given to Laplace to referee. Laplace immediately applied Lagrange's method, analyzed the eccentricity and (in modern parlance) the argument of perihelion, and showed that the variations of the eccentricity were likewise periodic. Laplace presented his own work in several parts between 14 July 1773 and 17 December 1774, and managed to include his work in the *Mémoirs* of the academy for 1772, all *before* Lagrange's paper appeared. In 1776, Lagrange demonstrated that the semimajor axes of the planets underwent only periodic variations. Thus Lagrange and Laplace showed that orbital parameters remain bounded, though they still needed to establish that the variations were not only periodic but also small. In 1784, Laplace provided that result.

Today, credit is often given to Laplace alone as having proven the long-term stability of the Solar System. This stems in no small part from Laplace's popular publications, beginning with *Exposition du système du monde* (1796), a popular account of celestial mechanics. In it, Laplace presented the nebular hypothesis of the origin of the Solar System. Laplace noted five key observations about the Solar System:

(1) planets orbit the Sun in the same direction and in roughly the same plane;
(2) planetary satellites likewise revolve around their primaries in the same direction and in the same plane;
(3) planets, satellites, and the Sun all rotate about their own axes in the same direction and in roughly the same plane (or so Laplace thought, though today we know it to be untrue);
(4) orbital eccentricities of planets and satellites are very small; and
(5) comets disobey all of the above, and appear to have their orbits randomly distributed.

Laplace noted that the only person to put forward an origin of the Solar System since the discoveries of Newton was **Georges Leclerc**, who had suggested that a cometary collision with the Sun yielded parts that later coalesced to form the planets. Laplace offered a new hypothesis: The Solar System began as a vast cloud, which began to collapse under its own gravitation, with portions of the cloud condensing into planets and their satellites. Laplace pointed to the Pleiades as examples of a case where a cloud might condense into a multiple star system. Although the nebular hypothesis as Laplace presented it is no longer considered valid, the current theory of the formation of the Solar System incorporates many of Laplace's ideas.

Système du monde was a mere prelude to a more ambitious and more mathematical work, *Mécanique céleste*, in which Laplace summarized everything known about celestial mechanics in five dense volumes. The work provided the first fully analytical solution to calculations of the orbital elements for a celestial body from three observations. The technique assumed that the second (middle) observation was exact, and that the first and third observations were to be approximated (*via* truncated series expansion) to a high degree of accuracy.

Laplace sent *Mécanique céleste*'s first two volumes, which appeared in 1799, to a rising star of French politics, Napoleon Bonaparte. Napoleon had been a student at the Military School, and in September 1785 Laplace had tested Napoleon in mathematics. Napoleon installed Laplace, though only briefly, as Minister of the Interior (1799), and later made him a Grand Officer of the Legion of Honor (1802), a Chancellor of the Senate (1803), and a Count of the Empire (1806). Laplace actively participated in the Institut de France, the *École Polytechnique,* and the *Bureau des longitudes*.

Lārī: Muṣliḥ al-Dīn Muḥammad ibn Ṣalāḥ ibn Jalāl al-Sàdī al-ˀIbādī al-Anṣārī al-Lārī

Born **Lār, (Iran), *circa* 1510**
Died **Āmid, Diyārbakr, (Turkey), 1572**

Muṣliḥ al-Dīn al-Lārī was an eagerly sought after scholar and teacher who worked and wrote in the fields of logic, mathematics, astronomy, law, Qur'ān-exegesis (*tafsīr*), and rational theology (*kalām*). He was born in the south-Iranian city of Lār and studied with Ghiyāth al-Dīn al-Shīrāzī (died: 1542), a scholar with profound interests in astronomy. Ghiyāth al-Dīn wrote, among other things, a commentary on the *Almagest* and a commentary on the astronomical handbook by **Ulugh Beg** and his collaborators. The first commentary claims to complete **Ptolemy**'s book, while the second maintains that it will deliver keys to the astronomers (for carrying out their profession). Thus, it may well be that Lārī studied these works as well as the entire scope of problems dealt with by *ˁilm al-hay'a* (astronomy) with Shīrāzī. From Iran, Lārī moved to India and worked some time between 1530 and 1556 at the Moghul court of Humāyūn (1508–1556). In 1556 he traveled to the Ottoman Empire, first to Aleppo, then to Istanbul, and finally to Diyārbakr. In Diyārbakr, Lārī worked for Governor Iskandar Pasha. In 1559, he was appointed head teacher at the Hüsrev Pasha school in Diyārbakr and the city's Muftī (a type of legal magistrate).

One mathematical work and three astronomical treatises are known to be extant today. The mathematical work discusses geometrical problems. The astronomical treatises are: a commentary, dedicated to Humāyūn, on **ˁAlī Qūshjī**'s introductory Persian text on astronomy, a text on dawn and twilight, and an astronomical treatise composed in the form of questions and answers. His most influential astronomical text, judged on the basis of the extant copies, was his commentary on Qūshjī's introductory text. Except for this work, none of Lārī's astronomical and mathematical writings have been studied so far.

Larmor, Joseph

Born **Magheragall, Co. Antrim, (Northern Ireland), 11 July 1857**
Died **Holywood, Co. Down, Northern Ireland, 19 May 1942**

Irish mathematician and theoretical physicist Joseph Larmor gave his name to the Larmor radius, frequency, and precession, which describe the motion of a charged particle in a magnetic field. He calculated these with special reference to the behavior of a low-mass, negatively charged particle called the electron, which he was the first to predict.

Larmor was born to Hugh Larmor, a farmer, and Anna Wright Larmor. He was named after his maternal grandfather and was the eldest child of a large family. Hugh Larmor gave up farming when Joseph was around six or seven to become a grocer and moved the family to Belfast, where Joseph attended the Royal Belfast Academical Institution. Upon completion of his schooling at the Institution, Larmor entered Queen's College, Belfast, where he received his BA and MA. Upon graduation in 1877 he went to Saint John's College, Cambridge, to study for the mathematical *tripos* there. Larmor lost a year due to illness, but returned with a vengeance. He was senior wrangler (first place in the *tripos* examinations) in 1880 – second place that year was J. J. Thomson – and won the Smith Prize.

Upon graduation Larmor was appointed a fellow of Saint John's College and promptly returned to Ireland to become professor of natural philosophy at Queen's College, Galway. In 1884 he became a member of the London Mathematical Society, serving as a council member from 1887 to 1912, president in 1890 and 1891, and treasurer from 1892 to 1914. Larmor remained at Galway for 5 years before returning to Saint John's as a lecturer in 1885. He was elected a fellow of the Royal Society in 1892 and served as its secretary from 1901 to 1912. In 1898, a lengthy compilation of three of Larmor's papers, later published as *Æther and Matter*, won the Adams Prize at Cambridge. In 1903, with the death of Sir **George Stokes**, he was appointed the Lucasian Professor of Mathematics at Cambridge, a post once held by **Isaac Newton** and currently held by Stephen Hawking.

In 1909 Larmor was knighted and served as a Member of Parliament for the University of Cambridge from 1911 to 1922. He made his first speech in 1912 defending the Unionists in a debate on Irish home rule, though his primary focus in Parliament was to support universities and education in general. Irrespective of the side Larmor took in the Irish debate, he always held the *Emerald Isle* dear to his heart, and he usually spent part of his long vacation there each year.

In 1915 the Royal Society awarded Larmor the Royal Medal, and then in 1921 the Copley Medal. He served on the council of Saint John's College for many years.

Larmor retired from the Lucasian chair in 1932, to be succeeded by **Paul Dirac**, but remained in Cambridge for another year or two before returning to Ireland, retiring at Holywood, County Down, near Belfast, his health deteriorating. Except for one brief return visit to Cambridge, he remained in Ireland. Larmor was a bachelor throughout his life.

Larmor's most significant contribution was the publication of his opus, *Æther and Matter*, in 1900. The work was actually a compilation, with slight revisions, of three important papers he wrote between 1894 and 1897 and published in the *Philosophical Transactions of the Royal Society* on the theory of the electron – the first such prediction of the particle. The work gained support when J. J. Thomson actually discovered the electron in 1897.

This, as with nearly all of his work, built upon Larmor's very first paper that dealt with the Principle of Least Action. **Arthur Eddington** viewed his enthusiasm for this principle as nearly mystical. Larmor's refusal to accept general relativity only waned when he began to see it in terms of the principle of least action.

Æther and Matter brought to a resounding end the plethora of material and mechanical models of the ether. But it did contain the bulk of Larmor's work on the development of the electron. It also contained experimental facts regarding the Lorentz transformation, and at times some authors have suggested the name be changed to the Larmor–Lorentz transformation. As we know, relativity sprang from this transformation, which is ironic considering Larmor's long disbelief in relativity.

In 1897, Larmor showed that the motion of ions in a molecule under the influence of a magnetic field was equivalent to the rotation of the group with an angular velocity about the axis of the field. This effect is now known as Larmor precession.

Larmor also contributed some direct astronomical and geophysical papers. Some of these topics included the correction of the period of the Eulerian nutation for the elasticity of the Earth, a correction for the fluidity of the ocean, a study of the problem of the variation of latitude, a study of the electrical conductivity in the upper atmosphere, and an analysis of sunspot frequencies.

Lassell, William

Born **Moor Lane, Bolton, (Greater Manchester), England, 18 June 1799**
Died **Maidenhead, Berkshire, England, 5 October 1880**

William Lassell constructed the first large equatorially mounted reflecting telescopes and proved both the viability and the utility of such large instruments. Using his large reflectors, Lassell discovered several satellites of the outer planets.

The son of Nathaniel Lassell, a timber merchant and Hannah (*née* Gregson) Lassell, William was raised in middle-class comfort in a distinctly commercial extended family. He began his education at an elementary school in Bolton and then, at the age of about nine, he entered an academy in Rochdale, Lancashire where Lassell remained for one and a half years. His father died in 1810 while he was still attending school. He started an apprenticeship as a commercial trader in 1814, and by about 1825 he had established himself as a partner in a Liverpool brewing business. Soon afterward, in 1827, he married Maria King of Toxteth.

Lassell was a reluctant, but nonetheless successful businessman spending his leisure hours in the study of astronomy and in developing his mirror-making skills, fashioning excellent mirrors from speculum metal, a difficult material with which to work, for all his telescopes. He had a flair for innovation. Lassell built two 7-in. reflecting telescopes in 1820, one Newtonian and the other Gregorian and commenced astronomical observations in 1821 using the 7-in. Gregorian. In 1836 he advised the Liverpool borough to build an observatory, which eventually came into operation in 1844. In the summer of 1840, Lassell established his own private observatory, Starfield, at West Derby in Liverpool.

Lassell was one of the first English astronomers to abandon the unwieldy altazimuth structures of the **William Herschel** era, constructing a 9-in. Newtonian reflector and installing it at Starfield in 1833 on an equatorial mounting of his own design. By then, Lassell was well established as an amateur astronomer and welcomed other Liverpool amateurs to his new observatory. One frequent visitor was **William R. Dawes** of Ormskirk. Dawes valued the opportunity to observe with Lassell's fine equatorial reflector and shared with the latter his fine library in Ormskirk on reciprocal visits as they formed a long-standing friendship. Lassell was present at Ormskirk when Dawes discovered Saturn's crepe ring.

In 1844, Lassell began contemplating the construction of a 24-in. aperture equatorial reflector. He traveled to Birr Castle in central Ireland to view **William Parsons**'s (Lord Rosse) mirror-making facilities. Hand polishing of so large a speculum-metal mirror following the techniques that Lassell perfected for his 9-in. mirrors would be impractical for the 24-in. mirrors. After several months of trial with a machine built by **James Nasmyth** along similar lines to Lord Rosse's machine, Lassell was not satisfied with the machine's ability. With Nasmyth's assistance, Lassell developed a new mirror-making machine which, by variable epicyclical movements, replicated the motion of the hand in the grinding and polishing processes. Upon completion of the 24-in. telescope in 1845, Lassell used it to discover Neptune's largest satellite, Triton, on 10 October 1846, but he had to wait until late summer of 1847 to obtain full confirmation.

Lassell co-discovered the eighth satellite of Saturn, Hyperion, the discovery date of which was considered by Sir **John Herschel** to have been 19 September 1848, the date of Lassell's second observation of it. **George Bond** and his father **William Bond**, observing at the Harvard College Observatory, independently discovered this satellite very slightly earlier. It was first observed by George on 16 September 1848 and confirmed by both astronomers the following night. Lassell also added to his tally of satellite discoveries in 1851, with the detection of two new satellites of Uranus, Ariel, and Umbriel.

In connection with his observations of Neptune, Lassell at first thought he observed an elongation of the planet's disk, which he interpreted as an indication that Neptune possessed rings similar to those of Saturn. A number of other individuals, including Dawes, testified to the existence of this elongation when viewing Neptune through Lassell's telescope, admittedly the most powerful in England at the time. In fact, **James Challis** and **John Hind** felt that they observed the elongation through other telescopes and at first confirmed Lassell's discovery. Always the skeptical observer, however, Lassell eventually traced the elongation to astigmatism caused by sagging of the 24-in. mirror.

During the 1850s, Lassell devised an improved "astatic" mirror-support system that minimized flexure of the heavy primary mirror, particularly at low altitudes. Following **Thomas Grubb**'s innovative earlier developments in this field, first used in 1835 on the equatorially mounted reflector at Armagh Observatory and later on the much larger reflectors at Birr, this formed the basis of modern mirror-support systems for large reflecting telescopes.

During 1859 and 1860 Lassell constructed an equatorially mounted 48-in. aperture Newtonian reflector at his residence of Bradstones, near Liverpool, where he had moved to avoid increasingly poor observing conditions at Starfield. The new telescope's tube was of a lattice construction to mitigate the formation of differently heated internal air currents, and also to equalize internal and external temperatures more rapidly.

Seeking clearer skies and also possibly enhanced opportunities for making astronomical discoveries, Lassell transported the 48-in. telescope to Valetta, Malta. His tests to delineate the performance of this telescope were published in the *Memoirs of the Royal Astronomical Society* in 1864. The telescope was not installed in a building, but remained in the open air when not in use.

Lassell spent 3 years (late 1861 to 1865) in Malta; he was assisted by **Albert Marth** for 2 of these years. They observed the planets and their satellites and discovered and measured the positions of nearly 600 new nebulae during the years 1863–1865.

In late 1865, Lassell offered the 48-in. telescope to the committee with responsibility for the construction of the Great Melbourne Telescope, but his offer was declined in favor of a proposal from Grubb. After Lassell's return to England from Malta, the 48-in. reflector was not used again and was eventually disposed of as scrap metal.

Although observation of planets and discovery of their satellites are most frequently cited as Lassell's observational interests, it should be noted that he also applied his large telescopes to the study of comets and made an extensive study of the Orion Nebula (M42). These observations were duly reported in various journals of the time. However, Lassell was not inclined to interpretation of his observations. He reported only complete and factual information about what he observed and thus avoided the complications other astronomers frequently encountered with such interpretations. His reported observations stand as exemplars of good observing practice in this regard.

Lassell was one of the most prolific observational astronomers of the 19th century, his results being reported in many issues of the *Memoirs* and *Monthly Notices of the Royal Astronomical Society*. Lassell was awarded an honorary LLD degree from the University of Cambridge. He was elected a fellow of the Royal Astronomical Society on 14 June 1839 and received the Society's Gold Medal in 1849 for the construction of his equatorial telescope and for the discoveries he made with it. He also served as the society's president from 1870 to 1872. Lassell was elected a fellow of the Royal Society in 1849, and was awarded a Royal Medal of the society in 1858. He was also a fellow of the Royal Societies of Edinburgh and Uppsala.

Leadbetter, Charles

Born **Cronton, (Mersey), England, 26 September 1681**
Died **London, England, 21 November 1744**

Charles Leadbetter was one of the first popular English commentators on **Isaac Newton**. Almost nothing is known about his life and work. He taught mathematics, navigation, and astronomy at the *Hand & Pen* in Cock Lane, London, England. Over a period of less than a decade, he published four books in London: *Astronomy, or, The true system of the planets demonstrated: wherein are shewn by instrument, their anomalies, heliocentrick and geocentrick places both in longitude and latitude* (1727), *A compleat system of astronomy …* (1728), *Astronomy of the satellites of the earth, Jupiter and Saturn: grounded upon Sir Isaac Newton's theory of the earth's satellite* (1729), and *Uranoscopia: or, The contemplation of the heavens* (1735).

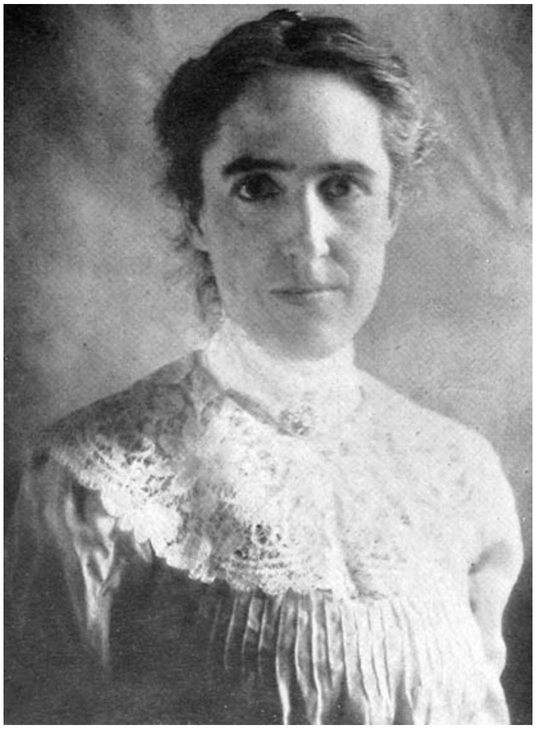
Leavitt, Henrietta Swan

Born **Lancaster, Massachusetts, USA, 4 July 1868**
Died **Cambridge, Massachusetts, USA, 12 December 1921**

American astronomer Henrietta Leavitt discovered the period–luminosity relation. This is a tight correlation between pulsation period and intrinsic brightness in the class of variable stars called Cepheids after their prototype, δ Cephei. The period–luminosity relation is extremely important as a standard candle that permits the determination of the distances of stars in clusters and galaxies too distant to be measured by their parallax.

One of a large number of women employed at Harvard College Observatory by director **Edward Pickering**, Leavitt was the daughter of Congregational minister Reverend George Roswell and Henrietta S. (*née* Kendrick) Leavitt, who traced their Puritan heritage to settlers at Hingham, Massachusetts in the 1640s. In 1887, Henrietta entered Oberlin College, excelling despite an inexplicable and progressive loss of hearing. She then enrolled at the Society for the Collegiate Instruction of Women, Radcliffe, where her charm and attentiveness made



her popular among her classmates, softening the often-traumatic effects of a now-profound deafness. She became immersed in astronomy while taking a course in her senior year at Radcliffe.

In 1872, **Henry Draper** had taken the first astronomical photographs that showed spectral lines in the ultraviolet as well as the visible portion of the solar spectrum. Then, during the 1880s, Pickering significantly advanced the study of the spectra of stars by employing a large prism in front of a photographic plate to capture an entire field of stars at once. As director of the Harvard College Observatory, he had ambitious plans to map the heavens using this technique. For this, he needed assistance.

Leavitt, who had begun volunteer work for Pickering upon her graduation, had to leave the observatory when a family crisis called her to Wisconsin. After 2 years, Pickering himself urged Leavitt to return at his expense. He offered to pay her 30 cents per hour (5 cents per hour more than other women working in comparable jobs at Harvard) and told her that if she had to leave the observatory again, she could take with her the materials and data she had collected. Pickering's offer of a raise in 1900 – to a woman, no less – was a rarity. Within a short time of her permanent appointment in 1902, Leavitt advanced to head the photometry department.

Almost immediately, Pickering chose Leavitt to execute his grand plan to redetermine star magnitudes using the most up-to-date photographic techniques. The accuracy of such data was crucial to astronomical investigation during this period, and Pickering's staff began with the "north polar sequence" as a standard for the entire sky. In 1904, 46 stars were selected, and 299 photographic plates taken with 13 telescopes were employed to establish this primary sequence. Leavitt and her colleagues then applied this scale to measure the magnitudes of thousands of stars in the heavens. Leavitt discovered 2,400 variable stars while making these stellar measurements, fully doubling the number of such stars known in her time.

Leavitt also observed four novae, various asteroids, and other celestial objects, and published 17 reports of her observations in the *Annals and Circulars of the Harvard College Observatory*. After Leavitt reported 843 new variables in the Small Magellanic Cloud, **Charles Young** of Princeton (in a letter to Pickering) called Leavitt a "star fiend" and professed himself both amazed and amused that he could not keep up with her.

Leavitt's groundbreaking discovery came from her examination of a very large number of images of the Large Magellanic Clouds [LMC] and Small Magellanic Clouds [SMC] (companion galaxies to our Milky Way, visible only from the Southern Hemisphere). These had been taken at the Harvard Southern Station in Arequipa, Peru, starting in 1905. Leavitt eventually found 1,777 Magellanic Cloud variables on these plates and was able to determine regular periods (ranging from less than a day to more than 100 days) for a small subset of them. In 1908, she plotted the average apparent magnitude of the LMC variables (whose light curves had a shape already known for galactic variables called Cepheids) versus the periods with which their brightness changed. Leavitt found a clear correlation, which was published under her own name in 1908.

This period–luminosity relation was detectable in the LMC because, although the galaxy's distance was not known, at least all the stars are at the *same* distance, so that apparent magnitude is a proxy for intrinsic magnitude at that distance. The absolute distances and magnitudes could be established only by measuring Cepheid distances in some other way or by understanding the underlying physics of the variability. Both have now been done, and Cepheid variables are, therefore, an enormously valuable astronomical tool for establishing the distance ladder in the cosmos (although the first calibration, by **Harlow Shapley**, was considerably in error, making the Milky Way seem larger and other galaxies less distant than they really are).

Leavitt herself was not able to follow up on her discovery until 4 years later when she confirmed the relationship with a larger number of stars in the LMC and in the SMC. Pickering believed that it was the observatory's responsibility to collect data, and it was up to others to explain them.

Leavitt's "record of progress" indicates the large number of projects she was working on simultaneously, including an investigation of Algol variables undertaken by **Henry Norris Russell**, measurements of the luminosities of stars in **Jacobus Kapteyn**'s selected areas, experiments to determine the colors of faint stars (including hypotheses on the redness of the fainter stars), methods of transforming photographic to visual magnitudes, and, with astronomers at Mount Wilson, determination of the exact photographic magnitudes of the North Polar Sequence of stars.

The information Leavitt supplied on the magnitudes of stars in the North Polar Sequence was adopted by the International Committee on Photographic Magnitudes for the Astrographic Catalogue for the *Carte du Ciel* map of the sky. By the time of her death, she had completed work on 108 areas. Astronomers interested in investigating the Milky Way referred to Leavitt's North Polar Sequence data for decades.

In 1925, the Swedish mathematician, and member of the Swedish Academy, professor Götha Mittag-Leffler sent a letter to Leavitt at the Harvard College Observatory. He wished to nominate her for the Nobel Prize in Physics for her discovery of the period–luminosity relationship that had done so much in advancing the science of astronomy. However, Mittag-Leffler was not aware that Leavitt had died of cancer. A Moon crater is named in her honor, and a memorial tablet, honoring her and the period–luminosity relation, hung for many years on the wall at Harvard College Observatory.

Lebedev, Petr Nikolaevich

Born **Moscow, Russia, 24 February/8 March 1866**
Died **Moscow, Russia, 1/14 March 1912**

Petr Lebedev's principal contribution to astronomy lay in demonstrating the existence of an extremely small physical pressure that light exerts on bodies. Such a pressure had been theoretically predicted by **James Maxwell**.

Lebedev was originally trained in business and engineering but then decided to study physics at the University of Strasbourg, under the guidance of August Kundt. He returned to his native land in 1891 and obtained a position at Moscow University; his first published research was on the Mossotti–Clausius theory of dielectrics. Lebedev was awarded his Ph.D. in 1900 for the above-mentioned research on light pressure. He also studied terrestrial magnetism.

Along with the solar wind, Lebedev's experimental demonstration of light pressure has helped to explain why comet tails are directed outward from the Sun. But as a politically progressive educator during a reign of reactionary conservatism, Lebedev was expelled from Moscow University and, after 1911, briefly operated his own laboratory, which was financed by private sponsors.

Lebedev was known as one of the most prominent physicists in prerevolutionary Russia. He founded the Lebedev Physical Society in Moscow. The Physical Institute of the Russian Academy of Sciences is now named after Lebedev. His name was also given to a large crater on the Moon's farside.

Leclerc, Georges-Louis

Born **Montbard, (Côte-d'Or), France, 7 September 1707**
Died **Paris, France, 16 April 1788**

Georges-Louis Leclerc de Buffon can be considered one of the pioneers of modern cosmogony, but is best known as a naturalist. Buffon's father, Benjamin Leclerc, was a French official; his mother was an educated woman with wealthy connections. He attended the Jesuit Collège de Godrans in Dijon and, at his father's insistence, began the study of law in 1723. By 1728, he was in Angers studying medicine, mathematics, and botany. Involved there in a duel, Buffon fled France and toured Europe in the company of the English Duke of Kingston, arriving eventually in England, where he was elected a fellow of the Royal Society.

Buffon returned to France on his mother's death to oversee the family estate at Montbard. Here he translated Stephen Hales' *Vegetable Staticks* and studied mathematics. In 1739, Buffon was appointed director of the Jardin du roi in Paris (the royal botanical garden, now the Jardin des Plantes). His work there stimulated his idea for writing a comprehensive natural history, the *Histoire* *naturelle, générale et particulière*, which appeared in 44 volumes between 1745 and 1804. (The last eight volumes were completed after his death by Count de Lacépède.) This work, the first modern systematic review of biology, anthropology, and geology, became very popular, more for its literary style and its beautiful illustrations than for its scientific accuracy. It was translated into various languages. Buffon also wrote papers about mathematics, physics, and agriculture.

The first volume of the *Histoire naturelle* contains a theory of the Earth, in which Buffon stated that the planets were made from matter ejected by the Sun through the collision of a comet. He was inspired by **Isaac Newton**'s opinion that comets were solid objects and that they could have enormous masses. (The famous comet of 1680 (C/1680 VI) was considered to have 28,000 times the Earth's mass.) The theory had to explain the initial momentum given to the planets and the fact that they all move in the same direction and nearly in the same plane. Moreover, since Newton believed that the density of the known seven planets decreased with their distance from the Sun, Buffon suggested that the less dense parts of the Sun were ejected further than the less dense. Although the idea of a comet collision is totally erroneous, it was the first scientific hypothesis about the origin of the planets based on Newton's gravitational theory. It can be considered a predecessor of the later tidal hypotheses of the origin of the Solar System by **Thomas Chamberlin** and **Forest Moulton**, and by **James Jeans**, although they were not inspired by it.

Buffon was a treasurer of the Paris Academy of Sciences, although he spent little time in Paris, undertaking most of his work on his Burgundian estate. There, he worked continuously, up to 12 hours a day, on his *Histoire naturelle*. Buffon was also a member of the Académie française, thanks to his literary talent, and various other academies. His wife died in 1769 leaving him with a 5-year-old son, later to be executed during the Revolution. Although well known during his life, Buffon was not liked by many of his fellow scientists and philosophers, particularly for his pretentious style. Ironically he is still known in France for his sentence: "Style is man himself."

Ledoux, Paul

Born **Forrières, Belgium, 8 August 1914**
Died **Liège, Belgium, 6 October 1988**

Belgian theoretical astrophysicist Paul Ledoux formulated the Ledoux criterion for convective instability. In 1947 Ledoux showed that the transport of energy by convection (gas flowing up and down) inside a star is somewhat inhibited when the lower layers contain more heavy elements than the upper layers. This always happens in evolved stars that have converted their central hydrogen to helium and perhaps on to heavier elements. The star adjusts to the situation by developing a zone in which the composition varies continuously. The process is now called semi-convection and is important in determining whether later evolution will be gradual or sudden and in determining what mix of heavy elements a star will later eject in a planetary nebula or a supernova explosion.

Born on the eve of World War I, Ledoux was quickly recognise as outstanding. He studied at Liège University and graduated *summa cum laude* in physics in 1937. After his military training period, Ledoux left Belgium with his wife to work at the Institute of Theoretical Astrophysics in Oslo, Norway. There, he had numerous talks with L. Rosseland, **Vilhelm Bjerknes**, and **Carl Störmer** and, using **Arthur Eddington**'s standard model, he proved that main-sequence stars would show vibrational instability if they reached a critical mass of the order of 90 solar masses. His stay in Norway was interrupted by the German invasion of Norway and of the Low Countries. After a short stay in the Stockholm Observatory at Saltjobaden, Sweden, the Ledouxs departed *via* the Far-Eastern route to Yerkes Observatory, Wisconsin, USA where they were welcomed by director **Otto Struve**. On the advice of **Subrahmanyan Chandrasekhar**, Ledoux resumed his work on vibrational stability of stars and published two papers in the *Astrophysical Journal*. However, in September 1941 he was drafted into the Belgian Army, in Canada and Great Britain. At the end of the war, Ledoux was a member of a meteorological team in the Belgian Congo. He nevertheless tried to continue his astrophysical research and thought that the virial theorem under his differential form could be used to study the radial pulsations of stars.

After obtaining a Ph.D. degree in Belgium in 1946, Ledoux resumed his work with Chandrasekhar and succeeded in generalizing **Karl Schwarzschild**'s criterion for convection in a region of the star where the molecular weight varies. This intermediate part of the star called a semi-convective zone was later recognized as playing an important role in the evolution of massive stars. He became lecturer at Liège University in 1956 and was promoted to a full professorship in 1959, being in charge of the teaching of theoretical astrophysics, analytical mechanics, and geophysics. After a stay in Princeton University in 1951/1952, where Ledoux explained the behavior of β Cephei stars through nonradial oscillations, he was recognized as a prominent scientist in the study of stellar stability. He was chosen as the author of the important review paper on stellar structure in the *Handbuch der Physik* (Vol. 51, pp. 353–604), while he wrote the chapter on variable stars with the Leiden astronomer Thomas Walravens.

Ledoux's accomplishments were recognized with doctorates *honoris causa* of the Free Brussels University and of the Catholic University in Louvain, Belgium and visiting professorships in several renowned universities in the United States. He received the Eddington Medal of the Royal Astronomical Society before becoming an associate in 1974, and the Janssen Medal of the Institut de France, of which he became a foreign associate in 1984. Ledoux was elected in 1959 as a corresponding member of the Académie royale des sciences, Lettres et beaux-arts de Belgique, and was the director of its Class of Science in 1973. In Belgium, he was the recipient of the Prix Franqui (1964) and of the Prix Décennal des Mathématiques Appliquées. Ledoux presided over the National Committee for Astronomy and was a member of the Scientific Council of the Royal Observatory. An active member of the International Astronomical Union [IAU], he served as president of its commission on the Internal Constitution of Stars of the IAU during the 1964–1967 triennium.

A patient and even-tempered man, Ledoux's advice was welcomed in many organizations. He was a member of several committees of the European Space Agency at beginnings in the early 1960s, attracting the attention of his colleagues to the importance of exploring the infrared region of stellar spectra, a rather prophetic view as has been recently revealed by several space observatories. Ledoux played an important role in the development of the European Southern Observatory where he acted as chairman of the Observing Program Committee and later as chairman of the council. In summary, it can be said that he brought to astrophysics many new and original ideas that later have been developed by several collaborators and under the auspices of international agencies.

Le Doulcet, Philippe Gustave

Born **Caen, (Calvados), France, 1795**
Died **Paris, France, 1874**

Gustave Doulcet, comte de Pontécoulant, retired from the military to devote himself to mathematical astronomy. The son of a well-known politician who supported the French Revolution, he served as a captain in the army prior to 1830. Pontécoulant had been a student at the École Polytechnique.

In his *Théorie analytique du système du monde*, Pontécoulant successfully made the *Mécanique Céleste* of **Pierre de Laplace** more accessible to a popular audience in France and England and, *via* translation, in Germany. This work included Pontécoulant's calculation that the perihelion of Halley's comet (IP/Halley) would occur on 31 October 1835, within 3 days of the actual event. Pontécoulant was a member of several scientific societies; a lunar crater at latitude 58°.7 S and longitude 66°.0 E is named in his honor.

Lefrançois de Lalande, Michel

➔ **Lefrançois [de Lalande], Michel**

Legendre, Adrien-Marie

Born **Paris (or possibly Toulouse), France, 18 September 1752**
Died **Paris, France, 10 January 1833**

Adrien-Marie Legendre was primarily a mathematician, publishing an important three-volume work on number theory and an equally important three-volume work on elliptic functions, and was the first to publish the method of least squares. Little is known of his early life though it is likely that he was from a well-to-do family. Legendre studied at the Collège Mazarin, graduating in 1770. He served as professor of mathematics at the École Militaire in Paris from 1775 to 1780. In 1795, Legendre was appointed a professor at the École Normale. He was married by the mid-1790s.

When **Pierre de Laplace** was promoted to an associate member of the Academy of Sciences in Paris, an *adjoint* position became opened, and Legendre was appointed to it in 1783. During the revolutionary era, Legendre was also one of the members of the Committee of Weights and Measures that established (1791) the metric system. Legendre survived the Terror, but the closure of the academy in 1793 deprived him of an income. As the Revolution had already destroyed his small fortune, Legendre was plunged into dire financial straits. Fortunately, in 1795, the academy reopened as the Institut National des Sciences et des Arts, and Legendre received one of the six positions in mathematics, which again provided him with a small income.

Legendre survived the turbulent revolutionary era only to fall from grace when he voted against a government-supported candidate for the national institute in 1824. Thereafter, the government withdrew its financial support of Legendre, and he died in poverty.

In astronomy, Legendre was first a member of the 1787 team to work with the Royal Observatory in Greenwich to measure the size of the Earth (for which Legendre became a member of the Royal Society of London in 1787). However, his main contribution came in 1805 when he published details of the method of least squares in his *Nouvelle méthode pour le détermination de l'orbite des Comètes* (New method for determining the orbit of Comets). The details appeared in an appendix, dated 6 March 1805. This caused a priority dispute with **Carl Gauss**, who claimed to have been using the method since 1795, but did not publish the details until 1809. By the strict standards of academic priority, Legendre, as the first to publish, should be considered the inventor of the method of least squares.

The problem Legendre sought to solve was the following: Any physical measurement of a quantity is subject to error. More specifically, when dealing with the planetary orbits, there are five geometrical parameters necessary to describe the elliptical orbit of an object about the Sun: the length a of the semimajor axis, the eccentricity e of the ellipse, the inclination i of the plane of the orbit to the ecliptic, the longitude Ω of the ascending node, and the argument ω of perihelion. A sixth parameter gives the actual position of the object along the elliptical orbit at a particular time. These parameters are not measured directly; instead, they emerge as the solution to a system of equations drawn from three (or more) complete observations of a celestial object. For example, if we wish to find the area of a rectangular field, we measure its dimensions and then compute its area. Thus, the determination of the orbital parameters of an object can be viewed as the solution to a system of equations in six unknowns, necessitating a minimum of three observations (with each observation supplying two of the unknowns). With more observations, the system of equations becomes overdetermined, and thus the question arises of finding the six parameters that best fit the observations.

The discrepancy between the actual position of the object (defined in relation to the six orbital elements or parameters) and the measured position of the object constitutes the error of observation. Legendre claimed (without proof) that, of all possible values for the parameters, the ones that minimized the sum of the squares of the errors were the ones most likely to be correct. Gauss gave a defective proof of the validity of this assumption, but the first rigorous justification was given by the Irish–American mathematician Robert Adrain in 1808.

Legendre also published a number of textbooks used throughout Europe and the United States. His *Éléments de géométrie* (Elements of geometry) (1794) was the principal introductory text used for nearly a century.

Leibniz, Gottfried Wilhelm

Born **Leipzig, (Germany), 1 July 1646**
Died **Hanover, (Germany), 14 November 1716**

Gottfried Leibniz was one of the most universal scholars Europe has produced: a mathematician, a philosopher, and a logician of the first order, as well as a considerable physicist, historian, jurist, and diplomat. His father, Friedrich Leibniz, was a professor of moral philosophy at the University of Leipzig. His mother Catherina, Friedrich's third wife, was the daughter of a prominent jurist and a very pious woman who took care of Gottfried and his two half siblings once her husband died in 1652. Leibniz was a very precocious child who spent many an hour in his father's library and taught himself Latin by reading Livy. His formal education took place at the University of Leipzig where he earned a degree in law in 1665. In 1672, Leibniz went to Paris, where he stayed until 1676. The Parisian period was crucial to his intellectual development, for there he was exposed to Cartesianism, and became acquainted with the leading thinkers of his time, including **Nicolas Malebranche** and **Christiaan Huygens**. By the end of his stay in Paris, Leibniz had invented the calculus, although he postponed its publication until 1684. This invention later became the source of a very acrimonious dispute with **Isaac Newton**, who, although he had invented his own version in the mid-1660s, did not publish it until 1693. Though the evidence suggests that Leibniz and Newton invented the calculus independently, it was Leibniz who produced the principal notation that is still in use and who had the greatest impact on the discipline through the work of his immediate followers, such as Guillaume de l'Hospital.

At the end of 1676, Leibniz became librarian to the Duke of Brunswick at Hanover, a post he held for the rest of his life. He traveled for some time in Italy to collect material for his history of the house of Brunswick, which, however, never saw the light of day. Perhaps because of this failure, and perhaps in part because of personal dislike, when Georg Ludwig, the Duke of Brunswick, became king of England as George I in 1714, he did not take Leibniz along to London as a court historian, in spite of Leibniz's pleas. Leibniz was compelled to remain in Hanover, where he died almost in disgrace.

Leibniz's astronomical contributions are to be found in his efforts at explaining planetary motions. Like Huygens, he never accepted Newtonian gravitation because of its apparent mechanical inexplicability. Quite reasonably, Leibniz became convinced that according to the Newtonians gravity is a primitive property of matter, that is, a property not further explainable in material terms. Although Newton, at least publicly, professed agnosticism on whether gravity is primitive to matter or not, some of his followers, such as **Roger Cotes**, seem to have been ready to think of universal gravitation as primitive in the sense of being essential to matter, and others, such as Samuel Clarke, publicly held that gravitation is a primitive feature of matter ultimately caused by continuous divine intervention. Leibniz took these views to be poor science and worse theology. As a result, although he clearly understood Newton's revolutionary achievement in connecting mechanics and astronomy in the *Principia*, he tended to play down its physical significance. Even if Newton had shown the exact mathematical relation between centripetal forces and **Johannes Kepler**'s area law, he had not given any explanation of them. In this respect, Newton had provided a clever mathematical model but not a physical explanation of the motions of the planets. **René Descartes**'s vortices, by contrast, provided a physical explanation of the motion of the planets, but a mathematically incorrect one, since, for example, Kepler's area law cannot be derived from it. Leibniz saw himself as providing a vortical theory that also is mathematically correct.

Leibniz's attempt is the *Tentamen De Motuum Coelestium Causis*, published in 1689 and, contrary to his claims, composed after he had seen Newton's *Principia*. In it, he argued that since all bodies tend to move uniformly and to recede along the tangent when moving in a curve, planets must be constrained and moved by an ethereal matter because their motion is not uniform – they move faster when closer to the Sun – and curved. Leibniz then supposed that this subtle matter moves around the Sun with harmonic motion, with a speed that is inversely proportional to the distances, or radii, from the Sun. Each planet floats in this fluid and is endowed with two motions: a transradial one in which it is carried by and moves exactly like the fluid (harmonically), and a radial motion, which Leibniz called "paracentric," in which it moves along the radius from layer to layer of the fluid. The paracentric motion itself is the result of two radial impulses, a gravitational one, the mechanism of which Leibniz did not explain, and a centrifugal one arising from the planet's transradial motion and measured by the square of the transradial velocity divided by the distance from the center. The transradial harmonic motion provides Kepler's area law, while the positing of a Keplerian elliptical orbit traversed with such a harmonic motion produces the inverse-square law of gravitation.

Although, at the end of the *Tentamen* Leibniz had to admit that in spite of the fact that his mechanical model of planetary motion involved a centripetal impulse toward the Sun, he had not provided an explanation of gravity. In letters, notes, and personal reworkings of the *Tentamen* he considered various mechanical models, apparently favoring two. One involved a fluid propagating from the center in accordance with the inverse-square law, in analogy with light. The fluid penetrated bodies through their pores, and since there was less receding fluid in them than elsewhere, they were pushed back toward the center in proportion to the number of their pores. The other was a modification of Huygens's model for terrestrial gravity based on fluid matter moving in all directions on spherical surfaces around the Earth. Leibniz assumed the equality of *vis viva* in each circle of fluid, suggesting that it could explain the stability of the fluid system, and managed to infer Kepler's third law and the inverse-square law.

The *Tentamen* was vehemently criticized by Newton and his followers, who argued that it bristled with errors. **John Keill**, giving public voice to Newton's views, called it "the most absurd piece of philosophy ever written." However, some of Newton's mathematical criticisms were ill taken, and some of the physical ones did not fare much better. For example, the claim that a vortical theory of attraction entails that bodies are pushed to the axis of the vortex and not to the center was based on Leibniz's mostly rhetorical praise of the alleged vortex theory of gravitation by Descartes, and not on Leibniz's actual unpublished models which, like Huygens's, overcome the problem. Similarly, E. J. Aiton has argued that Newton's critique of Leibniz's notion of centrifugal force as not being equal and opposed to gravitational force missed the point that Leibniz was working within a framework that owed more to Huygens than to him.

Still, Leibniz's theory did have very serious problems, some of which were pointed out early on. In spite of Leibniz's attempts, Huygens, whose rejection of nonmechanical gravitation was as firm as his, could not see the need for the harmonic vortex. He asked Leibniz why the harmonic vortex is necessary given Newton's system, in which "the movement of the planets is explained by the heaviness towards the Sun and the *vis centrifuga* which are in a balance." *Vis centrifuga* aside, Huygens's question was about the apparent redundancy of Leibniz's theory: Why did Leibniz want the harmonic vortex in addition to that which produces gravity? Leibniz replied that one reason was that the harmonic vortex explains why all the planets move roughly in the same plane and in the same direction, while a theory like Newton's cannot.

Huygens and **James Gregory** also noted that Leibniz's system fails to produce a satisfactory account of the motion of comets because they would be impeded by the Leibnizian vortices. Leibniz answered that the vortex does not significantly impede the motion of comets passing through it, although it does conserve the motion of planets in it. But even if one were to accept Leibniz's answer, his theory suffers from other problems. For one thing, how the fluid in harmonic motion can offer no resistance to radial motion while pushing the planet transradially is unclear. Nor is it clear how the harmonic vortex and the gravitational vortex postulated in an attempt to explain gravitational impulses can avoid interacting. More seriously, the harmonic vortex transports the planet, which therefore moves according to Kepler's law of the areas, but it is the gravitational vortex that rotates in accordance with Kepler's third law; in the end, Leibniz could not account for Kepler's three laws together.

Lemaître, Georges Henri-Joseph-Edouard

Born **Charleroi, Belgium, 17 July 1894**
Died **Charleroi, Belgium, 20 June 1966**

Belgian mathematician and theoretical cosmologist Georges Lemaître was the first to recognize that a number of things that are now taken to be important and obvious must be true about a general-relativistic universe (including the fact that it must expand). He was the son of Joeseph Lemaître and Maguerite Lannoy and received his basic education at a Jesuit school in Louvain, Belgium. He enrolled in 1911 as an engineering student at the city's Catholic University, but with the outbreak of World War I was called to service as an artillery officer, for which he was decorated. Returning to Louvain, Lemaître received a first degree in mathematics and physics in 1920, then enrolled in the Malines seminary. He was ordained as a priest in 1923 and was thereafter often referred to as Abbé Lemaître. Following his 1936 election to the Pontifical Academy of Sciences he was addressed as Monseigneur.

Lemaître spent the year 1923/1924 at Cambridge, England, studying solar physics and other topics with **Arthur Eddington**, and the years 1924–1926 in the United States, traveling widely, but primarily at Harvard University and the Massachusetts Institute of Technology [MIT]. His Ph.D. dissertation, awarded for the degree at Louvain in 1927, was partially prepared at MIT. It included early forms of a number of the ideas in relativity and cosmology that he published over the next decade. Lemaître was appointed to a professorship at Louvain and remained there the rest of his career, keeping some work in physics and astronomy alive during the very difficult years of World War II, when the staff was sometimes reduced to starvation wages. From the mid-1930s onward, he remained an authority on cosmology, but focused increasingly on topics like celestial mechanics and the motion of charged particles in the magnetic fields of the Earth and galaxy. These problems could be solved only by numerical methods, and Lemaître and his students did pioneering work in the exploitation of electronic computers and in setting up a computer laboratory in Louvain.

Lemaître scored a large number of "firsts" in relativity and cosmology between 1927 and 1934.

(1) He recognized that what is now called the Schwarzschild radius or horizon (for **Karl Schwarzschild**) at $R = 2GM/c^2$ is not a real singularity, so that physical objects can exist inside and outside of it. His thesis included a version of what is now called the Tolman–Oppenheimer–Volkoff equation of state, which permits calculating the structure of such objects.
(2) He demonstrated that the static universe of **Albert Einstein** is unstable and will eventually begin a runaway expansion or contraction. At various times, he supposed that the initial state of the Universe was close to this static model; at other times he contemplated many billions of years of alternating expansion and contraction, with us living in an expansion epoch extending for the past nine billion years or so.
(3) He wrote down the equations describing expanding space-time, in somewhat the same form as **Alexander Friedmann**, but also

recognized that these equations could pertain to the real, physical Universe.

(4) He incorporated the redshifts measured by **Vesto Slipher** into these equations and so found a value of 600 km/s/Mpc in 1927 for what is now called the Hubble constant. **Edwin Hubble**'s own, first, 1929 value for this was about 500 km/s/Mpc, and modern ones are in the range 55–70 km/s/Mpc.

(5) He pioneered the idea that physical conditions in the early Universe must have been very different, suggesting a cosmic egg or primordial atom, with a mass equal to the total mass of the Universe as then understood (enough to make a few billion galaxies of a few billion stars each) and density equal to that of an atomic nucleus, hence a "primordial atom." It would have had a radius only about 30 times that of the Sun.

(6) He was the first to show that Einstein's cosmological constant had a physical interpretation as a vacuum energy density that would exert negative pressure, and he held onto the idea that this was likely to be important in the real universe when Einstein and nearly everybody else abandoned the idea of a cosmological constant after 1929. It is part of modern cosmology, including Lemaître's negative-pressure interpretation.

Lemaître, in collaboration with Mexican physicist Manuel Vallarta, had suggested that cosmic rays (very high energy particles that pervade the galaxy) might be remnants of the primordial atom. It is now thought that they are largely accelerated by supernovae and their remnants. But Lemaître lived to hear from his successor at Louvain about the discovery of the 2.7 K cosmic microwave background radiation, which really is such a relic.

Lemaître received the prestigious Belgian Prix Franqui and was the first Eddington Medalist of the Royal Astronomical Society (London) in 1951. He served as president of the Pontifical Academy of Sciences from 1960 to 1966.

As a priest and cosmologist, Lemaître was very much aware of the problematic relationship between the Christian dogma of a world created by God and the scientific theory of a universe starting in a Big Bang. However, contrary to some other cosmologists (as well as theologians), he was careful not to confuse science and theology and not to use one of the fields as legitimization for the other. Lemaître believed that science and theology were separate fields and that cosmology neither confirmed nor refuted the Christian notion of a world created by God. This he made clear in his address to the 1958 Solvay meeting, where he pointed out that theoretical cosmology "remains entirely outside any metaphysical or religious question."

Lepaute, Nicole-Reine

Born **Paris, France, 5 January 1723**
Died **Saint-Cloud near Paris, France, 6 December 1788**

Nicole Lepaute participated with **Joseph–Jérôme Lalande** and **Alexis–claude Clairaut** in their calculations relating to comet P1/Halley. She also calculated solar eclipses and astronomical ephemerides. She is among the few women whose active participation in 18th-century science has been recognized. Lalande, in his *History of Astronomy*, paid tribute to her.

Nicole Reine Étable de la Brière was born in the Palais de Luxembourg, where her father was in service to the Queen of Spain, Elisabeth d'Orléans. In her childhood, she was recognized for her intelligence, love for and interest in books, and for her social gifts. Lepaute was fond of mathematics. On 27 August 1748, she married Jean André Lepaute, who later became the royal clockmaker.

From 1753, Jérôme Lalande had his observatory located at the main entrance to the Palais de Luxembourg; he had taken it over from **Joseph Delisle** when the latter moved to Saint Petersburg. Given the proximity of the observatory to Lepaute's residence, she and Lalande soon became acquainted. He reports that she observed and contributed to discussions and calculations. She also assisted her husband, producing tables of the number of oscillations per unit time for pendulums with different lengths. These results were inserted in the supplement to the *Traité d'horlogerie* published under her husband's name in 1760.

In the 1750s, the astronomical community was much interested in the return of the comet that **Edmund Halley** had predicted would return in 1758. In 1757, Lalande invited **Alexis–Claude Clairaut** to estimate the gravitational effects due to Jupiter and Saturn on the comet's orbit and to make a precise prediction for the date of its return. He also suggested that Lepaute might participate in the calculations. They calculated both the distance and the force due to each of the two perturbing planets for every degree along the comet's orbit for a 150-year period. In November 1758, some short delay in the comet's return could be announced to the academy.

In 1762, Lepaute was also involved in the calculations of the path and circumstances of an annular eclipse that was to occur on 1 April 1764. Many visibility shadow tracks for Europe and for Paris, with the time and percentage of the eclipse, were published and distributed to the public. Lepaute contributed to the annual *Connaissance des temps* of which Lalande was in charge; also for Lalande, she took an active part in computing ephemerides for Volume 8 (1784–1792) and, on her own, undertook the calculations for the first 2 years of Volume 9 (for 1793–1800) of the decennial publication *Ephémerides des mouvements célestes*, which Lalande edited from 1775.

Lepaute was a member of the Académie royale des sciences de Béziers, to which she presented some calculations relating to observations made during the 1761 Venus transit. Lalande reported that Lepaute's ceaseless calculations affected her eyesight, forcing her to abandon her scientific activities prematurely. Lepaute and her ailing husband moved to Saint-Cloud, where she died just 4 months before him. They had no children, but she cared for children from his family, introducing her nephew Joseph Lepaute Dagelet to astronomy. He became a member of the Royal Academy of Sciences in 1785 but died in the wreck of the ship *La Pérouse*.

Lalande paid tribute to Lepaute's talent and courage as she undertook the main part in the very laborious cometary computations. According to Lalande, Clairaut did the same but, for personal reasons, removed the words of acknowledgment from his work. According to Clairaut, Lepaute was *la savante calculatrice*.

Lescarbault, Edmond Modeste

Born **Châteaudun, Eure-et-Loir, France, 11 August 1814**
Died **Orgères, Orne, France, 1894**

A single observation by Edmond Lescarbault set off a decade-long but futile search for Vulcan, supposedly orbiting the Sun closer than Mercury. As a student, Lescarbault studied medicine and produced a thesis on typhoid fever, enabling him to serve as a country physician in Orgères, 75 miles southwest of Paris, from 1848 until 1872. But his passion was astronomy, and for it he constructed an observatory equipped with a refractor, a pocket watch, and a seconds pendulum, as well as a wooden board on which he did his computations.

The discovery of Neptune had been prompted by calculations carried out by **Urbain Le Verrier** concerning the irregularities of Uranus's orbit; Le Verrier also suggested that a similarly unknown planet could explain observed discrepancies in Mercury's orbit. Lescarbault read of Le Verrier's work, and informed him that on 26 March 1859, Lescarbault had observed an unusual black dot moving across the face of the Sun. He noted that it had transited the Sun in about 4.5 hours, and measured the inclination of its orbit as approximately 6°. His experience suggested that it was not an ordinary sunspot at all, but he delayed until December to inform Le Verrier, who immediately hurried to visit the doctor to substantiate the report. After interrogating the physician, and inspecting his observatory, Le Verrier became convinced of Lescarbault's credibility. Le Verrier named the putative planet "Vulcan," and had Lescarbault honored as a *Chevalier* (knight) of the French Legion of Honor, a title that was later taken away. A street in Orgères, however, still bears the name of Lescarbault.

In 1877, Le Verrier's list of half a dozen observations of Vulcan from 1802 to 1862 appeared in the Royal Astronomical Society's *Monthly Notices* along with a plea for astronomers to look for Vulcan. From his collected observations, Le Verrier had determined Vulcan's mass and orbital parameters, and even the date of a future transit: 22 March 1877. No one saw it then, or during the solar eclipses in 1860 or 1878, but several observations of something that might be Vulcan continued to be reported in various journals. **Johann Wolf**, as well as other astronomers, noted several "spots" that seemed to agree with a planet traveling in a sub-Mercury orbit.

Even so, the lack of consistent confirming observations made it clear that Vulcan did not exist, and that Lescarbault was not another **William Herschel**. The advancement of Mercury's perihelion would soon be explained instead by **Albert Einstein**, whose theory of general relativity removed Vulcan from the inventory of the Solar System and Lescarbault from the list of astronomical discoverers.

Archival papers of Lescarbault, and manuscripts with his annotations, are in the Municipal Library of Châteaudun.

Leucippus of Miletus

Born **Miletus (near Söke, Turkey), *circa* 480 BCE**
Died ***circa* 420 BCE**

Leucippus was said by **Aristotle** and others to be the originator of the idea of atoms.

Little is known about the life of Leucippus; it is thought that he founded the school at Abdera on the coast of Thrace near the mouth of the Nestos River. His most famous student was **Democritus**.

Aristotle, **Theophrastus**, and Diogenes Laertius refer to Leucippus as the first person to develop the basic ideas of atomism. It is difficult for modern scholars to separate his specific contributions to the theory from those of Democritus. However, Theophrastus, who studied under Aristotle in Athens and became the head of the Lyceum there after Aristotle (*circa* 323 BCE) seems to have been able to identify the major tenets of Leucippus's thinking, which can be summarized as follows: (1) both matter and void exist; (2) matter is composed of an infinite number of elements (*i. e*., atoms), which have an infinite variety of shapes and are always in motion; and (3) innumerable worlds of differing sizes are constantly being formed and destroyed by the interactions of various conglomerations of the elements.

Two written works are attributed to Leucippus: *Megas diakosmos* Great World System, *circa* 440–430 BCE) and *On Mind*. Diogenes Laertius briefly describes the cosmology found in the first work, which resembles earlier Ionian cosmologies (IX, 31; cited in Kirk *et al*., pp 416–418):

> The worlds come into being as follows: many bodies of all sorts of shapes move "by abscission from the infinite" into a great void; they come together there, and produce a single whirl, in which, colliding with one another and revolving in all manner of ways, they begin to separate, like to like. But when their multitude prevents them from rotating any longer in equilibrium, those that are fine go out towards the surrounding void as if sifted, while the rest "abide together" and, becoming entangled, unite their motions and make a first spherical structure. This structure stands apart like a "membrane" which contains in itself all kinds of bodies; and as they whirl around owing to the resistance of the middle, the surrounding membrane becomes thin, while contiguous atoms keep flowing together owing to contact with the whirl. So the earth came into being, the atoms that had been borne to the middle abiding together there. […] Some of these bodies that get entangled form a structure that is at first moist and muddy, but as they revolve with the whirl of the whole they dry out and then ignite to form the substance of the heavenly bodies.

Diogenes attributes some other intriguing ideas to Leucippus (the Earth is "drum-shaped," solar and lunar eclipses are explained by the tilting of the Earth). These particular accounts are somewhat incomprehensible, leading most scholars to speculate that this part of the text is inaccurate, and that there may be *lacunae*.

Overall, the significance of the early atomists can be overstated; nevertheless, it seems clear that this incipient form of a materialist paradigm contributed to the development of a more scientific astronomy. "The connexions between Democritus and Newton are evident; and it would be absurd to deny the link between ancient and modern atomism …" (Barnes, p. 343). However, this was scientific speculation in, as J. Barnes puts it, "the old Ionian fashion" – neither myth, nor abstract philosophy – but not strictly based on observation and experimentation in the modern sense.

Leuschner, Armin Otto

Born **Detroit, Michigan, USA, 16 January 1868**
Died **Berkeley, California, USA, 22 April 1953**

Armin Leuschner headed the astronomy department of the University of California at Berkeley for four decades, building what was widely accepted as the top graduate program in the United States and educating a number of the leading astronomers of the 20th century.

Leuschner's widowed mother took him to Germany in his infancy. Thus, although born in Detroit, he spoke English with a strong German accent. At 18, Leuschner finished the Gymnasium in Kassel and returned to the United States. Two years later, in 1888, he received his A.B. degree from the University of Michigan.

Leuschner then became the first graduate student at the new Lick Observatory, where director **Edward Holden** assigned him a photometry project. After a year, it was decided that he would alternate courses in mathematics and physics on the Berkeley campus of the University of California with research on Mount Hamilton.

Leuschner soon found that he liked the university and mathematics, and he did not like working under Holden, who was steadily arousing the enmity of the staff he had selected for the first mountaintop observatory. In 1890, Leuschner was appointed an instructor in mathematics at Berkeley, and a couple of years later an assistant professor. While still in the mathematics department, he took over the course in practical astronomy taught to civil engineers, and his title was changed to assistant professor of astronomy and geodesy.

Leuschner married Ida Louise Denicke, the daughter of influential University of California regent and wealthy San Francisco businessman Ernst A. Denicke, in 1896. They had three children. Leuschner spent the year 1896/1897 in Berlin, earning his Ph.D.

with high honors for a thesis on determining the orbits of comets. He had found his field, and it did not require living on a mountaintop or working under the by-now-hated Holden. On his return to Berkeley, Leuschner was promoted to associate professor of astronomy and geodesy and director of the Students' Observatory.

After Holden was forced to resign his position in 1897, relations between the Berkeley and Lick astronomical departments of the University of California, as they were soon titled, improved greatly. Leuschner worked well with Lick directors **James Keeler** (who died after 2 years in office) and **William Campbell** (who held the title for 30 years, the last 7 while also president of the University of California).

Keeler established the Lick fellowships to support graduate students who divided their time between studying mathematics, physics, and theoretical astronomy at Berkeley and doing research on Mount Hamilton under the Lick staff. While most of them did theses in astrophysics, they all learned a considerable amount of mathematics and theoretical astronomy at Berkeley. It is said that only one graduate student managed to obtain his Ph.D. without calculating an orbit for a comet or asteroid.

From 1907, until his retirement in 1938, Leuschner was professor of astronomy and director of the Students' Observatory. It was renamed the Leuschner Observatory in 1951 and moved off-campus in the 1960s.

Although he published a few early papers involving observations, Leuschner was very much a theoretical astronomer. His specialty was celestial mechanics, and his main contribution to research was the Leuschner method of calculating the orbits of asteroids or comets as soon as three observations were available. It was the custom at Berkeley for students to race to compute the first orbits of newly discovered objects. Such computations might take days with pencils and six-digit tables of logarithms, for which Leuschner's method was optimized. Other methods became more advantageous once desk calculators became available, but Leuschner and his staff insisted on the use of his method even in cases where the older, Gaussian method was superior. One of the objects whose orbit was first computed at Berkeley was the newly discovered planet Pluto.

When **James Watson**, who had directed the observatories of the Universities of Michigan and Wisconsin, died in 1880, he left a substantial bequest to the National Academy of Sciences, most of it to support determination of the orbits of the 22 asteroids he had discovered. Leuschner served for many years as chairman of the board of trustees of the Watson Fund of the academy, and used some of its income to support his Berkeley students. Much of his research effort was devoted to computing the orbits of Watson's minor planets, working with his former graduate students, Anna Estelle Glancy and Sophia Levy.

Two years before his retirement, in 1936, Leuschner presented to Berkeley provost Monroe Emanuel Deutsch a "summary of the present activities and standing of the men and women trained by the university for the profession of astronomy." He discussed 51 men and 12 women who had done graduate work in his department. The first two, **William Wright** and **Frederick Seares**, both Berkeley graduates, left in the 1890s without completing their Ph.D.s, but by 1936 Wright was the director of the Lick Observatory and Seares the assistant director of the Mount Wilson Observatory.

The remaining 61 completed their Ph.D.s at Berkeley (two of them in mathematics), and they included many more prominent astronomers, such as Dinsmore Alter, Priscilla Fairfield Bok, **Ralph Curtiss**, **Edward Fath**, Samuel Herrick, Jr., Hamilton Moore Jeffers, **Nicholas Mayall**, **Paul Merrill**, **Charlotte Moore** (later **Sitterly**), **Seth Nicholson**, **Frank Ross**, **Roscoe Sanford**, **Joel Stebbins**, **Peter van de Kamp**, and **Fred Whipple**. Leuschner proudly pointed out that nearly all were primarily engaged in research, many at the most prestigious observatories, and that 14 were or had been observatory directors.

Four more – Russell Tracy Crawford, Sturla Einarsson, William Ferdinand Meyer, and **Charles Shane**—had been hired by Leuschner as professors of astronomy at Berkeley. The only non-Berkeley Ph.D. who joined the department during Leuschner's time was **Robert Trumpler**, who transferred from the Lick Observatory. In addition, two of Leuschner's doctoral students, Sophia Hazel Levy (later McDonald) and Raymond Henri Sciobereti, were on the mathematics faculty at Berkeley and were continuing astronomical research. Leuschner noted that his department was ranked the best in the country in more than one survey at that time.

Leuschner held many leadership posts in the University of California, including dean of the graduate school and chairman of the board of research. One of the founders of the American Association of University Professors, he served as its president from 1923 to 1925.

Leuschner's honors included the James Craig Watson Gold Medal of the National Academy of Sciences in 1916, the Catherine Wolfe Bruce Gold Medal of the Astronomical Society of the Pacific [ASP] in 1936, and the David Rittenhouse Medal of the Franklin Institute in 1937. He served as president of the ASP three times and at the time of his death was its last charter member.

Leuschner's papers are in the Bancroft Library, University of California, Berkeley. Much of his correspondence can be found in the Mary Lea Shane Archives of the Lick Observatory, University of California, Santa Cruz.

Le Verrier, Urbain-Jean-Joseph

Born **Saint-Lô, Manche, France, 11 March 1811**
Died **Paris, France, 23 September 1877**

Urbain-Jean-Joseph Le Verrier explained the unruly behavior of Uranus by positing the existence of an unknown planet, which was subsequently discovered and named Neptune. His father, Louis-Baptiste Le Verrier, a civil servant, and mother, Pauline de Baudre, came from the lower Norman aristocracy. Their only son received his lycée education in Cherbourg, and failed the entrance examination to the École Polytechnique on his first try but was admitted in 1831. In 1837, he married Lucille Marie Clothilde Choquet, the daughter of his former teacher. They had three children: Léon, Lucille, and Urbain.

In 1837, Le Verrier was offered a position in geodesy and machines as an assistant to **Félix Savary** at the École Polytechnique. After Savary's death a few years later, Le Verrier succeeded him in the chair of astronomy. He devoted his attention to celestial mechanics to reclaim the heritage of **Pierre-Simon de Laplace**. His first memoir presented to the Paris Academy of Sciences addressed Laplace's solution to the stability of the Solar System. Later, Le Verrier laid the groundwork for a new theory of Mercury's orbit and successfully tackled the theory of several recently discovered periodic comets, on the basis of which he was successful in his bid for memberships in the academy on 19 January 1846.

Two months earlier, Le Verrier had published his first memoir on Uranus's orbital irregularities, a work he had undertaken with encouragement by **François Arago**. By revising calculations by **Alexis Bouvard** concerning the perturbations on Uranus's orbit by Jupiter and Saturn, Le Verrier lowered the value of the observed anomaly. In his second memoir, read on 1 June 1846, he boldly asserted the impossibility of explaining the remaining anomaly in terms of gravitation forces exerted by the Sun and the known planets. Without questioning **Isaac Newton**'s universal law of gravitation, Le Verrier concluded that a hypothetical planet could account for observed irregularities and determined a position based on an orbit in the ecliptic plane and Bode's law that suggested a radius twice that of Uranus.

In his third memoir, read on 31 August 1846, Le Verrier gave more precise limits within which one should look for the new planet and even predicted its apparent size. His letter to Berlin astronomer **Johann Galle** directly led to Galle's discovery of Neptune on 23 September 1846. Even in the controversy surrounding a similar prediction by **John Adams**, Le Verrier's sudden fame was not lessened by priority claims about this striking triumph of mathematical physics.

As early as 1847, Le Verrier drafted a plan for the future of astronomy that would keep him busy for the rest of his life. Aside from a minor project to reduce the positions of many fundamental stars and correct values given by **Friedrich Bessel**, he planned to track down every discrepancy between theoretical tables and actual observations of the planets. To determine the motion of planets, he would compute the 469 terms of the perturbation function. For each discrepancy with observation, Le Verrier would try to modify the mass of the perturbing planets, or else look for other causes of perturbation. His study of the motions of the Sun and the inner planets led to him to conclude that the secular motion of Mercury's perihelion was larger than expected by 38 arcsec per century. He also improved the measured values of the solar parallax (a 3% increase), the mass of Mars (a 10% decrease), and the mass of the Earth (a small increase).

Mercury's secular anomaly remained as the only significant unexplained discrepancy. In 1859, Le Verrier doubted that a planet orbiting closer to the Sun would account for the anomaly, arguing that that it would already have been observed. Considerable excitement was aroused by **Edmond Lescarbault**'s alleged observation of a planet transit over the surface of the Sun at the end of 1859. Le Verrier endorsed his observations and led a French party to Spain to observe the total solar eclipse on 18 July 1860 in the vain hope of seeing Lescarbault's planet. Le Verrier had nonetheless firmly established the existence of Mercury's secular anomaly, which would be explained by **Albert Einstein**'s theory of general relativity. For this work, he was awarded the Gold Medal of the Royal Astronomical Society in 1868. In 1876, he received it again after having formulated theories of the motion of Jupiter, Saturn, Uranus, and Neptune.

In 1854, Le Verrier was placed in charge of the Paris Observatory, replacing Arago. At the same time, the imperial regime restructured French astronomical institutions, making the observatory independent of the Bureau des longitudes and granting its director greater authority. Le Verrier pursued Arago's effort to equip the observatory with the latest precision technology, reorganized work, and established stricter observation routines, emphasizing the reduction and regular publication of observations and encouraging the discovery of new asteroids. Feeling that the Paris environment was a hindrance to some delicate instruments, such as **Jean Foucault**'s great telescope, he reorganized the Marseilles Observatory in 1862 as a branch of the Paris Observatory. Le Verrier trained a younger generation of astronomers and meteorologists such as **Jean Chacornac**, **Camille Flammarion**, **Emmanuel Liais**, Edme Hippolyte Marié-Davy, **Georges Rayet**, **Édouard Stéphan**, and **Charles Wolf**. He endeavored to make the observatory a useful auxiliary to the modern industrial state. Le Verrier organized a meteorological service using telegraphy to gather observations from the whole country and foreign observatories and to dispatch daily forecasts. Through the telegraph, he synchronized public clocks in Paris in the 1870s. In 1864, Le Verrier founded the Association française to sponsor scientific research and diffuse its discoveries into civil society.

Le Verrier's heavy-handed control over astronomy in France was strongly resisted. In 1854, Arago's former assistants were pushed out, and the Academy of Science and the Bureau des longitudes were used as strongholds for independent astronomical research. Throughout the 1860s, Le Verrier engaged in epic fights at the academy, in particular with **Charles Delaunay**, whose lunar theory he vigorously attacked. Le Verrier's personnel also resented his autocratic leaning. After Liais and Flammarion were forced out, they fought a public vendetta against Le Verrier. By the beginning of 1870, the atmosphere inside the observatory had soured to such a degree that all 14 astronomers working there resigned *en bloc*, and brought on Le Verrier's dismissal. After his successor Delaunay's untimely death in 1872, he was called again to the observatory directorship, where his somewhat smoother second term ended with long illness and death on the 41st anniversary of Neptune's discovery.

Le Verrier was made a member of the Bureau des longitudes, while a chair in celestial mechanics was created for him at the Sorbonne (the University of Paris). After the reestablishment of the Republic in 1848, Le Verrier was elected to Parliament, to take care of educational reforms and questions related to telegraphy and railways. In 1852, Emperor Napoléon III called him to the Senate.

Lexell, Anders Johan

Born **Turku, (Finland), 24 December 1740**
Died **Saint Petersburg, Russia, 11 December 1784**

Anders Lexell was the first Finnish astronomer and mathematician of international fame. He was the first to suggest the modern view of short-term comets. His parents were Jonas Lexell, a goldsmith and politician, and Magdalena Catharina Björkegren. Lexell never married.

Lexell studied in Turku, obtaining a master's degree in 1760, and then moved to Uppsala. In 1763 he became a docent of mathematics in the Academy of Turku. However, he found the international connections too limited. In 1768 Lexell sent a paper on integral calculus to **Leonhard Euler**, who was then with the Saint Petersburg Academy of Sciences, and applied for a job. He was nominated an adjunct, and moved to Saint Petersburg. In 1771 Lexell became professor of astronomy. He enjoyed the work in the academy with Euler, and although he was invited as a professor to the Academy of Turku in 1775, he never went there, and finally resigned his Turku post. After Euler's death in 1783, Lexell was elected his successor as the professor of mathematics in the academy. He held the chair only for a short time; he died after suffering from a tumor.

The orbit of the comet found by **Charles Messier** in 1770 had turned out to be problematic; a parabolic orbit typical for comets did not fit the observations. Lexell found that the orbit was an ellipse with an orbital period of only 5.6 years. However, the comet was never seen again. Lexell realized that the comet had passed close to Jupiter in 1767; the encounter had made the orbit elliptical, and another encounter had ejected it from the Solar System. Thus he was the first to suggest the currently accepted model of short-period cometary orbits. Since the motions of the satellites of Jupiter were not affected, Lexell also concluded that the mass of the comet must be very small.

In 1780/1781 Lexell made a trip to Germany, France, England, the Netherlands, and Denmark. In March 1781 **William Herschel** detected a new object, which was first considered a comet. Lexell, who was then in London, found that the observations could be explained if the object moved on a circular orbit. Therefore, it was not a comet but a new planet, originally called Georgium Sidus in honor of King George III, but later renamed Uranus.

In addition to these contributions Lexell wrote about 60 papers on mathematics and astronomy, the topics of which included the solar parallax, lunar and cometary theory, differential equations, elliptic integrals, and geometry. He published most of his works in the volumes of the Saint Petersburg Academy of Sciences. In 1935 Lexell was honored by having a lunar crater (35°8 S, 4°.2 W) named for him.

Li Chunfeng

Born **Yong County, Qizhou, (Shaanxi), China, 602**
Died **China, 670**

Li Chunfeng contributed to the study of armillary spheres and to the improvement of the calendar. His father, Li Bo (Huangguanzi), his son Li Yan, and his grandson Li Xianzong all served as *Taishiling* (director of the Imperial Bureau of Astronomy and Calendrics). Li Chunfeng fully understood astronomy, mathematics, and divination. He was appointed *Jiangshilang* (a low-level official post) in the *Taishiju* (Bureau of Astrology and Historiography) in the early Zhenguan

(627–648) period because of his objection to the Wuying calendar of Fu Renjun. In the 7th year of the Zhenguan period (633), Li Chungfeng made an armillary sphere, which was the first design using the three-layer armillary. At the same time, Li Chungfeng wrote *Faxiang zhi* (A history of instruments and their uses) in seven volumes for the emperor. It summarized and analyzed ancient armillary spheres.

Li Chunfeng was promoted several times to official posts: *Chengwulang*, *Taichang*, and *Taishicheng*. He edited the *Tianwen zhi* (Monograph on astronomy and astrology), *Lüli zhi* (Monograph on harmonics and the calendar), and *Wuxing zhi* (Monograph on the five phases) in both the *Jin shu* (History of the Jin dynasty) and *Sui shu* (History of the Sui dynasty). The *Tianwen zhi* of the *Jin shu* summarized the history of astronomy in ancient China in greater detail than ever before. In about 648, Li Chunfeng was promoted to *Taishiling*.

In 664, Li Chunfeng worked out the Linde calendar and published it the next year. In the Linde calendar, not only was Liu Chuo's quadratic interpolation with equal intervals applied, but other calculation methods were also improved and perfected. Li Chunfeng's calculation methods were regarded as concise and precise. He also once predicted a solar eclipse.

To meet the needs of mathematical education in the dynasty, Li Chunfeng collated *The Ten Mathematical Classics* and added his commentaries to them with the assistance of Liang Shu, Wang Zhenru, and others. *The Ten Mathematical Classics* exerted great influence on the development of mathematics in China, and even in neighboring countries. Li Chunfeng's commentaries on other works are also of great importance. For instance, some paragraphs he wrote on the *Zhuishu* by **Zu Chongzhi** and his son Zu Geng became the only surviving record of the work after the loss of the *Zhuishu*. Other works by Li Chunfeng include *Dianzhang Wenwu zhi* (A history of cultural geography and dynastic regulations) and *Yisi Zhan* (Divinations of the year *Yisi*).

Liais, Emmanuel-Benjamin

Born **Cherbourg, Manche, France, 15 February 1826**
Died **Cherbourg, Manche, France, 5 March 1900**

Emmanuel Liais was a prolific author, politician, and investigator of diverse astronomical and meteorological phenomena. His personality and idiosyncracies, however, kept him from acquiring a broader reputation within the mainstream astronomical community.

Liais was the third child of Anténor Liais, a prosperous trader from Cherbourg, France, and his wife Mathilde Françoise Dorey. After 1847, Liais began sending astronomical and meteorological observations to the French Academy of Sciences, which drew the attention of Paris Observatory director **Dominique Arago**. In 1854, Liais was one of four astronomers appointed by Arago's successor, **Urbain Le Verrier**. During his tenure there, Liais organized an extensive meteorological telegraphic service and set up a magnetic observatory. His astronomical work was mainly concerned with instrumentation. He developed precise electromagnetically regulated clocks. To try and minimize or eliminate the "personal equation" from observations, Liais conceived, before Carl Braun and Antoine Rédier, the notion of a traveling wire micrometer, or impersonal micrometer, which was not implemented before Johann Adolf (Hans) Repsold's independent fabrication in 1890.

Named director-adjunct of the Paris Observatory in 1857, Liais later clashed with Le Verrier and requested to be sent to Brazil to observe the solar eclipse of 1858. On that occasion, he was among the first to obtain photographs of the phenomenon. Using a polariscope, Liais demonstrated the existence of a "third atmosphere," or corona, around the Sun. For the next 6 years, he remained in Brazil, observing comets and discovering one himself in 1860. Liais produced estimates of the height of the Earth's atmosphere and studied the zodiacal light. He was the first to contest **Edmond Lescarbault**'s purported observation of a hypothetical planet between Mercury and the Sun whose existence had been conjectured by Le Verrier. The following year, Liais demonstrated that the Earth's path had crossed the plane of a comet.

Liais returned to France in 1864 where he published a treatise on astronomical instrumentation as applied to geodesy and navigation, along with a popular book on astronomy, entitled *L'Espace céleste* (1865), which was illustrated by his wife, Margaretta Trouwen van de Kranenbroeck. Liais's idiosyncratic account interwove his voyages of exploration in Brazil with astronomical observations and original findings. Rejected by the Academy of Sciences, Liais went back to Brazil where he was named director of the Imperial Observatory at Rio de Janeiro (1871). Apart from a visit to France to acquire new instruments, he pursued research on comets and planetary motions at the Rio Observatory. Upon retiring from astronomy, Liais returned to Cherbourg and was elected mayor in 1882, a position he held (with a short interruption) until his death.

In his patriotic book on the *Intellectual Supremacy of France*, written in the wake of the Franco–Prussian War, Liais argued against specialization in the sciences. Ever the generalist, he nonetheless produced original work in astronomy and astrophysics as well as in meteorology, physics, geology, and botany. Yet, largely an outsider, Liais failed to acquire the recognition he had yearned for from his colleagues.

Lindblad, Bertil

Born **Orebro, Sweden, 26 November 1895**
Died **Stockholm, Sweden, 25 June 1965**

Swedish stellar astronomer Bertil Lindblad published the first quantitative discussion of the Milky Way as a rotating stellar system. He graduated from the Gymnasium in Orebro, where his parents (army officer Birger Lindblad and Sara Waldenstrom) were stationed, and entered the university at Uppsala in 1914, having seen that summer a total solar eclipse from the north of Sweden, directing his interest toward astronomy. Lindblad studied mathematics, physics, and Latin, as well as astronomy, but worked in the laboratory of Allvar Gullstrand (who received the 1911 Nobel Prize in Physiology and Medicine for work on optics of the eye) to support himself, and briefly considered switching to medicine. In fact, he completed a Ph.D. in 1920, having worked with **Östen Bergstrand** on quantitative measurements of the colors of stars and spectroscopic criteria for absolute brightness. After a year and a half at Mount Wilson Observatory and Lick Observatory, Lindblad declined the offer of a permanent position at Harvard College Observatory to return to Uppsala, where he met and married Dagmar Bolin in 1924. They had a daughter and three sons, one of whom, Per Olof Lindblad, recently retired from a distinguished astronomical career.

In 1927, Lindblad was appointed astronomer of the Royal Swedish Academy of Sciences and director of the Stockholm Observatory, where he oversaw the construction of a new facility, in Saltsjobaden, away from the worst of the city lights. Lindblad and his associates in Uppsala and Stockholm were the first to develop quantitative ways of measuring stellar spectral classes, in contrast to the eye estimates from low-resolution spectra epitomized by **Annie Cannon**. Values of integrated intensities of strong, key lines and slopes and discontinuities of the spectral continuum could be calibrated on a few stars of known distance (hence luminosity) to determine the luminosities of many others too far away for direct parallax determination. Giants and supergiants, for instance, have stronger bands of CN (cyanogen) and smaller discontinuities at the edge of the Balmer sequence of hydrogen lines than do dwarf stars like the Sun.

In 1925, Lindblad began considering the implications of a center for the Galaxy as far from the Sun as the 20 kpc measured by **Harlow Shapley** in 1921 and how this might be reconciled with the Sun-centered stellar system of **Jacobus Kapteyn**. He thought in terms of a rotating disk of stars, with those closest to the center moving fastest (just as Mercury orbits the Sun faster than does Pluto). He recognized that such rotation would imply a definite pattern in the sky for motions of stars along the line of sight (radial velocities) and perpendicular to it (proper motions). When **Jan Oort** published observations showing the expected pattern in 1927, he called the paper observational support for Lindblad's hypothesis. Lindblad's own picture of the Galaxy, evolved using methods pioneered by **James Jeans**, had a number of stellar subsystems, with the roundest rotating the most slowly. Modern data confirm the general idea. He also recognized that small excursions ("epicycles") of the motions of the stars around their circular orbits would account for an asymmetry in which stars further than average from their circles appear to lag the average rotation ("asymmetric drift").

In later years, Lindblad attempted to analyze the structure of spiral galaxies in terms of the orbits of stars, including what are now called spiral density waves, which rotate around the galactic centers faster than do the stars themselves, producing spiral patterns that can last much longer than the rotation periods of the galaxies. The details of this process remained unclear to the end of his life and remain so today. Lindblad also studied the growth of interstellar dust grains, especially the phase where a few large molecules clump together to form condensation cores.

Lindblad served as the president of the International Astronomical Union (1948–1952), and immediately thereafter as president of the International Council of Scientific Unions (1952–1955). He was twice elected president of the Swedish Academy of Sciences, chaired the Nobel Foundation in 1965, and was also chairman of the Swedish Natural Science Research Council at the time of his death. Lindblad received a number of honorary degrees and Gold Medals from the Royal Astronomical Society (London) and the Astronomical Society of the Pacific. He on several occasions declined prestigious professorships outside Sweden, giving rise to the folktale of Lindblad's law, that an astronomer ends up living where his wife was born. Along with **Adriaan Blaauw** and others, he was one of the key organizers of the European Southern Observatory and served as president of its council in 1956 and again for a few months before his death.

Lindemann, Adolf Friedrich

Born **Langenberg, (Rheinland Pfalz, Germany), 13 May 1846**
Died **England, 25 August 1931**

Adolf Lindemann was an amateur observer who devised an electrometer and other instrumentation, and was a supporter of other astronomers. At the age of 14, he built a telescope with an equatorial mount; he claimed that his proudest moment was when he set a star by its vernier scale and found it exactly on the crosshairs. His early ambition was to be an explorer, but he trained as an engineer and instrumentmaker at Nuremberg, where he continued his astronomical interest by undertaking the reduction of Georg von Neumayer's Australian observations.

Adolf was the father of Frederick Alexander Lindemann, professor of physics and head of the Clarendon Laboratory at Oxford between the wars; this son is better known as Lord Cherwell, friend of Winston Churchill, advisor to the Churchill War Cabinet on science, and head of the British Scientific Intelligence during World War II. Adolf's mistaken title of "professor" likely resulted from the paper in which the Lindemann electrometer first appeared and which Adolf published jointly with his son. Adolf had six other children, two born at Sidmouth, England, the family's main place of residence.

While working for Ertel and Sons in Munich, Lindemann continued his training as an instrument engineer, believing that an ability to make or repair any scientific instrument would be an invaluable skill in his chosen ambition of exploration. He also developed knowledge and skill of surveying, but suffered a severe attack of typhoid fever, leaving him unable to cope with extremes of climate.

Lindemann came to England in about 1870 during the Franco–Prussian War, perhaps because of anti-Semitism, though he maintained his association and interest in his native region and returned there frequently. At Woolwich, Lindemann took a position with Siemens Brothers; in 1874, he became head of the department charged with the responsibility for laying the first transatlantic cable between the United States and Ireland in 1875. In 1872, Lindemann applied for membership of the Royal Astronomical Society and was elected a fellow in 1874. Three of his four sponsors were from the Royal Greenwich Observatory. His astronomical interest and knowledge quickly earned him respect among professional astronomers.

While on a fossil hunting holiday in the Rhineland in 1876, Lindemann accepted a challenge to construct a waterworks to supply the town of Pirmasens, a project that brought him into contact with a banker, Benjamin Davidson. Davidson died a few years later, leaving his wife, Mary, with a family and some fortune; Adolf, a rich man himself, married Mary on 6 May 1884. That year, Lindemann moved from London to Sidholme, Sidmouth in Devon, where he lived until 1928 and where he built a small observatory and workshop.

Lindemann surveyed several potential sites in Europe for building astronomical observatories. He met **Maximilian Wolf** and assisted him in the choice of a site for the Königstuhl Observatory at Heidelberg. Wolf visited Lindemann at Sidmouth in 1896 and stayed with them at Sidholme; such was their friendship that Lindemann left money to Wolf in his will.

Lindemann spent much of his time at Sidmouth building and perfecting accessories for his observatory's instruments. He devised an ingenious chronograph and a revolving eyepiece that found application in many other observatories. Each ocular of the eyepiece was electrically heated to overcome condensation and came automatically into the focus position. Throughout the Sidmouth years, Lindemann spent considerable time and effort perfecting a telescope design similar to the coudé pattern that was evolving independently and simultaneously. Lindemann's telescope featured two plane mirrors, inclined at 45° to the polar axis, that could be rotated in right ascension and declination, enabling the light to be reflected down the polar axis. The fixed telescope was excellent for photography and experiments in spectroscopy and photometry; similar techniques are applied in coelostat (two mirror) and siderostat (single mirror) instruments.

In 1915, Lindemann published a paper showing how to photograph bright stars in broad daylight by placing a target star in the center of the telescope's field and excluding as much sky light as possible with an iris diaphragm. An electrically timed shutter determined the period that the cell was exposed to the stellar light and during which a Lindemann electrometer received charge. He invented this electrometer, a derivative of the quadrant electrometer; it featured a glass fiber needle, coated with platinum about 30 microns thick, suspended at the center of a silica torsion thread 3 microns thick and attached at each end to a silica frame that kept it under tension. The needle was suspended so that it could deflect between the quadrant plates which were kept at a fixed electric potential. The glass fiber needle was carefully balanced so that the zero point and sensitivity of the instrument was independent of its position or tilt. Because the whole instrument was very lightweight, it could be placed in the position of his telescope's eyepiece. The Lindemann electrometer became a portable physics instrument, its design discussed in many standard electricity textbooks prior to the electronic age. All of Lindemann's pieces of apparatus were made by his own hands in the Sidholme workshop.

As late as June 1931, Lindemann visited the Royal Greenwich Observatory to enquire if and how the Earth's magnetic variations might affect the timekeeping of metal-compensated and invar steel pendula.

Johann Palisa at the Vienna Observatory discovered two minor planets on 29 August 1916; he named one of them for Lindemann, the other after Max Wolf. His original citation for these planets, in translation, reads: "Planet 828 I dedicate to Herr Lindemann, who unselfishly and generously supports astronomical research."

Lindsay, Eric Mervyn

Born **Portadown, (Northern Ireland), 26 January 1907**
Died **Armagh, Northern Ireland, 27 July 1974**

Eric Lindsay, one-time director of the Armagh Observatory, Northern Ireland, was a great popularizer of astronomy in his native land, a persuasive proponent of international collaboration in astronomy, and a gifted observational and theoretical researcher.

Lindsay was the seventh and youngest son of Richard and Susan Lindsay. He was schooled at the King's Hospital School, Dublin, before graduating from Queen's University, Belfast, in 1928. He continued his studies at Harvard University under **Harlow Shapley**, who remained one of Lindsay's closest friends throughout his life. After gaining his Ph.D. in 1934 he became the senior assistant at the Boyden Observatory near Bloemfontein, South Africa. Linday married Sylvia Mussells, formerly as assistant astronomer at Harvard, in South Africa in 1935.

Much of Lindsay's observational work in South Africa concerned the Magellanic Clouds, and these were to remain his chief area of interest throughout his research career. His pioneering studies of star clusters in the Magellanic Clouds produced remarkably complete and authoritative catalogs of these important objects. Lindsay also studied variable stars, emission-line objects, and diffuse nebulae in these neighboring galaxies.

On the death of **William Ellison** in 1936, the directorship of Armagh Observatory, close to Lindsay's hometown, became vacant, and Lindsay was faced with the possibility of returning to Northern Ireland. When his old research advisers at Harvard University, Shapley and **Bart Bok**, heard that Lindsay was considering the directorship at Armagh, one was heard to remark "That fool, Lindsay, has gone and ruined himself." But Lindsay was, in fact, to create for himself a successful career in Ireland and in the process completely revitalize both Armagh Observatory and Irish astronomy in general.

The situation at Armagh prior to Lindsay's arrival was dire; there were no serviceable astronomical instruments or staff, and funds were almost nonexistent. Always a shrewd and perceptive man, Lindsay realized that for the observatory to survive, involvement in major international projects was essential. He thus began strengthening the practical cooperation with the Boyden Observatory that was to remain an important part of Armagh's work. Lindsay secured the support of the Northern Ireland government and brought the distinguished Estonian astronomer, **Ernst Öpik**, from Harvard in 1947. Öpik became Lindsay's successor as director of Armagh and edited the *Irish Astronomical Journal* from there for many years. The observatory's fortunes advanced and, after many years of perseverance and persuasion, the Armagh–Dunsink–Harvard Telescope was set up at Boyden, widely regarded as one of the first examples of a collaborative international observatory. Lindsay formed many valuable associations during his promotion of Irish astronomy, among them Eamon de Valera, former Prime Minister and President of Ireland, who had himself studied mathematical physics and retained an interest in science.

Lindsay was awarded an OBE in 1963.

Lipsky, Yuri Naumovich

Born **Dubrovno near Vitebsk, (Belarus), 22 November 1909**
Died **Moscow, (Russia), 24 January 1978**

Yuri Lipsky was a Soviet astrophysicist who specialized in the field of lunar studies and selenography. During the late 1950s and early 1960s, he became the principal interpreter of the first photographs of the Moon's farside.

Lipsky began his adult life as an industrial worker. He was both a graduate (1938) and post-graduate of Moscow University, where he came under the influence of **Vasilii Fesenkov**. Lipsky also served in the Soviet defense against Germany's invasion during World War II. By 1963, he was appointed chief of the Physics of the Moon and Planets Department at the Sternberg State Astronomical Institute of Moscow University. His personal bibliography is not very vast, and not all of his scientific results were confirmed over the course of time.

Lipsky's reputation arose in connection with his interpretation of the first photographs of the farside of the Moon, which revealed the surprising *absence* of lunar maria as compared to its nearside. Lipsky maintained close contacts with Sergei Pavlovich Korolev, the chief designer of Soviet cosmonautics. Lipsky analyzed the photographs from the Luna-3 spacecraft flyby made in 1959 and from the Zond-3 flyby made in 1965. In the style of that period, he was the driving force behind a politically motivated endeavor to name landscape features on the lunar farside. Under his *aegis*, the first full globes of the Moon's surface and a number of selenographic maps were composed in the USSR. A crater on the farside has been named for him.

Littrow [Littroff], Johann Joseph (Edler) von

Born **Bischofteinitz, (Czech Republic), 11 March 1781**
Died **Vienna, (Austria), 30 November 1840**

Johann von Littrow was an observatory director and one of the first astronomers to recognize the existence of the solar chromosphere. Born into a German-speaking family, he entered the University of Prague in 1802. After wide-ranging studies, Littrow took a post as tutor in Vienna. There he came under the influence of J. Hall, the director of the Realschule, which led to his study of astronomy. In 1807, Littrow assumed the professorship of astronomy at the University of Cracow after the Austrians occupied that part of Poland. At this time he changed his family name from Littroff. Littrow married Karoline von Ullrichsthal; they had five sons, one of whom, **Karl von Littrow**, would succeed his father in Vienna 2 years after his father's death.

Littrow moved to Kazan in 1809 to direct the observatory there. He became a corresponding member of the Russian Academy of Sciences in 1813. In 1816, he became codirector of the Ofen Observatory in Buda (modern Budapest). In 1819, Littrow was appointed director of the Vienna Observatory and professor of astronomy at Vienna University. He also held the chair of higher mathematics at the university from 1834 to 1837.

Littrow's astronomical work was collected in his *Theoretische und practische Astronomie* (Theoretical and practical astronomy, 3 Vols., 1821–1827). He also wrote on algebra, geometry, chronometry, physics, and optics. His *Dioptrik, oder Anleitung zur Verfertigung der Fernröhre* (Dioptrics, or guide to the manufacture of telescopes, 1830) was a general survey of optics with a focus on telescope making. In 1839, Littrow's *Atlas des gestirnten Himmels* (Atlas of the starry heavens) appeared in Stuttgart for professionals employing **Johann Bode**'s constellations.

Littrow was a noted popular writer. His 1825 *Populären Astronomie* (Popular astronomy) was widely read. (Geneticist Gregor Mendel was influenced by it.) From 1834 to 1837, Littrow's enormously successful four-volume *Die Wunder des Himmels* (The wonders of the heavens) appeared, selling some 10,000 copies. He is said to have devised a scheme to signal intelligent life on other planets by building large canals in geometric patterns, filling them with water and oil, and lighting them at night.

Littrow was knighted by Emperor Franz Josef II. The lunar crater Littrow is named for him.

Littrow, Karl Ludwig von

Born **Kazan, Russia, 18 July 1811**
Died **Vienna, (Austria), 16 November 1877**

Karl von Littrow was the son of **Joseph von Littrow**. He became an assistant to his father at the Vienna Observatory in 1831. Littrow specialized in the study of asteroids, and computed the orbits of the more important of these. He also computed the orbits of comets. In 1842 he succeeded his father as director of the Vienna Observatory.

Lobachevsky, Nikolai Ivanovich

Born **Nizhni Novgorod, Russia, 20 November/2 December 1792**
Died **Kazan, Russia, 12/24 February 1856**

Nikolai Lobachevsky is remembered as one of the founders of non-Euclidean geometry. Although he was born into a poor family (made even poorer by the death of his father when he was seven), Lobachevsky's mother ensured that he received a good education. In 1802, he entered the Gymnasium in Kazan, a city on the confluence of the Kazanka and Volga rivers, in Tatarstan, Russia. Lobachevsky remained at the school until 1806; in the following year he gained admission to the recently founded Kazan University (1805). There, he was much influenced by the German mathematician, Johann Martin Bartels, a former teacher of **Carl Gauss**. By 1812, Lobachevsky was awarded his master's degree in physics and mathematics. In succession, he was appointed an extraordinary professor of mathematics in the university (1814), an ordinary professor (1822), and, in 1827, to the rectorship in Kazan, a position he held until 1846. In 1832, Lobachevsky married Varvara Aleksivna Moisieva; the couple had seven children.

Lobachevsky became interested in the problem of the parallel postulate in Euclidean geometry, a problem that had long taxed the finest mathematical minds in Europe. In his early years, he does not seem to have deviated from the standard geometrical thinking of those days but, in February 1826, Lobachevsky read a paper, "Exposition succincte des principes de la géométrie," to the Department of Physical and Mathematical Sciences at Kazan. This appears to have been the first public disclosure of non-Euclidean geometry and, with it, the solution to the parallel postulate problem. Roughly speaking, this problem can be explained two-dimensionally as follows: The axioms of Euclidean geometry can be arranged in such a way that by assuming up to, but not including, the last axiom (the parallel postulate), one can show that, given any line L and point P not on L, there exists at least one line through P parallel to L. It can then be shown that there are actually two (and only two) possibilities: Either there is a unique such line (which, if taken as the final axiom, produces Euclidean geometry) or else there are infinitely many such lines. If this latter possibility is considered, then the non-Euclidean geometry discovered by Lobachevsky results. The elegant axiomatic formulation of geometry referred to here is essentially that of the German mathematician, David Hilbert, who clarified this issue at the end of the 19th century.

In 1829, Lobachevsky published an extended version of that paper in the *Kazanski vestnik* (*Kazan Messenger*), under the title, "On the Principles of Geometry." This paper also considered the physical geometry of space (*i.e.*, whether it was Euclidean or non-Euclidean). Independently of Lobachevsky, a young Hungarian mathematician, Jànos Bolyai, had arrived at similar conclusions but hesitated in publishing them. When Bolyai did publish his results (in an appendix to the book, *Tentamen* [1831], written by his father Wolfgang), Lobachevsky's paper had been in print for 2 years. In any case, the mathematician, Gauss, had explored related possibilities even earlier but never published his findings.

The firm rootedness of Euclidean geometry, together with the abstractions inherent in the new geometry, meant that, at first, little attention was paid to the work of Lobachevsky and Bolyai. However, the rather elegant formulations of this geometry later given by **Felix Klein** and **Jules Poincaré** helped its recognition by giving it some intuitive appeal. Further understanding of non-Euclidean geometry arose from the work of Georg Friedrich Bernhard Riemann (1866), who generalized the foundations of geometry and initiated the study of differential (or Riemannian) geometry. The final link in this chain was then provided by the axiomatic treatment of geometry given by Hilbert (as mentioned earlier).

In 1916, **Albert Einstein**'s general theory of relativity, the most successful theory of gravity to date, took Riemannian geometry as its mathematical basis. In this sense, Lobachevsky (and Bolyai) were very important players in the development of modern physics and, indeed, in modern astronomy, since the initial (and successful) tests of Einstein's theory were essentially astronomical in nature. One of these tests resolved the long-standing problem associated with the orbit of the planet Mercury. Another involved the deflection of starlight at the edge of the Sun, and this was then witnessed during a total solar eclipse. The great English geometer, William Kingdon Clifford, called Lobachevsky the "Copernicus of Geometry."

During his lifetime, Lobachevsky achieved many more things than just success in geometry. He reorganized the library and museum facilities in Kazan and was a major force in rebuilding the university after its disastrous fire of 1842. In that same year, he was elected to the Göttingen Gesellschaft der Wissenschaften for his work on non-Euclidean geometry. Strangely, and without explanation, he was removed from his professorship and rectorship in 1846. Toward the end of his life, Lobachevsky became blind; his last work, *Pangéométry*, had to be dictated to a scribe.

Lockyer, Joseph Norman

Born **Rugby, Warwickshire, England, 17 May 1836**
Died **Sidmouth, Devon, England, 16 August 1920**

Sir Norman Lockyer was a talented solar observer who used the newly invented spectroscope to examine the properties of the Sun's component parts. Lockyer is remembered for the discovery of helium in the solar spectrum (later found on the Earth) and as the founding editor of the prestigious journal *Nature*. He was born to Joseph Hooley Lockyer, a pharmacist and founder of Rugby's literary and scientific society, and to Anne Norman. He was educated in private schools in Kenilworth, Warwickshire, and Weston-super-Mare, Somerset, and later studied in Switzerland and France, before joining the British War Office. In 1858, Lockyer married Winifred James, with whom he had nine children before she died in 1879. In 1903, he married Thomazine Mary Browne, who lived until 1943.

In 1858, Lockyer observed an eclipse of the Sun, his first recorded interest in solar observation. Lockyer came to astronomy just when the spectroscope became available. Others used spectroscopy to investigate stellar spectra, but Lockyer took up the technically trickier task of obtaining spectra from different portions of the solar disk.

During the 1850s and 1860s, astronomers debated whether the features seen during total eclipses – the soft white glow of the corona and the fiery red prominences – belonged to the Sun or to the Moon. Lockyer's first major scientific discovery, in 1868, was his achieving separate spectra for the prominences and chromosphere when the Sun was not eclipsed, indicating that these belonged to the Sun. Remarkably, the French Academy of Sciences received notification of the observation of prominence spectra from two separate scientists at the same meeting, Lockyer and the distinguished French observer **Jules Janssen**. There was no unseemly squabble over precedence, and the French government struck a medal commemorating both men.

In the laboratory, Lockyer and his assistants reproduced most of the lines observed in the solar spectrum, but one particularly bright line, classified D_3, remained unidentified. Around 1869, Lockyer made the bold suggestion that the D_3 line was formed by an element not found on the Earth. He named it helium after "helios," Greek for Sun. Helium did indeed turn out to be a new element, the next lightest after hydrogen, and the second most abundant in the Universe.

The best way to obtain spectra of the outer atmosphere of the Sun is to blank out the visible disk, the photosphere; to do that properly required a total solar eclipse. For 35 years, Lockyer (latterly with his son, Jim) attended a remarkable series of solar eclipses in Sicily (1870), Ceylon (1871), America (1878), Egypt (1882), Grenada (1886), Lapland (1896), India (1898), Spain (1900), and Majorca (1905).

Lockyer was keen to bring his discoveries to a wider audience. He was an excellent public speaker, delivering talks to enthusiastic audiences all over Britain. Lockyer contributed articles on science to *The Reader*, a popular journal; when it folded, he launched a new journal, *Nature*, dedicated entirely to the natural sciences in 1869. It quickly moved from a journal of exposition to one of original research, and is now one of the most important research journals in the world.

During the 1870s, Lockyer was secretary to the Devonshire Royal Commission, which overhauled the teaching of science in Britain. One of its major achievements was the establishment of the South Kensington campus in London, now home to Imperial College and the Science and Natural History Museums. Here, Lockyer also founded a solar observatory.

In 1887, Lockyer published *The Chemistry of the Sun*, which put forward a radical new theory, "the dissociation hypothesis." Its details have been found wanting, but the heart of the theory remains valid: Within the Sun, atoms become ionized, splitting off their outer electrons into a sea of particles or plasma.

Likewise, the other great theory Lockyer championed, the meteoritic hypothesis, has now been superseded. He believed that much of the Universe's structure resulted from meteoritic bombardment, *i. e.*, that comets, asteroids, and even planets were formed by the accumulation of meteoritic debris. This is not far from current theories of formation for the smaller bodies of the Solar System, but Lockyer argued that this hypothesis explained the evolution of stars along a sequence of stellar types and even the formation of spiral galaxies such as the Andromeda nebula. On both counts, he was completely mistaken. His scenario for the formation and evolution of stars was, though, a precursor of the giant-and-dwarf theory of **Henry Norris Russell**.

In 1883, there was a series of spectacular sunsets. Lockyer analyzed their spectra and attributed them to dust from the explosion of Krakatoa. Lockyer asserted that volcanic and meteorological events on Earth were driven by the solar cycle. Lockyer and his son produced a body of work correlating weather patterns around the world with solar behavior; the Lockyers' painstaking observations helped establish meteorology as a predictive science.

On holiday in Greece in 1890, Lockyer wondered if there was any astronomical significance to the alignment of Greek temples. Subsequent holidays saw him visiting the pyramids, Stonehenge, and stone circles around Britain. Lockyer was perhaps the first person to systematically investigate astronomical alignments for ancient monuments; his resulting *Dawn of Astronomy* was a seminal work for archeaoastronomy.

In his later years, Lockyer continued to steer the direction of British science, taking on the presidency of the British Association, and founding the British Science Guild (1904), a forum for debate on science policy. In his 70s, when authorities proposed relocating the solar observatory from South Kensington, Lockyer believed that the proposed site in Cambridge was too close to the city lights, and resolved to found his own observatory. The Norman Lockyer Observatory, at Sidmouth in Devon, first opened in 1912 but soon shut because of World War I, and did not open fully until 1919. After Lockyer's death, the observatory came under the stewardship of Jim Lockyer. Astronomical research continued until 1961, geophysical research until 1980. The Norman Lockyer Observatory Society currently runs the site as an educational establishment.

Lockyer received many awards, including the 1874 Rumford Medal from the Royal Society and the 1875 Janssen Medal from the French government, as well as honorary degrees: Hon LLD from the universities of Glasgow, Edinburgh, and Aberdeen, Hon Sc.D. from the Universities of Cambridge and Sheffield, and an Hon D. Sc. from Oxford University. He was elected a fellow of the Royal Society in 1869, named the Rede Lecturer at Cambridge in 1871, and created a Knight Commander of the Order of the Bath [KCB] in 1897. In 1903/1904, Lockyer served as the president of the British Association.

Lodge, Oliver Joseph

Born **Penkhull near Stoke-on-Trent, England, 12 June 1851**
Died **Lake near Salisbury, England, 22 August 1940**

British physicist Oliver Lodge touches on astronomy primarily through his discussions around 1919 of the significance of the gravitational deflection of light – see **Arthur Eddington** – and the possibility of gravitational lensing of one star by another. Lodge was the eldest of nine children of a wealthy supplier of materials for the pottery industry. After grammar school, he entered the family

business, but found it less than congenial, and used periodic visits to London to hear the lectures of John Tyndall (1820–1893) and others at the Royal Institution. Lodge resumed his education in about 1872, and received a D.Sc. from University College London in 1877. His early publications touched on electricity, magnetism, and other standard topics in physics.

Lodge began teaching physics at Bedford College for Women and University College London. He was appointed professor of mathematics and physics in 1881 at the new University College, Liverpool, and principal of the University of Birmingham (also new) in 1900, from which he retired in 1919. He and his wife, *née* Mary Marshall, had 12 children.

The most important of Lodge's scientific contributions were made from Liverpool, particularly to the theory of the ether and to propagation of electromagnetic fields. He was able to show that the (then widely accepted) ether could not be carried along by moving bodies, and this can be seen as a step toward **Albert Einstein**'s theory of special relativity. He is remembered for his lecture commemorating the early death of Heinrich Hertz (1857–1894) held at the Royal Institution in London in June 1894. Lodge stressed the experimental aspects of Hertz's work on electromagnetic waves. Lodge himself introduced the idea of a coherer as a detector of waves, an improvement over Hertz's resonator, and it helped to lead Guglielmo Marconi (1874–1937) of Italy and Aleksandr Popov (1859–1906) of Russia to the development of wireless telegraphy.

After about 1900, Lodge was engaged primarily in organizational activities and popularization of science. He also became interested in psychic research, including telepathy and telekinesis and the possibility of communicating with the spirits of the dead (partly in association with Arthur Conan Doyle, author of the Sherlock Holmes stories). Lodge received among many other honors the Rumford Medal of the Royal Society of London (1898) and the Faraday Medal of the Institution of Electrical Engineers (1932). He was knighted in 1902, and there were many years when every volume of *Nature* contained at least a note from him on topics of current interest in physics.

Lohrmann, Wilhelm Gotthelf

Born **Dresden, (Germany), 31 January 1796**
Died **Dresden, (Germany), 20 February 1840**

Wilhelm Lohrmann's profession as a cartographer had a strong, positive influence on his avocation as an amateur astronomer and selenographer. His parents, Wilhelm Gotthelf Lohrmann and Sophie Michaelis, were brickmakers. Lohrmann attended the garrison school between 1802 and 1810 and then, until 1814, the construction school at the Dresden Arts Academy. In 1815 he joined the survey office, which was founded to supply charts for the tax office, and was appointed head of the lithographic printing office in 1823. In this position Lohrmann prepared the topographic data for the maps that were printed and published as the *Geognostische Specialkarte des Königreiches Sachsen* between 1836 and 1845.

When, in 1828 the new technological education institute was opened, a predecessor to the college, Lohrmann was appointed director. The same year he also took over the responsibility for the Königlich Mathematisch–Physikalischer Salon (Royal Mathematical–Physical Collection). In this position Lohrmann erected a small astronomical observatory and defined the local meridian by setting up pillars near Rähnitz-Hellerau and Rippchen near Dresden.

Lohrmann had begun astronomical observations from his home in 1821. His main interest was the topography of the Moon, and he published four parts of his *Topographie der sichtbaren Mondoberfläche* (Topography of the visible lunar surface) as early as 1824. This work was completed in 1836 and followed by his *Kleine Karte des Mondes* (Small map of the Moon) with a diameter of 38.5 cm (15–1/16 in). A larger map based on Lohrmann's work was published in 1878 (38 years after his death) by **Johann Schmidt** and republished by Paul Ahnert in 1963. This work was highly commended by **Simon Newcomb** and influenced **Wilhelm Beer** and **Johann von Mädler** and their *Mappa selenographica*. Schmidt also used much of Lohrmann's data and drawings for his book *Der Mond* (*The Moon*), published in 1856. Further works by Lohrmann were *Das Planetensystem der Sonne* (Dresden, 1822), *Meteorologische Beobachtungen* (1831–1833), and an article on meteorites in Ludwig Gilbert's *Annalen der Physik* in 1823.

Lohrmann was married twice, in 1819 to Christiane Amalie, daughter of the master baker Seifert, and in 1828 to Henriette, daughter of professor Dr. C. E. Raschig, a military surgeon of the general staff. With his first wife he had four sons and two daughters, with his second wife three sons and one daughter. He died of typhoid fever. He is honored by the minor planet (4680) Lohrmann and a lunar crater.

Lohse, Wilhelm Oswald

Born **Leipzig, (Germany), 13 February 1845**
Died **Potsdam, Germany, 14 May 1915**

German observational astronomer Wilhelm Lohse founded the archive of astronomical photographic plates at Potsdam Observatory, one of the oldest in the world. Lohse graduated in the natural sciences (particularly chemistry) from Leipzig University. In 1870, he began work at F. von Bulow's private observatory at Bothkamp, Germany under **Hermann Vogel**. Their work in spectral analysis established Bothkamp as a major astrophysical facility. With the founding of the government-supported Potsdam Observatory in the 1870s, Lohse moved there with the position of *hauptobservator* (head observer) under Vogel's directorship. He continued to observe there until near the end of his life and established the Potsdam plate archives, illustrating the value of photography to traditional astronomical work. It vies with the archives at Harvard College Observatory for the oldest collection of useful plates (though Harvard has daguerreotypes of the Moon dating from the early 1850s). The Potsdam collection was partly destroyed during World War II.

Lomonosov, Mikhail Vasilievich

Born **Denisovka, (Lomonosovo), Russia, 8 November 1711**
Died **Saint Petersburg, Russia, 15 April 1765**

The first Russian scientist–educator–poet–innovator, Mikhail Lomonosov left an appreciable trace in all the sciences of the 18th century. His works on astronomy, physics, chemistry, engineering, history, economy, geology, geography, and literature for a long time determined how these arts and sciences would develop in Russia.

Lomonosov was born in a family of well-to-do peasant fisherman in the north of Russia. His village was near the coast of the White Sea at a latitude of 64°. Lomonosov's father constructed a perfectly equipped galiot, on which his son and he sailed the Arctic Ocean up to a latitude of 70°. Mikail should have continued in his father's trade as the fisherman's sole successor. However, at age 19, Lomonosov stealthily left his father's house for Moscow, to receive an education. Hiding his country origin, he studied in Moscow, then in Saint Petersburg, and finished his education in Germany, at the universities of Marburg and Freiberg.

In 1745 Lomonosov became a professor at the Saint Petersburg Academy of Sciences – the first Russian, as the other scientists in the academy had been invited from abroad. In 1756 some land was granted to Lomonosov, at the center of Saint Petersburg, where he built a house that included a mosaic workshop and chemical laboratory.

Lomonosov was married (1740) to a German woman, with whom he became acquainted during his studies in Germany. The couple had one daughter.

Lomonosov had a quick temper that worked against him in court intrigue. Later the great Russian poet Aleksandr Pushkin, who admired the scientist, wrote: "I as Lomonosov do not want to be a buffoon even for the Lord."

Lomonosov engaged in astronomical and optical research during the last years of his life, while already a mature scientist. He is responsible for much of the Russian astronomical terminology.

In optics Lomonosov designed (1760/1761) a telescope employing a siderostat. The main tube sat motionless, pointed in a horizontal direction, and starlight was directed into it with the help of a flat, rotating mirror. Otherwise, such telescopes entered into use only in the second half of the 19th century.

In 1762 Lomonosov offered a new reflector design in which the main mirror is slightly inclined to the axis of a tube (by, *e. g.*, 4°). The secondary flat mirror is absent (or is off-axis) in this scheme. Independently of Lomonosov the idea was put to use by **William Herschel** in 1789.

Lomonosov was also engaged in development of a "night visual tube," the purpose of which was to allow an observer to more distinctly see a target under weak illumination. This tube looked similar to a normal telescope, and his contemporaries did not recognize anything new in it. The principles of its action were formulated only in the 20th century as new discoveries were made in the physiology of sight. Among other Lomonosov inventions appear the refractometer, an incendiary tool consisting of mirrors and lenses; seaworthy instruments; and other optical devices. Unfortunately, even the drawings of some of these were not kept.

Lomonosov studied the figures of objective mirrors using a test with an aperture mask that was likely similar to the more sophisticated Hartmann test. He was the first in Russia to develop photometric methods, by improving **Christiaan Huygens**'s device (described in *Cosmotheoros*, 1698) and by carrying out measurements with it during a solar eclipse.

In astronomy, Lomonosov put forward an original theory of a comet's structure in which electricity forces luminescence in the comet's tail. In 1761, he observed the transit of Venus from his home observatory. Lomonosov described details of this phenomenon in "The Appearance of Venus on the Sun …." He interpreted the turbidity of the solar disk's edge at first contact, and the formation of a luminous "blister" at third contact, as being the result of the presence of an atmosphere surrounding the planet. This work was published in Russian and German, but remained almost unnoticed. In 1769 a similar explanation of the phenomenon was given by English astronomer **Nevil Maskelyne**, and later such a conclusion came from other astronomers as well, *e. g.*, **Johann Schröter** and Herschel. Lomonosov was a strong supporter of ideas about the plurality of inhabited worlds.

In other, related fields, Lomonosov (in a 1748 letter to **Leonhard Euler)** formulated a law of conservation of mass and verified it by experiments on the oxidation of metals. (The results of these experiments were confirmed in 1773 by the French chemist Antoine-Laurent Lavoisier.) He also gave much attention to the study of gravitation with the help of special pendula and other devices.

Lomonosov's role as popularizer and organizer of science was huge. For example, he described many difficult scientific phenomena in poetic form. With amazing insight Lomonosov thus described processes occurring in the Sun, ones proven by astrophysicists more than 100 years later:

Tam ognenny valy stremiatsa
I ne nahodjat beregov,
Tam vihri plamenny krutjatsa
Borjusshis' mnozhestvo vekov:
Tam kamni, kak voda, kipjat,
Gorjasshi tam dozhdi shumjat.

Lomonosov helped found (1755) the Moscow University that nowadays carries his name. In 1956 presidiums of the USSR Academy of Sciences established the Lomonosov Gold Medal, which was presented for outstanding works in the natural sciences. His name appears on maps of the Moon and Mars.

Loomis, Elias

Born **Willington, Connecticut, USA, 7 August 1811**
Died **New Haven, Connecticut, USA, 15 August 1889**

As an astronomer, Elias Loomis was recognized primarily as an educator. He wrote numerous textbooks on astronomy and mathematics. However, his contributions to original astronomical research were comparatively minor, whereas in meteorology he played an impressive role, devoting the last 20 years of his life mainly to meteorology.

Loomis, the eldest son of the Reverend Hubbell and his wife Jerusha (*née* Burt) Loomis, was a descendent of Joseph Loomis, who came from England in 1638 and settled in Windsor, Connecticut in 1639. At an early age Loomis displayed excellent linguistic skills, having read the New Testament in its original Greek. He was admitted to Yale at age 14, but because of frail health did not actually begin attending classes for another year. After graduating in 1830, Loomis taught mathematics for a year and a half at Mount Hope Institute in Baltimore, and then entered Andover Theological Seminary in expectation of becoming a minister. At Andover he was the most proficient scholar in Hebrew. But in 1833 Loomis was appointed a tutor at Yale, where for a year he chose to teach Latin.

After the spectacular return of the Leonid meteor shower in 1833, Loomis switched his major interest from linguistics to astronomy, becoming **Denison Olmsted**'s assistant. In October 1834, Loomis presented a paper at the Connecticut Academy of Arts and Sciences on **Ernst Chladni**'s specifications on how to determine the heights of meteors from observations at two widely separated stations, and the successful results obtained by **Heinrich Brandes** and **Johann Benzenberg** on the meteors of 1798. Loomis then contacted professor Alexander Catlin Twining (1801–1884) of the United States Military Academy, West Point, New York with plans for him to observe the Leonids of 1834 from New Haven, and Twining from West Point. Their results were described by **Hubert Newton** as "only marginally successful," but theirs were the first such observations undertaken in America.

Loomis and Olmsted were the first in America to recover comet 1P/1835 P1 (Halley). With the slow international communication in those days, they were unaware that some 25 days earlier Étienne Dumouchel (1773–1840) in Italy had already spotted the comet.

In the spring of 1836 Loomis was called to Western Reserve College in Ohio as chairman of mathematics and natural philosophy. A condition of his acceptance was that he be allowed to spend a year in Europe studying and acquiring the necessary telescopes and clocks to equip a small observatory. Loomis spent the rest of 1836 and most of 1837 in Paris attending the lectures of **Jean Biot**, **Simeon Poisson**, and **Dominique Arago** among others.

In London, Loomis acquired a 4-in. Simms equatorial refractor, a 3-in. Simms transit circle, and a clock with a mercurial pendulum by Molineaux. On arriving at Western Reserve in Hudson, Ohio, Loomis supervised the construction of one of the first permanent observatories to be established in the United States. In his address at the dedication of the observatory, Loomis decried the lack of astronomical observatories in the United States, an issue frequently repeated by him and others. When not teaching classes, Loomis devoted most of his time to careful determination of the latitude and longitude of the observatory. In those early days of expansion to the West, the Western Reserve observatory provided a vital benchmark for the mapping of the United States west of the Appalachian Mountains.

In 1844 Loomis was offered a professorship at the University of New York. There he undertook writing a successful series of mathematics texts as well as one of his better-known treatises, *The Recent Progress of Astronomy, Especially in The United States*, and an expanded version of *Recent Progress* in 1856. Loomis's survey of American observatories was also published in expanded form in *Harper's New Monthly Magazine* over several issues. Some of the observatories described have passed out of existence with little documentation other than the Loomis articles.

In 1860 Loomis was finally appointed as Olmsted's successor at Yale. By that time he had published his *Treatise on Astronomy*, and a few papers on meteors, comets, and sunspots, but his interests had shifted mainly to other fields, especially meteorology, the Earth's magnetic field, and the aurorae. He was the first to prepare a map of the frequency distribution of the aurorae.

A compilation by Newton of the publications of Loomis gives 164 titles, including 26 full length treatises: five in astronomy, 15 in mathematics, one in meteorology, one on astronomy and meteorology, three on Loomis genealogy, and one on natural philosophy (now called physics). His textbooks in mathematics cover the entire range from arithmetic for children through advanced calculus and analytic geometry for college students. Some 600,000 copies of his astronomy and mathematics treatises were sold, providing him a substantial income.

The research papers on astronomy that Loomis published dealt mainly with objects in the Solar System, especially early observations of meteors and comets. Apart from what was included in his treatises, Loomis wrote only three papers on stars. They included a comparison of two star catalogs in 1854, a study of the eclipsing variable Algol, for which he correctly concluded that the period is not constant, and a suggested new period for the peculiar variable η Carinae. **Rudolf Wolf** had determined a period of 46 days based on two early observations in 1677 and 1751, followed between 1815 and 1861 by what appears to be a partial cycle around maximum. Loomis, using exactly the same data, derived a period of 76 days, declaring Wolf's period erroneous. Actually both periods do satisfy the given data but later observations confirmed neither.

Loomis was a pioneer in the study of terrestrial magnetism. As early as 1836 he made observations at Yale on the variation of the magnetic needle. In 1870 he published an important paper relating terrestrial magnetism and aurorae to sunspot activity.

The aurora borealis was exceptionally bright as seen from New Haven on 28 August 1859 and remained bright each night until 4 September 1859. Loomis was intrigued and collected observations from Europe, Asia, and the Southern Hemisphere. He then compiled as much material as possible on previous brilliant displays. From his analyses Loomis concluded that when there are brilliant displays in the Northern Hemisphere there are simultaneously displays in the Southern Hemisphere. The lower heights of the displays he found to be about 50 miles above the Earth while streamers reached upward to 150 miles.

After 1869, Loomis published no research papers specifically on topics in astronomy. Instead, he spent 20 additional years on meteorology, and it is in that science that he made his most important original contributions. As early as 1837 he published hourly meteorological observations, stimulated by two then prevalent contradictory theories of storms. By 1846 Loomis had developed a unique system of data collection and analysis and published the first synoptic weather map. This new technique of presenting weather information exerted a profound influence on meteorology in the following decades during which the competing theories of storms were resolved. His mapping technique formed the basis for weather forecasting. After returning to Yale in 1860 Loomis compiled meteorological data for New Haven and surroundings, spanning 86 years. In 1871 the United States Signal Service was established, providing daily weather maps according to the plans Loomis had envisioned 30 years before. Loomiss' final paper in a series called *Contributions to Meteorology,* was printed by the National Academy of Sciences in 1889.

Loomis was a member of the National Academy of Sciences, the American Philosophical Society, and the American Academy of Arts and Sciences, and an honorary member of the Philosophical Society of Glasgow, the Royal Irish Academy, the Royal Meteorological Society of London, and the Societa Meteorologica Italiana.

In 1840, Loomis married Julia Elmore Upson of Tallmadge, Ohio who died in 1854. They had two sons, one of whom, Francis Loomis (1842–1918), earned two Ph.Ds in astronomy, the first from Yale University in 1866, and another from Göttingen University in 1869. When Elias Loomis died, he willed his $300,000 estate to the Yale Department of Astronomy, the interest (after lifetime provision for his sons) to be devoted to salaries for the observation and reduction of astronomical data, and defraying costs of their publication.

Lord Kelvin

➜ **Thomson, William**

Lorentz, Hendrik Antoon

Born **Arnhem, the Netherlands, 18 July 1853**
Died **Haarlem, the Netherlands, 4 February 1928**

Dutch physicist Hendrik Lorentz matriculated at the University of Leiden, earning a Ph.D. from there in 1875. His dissertation theoretically explained the Zeeman Effect. Lorentz eventually joined the faculty of his *alma mater*.

Lorentz discovered, independently from **George FitzGerald**, the phenomenon of the Lorentz–FitzGerald contraction and created the Lorentz equations (or transformations) that so influenced **Albert Einstein**. In his career he investigated electromagnetic theory, as well as the theories of motion, gravity, and thermodynamics.

Lorentz received the 1902 Nobel Prize in Physics along with **Pieter Zeeman**. Their prize-winning work has great astrophysical application because it showed how spectral lines could be used to measure the magnetic fields of the Sun, stars, and interstellar gas.

Lorenzoni, Giuseppe

Born **Rolle di Cison di Valmarino, (Veneto, Italy), 10 July 1843**
Died **Padua, Italy, 7 July 1914**

Giuseppe Lorenzoni was a pioneering solar spectroscopist, independent discoverer of the presence of neutral helium in the Sun, and director of the Padua Observatory (1878–1914). Lorenzoni attended primary schools in Follina (Treviso), under the instruction of his father, and in Treviso itself. Between 1856 and 1860, he was a student at the I. R. Scuola Reale Superiore in Venice, under the protection of Italian educationalist Luigi Alessandro Parravicini. Lorenzoni matriculated at the University of Padua in 1860 and received his degree in engineering in 1864. But in the previous year, he had gained a position at the Padua Observatory as assistant to the elderly director, **Giovanni Santini**. In that same year (1863), Lorenzoni married Michelina Ferrari, but no children resulted from the marriage.

At the Observatory, Lorenzoni was entrusted with meteorological observations, and in a short time was able to replace obsolete instrumentation, to have a new meteorological station built to the north of the observatory tower, and to continue those observations, which today extend back almost 200 years. Lorenzoni carried out analyses of rainfall in Padua extending nearly 150 years, and wind directions for over 10 years.

In 1867, Lorenzoni began teaching theoretical geodesy and astronomy (the latter in place of Santini) while supporting various management duties at the observatory. He also began making astronomical observations, chiefly of meteors, which **Giovanni Schiaparelli** had recently demonstrated to be "cometary dust."

Lorenzoni first approached the new science of astrophysics on the occasion of a total solar eclipse, visible from Sicily in 1870. To partake in this astronomical event, a scientific commission was created by the Italian king. Santini was appointed president of the commission and charged with organizing the expedition and planning its scientific observations. Lorenzoni was assigned the task of observing the solar corona and prominences by means of a Hofmann direct-vision spectroscope, purchased expressly by the commission. This cooperative endeavor suggested to **Angelo Secchi** the formation of a *Società degli Spettroscopisti Italiani* to coordinate observations of the Sun. In 1872, the first issue of the *Memorie della Società degli Spettroscopisti Italiani*, the world's first astrophysical journal, was published. Lorenzoni became its lead author. One of the bright emission lines that he observed (λ 4471 Å) during the eclipse was that associated with neutral helium. Only later did Lorenzoni come to learn that the same spectral line had been previously noted by American astronomer **Charles Young**.

In the coming years, Lorenzoni took part in the program of spectroscopic observations coordinated by **Pietro Tacchini** in Palermo and Secchi in Rome. But the unfavorable climate of Padua, the difficulties of observing from the top of the observatory tower with a small 11-cm equatorial telescope, the lack of funds needed to update the obsolete astronomical equipment, and finally the task of helping Santini, all prevented Lorenzoni from devoting himself more fully to research in the "New Astronomy."

In 1873, Lorenzoni was appointed a member of the Italian Geodetic Commission (replacing Santini), and from then onward his main activities consisted of measurements of longitude and relative gravity and of coordinating the commission's work. The Italian government was more concerned with financing geodetic studies and the preparation of new geographic maps of Italian territory than in purchasing new expensive telescopes. Lorenzoni made important contributions to geodetic studies, *e. g.*, his determination of absolute gravity (1888) on the ground floor of the observatory tower, using a Repsold instrument, was well known. But he did not neglect astronomy.

During these years, Lorenzoni improved his knowledge of the mechanics and optics of astronomical and geodetic instruments. In 1874, he took charge of all the instruments in the observatory workshop in preparation for shipping them to India for the Italian mission (led by Tacchini) to observe the transit of Venus. In 1881, he was able to purchase a 187-mm Merz refractor, which the observatory later used in the determination of the solar parallax during the opposition of asteroid (433) Eros in 1900. Concurrently, Lorenzoni was appointed professor of astronomy at the University of Padua in 1872, and became full professor and director of the observatory in 1878, after Santini's death.

Lorenzoni is remembered as an outstanding teacher at the University of Padua. He had many clever pupils, including **Antonio Abetti**, who became director of the Observatory of Arcetri; Giuseppe Ciscato, director of the latitude station of Carloforte (Cagliari); Bortolo Viaro, who became director of the Observatory of Catania; mathematician Tullio Levi-Civita; **Emilio Bianchi**, director of the Observatory of Brera-Milan; Antonio Maria Antoniazzi, who succeeded Lorenzoni as director of the Observatory of Padua; and many others.

Finally, Lorenzoni published careful research on the history of the Padua Observatory, dating from 1767, and of his predecessors, especially Giuseppe Toaldo and Santini.

Lovell, Alfred Charles Bernard

Born **Oldland Common near Bristol, Gloucestershire, England, 31 August 1913**

Bernard Lovell, together with Martin Ryle and Stanley Hey, were responsible for the early development of the discipline of radio astronomy in Britain.

Lovell was the only child of Gilbert Lovell and Emily Laura Adams. In 1931 he enrolled as a physics student at the University of Bristol and stayed on to do postgraduate research. Lovell obtained his Ph.D. degree, with a thesis concerning the electrical conduction characteristics of thin metal films, in 1936. That same year he was appointed a lecturer in physics at the University of Manchester.

At the University of Manchester Lovell worked with the eminent physicist **Patrick Blackett**. Blackett was convinced that the energy spectrum of cosmic-ray particles would reveal some hidden fact of cosmic significance, and Lovell was assigned the task of measuring particle energies using a cloud chamber. But when World War II broke out, he was told to report to a military installation on the English coast and found himself working on the fledgling techniques of radar detection. Lovell's wartime work included the development of early versions of the lock-and-follow radar fitted to various Royal Air Forcé fighter squadrons, and later, a ground-targeting radar system known as H_2S, which was fitted to Stirling and Halifax bombers.

Once the war was over, Lovell was released from his duties and returned to research at the University of Manchester. In the course of his wartime work he had witnessed sporadic, unexplained echoes on coastal defense radar systems and had wondered if these were due to the passage of cosmic rays through the atmosphere. Lovell acquired some ex-army radar equipment to investigate this idea and installed the system at a rural site called Jodrell Bank (some 20 miles south of Manchester) in order to escape the radio interference in the center of the city. He soon found that these radar echoes were not from cosmic rays but from meteor trails. Throughout the late 1940s Lovell and his coworkers investigated meteor trajectories and velocities using radar techniques and were able to show that many meteors originate in the dust tails of comets. Inspired by the emerging science of radio astronomy, they eventually turned their attention to detecting cosmic radio waves, and an early telescope at

Jodrell Bank was the first to discover radio waves coming from the Andromeda galaxy, M31.

Circa 1950, Lovell developed plans for an ambitious new telescope at Jodrell Bank. Construction of the 250-ft.-wide telescope, still the world's largest fully steerable radio telescope, began in 1952. The project suffered from rising costs and was almost cancelled on several occasions, Lovell himself narrowly avoiding imprisonment as a result. The telescope was eventually completed in the summer of 1957. That October, the Soviet Union launched the first artificial satellite, Sputnik I, into Earth orbit, and the telescope at Jodrell Bank was famously able to track the carrier rocket by radar. It continued to play an important part in the early days of space exploration, *e. g.*, receiving the transmission of the first photograph of the farside of the Moon from the Soviet Lunik 3 probe. The telescope, which was named the Lovell telescope in 1987, in honor of its founder, has been crucial in the discovery of quasars, the confirmation of the existence of pulsars, and the detection of maser emission from star-forming regions.

Lovell's legacy is immense. The telescopes he conceived and initiated continue to play a critical role in the study of diverse astronomical phenomena. Lovell was elected to the chair of radio astronomy at Manchester in 1951 and was director of the Nuffield Radio Astronomy Laboratories (now named Jodrell Bank Observatory) until his retirement in 1981. He was knighted in 1961.

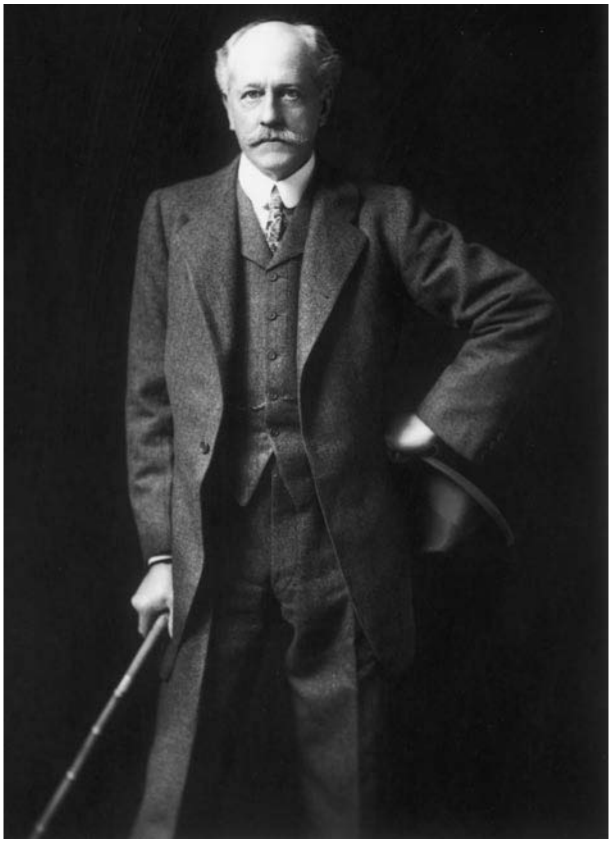
Lowell, Percival

Born **Boston, Massachusetts, USA, 13 March 1855**
Died **Flagstaff, Arizona, USA, 12 November 1916**

Percival Lowell's fame and notoriety arose from his claims about the existence of intelligent life on Mars, based on what he regarded as irrefutable evidence for network of canals on the surface of the planet visible from the Lowell Observatory. These sensational claims obscured much of his other work including the search for a ninth planet in the Solar System, which eventuated after his death in the discovery of Pluto, and his interest in cosmogony, which was explored in three books and numerous articles. Even less attention has been paid to his 10-year-long exploration of East Asian culture, which, together with his planetary research, was intended to provide further support for Herbert Spencer's monumental synthetic philosophy.



Son of Augustus and Katharine Bigelow (*née* Lawrence) Lowell, Percival Lowell was born into a wealthy and distinguished Boston family. On both sides, he descended from the original investors in the Lowell and Lawrence cotton mills. Among his siblings, younger brother A. Lawrence Lowell succeeded to the presidency of Harvard University in 1909, while sister Amy achieved renown as a cigar-smoking poet and one of the leaders of the imagist movement. Percival Lowell graduated from Harvard University in 1876 and launched a career as an investor in Boston; in 1883 he made his first trip to Japan. Over the next 10 years, he made four additional trips to Asia before turning to astronomy in 1894. On 10 June 1908 at the age of 53, Lowell married Constance Savage Keith, a union which produced no offspring.

Lowell's interest in Japan grew out of boredom with the routines of business life and impatience with the parochialism of his Boston family and friends. Through his travels, he hoped to create a more interesting life for himself, overcome his parochialism, and obtain a clearer sense of the racial hierarchy among peoples of the world. In the course of his travels, Lowell explored geographical sites and cultural phenomena then unknown in the west. Following a visit to Korea in 1883, he became the first westerner to write about that newly opened country based on firsthand observation. Lowell also visited and described the remote Noto Peninsula in Japan. His discovery, on Mount Ontake, of Shinto pilgrims who put each other into trances became the subject of *Occult Japan* (1894), an important contribution to the literature on subconscious states of mind. But Lowell's books on Japan will be best remembered for their insistence on the arrested mental development of the Japanese, which rendered them incapable of understanding western science.

Immediately following his return to Boston from Japan, Lowell made a sensational debut in astronomy by funding an expedition to Flagstaff, Arizona designed to take advantage of the 1894 Martian opposition to look for evidence of life on Mars. For this purpose, he hired as his assistants **William Pickering**, brother of **Edward Pickering**, the director of the Harvard College Observatory, and **Andrew Douglass**. Pickering and Douglass had recently returned from a stint at the Arequipa (Peru) station of the Harvard College Observatory. Following their recommendation, the Lowell Observatory was located in a similar high desert environment near the San Francisco Mountains, which could be expected to foster good seeing and clear skies.

Lowell's Martian observations in 1894 and during subsequent oppositions of the planet attracted widespread attention. Leading figures in the astronomical community disputed the existence of the canals on Mars as well as Lowell's contention that the Martian atmosphere could support intelligent life. Lowell, however, was undeterred by his critics. During the oppositions of 1905, 1907, and 1909, Lowell offered fresh evidence for the existence of the canals and in 1907 financed an expedition to Chile, under the leadership of his friend, the Amherst astronomer **David Todd**, to clinch the case for the existence of life on Mars. Nonetheless, by 1909, a consensus had developed among leading professional astronomers, including **Edward Barnard**, **George Hale**, and **William Campbell** based on their own observations, that there was no credible evidence for the existence of the canals or of intelligent life.

Meanwhile, Lowell launched two less sensational projects, which he may have hoped would improve his reputation in the astronomical community. In 1905, he began both a mathematical and an observational search for a ninth planet in the Solar System based on unexplained perturbations in the orbit of Uranus. These explorations continued unsuccessfully until Lowell's death in 1916. Fourteen years later, after the Lowell Observatory renewed the search for planet X, a new planet – different from Lowell's predicted planet in size and orbit – was discovered by **Clyde Tombaugh**, a young assistant at the observatory. Recognition of Lowell's role in this discovery was reflected in the presence of his initials in Pluto, the chosen name for the planet.

Lowell also forcefully entered the debate over the origins of the Solar System. Ever since his undergraduate years, he had endorsed the nebular hypothesis which identified the origin of the Solar System in a gaseous nebula. Not until 1902, when the nebular hypothesis was under attack, did Lowell take up this issue systematically in a series of lectures delivered at the Massachusetts Institute of Technology. Over the next 14 years, he published three books that endorsed a modified version of the nebular hypothesis as well as Herbert Spencer's notion that the continuing operation of evolution after the formation of the Solar System had produced an increasingly heterogeneous world of inorganic, organic, and social forms. As with his Martian findings, Lowell's Spencerian interpretation of history was attacked, this time by specialists in various fields.

The controversial nature of his work notwithstanding, Lowell contributed in important ways to the advancement of astronomy and of Asian studies. In the latter field, he called attention to the distinctive attributes of Japanese culture and to its artistic achievements. In the former, he inspired a succeeding generation of scientists to take up the search for extraterrestrial life. In this sense, Lowell might be regarded as a founding father of the Viking and Mariner missions. In addition, while sometimes diverting professional astronomers from other important work, the controversy over the canals of Mars called attention to research on the Solar System, which had been somewhat neglected. Lowell's legacy also included the observatory he founded, which was notable for its location and the staff he recruited. He helped to pioneer the exploration of good seeing in remote areas by making atmospheric conditions a key element in locating and maintaining the observatory in Flagstaff. Its successful operation was due to Lowell's recruitment of competent young astronomers who made important contributions to the profession. **Carl Lampland**'s photography of the nebulae was widely respected, as was **Earl Slipher**'s planetary photography. **Vesto Slipher**'s measurement of the high radial velocities of nebulae provided key initial evidence to support the concept of an expanding Universe. On Lowell's death and according to his wishes, V. M. Slipher assumed the directorship of the observatory.

While director of the observatory, Lowell served simultaneously as nonresident professor of astronomy at the Massachusetts Institute of Technology, where he gave occasional lectures. He was also fellow of the American Academy of Arts and Sciences, and a member of the Astronomical and Astrophysical Society of America. He was a Janssen Medallist of the Société Astronomique de France, 1904, and Medallist of the Sociedad Astronomica de Mexico, 1908. He received honorary degrees from both Amherst College, 1907 (LLD) and Clark University, 1909 (LLD).

Lower, William

Born **Cornwall, England, 1569 or 1570**
Died **(Dyfed), Wales, 12 April 1615**

Sir William Lower was a gentleman and statesman who became a close collaborator of **Thomas Harriot**, through whom he obtained a telescope and made some of the first ever telescopic astronomical observations. Lower was the eldest son of and heir to Thomas Lower of Winnow. He attended Oxford University, entering Exeter College in 1586. He subsequently studied at the Middle Temple in London. Lower was elected to represent Bodmin, Cornwall, in Parliament in 1601; from 1604 to 1611, he represented Lostwithiel, Cornwall. He was knighted by King James I in 1603.

Around 1601 Lower married Penelope Perrot of Carmarthenshire, heir to the estate of her father, Sir Thomas Perrot. Lower moved to the Perrot estate at Trefenty near Saint Clears. When Lower died, he was survived by his wife and a daughter, Dorothy, but his wife was pregnant at the time of his death and later gave birth to a son, Thomas. Several other sons had predeceased him. His wife later remarried and moved to London.

Following the death of Perrot, Penelope's mother married the Earl of Northumberland in 1594, which brought Sir William and Northumberland into close contact. The latter was patron to Harriot, who lived at the earl's estate at Syon House, near London. Lower and Harriot began a productive friendship that lasted many years, corresponding regularly on scientific matters, with Lower acting as a confidant. It is from this correspondence that we know of Lower's scientific activities. These letters show a broad range of interests, including contemporary developments in astronomy, mathematics, and physics.

In 1607 Lower observed a bright comet first seen in September, now known to be comet 1P/Halley. He first noticed it in Ursa Major on 17 September while traveling across the Bristol Channel toward Wales. Lower made regular observations up to 6 October, using a cross-staff. These observations were sent to Harriot but were not published until 1784 (by **János von Zach**), being used by **Friedrich Bessel** to compute the orbit of the comet.

Harriot, who had a good knowledge of optics, learned of the development in 1608 of the telescope in the Netherlands. He experimented with his own telescopes before mid-1609 and presented Lower with an example manufactured by his assistant, Christopher Tooke, at Syon House. Lower used the instrument to make a series of observations of the night sky, aided by a friend, John Protheroe (or Prydderch) from the estate of Nantyrhebog (or Hawksbrook) not far from Trefenty. Lower enthusiastically requested Harriot to provide more telescopes for which he offered to pay. It appears that he observed from a building on some high ground at Trefenty, which was arguably among the very first observatories equipped with a telescope.

Lower's telescopic observations of the Moon have attracted the most attention. A letter to Harriot of 6 February 1610 has attained some notoriety. In this he wrote:

> According as you wished, I have observed the moone in all his changes. In the new manifestlie I discover the earthshine a little before the dichotomie; that spot which represents unto me the man in the moone (but without a head) is first to be seene. A little after, neare the brimme of the gibbous parts toward the upper corner appeare luminous parts like starres; much brighter than the rest; and the whole brimme along looks like unto the description of coasts in the Dutch books of voyages. In the full she appears like a tart that my cooke made me last weeke; here a vaine of bright stuffe, and there of darke, and so confusedlie all over. I must confess I can see none of this without my cylinder.

Lower received news of **Galileo Galilei**'s telescopic discoveries via Harriot shortly after the publication of *Sidereus Nuncius* and responded with excitement. He visited Syon House in December 1610, and he and Harriott observed the Galilean satellites of Jupiter. Lower was present when Harriot first observed sunspots at sunrise that month. However, on returning to Carmarthenshire, neither he nor Protheroe could see the Galilean satellites, indicating the lower quality of their telescope compared to those of Harriot. Lower himself saw sunspots from Syon House in December 1611.

Lower and Harriot failed to publish their results – unlike Galilei – even though they were often aware of their significance; indeed Lower's letters to Harriot included occasional pleas for Harriot to publish his scientific findings. Galilei's discoveries therefore made a major impact on scientific thought while Lower, perhaps understandably, has received only modest attention.

Löwy, Kornel

➲ **Lanczos, Cornelius**

Löwy [Loewy], Maurice [Moritz]

Born **Marienbad (Mariánské Lázně, Czech Republic), 15 April 1833**
Died **Paris, France, 15 October 1907**

Paris Observatory director Maurice Löwy earned his reputation in celestial mechanics, particularly for his work on determining the orbital parameters of asteroids. He was born to a Jewish family, not, as is sometimes said, in Vienna but in Marienbad, at the time a city in the Austro–Hungarian Empire but now located in the Czech Republic not far from the German border. When Löwy was 8 years old, his family arrived in Vienna in order to avoid the endemic Jewish persecutions of the day.

In 1856, Löwy worked as an assistant at the Vienna Observatory, where his work on orbits of newly discovered minor planets drew considerable attention. Nevertheless, in the middle of the 19th century, the administration of the Austro–Hungarian Empire did not allow any Jewish-born person to obtain a university teaching position without converting to Catholicism. Because Löwy refused to renounce, he could not find any permanent position in Austria.

Fortunately for Löwy, **Karl Littrow**, director of the Vienna Observatory, enjoyed a very good scientific relationship with French astronomer **Urbain Le Verrier**, director of the Paris Observatory. During 1860, Littrow seems to have asked Le Verrier to welcome Löwy as a trainee assistant in Paris. After Le Verrier agreed, Löwy began his fruitful work at the Paris Observatory on 15 August 1860. Löwy served as deputy headmaster there from 1878 to 1896, and succeeded **Felix Tisserand** as director in 1896, a position he held until his death.

Löwy first carried out an investigation of the orbital parameters of comets and small planets, especially comet C/1858 L1 (Donati) and the minor planets (45) Eugénia and (99) Dike. He also participated in astrometric observations, including meridian passages. After a few years, Löwy earned the title "astronomer." When he obtained French citizenship on 4 July 1868, he changed his name to Maurice Loewy, which he retained the rest of his life.

From 1873 to 1880, Löwy specialized his work in astrometry. He accomplished thorough measurements of longitude differences. He was also involved in the improvement of the yearly *Connaissance des Temps*, published by the French Bureau des longitudes, as well as in the improvement of methods to determine astronomical refraction and aberration.

At the same time, Löwy also worked on enhancing astronomical instrumentation, especially telescopes. He developed the principle of the equatorial coudé telescope, six of which were constructed around the world. The first equatorial coudé telescope, equipped with a 27-cm lens, was installed at the Paris Observatory in 1882. The grand equatorial coudé, equipped with a 60-cm lens, was finally installed in 1890 at the Paris Observatory with the financial help of the generous patron Raphaël Bischoffsheim (1823–1906). Both instruments were built by the French opticians **Paul** and **Prosper Henry** in Paris.

Using the grand equatorial coudé, it was possible to obtain a very precise photographic map of the Moon for the entire visible disk and with a good level of homogeneity. Löwy's *Atlas photographique de la Lune*, with 10,000 photographic plates, was realized in collaboration with the French astronomer **Pierre Puiseux** between 1896 and 1910. This atlas served half a century for many selenographic studies and was the standard reference for lunar geography. The grand equatorial coudé remained in use after 1910 for astrophysical investigations, especially in spectroscopy, but the results were not excellent. After the dismantling of the telescope, the 60-cm lens was transferred to the Pic du Midi Observatory, where it is still in use.

As director of the Paris Observatory, Löwy reorganized its scientific programs and created a board of physical astronomy. In 1900, he proposed an international campaign for observing the recently discovered minor planet (433) Eros in order to determine the value of the solar parallax. Until then, the value had not been clearly ascertained, based mainly on rare Venus transits or on Mars perihelic oppositions. Fifty-eight observatories took part in the new project, which involved many photographs over several years. The Paris Observatory coordinated the observations and conducted the calculations. The final results arrived only after Löwy's death: a solar parallax of 8.806″ (currently accepted value = 8.794″).

During the French Council of Observatories held at the Ministry of Public Instruction for the designation of the new directors of the Marseilles and Algiers Observatories (while speaking in favor of one of the candidates), Löwy died suddenly from a heart attack. He had spent more than 50 years working in astronomy.

In honor of his work, Löwy received the prestigious Gold Medal of the Royal Astronomical Society of London in 1888. He was a member of the Bureau des longitudes (1872) and of the Académie des sciences, where he was elected a member of the astronomical section (7 April 1873), vice president in 1893, and president in 1894. He was also a member of the Comité Permanent de la Carte du Ciel, then its president. A 22 by 26 km embanked lunar crater, located at 33° west and 23° south in the east side of Mare Humorum, has been named in his honor.

Loys de Chéseaux, Jean-Philippe

Born **Lausanne, Switzerland, 4 May 1718**
Died **Paris, France, 30 November 1751**

A simple question that arises from nature is, "Why is the sky dark at night?" The darkness of the nocturnal sky has intrigued observers for centuries, but it was necessary to wait until the 18th century to recognize that the reason for the sky's darkness was not at all obvious. It was a young Swiss astronomer, Jean-Philippe Loys de Chéseaux, who provided one of the first formulations of the problem in 1744, although **Johannes Kepler** had arrived at a similar conclusion *circa* 1610.

Loys de Chéseaux was the son of Paul Loys, the Seigneur of Chéseaux, and grandson of the mathematician and philosopher Jean-Pierre de Crousaz, a professor of mathematics and philosophy at the Academy of Lausanne and a corresponding member of the Académie des sciences in Paris. Crousaz was also the first person in Lausanne to teach in the French language.

Loys de Chéseaux possessed a gift for languages – Latin, Greek, and Hebrew constituted some of his favorites – and exhibited an early predilection for the sciences. At a young age, he displayed an exceptional talent and a growing intelligence that allowed him, at the age of 17, to publish in Paris three essays under the title, "Essais de physique" (1735). The success of these publications enabled certain critics to detect hints of his grandfather's abilities in the writings.

To acquaint himself with astronomy, Loys de Chéseaux installed an observatory on his father's lands at Chéseaux. It was seemingly well equipped, having "a pendulum clock, (plus) a quadrant made from brass and complete with sights capable of accurately (measuring) angles as small as 15 seconds [of arc]." The observations that he made between 1736 and 1747 allowed him to prepare two manuscripts, *Traite de la Comète* (1744) and "Nouvelles méthodes" (1747). However, the latter remained unpublished.

At that time, many German princes went to Lausanne to study at the academy. A literary society was created at the residence of the Count de Lippe, where meetings were held every Saturday and members presented their works. Loys de Chéseaux attended one of these meetings, on 22 December 1742, along with his father. The works that they presented were "La réformation du calendrier," "Un catalogue des nebuleuses," "Discours sur la figure de la Terre," and "L'influence de l'exemple." Loys de Chéseaux did not read his *Traiti de la Comète* until 28 March 1744. When published that same year in Lausanne, it consisted of four parts. The first constituted an introduction "to facilitate its reading by non-mathematicians."

In this treatise, Loys de Chéseaux considers all of the observations he made of comet C/1743 X1 seen from late 1743 into 1744. He discusses both the instruments and the methods he used, and calculates an ephemeris for the comet. Three sets of observations are presented in the study: those made of the comet in Paris by **César Cassini de Thury**; those recorded in Geneva by Jean-Louis Calandrini, the mathematician who jointly held the first chair in mathematics at the Academy of Geneva along with Gabriel Cramer, and those recorded by Loys de Chéseaux on his lands. He also describes a method for determining the position, the size, and the form of the comet's tail.

Finally, there is a chapter "on the intensity of light, its propagation in the ether [,] and on the distance of the fixed stars," from which Loys de Chéseaux concludes that "either the number of stars is finite or it has to be assumed that interstellar space is filled with a light-absorbing fluid." This proposition forms the basis for what might be called Loys de Chéseaux's paradox, and which can be formulated as follows: Imagine the space surrounding us to be the superposition of spherical shells. In each of these supposed shells, a star is sending out quantities of light that, from our vantage point, varies inversely with the square of the distance. If space itself were infinite, then the sum of all these contributions would produce a sky that was brilliantly illuminated in all directions. However, this conclusion is plainly contradicted by what we observe in the night sky. This is the paradox of the dark night sky that was recognized by Loys de Chéseaux.

Loys de Chéseaux's work was then forgotten for more that three quarters of a century until, in 1823, the German doctor and naturalist **Heinrich Olbers** raised the same questions as his predecessor. A number of historians have mistakenly attributed the paradox to Olbers himself, and such references have, consequently, been made to Olbers's paradox (but sometimes to the de Chéseaux–Olbers paradox).

In Loys de Chéseaux's time, the Universe was believed to be static; its expansion and subsequent cooling remained unknown before the 20th century. In addition, it possesses a finite age and "radius" (or visual horizon), beyond which we cannot hope to see; its most distant objects are the oldest. More refined calculations have shown that, in order for the night sky to present as much light as the Sun, either the density of stars in space or the length of a star's average lifetime would have to be around 100 billion times greater than at present.

Loys de Chéseaux later discovered comet C/1746 P1. He forwarded an essay, "Nouvelle méthode de calculer la position des orbites des comètes òu de resoudre le problème des trajectoires cosmetiques," to the Académie des sciences in Paris, which named him a corresponding member in 1747. More than a century later, **Camille Bigourdan**, an astronomer at the Paris Observatory, found two manuscripts written by Loys de Chéseaux. They were "Memoire ou la grandeur de la Figure de la Terre" and "Nouvelles méthodes." The latter is divided into two parts. In its first part, Loys de Chéseaux presents an improved version of his theory formerly described in *Traite de la Comète*. In the second part, he proposes a new theory in which "the sun is the center of the movement of the comets" that travel in "orbits of which the plane passes through the center of the centripetal forces."

Loys de Chéseaux, who in addition was a theologian, calculated the movements of the Sun and Moon relative to those described in the *Book of Daniel* and the occurrences of equinoxes and solstices in Jerusalem at the time of the Old Testament story. He authored a "Dissertation chronologique" (1748), in which he tried to establish the date of the eclipse that occurred after Christ's death and, in this way, determine the exact time of the crucifixion.

The works of Loys de Chéseaux attracted the attention of the scientific community in his day. Many academies and learned societies named him as a corresponding member, including the academies of Saint Petersburg, Göttingen, and Stockholm, as well as the Royal Society of London. He was offered the opportunity of directing the observatory at Saint Petersburg but declined the invitation, preferring to live modestly on his native lands. In 1751, after much urging by his friends, he traveled to Paris, where Loys de Chéseaux was presented to the Académie des sciences. Tragically, he soon fell ill and died.

Lubieniecki, Stanislaw [Stanislas, Lubienitzky]

Born **Racców near Cracow, Poland, 23 August 1623**
Died **Hamburg, (Germany), 18 May 1675**

Stanislaw Lubieniecki is remembered for a three-volume work on comets that he published in the mid-17th century. Lubieniecki's father, Krzysztof Lubieniecki, was head of the Unitarian community in his town. During the Thirty Years War, Raców, and the local academy where Lubieniecki studied, were largely destroyed. Afterward, his father educated him and took him on frequent voyages to meetings with the Polish aristocracy.

After traveling to the Netherlands and France, Lubieniecki returned to Poland in 1650; he became an assistant preacher at Torun in 1652 and then a vicar in Czarców. At the close of the Thirty Years War (1660), the Unitarians were accused of having collaborated with the Swedish army. Lubieniecki, who was involved in peace negotiations with Sweden, fled to Copenhagen. In 1661, he traveled to Hamburg and settled there the following year.

When the Great Comet C/1664 W1 appeared in the sky above Hamburg, Lubieniecki corresponded about this phenomenon with Petrus van Bruxelles and **Ismaël Boulliau** in Paris and Henry Oldenburg (secretary of the Royal Society) in London. Lubieniecki collected his observations and those of others into the three-volume *Theatrum Cometicum (1666–1668)*. The first volume was filled with letters regarding the subject, the second contained an extensive catalog of materials on previous comets, and the third dealt with the astrological significance of comets. Lubieniecki showed a depiction of the star of Bethlehem as a comet and argued that the great fire of London had been a product of divine retribution (foretold by the comet of 1664).

In 1667, Lubieniecki suffered religious persecution in Hamburg and removed to Altona, a neighboring Danish town. In 1674, he returned to Hamburg, although his theological and political opponents were still watchful. Lubieniecki's important account of his native country's religious turmoil, *Historia reformationis Polonicae* (1685), was published posthumously. Reportedly poisoned by a servant, Lubieniecki instead may have died from ergotism, a toxic fungus that was then quite common.

Ludendorff, Friedrich Wilhelm Hans

Born **Thunow near Köslin, Poland, 26 May 1873**
Died **Potsdam, Germany, 26 June 1941**

Hans Ludendorff's many publications in *Astronomische Nachrichten* summarize his work in photometry, spectroscopy, double stars, variable stars, and statistical analyses of radial velocities.

Ludendorff earned his Ph.D. in 1897 from the University of Berlin. He served as an assistant at Hamburg Observatory before transferring to the Potsdam Observatory. There, Ludendorff served as *observator* (observer) from 1905 to 1915 and as *hauptobservator* (chief observer) until 1921, when he succeeded **Gustav Müller** as director, a position he held until 1939, when he retired. Ludendorff was, with Müller, the editor of the quarterly journal of the Astronomische Gesellschaft.

Ludendorf's early papers discussed observations of comets and minor planets, but he later devoted his attention to variable stars, especially those of long period, for which he established a classification scheme. Toward the end of his life, he became a scholar of Mayan astronomy.

Lundmark, Knut Emil

Born **Älfsby, Sweden, 14 July 1889**
Died **Lund, Sweden, 23 April 1958**

Swedish astronomer Knut Lundmark is best remembered for having been the first to propose Crab Nebula as the remnant of the 1054 guest star (supernova) on the basis of its location, quite close to that given in translated Chinese records. He also almost discovered what is now called Hubble's law. Lundmark was the son of Johann August Lundmark (1848–1896) and Lovisa Eriksdotter (1852–1939) and married Birgit Lundmark (1886–1974) with whom he is buried in the churchyard in Älfsby.

Lundmark began studies at the University of Uppsala in 1908, receiving a first degree in 1912 and a doctorate in 1920 for a thesis, carried out under **Östen Bergstrand**, on methods of distance measurement in astronomy, including the apparent diameters and apparent brightnesses of nebulae, individual very bright stars, and nova explosions, and calibrating these on known events in the Milky Way. He derived a distance to M31, the Andromeda Galaxy, of 175,000 parsecs, about one-quarter of the best modern distance, at a time when the majority of astronomers doubted the very existence of galaxies outside our Milky Way. Lundmark worked as an assistant at Uppsala Observatory until his appointment as professor of astronomy at Lund University (where his predecessor had been **Carl Charlier**) and remained at Lund for the remainder of his career, mentoring **Bengt Stromgren**, among others.

An appendix to Lundmark's thesis suggested (as **Heber Curtis** advocated at the same time) that there might be two classes of novae of very different brightness. Lundmark's class of "giant" or "upper class" novae consisted of what we now call supernovae, which were recognized by **Walter Baade** and **Fritz Zwicky** in 1933/1934. Baade and Zwicky generally receive credit for the idea.

Later Lundmark called attention to the discrepancy between distances to Andromeda determined from Cepheids and from three other methods based on novae, giant stars, and globular clusters. In his review published in 1946 the first three gave an average 540 kpc, while Cepheids indicated a shorter distance, 400 kpc (even with the new zero-point of the period–luminosity relation, derived by **Henri Mineur** in 1944). The higher value heralded the approaching reformation in the old distance scale based on Cepheids. In this review Lundmark concluded that supernovae, which he had identified as a class 25 years earlier, seem to furnish an excellent distance indicator, with a small scatter in their maximum luminosity. The work with low and high redshift Type Ia supernovae in recent years has confirmed this.

Lundmark played an interesting role in the debate on the detectable rotation in spiral nebulae. During his visit to the Mount Wilson Observatory in 1921–1923, Lundmark measured proper motions on **Adriaan van Maanen**'s plates of M33, which according to Van Maanen showed rotation (as did some other nebulae measured by him, suggesting very short distances). Lundmark did not find any systematic motions.

In 1924, Lundmark attempted to determine the motion of the Sun relative to the spiral nebulae, whose radial velocities had been measured by **Vesto Slipher**. He allowed for the possibility of overall expansion or contraction of the system of nebulae, which might depend on distance, through what was called a K term. The correlation Lundmark suggested began with velocities increasing with distance near us, but turned over with a negative quadratic term, which would have prevented any velocities larger than about 3,000 km/s ever being seen. Thus it was left for **Edwin Hubble** in 1929 to find the linear relation that we now call Hubble's law and interpret it as evidence for overall expansion of the Universe.

The work of Hubble and Lundmark on classifying the main types of galaxies also overlapped in time, with Hubble again getting most of the credit, perhaps less fairly in this case. Both recognized spiral and elliptical types and a less orderly class of irregulars, including the Magellanic Clouds.

Following Charlier's ideas, Lundmark had expected a hierarchical arrangement of structure in the Universe, with clusters of galaxies, clusters of clusters, and so forth. His attempt to compile a catalog of galaxies sufficiently extensive to reveal such structure failed to attract sufficient labor and funding from the community. (It is now known that instead of a stiff hierarchy, there is a fractal-like distribution with a possible cross–over to homogeneity around 100 MPC). Lundmark also made significant contributions to stellar astronomy (reviewed in the *Handbuch der Astrophysik* in 1932/1933) and to teaching and public education, *via* lectures, popular articles, and books. He apparently never felt entirely at home within a Universe of finite age and, perhaps, finite size, so different from that envisioned by his childhood hero **Camille Flammarion**.

Luther, Karl Theodor Robert

Born **Schweidnitz (Swidnica, Poland), 16 April 1822**
Died **Düsseldorf, Germany, 15 February 1900**

Karl Theodor Robert Luther was a zealous discoverer of minor planets during a time when photography was not available to make the task easier. He was born to August Luther and his wife, Wilhelmine von Ende. After being educated at home and at the local high school, Robert went to Breslau (1841–1843) and Berlin (1843–1848) to study astronomy. Luther enjoyed a long and productive career. He died after a short illness, survived by his son, Wilhelm, and his wife, Caroline (*née* Märker), whom he had married in 1859.

In 1843 at Berlin as the pupil of **Johann Encke**, Luther helped with calculations for an astronomical almanac. In 1850, he was promoted to second observer and worked at the 9-in. refractor. At the end of 1851, astronomer **Franz Brünnow** invited Luther to come to the Charlottenruhe Observatory in Bilk near Düsseldorf to succeed him there as director. This small observatory, founded by **Johann Benzenberg** in 1844, was equipped with a 4.6-in. aperture, 6-ft. focal length Merz refractor; it was replaced in 1877 by another Merz, this one being a 7.3-in. aperture, 7-ft. focal length refractor on a Bamberg mount.

Luther concentrated on positional observations, and found 24 minor planets between (17) Thetis in 1852 and (288) Glauke in 1890. He regularly observed five minor planets – (6) Hebe, (11) Parthenope, (56) Melete, (61) Danaë, and (288) Glauke – yielding orbital parameters of high accuracy. Luther also made observations for the Berlin celestial chart, which led to positions for 4,302 stars. In his latter years, his sense of hearing faded, making impossible the "eye-and-ear" method of positional astronomy. In leaving the observations to his son Wilhelm, Robert Luther instead concentrated on the necessary calculations.

Luther was honored several times for his observations. On 9 June 1854, he was elected associate of the Royal Astronomical Society in London, and in 1855, he received a honorary Ph.D. from the University of Bonn. Between 1852 and 1861, Luther was presented with the Prix Lalande seven times by the Academy of Sciences in Paris. In 1863, he joined the Astronomische Gesellschaft as one of its first members, and in 1868 the Société Impériale des Sciences naturelles de Cherbourg. On 4 March 1897, he was given the title of honorary professor by Kaiser Wilhelm I. Luther is also honored by the minor planet (1303) Luthera and a lunar crater name.

Luyten, Willem Jacob

Born **Semarang, (Indonesia), 7 March 1899**
Died **Minneapolis, Minnesota, USA, 21 November 1994**

Dutch–American observational astronomer Willem J. Luyten is best remembered for the discovery and cataloging of a very large number of stars that move rapidly across the sky, either because they are very close to us, because they are old and genuinely fast moving, or both. Luyten was raised on the island of Java by parents from the province of North Holland, who had settled in what was then the Dutch East Indies, where his father taught French in the local high school. He was fluent in French, Dutch, German, and English by the time he graduated from high school in the Netherlands, where the family had relocated in 1912, and added other languages later. His interest in astronomy was aroused by the sight of Halley's comet (IP/Halley) in 1910.

Luyten began making and publishing astronomical observations (mostly of variable stars) in 1912, and, with a last paper in the year of his death, his record of publication through 72 years is close to a world record. Luyten received a BA from the University of Amsterdam in 1918 and a Ph.D. in 1921 from the University of Leiden, where he worked with **Ejnar Hertzsprung** on stellar motions. He held positions at Leiden (1920/1921), Lick Observatory (1921–1923), Harvard College Observatory under **Harlow Shapley** (1923–1927), and the University of Minnesota (assistant to associate to full professor to emeritus).

From the beginning Luyten made extensive use of a method (invented by Hertzsprung) by which the apparent brightness of a star and the rate at which it moves across the sky (its proper motion) could be combined to yield an estimate of distance. He was therefore able to provide the first realistic census of the numbers and types of stars in the solar neighborhood, extending eventually to stars only 0.01% as (intrinsically) bright as the Sun.

During the last 2 years of his Harvard appointment, Luyten worked at Bloemfontein, South Africa, where he met and married Willemina Miedema. Their three children all entered into professional employment. He used the Bruce telescope (which Harvard had moved to South Africa from Arequipa, Peru in 1910) to obtain about 300 plates of the southern sky, beginning a second complete southern survey that could be compared with the first 1896–1910 set of images to look for stars whose location had changed. Luyten himself examined all plate pairs with a blink comparator (which flashes two images back and forth quickly, so that the observer can look for changes in brightness and position). Luyten and his colleagues (including the author) eventually found 94,263 stars with significant motions, with the final catalog appearing in 1963. The so called Luyten "Proper Motion Catalogues" remain a fruitful source of interesting, faint, and nearby stars down to the present.

The "Bruce Proper Motion Survey" also yielded a rich harvest of the burnt-out stars called white dwarfs (sometimes known as degenerate dwarfs because their pressure comes from electrons crowded tightly together). Luyten collaborated with E. F. Carpenter of the University of Arizona, E. Gaviola of Cordoba Observatory, and **Guillermo Haro** of Tonantzintla Observatory in Mexico to obtain colors, and later spectra, of the faint stars in the survey. He was responsible for the largest collection of precise data for white dwarfs until Olin J. Eggen and **Jesse Greenstein** took up the problem in 1963 with the Palomar 200-in. telescope. Luyten recognized the categories whose surfaces were covered with thin layers of hydrogen (commonest), helium, or, in one case (Van Maanen's star), calcium and iron.

In order to extend the search for nearby stars still fainter and into the North Celestial Hemisphere, Luyten tackled the problem of making precision measurements of the thousands of 6° × 6° plates being exposed in the National Geographic/Palomar Observatory Sky Survey (named for its principal financial supporter and for the

Palomar Schmidt telescope where all the plates were exposed). He quickly realized that a traditional blink comparator would require hundreds of astronomer-years to examine all the plate pairs (perhaps even more so for him, since he had lost the sight of one eye in a tennis accident in 1925). Luyten approached the Control Data Corporation [CDC] with plans to build a device that would scan the plates rapidly and record the darkness of the exposed emulsion at each point (called a microdensitometer). The CDC machine, designed primarily by James Newcomb and Anton LaBonte, became the fastest of a new, 1960s generation of automatic machines for rapid plate measurements and comparisons. In a few years, the Minnesota group had found proper motions for about 300,000 stars, doubling the data base. The catalogs that emerged from this effort are among the most widely used in the field.

Luyten's technical publications numbered more than 500, in addition to popular articles for the *New York Times*, the *Minneapolis Star and Tribune*, and other papers. His honors included election to the National Academy of Sciences, the Bruce Medal of the Astronomical Society of the Pacific, and honorary degrees from Case Western Reserve and the University of Saint Andrews. He participated in eclipse expeditions to Ensenada, Mexico in 1923 and Lapland in 1927, and held Guggenheim fellowships in 1928–1930 and 1937/1938.

Luyten's relationships with the rest of the astronomical community were colored by impatience and a sharp tongue and pen when faced with work that he regarded as of less than the highest standard. Correctly measuring the apparent brightness of very faint stars is notoriously difficult, and he coined the name "The Weistrop watergate" for counts of the number of faint, cool hydrogen-burning stars nearby that he believed contained far too many such stars. For better or for worse, Luyten was right. Such stars are commoner than brighter ones like the Sun, but not so common that their collective mass dominates local galactic structure.

Lyot, Bernard

Born **Paris, France, 27 February 1897**
Died **Cairo, Egypt, 2 April 1952**

French planetary and solar astronomer Bernard Lyot built the first successful coronagraph and used it to record the first spectra and images of the solar corona taken outside total eclipses. Lyot, the son of a Parisian surgeon, built a small observatory at the age of 16 and joined the amateur Société Astronomique de France 2 years later, but studied engineering at the École Supérieure d'Électricité at the urging of his family. Graduating in 1917, in the midst of World War I, he soon found work at the École Polytechnique (Paris), working with physicist Alfred Pérot on aerial and maritime navigational aids for the French army. At the end of the war, Lyot became a teaching assistant in Pérot's laboratory and pursued a higher degree, demonstrating such dexterity and insight into optical instruments that Pérot recommended his appointment to the staff of the Meudon Observatory in 1920. He became assistant astronomer in 1925, astronomer in 1930, and chief astronomer in 1943.

Because reflected light is polarized, Lyot thought the reflected sunlight by which we see the Moon and planets should be too, and that existing polarimeters were simply not sensitive enough to see the effect. He built a photoelectric polarimeter with a sensitivity of a part in 1,000 and used it to show, from the amount of polarization as a function of the angle at which the light was reflected, that the Moon, Mercury, and Mars all have rather similar rocky surfaces, but that Mars has dust storms and the Moon probably a layer of volcanic ash. Lyot also thought he had detected water vapor features in the light reflected from Venus (but the actual amount is too small for him to have seen).

Lyot came to the idea of the coronagraph through wanting to observe Mercury as close in the sky to the Sun as possible, to see how the reflected light changed. Atmospheric dust at Meudon prevented this, so he went to the Pic du Midi Observatory high in the Pyrenees. This was better, but Lyot decided that a good deal of the scattered sunlight that kept him from seeing Mercury up close was actually being scattered in the observing equipment (contrary to the general wisdom of the time). He modified his telescope by covering the rim of his lens and placing a small circular disk where it would block direct sunlight, and was able to complete the planetary project. By chance, Lyot also saw a large prominence on the solar limb and resolved to attempt to study the corona without waiting for an eclipse the next year. The basic coronagraph design was similar: a lens with its edges blocked by a diaphragm and an occulting disk to block direct sunlight. He later added a second diaphragm to stop light diffracted around the edges of the first one. In 1930 and 1931, Lyot showed that the light getting through had the characteristic polarization seen during eclipses and saw the distinct coronal emission line at 5303 Å (whose cause was not then known). He took the first photographs of the inner corona outside an eclipse.

When solar activity began to resume in 1935, Lyot returned with an improved coronagraph, measuring very accurate wavelengths for the emission features (which eventually led to their identification with highly ionized atoms of common elements by **Walter Grotrian** and **Bengt Edlén**). Lyot also noted that the emission lines were very broad, suggesting that the corona must be exceedingly hot, as proved to be the case. He also began producing time-lapse films of prominence eruptions in a style pioneered by **Robert McMath**. These attracted a great deal of attention at the 1938 general assembly of the International Astronomical Union.

Lyot also developed a quartz-polaroid monochromatic filter, which would pass only the light of one emission line, for instance, Balmer α. The idea was originally his, though the first device was built and operated by **Yngve Öhman**. Lyot's passed an even narrower wavelength range, about 3 Å (versus 50 Å for Öhman's), and led to superlative movies of prominences and photographs of the corona.

Despite his having invented the device that made expeditions to observe solar eclipses unnecessary, Lyot was himself an enthusiastic participant in these, and it was a heart attack on the journey home from the exhausting mission to the Khartoum eclipse that led to his death. Lyot's work was recognized by election to the Académie des sciences, gold medals from the Royal Astronomical Society and from the Astronomical Society of the Pacific, and by the establishment of a commission of the International Astronomical Union which focuses on the kind of work he pioneered (chromospheric phenomena, later merged into solar activity).

Lyttleton, Raymond Arthur

Born **Oldbury, Worcestershire, England, 7 May 1911**
Died **Cambridge, England, 15 May 1995**

British theoretical astronomer Raymond Lyttleton worked primarily on dynamical problems, having put forward and explored the mathematics of a variety of ideas concerning the structure of comets, the origin of the Solar System, stability of rotating objects, accretion and evolution in binary systems, and the interior structure of the Earth.

Ray Lyttleton was the third child and only son of Irish parents, Agnes (*née* Kelly) and William John Lyttleton. He was educated in the schools of Birmingham and at Clare College, Cambridge, receiving a first class degree in the mathematical *tripos* in 1933. He was awarded a Ph.D. in 1937 for work done partly in Cambridge with **William Smart** on the three-body problem and partly in Princeton with **Henry N. Russell** on the formation of the Solar System (while he held a Proctor Visiting Fellowship). Lyttleton was a fellow of Saint John's College from 1937 onward and was appointed to a personal professorship in 1969. His war work applied mathematical ideas to supplies, the accuracy of antiaircraft shells, and minefield clearance.

Lyttleton's 1939 marriage to Meave Margaret Hobden remained childless. His recreations included cricket, piano playing, accurate writing of both fiction and nonfiction, golf, and, according to *Who's Who*, "wondering about it all." He received top-of-the-line medals from the Royal Society (London) and the Royal Astronomical Society, and served on enough committees and editorial boards to have concluded: that the optimum number of people on a committee is 0.7 and (2) that the average number of readers per technical paper also is 0.7, including the referee, but excluding the author.

Lyttleton's contributions were largely based on dynamical considerations, typical of applied mathematicians educated at Cambridge University. His thesis consists of two papers published in the *Monthly Notices of the Royal Astronomical Society*, which he wrote while visiting Princeton University under the influence of Russell. Theories of the origin of the Solar System widely accepted in the pre-World War II period were those of **James Jeans** and **Harold Jeffreys**, building on a late nineteeth century idea of **Thomas Chamberlin** and **Forest Moulton**, who postulated that a star either passed very close to or even collided with the Sun to pull out material that would later cool and form planets. Russell pointed out that most of the angular momentum of the Solar System is in the orbital motion of the planets, and that the theories of Jeans and Jeffreys could not give sufficient angular momentum to the material torn out of the Sun. Lyttleton showed that if the Sun were a member of a binary, and an intruding star either collided or passed very close to the companion, the angular momentum problem could be solved. The idea was later modified by **Fred Hoyle**, who postulated that the companion became a supernova and the remnants of the explosion were captured by the Sun to form the planets. Lyttleton also argued that Pluto was originally a satellite of Neptune, which escaped during a close approach Triton, the present satellite of Neptune.

The phenomenon of accretion takes place when a star enters a gas cloud. A significant amount of the gas cloud is accreted to the star, because the gas cloud is attracted to the star by its gravity. The material that falls upon the star generates heat. Lyttleton discovered this phenomenon with Hoyle, and attempted to explain the variation of the terrestrial climate by the Sun's encounter with interstellar clouds. Accretion is a mechanism whereby a large amount of radiation is generated, such as in x-ray sources or active galactic nuclei.

With Hoyle and Herman Bondi, Lyttleton also investigated the structure of red giants.

Another Lyttleton inquiry involved the stability of rotating liquid masses. The Earth is flattened toward the Equator owing to rotation. If the rotation were much faster, the flattening would be greater. Material that constitutes planets may be regarded as fluid when considered on a large scale. Mathematicians such as **Jules-Henri Poincaré** and **George Darwin** discussed the shapes that rotating liquid masses would assume. As the rotation gets faster, ellipsoids (with three different axes), and not spheroids (a form with axial symmetry), become possible figures of equilibrium. At a certain stage, these figures are no longer stable and begin to separate into two pieces. Some scientists assumed that binary stars might have formed this way. Darwin assumed that the Moon separated from the Earth owing to this instability, and the tidal friction subsequently brought the Moon to its present orbit. Lyttleton showed that separating two bodies could not form a binary: The two bodies formed by the instability would, in the absence of other gravitating bodies, recede to infinity from each other. He also showed on dynamical grounds the possibility that the two separating bodies would be the Earth and Mars, the Moon being a droplet between the two main bodies. It is interesting to note that at present, instead of the rotational instability, actual collision is suggested to account for the origin of the Moon.

It may seem curious, but until the middle of the 20th century, there was no consensus as to what comets were really made of. Accepting the model of a comet advocated by Russell, namely, that a comet is an aggregate of tiny particles, Lyttleton suggested that they are formed by accretion of interstellar dust grains. This theory has turned out to be untenable, and **Fred Whipple**'s theory of an icy nucleus model has come to be accepted. However, together with J. Hammersley, Lyttleton showed how quickly (astronomically speaking) comets are expelled from the Solar System by the perturbations of the major planets. Their theory is more rigorous than the work of Van Woerkom, on which **Jan Oort** developed the well-known idea of a cometary cloud surrounding the Sun. Lyttleton also pointed out that the distribution of perihelia of comets can be used to test a theory of their origin, or mechanism of supply, a method currently adopted in such investigations.

One of the other problems Lyttleton investigated with Bondi is a possible consequence of a hypothetical small difference between the charges of the proton and the electron. If there were indeed a small difference, that would contribute to the expansion of the Universe. Later, their assumption was tested to be negative, but it contributed to the reinvestigation of the basic assumption of physics.

A geophysical problem considered by Lyttleton is the possible shrinkage of the Earth needed to explain the formation of folded mountains. Before the plate tectonics theory came to be widely accepted, the well-known geophysicist **Harold Jeffreys** had calculated how much shortening of the Earth's circumference was needed to explain the formation of folded mountains. Lyttleton showed that if the core of the Earth were a high-pressure phase of the mantle material, a gradually growing core could provide the shrinkage. This is not tenable any longer; plate tectonics can provide viable explanation for the formation of folded mountains.

Again together with Bondi, Lyttleton investigated a fluid motion that could be induced in the Earth's core owing to a slowing down of the rotation by tidal friction.

Some of the ideas Lyttleton developed are now generally regarded as untenable. These include a tidal origin for the Solar System, a phase change rather than composition discontinuity between the mantle and core of the Earth, a rubble-pile picture of cometary nuclei, and a mass for Mercury small enough for it to be made of the same chemical mix as Venus, Earth, and Mars.

M

Maclaurin, Colin

Born **Kilmodan, Argyllshire, Scotland, February 1698**
Died **Edinburgh, Scotland, 14 June 1746**

Colin Maclaurin was, perhaps, the last of the great British mathematicians of the period following **Isaac Newton**. His geometrical methods influenced French work in celestial mechanics. An equilibrium shape of a rotating fluid body called a Maclaurin was thought for many years to be relevant to the formation of binary stars from single, rotating gas clouds.

Maclaurin's father, a parish Minister, died 6 weeks after Colin's birth, and his mother died when he was nine. His uncle, Daniel Maclaurin, Minister in Kilfinnan on Loch Fyne, took responsibility for him. In 1709, Maclaurin entered the University of Glasgow and, although a career in the church was originally intended, he was introduced to Euclid's *Elements* and turned his attention to mathematics and physics. After 4 years, he graduated MA with a thesis, "On the Power of Gravity."

In 1717, Maclaurin was appointed professor of mathematics at Marischal College, Aberdeen, aged only 19 (the youngest professor recorded at any university). Shortly afterwards, he became a good friend and disciple of Newton and, at this time, was elected to a fellowship of the Royal Society of London. Maclaurin travelled widely in Europe between 1722 and 1725. In 1724, he was awarded a prize from the Academy of Sciences in Paris for his work, "On the Percussion of Bodies."

Early in 1726, Maclaurin was appointed to the chair of mathematics at the University of Edinburgh, which he held for the remaining 20 years of his life. During this period, he was a major force in the world of mathematics. His contributions were not only to analysis and geometry but also to physics and astronomy.

During his time in Edinburgh, Maclaurin's efforts were important in the formation of scientific societies. A member of the Society for the Improvement of Medical Knowledge from 1731, he helped broaden its purview. The result was the new, more inclusive organization, the Philosophical Society of Edinburgh, founded in 1737. It was the latter society that, in 1783, was the catalyst for the foundation of the Royal Society of Edinburgh, which is still Scotland's premier learned society.

In 1733, Maclaurin married Anne Stewart, and this union produced 7 children.

An assessment of Maclaurin's place amongst the great mathematicians is obscured by, among other things, the difficulties in assigning priorities to certain mathematical discoveries. Nowadays, his name is known to all mathematicians because of Maclaurin's series. This result appeared in his book, *Treatise of Fluxions*, published in 1742, but the author acknowledged that it was a special case of an earlier result due to Brook Taylor in the latter's book, *Methodus Incrementorum* (1715). In any case, this result was, at least in some form, known to earlier workers, including **Jacob Bernoulli** and the Scottish mathematicians, **James Gregory** and James Stirling. On the other hand, Cramer's rule for systems of linear equations, Cauchy's integral test for convergence, and Bezout's theorem on the intersection of curves were developed by Maclaurin several years before those mathematicians whose names are now associated with them.

In the *Treatise of Fluxions*, Maclaurin gave a systematic account of Newton's theory of fluxions, mainly in response to an attack on these ideas by the Irish philosopher George Berkeley, in the latter's *Analyst* of 1734. Maclaurin's book also contained an account of his work on the gravitational stability of ellipsoids. This was accomplished by employing classical mechanics rather than fluxions. **Alexis Clairaut**, after reading Maclaurin's text, reverted to geometrical methods to attack the figure-of-the-earth problem.

Maclaurin also dealt with the tides (based on material that had previously been awarded a prize by the Paris Academy in 1740). In addition to the above, there were two other posthumous books, *Treatise of Algebra* and *An Account of Sir Isaac Newton's Philosophy*.

Maclaurin was also involved in some more practical branches of mathematics and in the organization of the defenses of Edinburgh against the Jacobite forces in 1745. When Edinburgh fell, Maclaurin fled to York. Although he soon returned, these exertions, together with a fall from a horse, seriously weakened his health, and he died shortly afterward.

Maclear, Thomas

Born **Newtownstewart, Co. Tyrone, (Northern Ireland), 17 March 1794**
Died **Mobray near Cape Town, (South Africa), 14 July 1879**

Thomas Maclear, the third director of the Royal Observatory at the Cape of Good Hope, established it as a leading astronomical observatory during his 36-year tenure. Thomas, eldest son of the Reverend James Thomas Maclear and Mary Magrath of Newtownstewart, was sent at age 15 to England to be cared for by his mother's brothers. Thomas was apprenticed to one of them, Dr T. Magrath, an eminent surgeon at Biggleswade, near Bedford, 50 miles north of London.

In 1814, Maclear went to London to study medicine at Guy's and Saint Thomas's Hospitals, and was admitted a member of the Royal College of Surgeons in 1815. He accepted the post of house surgeon at the Bedford Infirmary and, in 1823, joined his uncle's medical practice. In 1825, Maclear married Mary Pearse. He became acquainted with captain **William Smyth**, who established an observatory nearby. Maclear frequently visited Smyth's observatory, where he met Francis Beaufort and **John Herschel**, who became his lifelong friends.

In 1828, Maclear joined the Astronomical Society of London, setting up his own observatory at Biggleswade using a small transit instrument and a Dollond refractor on loan from the society. Maclear became expert in predicting lunar occultations, and calculated the occultations of Aldebaran (1829–1831) for ten European observatories. He corresponded about occultations with **Thomas Henderson**, then director of the Royal Observatory at the Cape of Good Hope. Maclear was elected a fellow of the Royal Society in December 1831.

After Henderson's resignation from the Royal Observatory at the Cape of Good Hope, the Admiralty offered the position to Maclear. His uncle disapproved; Maclear's annual salary as doctor brought in about £800, whereas the Cape post offered only £600, and Henderson had warned him of many difficulties. Nevertheless, Maclear decided to go, perhaps comforted by Herschel's plan to travel to the Cape to carry out a survey of the southern skies.

Maclear and his family, including his wife, five daughters, a governess, a nursemaid, and a manservant, arrived at the Cape on 7 January 1834 after a grueling 3-month voyage. His youngest daughter was suddenly taken ill and died within 2 days. The Herschels arrived at the Cape soon afterwards; Maclear and Herschel kept in close contact by letter.

When Maclear arrived at the Cape, he immediately inspected the Troughton mural circle, which had given trouble to his predecessors, **Fearon Fallows** and Henderson. Maclear confirmed their opinions that only by averaging the readings on all six microscopes could reliable results be achieved with the mural circle, a cumbersome process that delayed observational progress. His progress was further delayed when his one assistant, lt. William Meadows, proved unsatisfactory and left in December 1834. Meadows was eventually replaced by **Charles Piazzi Smyth**, the second son of captain Smyth. Maclear and Herschel observed the reappearance of Halley's comet (IP/Halley) in 1836, and made accurate observations of its path. After Herschel departed for England in March 1838, he reported favorably on Maclear's work, and recommended sending him more equipment and assistants.

One of Maclear's original instructions was to remeasure the meridian arc that **Nicolas de La Caille** had measured during

1751–1753. The arduous survey required most of the observatory's resources from 1837 to 1847. It showed that La Caille's measurements had been accurate but had not made allowance for the gravitational attractions of mountains on the plumb-bob.

The establishment of a magnetic observatory in 1841 was part of a global network of magnetic and meteorological observatories promoted by general **Edward Sabine** and supported by Herschel and others. Buildings and instruments were set up and run for 3 years by a detachment of the Royal Artillery, but when the magnetic observatory was transferred to the Admiralty in 1846, Maclear was instructed to add these observations to his duties. The magnetic work declined after 1857 and ceased on Maclear's retirement in 1869.

In 1833, Henderson had established a time service for vessels moored in Table Bay. Each night, a gun was fired to synchronize marine chronometers. Captain Robert Wauchope improved it with a time ball, which slid down a pole at an advertised time. His idea was adopted immediately by the Royal Observatory, Greenwich, in 1833 and by the Cape Observatory in 1836. A second time ball was erected at Simon's Town in 1857; they were connected to the observatory by electric telegraph in 1861. By August 1865, Maclear proudly declared that each day at one o'clock, the observatory ball, the Simon's Town ball, the Cape Town time gun, and the Port Elizabeth ball were discharged simultaneously.

In 1845, when Piazzi Smyth was appointed to succeed Henderson at Edinburgh, Maclear appointed William Mann as his first assistant. Mann helped erect and operate three new refractors: A 3-in. Dollond, a 3-in. Jones, and a 7-in. Mertz. A transit circle by Troughton and Simms was erected in the room formerly occupied by the "Mural Circle." Observations started in January 1855.

In 1859, Maclear spent a few months visiting England, Ireland, Paris, and Brussels. In June 1860, he was rewarded with a knighthood. The death of his wife in July 1861 caused him much grief, but his large family – six children were born in Cape Town – provided comfort to him. For his work on the extension of La caille's arc measurements, Maclear received the Lalande Prize of the French Academy of Sciences in 1867. In 1869, he was awarded the Gold Medal of the Royal Society. Other awards included membership of the Academy of Sciences of Palermo (1835), corresponding member of the Imperial Geological Institute and Geographical Society of Vienna (1858), and correspondent of the Institute of France (1863).

Maclear was greatly interested in exploration; with John Herschel he served on the Committee of the Association for Exploring Central Africa. In 1850, Maclear met David Livingstone and taught him how to use a sextant. They remained lifelong friends, and Livingstone sent his sextant and chronometer readings to Maclear for reduction. Maclear enthusiastically supported measures to improve the well-being of the Cape colony, taking particular interest in the provision of lighthouses, the standardization of weights and measures, and the improvement of hygiene.

After retiring from the observatory in 1870, Maclear went to live at Mobray, near Cape Town. He became blind in 1876. Half a dozen topological features in Cape Province carry his name; a 20-km-diameter lunar crater at 10°.5 N, 20°.1 E is named for him.

Mädler, Johann Heinrich von

Born **Berlin, (Germany), 29 May 1794**
Died **Hanover, Germany, 14 March 1874**

Johann von Mädler published a celebrated chart of the Moon and the first scientifically based selenography. He was also the author of the first map of Mars, made contributions to stellar astronomy, and compiled a useful history of astronomy.

Mädler was born into the family of a master tailor. Though frail as a child, at the age of 12 he was sent to the Friedrich-Werdersche Gymnasium in Berlin where he received a sound grounding in science and mathematics. His interest in astronomy was inspired by the Great Comet of 1811 (C/1811 F1). Although Mädler was an excellent scholar, he was unable to enter the university at the age of 19. An outbreak of typhus claimed both his parents, so instead of an academic career he considered it his duty to support four younger siblings. He enrolled in the tuition-free Kürstenschen seminary to prepare for a career as an elementary school teacher. At the same time, Mädler began giving lessons as a private teacher. In 1817, he got a job as a schoolmaster of calligraphy, and in 1819, Mädler founded a school for poor children. Meanwhile, he found time to attend lectures at the University of Berlin as an external student. Under the supervision of **Johann Bode**, **Johann Encke**, and Gustav Peter Lejeune Dirichlet (1805–1859), he studied astronomy and higher mathematics. With his enhanced education, Mädler was in a position to give private lessons at a higher level, a turning point in his life.

In 1824, **Alexander von Humboldt** introduced Mädler to the Berlin banker **Wilhelm Beer**, who applied to Mädler for lectures in higher mathematics and astronomy. Attracted by Mädler's lectures, Beer decided to set up his own observatory with Mädler as the main observer. A 97-mm refractor was installed in a small dome in the Tiergarten near Beer's home in 1828. There, Mädler and Beer began one of the more successful collaborations in the history of astronomy.

Mädler and Beer chose to map the surfaces of the Moon and Mars for their first projects. They observed Mars intently during that planet's perihelic opposition in September 1830, made drawings, and attempted to measure the coordinates of the most distinct spots. Their study left little doubt that the markings on Mars were permanent and disproved the previous belief that the spots on Mars were similar to the clouds of the Earth. In 1840 Mädler combined all the observations and drew the first map of Mars ever published. In the opinion of **Camille Flammarion,** Mädler and Beer deserve to be remembered as the true pioneers in this new conquest of Mars, a planet that had been the subject of intense study by "a phalanx of astronomers" for more than a century.

From 1830 to 1836, Mädler and Beer also observed the Moon. Mädler first measured the positions of a network of 106 reference points scattered across the lunar surface with a filar micrometer. Using these benchmarks, Mädler and Beer then measured the positions of 919 lunar formations, the heights of 1,095 mountains, and the diameters of 150 craters. On the basis of these measurements Mädler prepared the first scientifically designed lunar chart, *Mappa Selenographica*, which was published in four parts between 1834 and 1836. In 1837, a descriptive volume *Der Mond, nach zeinen kosmischen und individuellen Verhaltnissen oder allgemeine vergleichende selenography* (The Moon, concerning its cosmic and individual conditions or general comparative selenography) followed. In contrast to most of their predecessors, Mädler and Beer viewed the Moon as an airless, lifeless, and unchanging globe.

It is well known that both in the Mars project and in the lunar mapping and later in preparation of the *Selenograph* Mädler carried out most of the work, the observations, computation, map preparation, and writing. In the lunar-mapping project alone, Mädler spent 600 nights at the telescope. Although some observations were contributed by Beer, his role was primarily that of a patron who made the observatory available to Mädler.

In 1836, primarily because of the favorable reception of the lunar map, Encke employed Mädler as an observer at Berlin Observatory, a welcome relief from his previous occupation as a schoolteacher and part-time astronomer. Probably the best year in Mädler's life, however, was 1840 when he moved to Dorpat, Russia (now Tartu, Estonia) as the director of the observatory and professor of astronomy at the university, replacing **Friedrich Struve** when the latter left to found the Pulkovo Observatory. In the same year, Mädler married a poetess, Minna von Witte.

At Dorpat Observatory, Mädler used the 9-in. Fraunhofer refractor (the Great Dorpat refractor) for micrometric measurements of double stars from the catalog by Friedrich Struve. For 513 binaries he found the presence of orbital motions, for 15 binaries he calculated the orbit parameters. For 3,222 stars with positions observed by **James Bradley** from 1750 to 1762, Mädler found new positions on the basis of meridian observations at Dorpat Observatory and at other observatories, and calculated the proper motions. Subsequently these proper motions were used to study the motions in the stellar universe and to determine the solar motion parameters. Mädler correctly supposed that the motions of stars are governed by the collective gravitational field, but due to rather crude observational data of his time he was mistaken when he found that the center of our stellar system resides in the Pleiades cluster, not far from 180° from the true center of rotation in Sagittarius. In several papers and comments Mädler wrote about the sizes and periods of rotation of the planets.

In Dorpat, Mädler wrote popular books, read popular lectures, and actively contributed to local newspapers, besides doing the ordinary astronomer's work. The director's house near the observatory was a meeting place for literature for local friends. In 1865, Mädler retired from Dorpat University and went back to Germany to live in Wiesbaden, Bonn, and Hanover. In his retirement years, Mädler published an extensive and useful history of astronomy.

Mädler was a member of many scientific societies, the Madrid, Munich, and Wien academies and the Royal Astronomical Society among them. Nevertheless, he was not appointed to the Saint Petersburg academy because his relations with the influential academician Struve were not good. Struve also unsuccessfully opposed Mädler's appointment to the professorship at Dorpat University.

Magini, Giovanni Antonio

Born **Padua, (Italy), 13 June 1555**
Died **Bologna, (Italy), 11 February 1617**

Working at the cusp of Ptolemaic and Copernican astronomy, Giovanni Antonio Magini attempted to combine the best elements of both. Although Magini's theories have traditionally been identified as opposing **Galileo Galilei**'s, there is recent evidence that Magini

supported certain aspects of Galilei's work. Magini's contributions to mathematics and geography were also noteworthy.

Magini completed his early studies in Padua and then attended the University of Bologna, graduating in June 1579 with a degree in philosophy, although he had shown great interest in mathematics since childhood. After **Egnatio Danti** was transferred to Rome in 1587 the Bologna Senate called a competition for the chair of mathematics, which was assigned to Magini in August 1588. The Paduan scientist was chosen over the young Galilei, who had also applied for the chair, not only because of Magini's greater experience and notoriety at the time, but also because he had already published volumes of ephemerides and astronomical tables.

In addition to teaching Euclid, Magini also focused in particular on astrological and astronomical subjects, such as the theory of the planets, and on commentaries to **John of Holywood**'s *Sphaera Mundi* and **Ptolemy**'s astronomy. In 1597 he was given a lifetime teaching position and also received permission to go to Mantua. At the Gonzaga court, in 1599, Magini tutored the children of Duke Vincenzo, for whom he also wrote several astrological opinions. The sterling reputation he had earned among his peers was due also in part to his vast correspondence with all the illustrious scholars of his time, including Galilei, **Tycho Brahe**, and **Johannes Kepler**. Magini established an excellent rapport with Kepler, who in 1610 asked him to come to Prague to work with him on the new astronomical ephemerides. Magini did not accept Kepler's invitation, not only because he and the German astronomer had different viewpoints, but also because he did not want to leave the prestigious chair at Bologna.

According to 19th-century historian Antonio Favaro (editor of the complete edition of Galilei's works), Magini was one of Galilei's most dogged opponents. However, on the basis of recent studies by G. Betti, this view of Magini as Galilei's "enemy" seems exaggerated, particularly since Magini was probably the true author – or at least the direct inspiration – of the 1611 *Epistola Apologetica* against Martin Horky, written in Galilei's defense. Moreover, Magini's two best disciples, Cesare Marsili and Giovanni Antonio Roffeni, were Galilei's most ardent supporters in 17th-century Bologna.

Magini's attitude toward the Copernican system is intriguing. Although he was convinced that the Earth did not move, in some of his works he accepted **Nicolaus Copernicus**' theory as a working hypothesis. He justified this because it simplified calculations and yielded results that better matched observations, even though, in Magini's opinion, the theories were unlikely. Nonetheless, he never agreed with the concept of the Copernican system from a philosophical standpoint, replacing it with his own planetary model that combined the ideas of Copernicus and Ptolemy, and even added several new hypotheses. Magini claimed there was a need for a theory of planets that abandoned the model of the Alphonsine Tables in order to comply with recent observations, but rejected Copernicus' absurd hypotheses. Magini completely changed the Ptolemaic theories of the Sun and the Moon but adhered to the Ptolemaic system for the other five planets, albeit eliminating the equants. Furthermore, he accepted the idea that the stars and planets were pulled by their orbits or spheres and that they could not move independently. He also asserted that there had to be a ninth and tenth sphere between those of the fixed stars and the prime mover. For his theory of the Moon, Magini agreed with Copernicus in affirming that Ptolemaic theory did not comply with observation and experience. He later adopted the cosmological system of Brahe, with whom he established a rapport of both friendship and scientific collaboration. However, he modified the Tychonic system with elements from Kepler's astronomy. Magini defined his new theory in the *Tabulae novae iuxta Tychonis rationes elaborate,* but the work was unfinished when he died and was published posthumously in 1619. However, in 1623, 6 years after Magini's death, the Tribunal of the Holy Office ordered Magini's entire astrological library confiscated.

Magini was far more skilled at calculation than at theory, and the ephemerides he calculated for the years 1581 to 1630 are proof of this. He was a very talented instrument maker. He also wrote *Breve istruzione sopra le apparenze et mirabili effetti dello specchio concavo sferico* on concave mirrors. In 1592, Magini published *Tabula tetragonica sui quadrati dei numeri naturali*, which made it possible to determine the product of two factors, such as the difference between two squares. In 1609, he drew up accurate trigonometric tables in which he introduced new terms for the functions now known as cosine, cotangent, and cosecant. The nomenclature used by Magini attracted several followers and was adopted by **Bonaventura Cavalieri**. Magini also contributed to practical geometry with treatises on the sphere and on the application of trigonometry. He described the use of the quadrant and the astronomical square. Magini was the first person to suggest the use of the decimal point to separate the whole number from the decimals.

Magini was also active in medical astrology. He wrote a commentary on Galen's treatise, confirming that the stars govern the world of nature, and he recommended studying the annual recurrences of nativities and elections, essential for observing when the patient became ill, the critical days in the course of the illness, and the best times to administer medicine.

Magini's importance as a geographer and cartographer is undisputed. His edition of Ptolemy's *Guide to Geography*, which first appeared in Venice in 1596, is extremely important, not so much for Magini's careful descriptive comments but because he added 37 new maps to the 27 Ptolemaic maps, forming a true modern atlas.

However, the work to which Magini devoted most of the latter part of his life was an atlas of Italy, for which he prepared his own maps. Most of them were original and based on official surveys that various Italian governments had done. Because of this work, which Magini funded out of his own pocket, he was perennially in financial difficulty. The definitive compilation of the entire atlas, dedicated to Ferdinando Gonzaga, was published posthumously by Magini's son Fabio in 1620 with the title *Italia di Gio. Ant. Magini data in luce da Fabio suo figliolo*. The work, which had 61 tables and a brief commentary, enjoyed widespread and lasting fame.

Magini was buried in the Church of the Dominicans, with an epitaph dictated by his disciple Roffeni. His chair was offered to Kepler who, in a letter dated 15 May 1617 addressed to the rector of the University of Bologna, regretfully turned down the offer, fearful that as a Protestant he would feel ill at ease in a Catholic environment.

Maimonides: Abū ʿImrān Mūsā [Moses] ibn ʿUbayd Allāh [Maymūn] al-Qurṭubī

Born **Cordova, (Spain), 1145 or 1148**
Died **Fusṭāṭ, (Egypt), 1204**

Maimonides, the renowned Jewish theologian and physician, also wrote on the relationship between Judaism and the sciences, astronomy in particular. He spent his formative years in Spain and North Africa. He eventually settled in Fusṭāṭ, near present-day Cairo where he achieved his great fame in learning and communal leadership. Nonetheless, Maimonides remained attached to the intellectual outlook of the western part of the Islamic world throughout his life, and this is especially true of his work in astronomy. In his youthful search for guidance, especially in matters of cosmography (which were later to be a major concern), he sought out the son of **Jābir ibn Aflaḥ** as well as some pupils of **Ibn Bājja**. Indeed, his career affords us one of the clearest examples of the distinctive features of the western Islamic astronomical tradition. Maimonides contributed to the Arabic astronomical literature by editing (*i. e.*, preparing corrected versions of texts that had become problematic) books written by two of his Andalusian predecessors, the above-mentioned Jābir and Ibn Hūd, ruler of Seville.

Astronomical issues are stressed at several places in Maimonides' great work of religious thought, the *Guide of the Perplexed*. The most detailed discussion is found in Part Two, Chapter 24, which is devoted entirely to a review of the state of what may be anachronistically called cosmology or celestial physics. Aristotelian physics had established by means of what were then taken to be irrefutable proofs that the motions of the heavenly bodies must be circular, with the Earth at the center. **Ptolemy**'s models clearly violate these principles. All of the solutions that had been offered to date were critically scrutinized and rejected; these included the proposals of **Thābit ibn Qurra** and Ibn Bājja, for which Maimonides remains our only source. Did Maimonides consider the problem insoluble, or to put it differently, did he think the "true configuration" to be beyond human ken? Opinions have differed sharply on this point. It is noteworthy, however, that Maimonides breaks away from some of the Andalusians in that he does not think the solution to lie in rediscovering **Aristotle**'s cosmology. Maimonides firmly believed that astronomy had advanced considerably since Aristotle's day. Although the Stagirite's proclamations in physics remain true, his teachings in astronomy can no longer be maintained. In this respect Maimonides' position is closer to that of the Egyptian **Ibn al-Haytham**.

Maimonides' sole contribution to mathematical astronomy is his procedure for determining the visibility of the lunar crescent, which takes up several chapters of his great law code, the *Mishneh Torah*. Before the calendar was fixed, Jewish law required that the beginning of each month be certified by the court at Jerusalem. No month can exceed 30 days. Hence, if the crescent is not seen on the eve of the 29th, the declaration of the new month is automatic. Maimonides' procedure is necessary only for those instances where witnesses do report a sighting on the eve of the 29th. Specifically, the members of the court need to know whether a sighting is possible, so that they may convene in the expectation of witnesses; and they need a few details about the appearance of the crescent for purposes of cross-examination. Conversely, the court needs to know when a sighting will be impossible, so as to be able to reject any purported sightings.

With these facts in mind, it will be readily understood why Maimonides presents his method in "cookbook" fashion. Solar and lunar parameters, listed by Maimonides, can be plugged in, and the computation is then carried out step-by-step. Eventually the result is a simple yes or no answer; if the answer is yes, some additional information about the appearance of the crescent can be obtained. Theoretical explanations or justifications are kept to a bare minimum. Certain parameters, for example the geographical latitude, are built in, since the computation is meant to be true only for Jerusalem and its environs. Maimonides states that he has allowed himself some approximations, but, he assures us, the round-off errors cancel each other out, so that there is no net effect on the computation.

Maimonides issued some critically important and repercussive statements on the relationship between Judaism and the sciences, astronomy in particular. He asserted that ancient Rabbinic views on the structure of the heavens have no privileged position. The tenets of astronomy can be proven or rejected by universal and invariant rules of logic; hence their source, or, as we might say, the cultural context out of which they emerge, is irrelevant. On the other hand, astronomy is by no means a "secular" science. Knowledge of God, the attainment of which is a primary religious obligation, can be approximated – Maimonides denies that it can be fully achieved – only by inference from creation. The stars are the most noble bodies in creation, and the study of their motions is one of the most religiously fulfilling activities at our disposal.

Majrīṭī: Abū al-Qāsim Maslama ibn Aḥmad al-Ḥāsib al-Faraḍī al-Majrīṭī

Born **Madrid, (Spain), first half of the 10th century**
Died **Cordova, al-Andalus, (Spain), 1007**

Maslama al-Majrīṭī was considered by his Andalusian contemporaries as the foremost authority of his time in the field of astronomy. He traveled as a young man to Cordova, the capital of the Umayyad caliphate, where he studied and worked until his death. His achievements are mainly in the field of mathematical astronomy, although it is known that he wrote on commercial arithmetic (*muʿāmalāt*) and was also a renowned astrologer. Historians have at times misattributed to Majrīṭī works on magic and alchemy.

In addition to his own compositions, Majrīṭī's importance lies within the context of Andalusian science and his activity in scientific teaching. Majrīṭī was the founder of an original school of Andalusian astronomers in which the disciplines of arithmetic and geometry were also cultivated. Majrīṭī's disciples, who include outstanding figures like **Ibn al-Samḥ**, **Ibn al-Ṣaffār**, and Ibn Bargūth (died: 1052), spanned three generations and greatly influenced the development and expansion of the exact sciences throughout al-Andalus. Majrīṭī brought together for the first time in al-Andalus two distinct mathematical traditions, namely the tradition of *farā'iḍ* (religiously based division of inheritances) and the tradition of mathematically based philosophical sciences, a category that included astronomy. Majrīṭī's combining of these two mathematical branches reflects the interests of his two known teachers: ʿAbd al-Ghāfir ibn Muḥammad al-Faraḍī, who wrote a treatise on *farā'iḍ*, and ʿAlī ibn Muḥammad ibn Abī ʿīsā al-Anṣārī, who is reported to have known astronomy.

In the field of astronomy, Majrīṭī was the first Andalusian to make his own astronomical observations. According to **Zarqalī**, he observed the star Regulus in the year 979 and found its ecliptical longitude to be 135° 40′. Starting from the determination of the longitude of this star, Majrīṭī was then able to determine the longitude for all fixed stars, thereby establishing a movement of precession of the equinoxes of 13° 10′ with respect to the epoch of compilation of the catalog of stars in **Ptolemy**'s *Almagest*.

The above value for the longitude of Regulus appears in the table of stars that accompanies Majrīṭī's commentary on Ptolemy's *Planisphaerium*, which is a treatise on the stereographic projection of the sphere (the basic technique for the construction of the standard astrolabe). Some historians mistakenly thought that Majrīṭī may have learned Greek and translated the *Planisphaerium* himself, but recent investigation has shown that he most likely revised an eastern Arabic translation of the work. Indeed, Majrīṭī's text contains several additions to the work of Ptolemy that considerably improved the procedures for tracing the fundamental lines of the astrolabe and for locating the fixed stars of its rete, or star map on the instrument, using several kinds of coordinates. In the second part of this work, Majrīṭī deals with a number of problems of spherical astronomy using the Theorem of Menelaus, which was the unique trigonometric tool employed in his time and upon which he had previously written several notes in another work.

Majrīṭī's major work in astronomy was the adaptation that he made, together with his disciple Ibn al-Ṣaffār, of **Khwārizmī**'s *Sindhind zīj*. This 9th century astronomical handbook with tables and explanatory text was based primarily on Indian methods, and thus differed from later Islamic astronomical material, which relied on planetary models laid out in the *Almagest*. Although Khwārizmī's original text appears to be lost, a Latin version by **Adelard of Bath** (12th century) of Majrīṭī's revision is extant. This text, which is referred to as the *zīj* of Khwārizmī-Maslama (Majrīṭī), contains tables derived from Khwārizmī's original *zīj* (which had material based upon Persian and Ptolemaic traditions in addition to Indian ones) as well as material and tables that were adaptations, additions, or replacements introduced by Majrīṭī and Ibn al-Ṣaffār. The aim of the Andalusian astronomers was to adapt the original tables to the time and place in which they were living. For example, the Persian solar calendar used in Khwārizmī's tables was replaced by the Muslim lunar calendar, and some tables that were observer-specific were adapted to the geographical coordinates of Cordova. Khwārizmī's mean motion tables were calculated for radix positions corresponding to the meridian of Arīn (the center of the world in the Indian systems). A significant outcome of using Cordova's longitude was that Majrīṭī provides the earliest evidence of an important correction to the size of the Mediterranean Sea to its actual size; this was preserved in most Andalusian geographical tables. On the whole, the transformations affected the tables for chronology, mean motions, mean conjunctions and oppositions, and visibility of the lunar crescent. They also involved the addition of new tables related to the astrological practices of equating the houses and projecting the rays. Moreover, the contents of the final version of the *zīj* suggest the redactors included some elements that, though not strictly necessary, were in use in contemporary Andalusia. This is the case of the two trigonometric tables that are extant in the Latin translation, one for the sine (based on a radius of 60 parts) and the other for the cotangent (shadow length), which presumably were not used in the original *Sindhind*. Other Andalusian contributions found in the *zīj* are the reference to the Hispanic era (38 BCE) in the chronological part, the use of the meridian and latitude of Cordova for certain tables, and improved calculation methods that were both accurate and easier to use.

As a professional astrologer, Majrīṭī was also interested in the conjunction of Saturn and Jupiter, which took place in 1006/1007; with it he foretold a change of dynasty, ruin, slaughter, and famine.

Makaranda

Flourished **Kāśī (Vārānasī, Uttar Pradesh, India), 1478**

Makaranda, surnamed Ānandakanda, computed many tables of astronomical phenomena that he published in very useful forms. A reputed astronomer of Kāśī in North India, the hub of intellectual activity in India during medieval times, Makaranda was a follower of the Saura School, one of four principal schools of Hindu astronomy active during the classical period (late 5th to 12th centuries).

Makaranda's work, known simply as *Makaranda*, is an extensive treatise containing many astronomical tables that enable one to read the dates and times of different celestial phenomena. The tables span a large number of years after 1478, when they were commenced. The astronomical phenomena covered by Makaranda are *tithi*s or lunar days, *nakṣatra*s, or asterisms, *yoga*s marking complementary positions of the Sun and Moon, *sam̄krānti*s, or the times of entry of the Sun into the zodiacal signs, the mean motions of the planets and their anomalies, the length of daylight on different days, weekdays, and times of eclipses. As a way of making access to the work easier, Makaranda provided, in certain cases, two sets of tables, one for single years and the other for groups of years.

The labor involved in the preparation of these tables must have been enormous and entailed much ingenuity. But this labor has benefited later generations of astronomers and astrologers by reducing their own time and effort. Makaranda's works are among the most popular in North India, especially at Bihar and Bengal. More than 20 commentaries were prepared on Makaranda's work by later astronomers that explained the principles of construction of the tables and their practical use, which attest to their popularity among the masses.

Makemson, Maud Worcester

Born **Center Harbor, New Hampshire, USA, 16 September 1891**
Died **Weatherford, Texas, USA, 25 December 1977**

Maud Worcester Makemson, astronomy professor and director of the observatory at Vassar College, New York, worked in celestial mechanics and was a pioneering practitioner of archaeoastronomy (especially Polynesian and Mayan astronomy) and astrodynamics (the application of celestial mechanics to spacecraft).

Makemson took up astronomy late in life. Born Maud Lavon Worcester, daughter of Ira Eugene and Fannie Malvina (*née* Davisson) Worcester, she studied classics at the Boston Girls' Latin School (graduating in 1908) as well as at Radcliffe College; eventually she became conversant with Latin, Greek, French, German, Spanish, Italian, Japanese, and Chinese. After a year at Radcliffe, she began teaching in a rural one-room school in Sharon, Connecticut.

In 1911, Worcester moved with her family to a ranch in Pasadena, California. There she met farmer Thomas Emmet Makemson, whom she married the next year (1912), and moved with him to Arizona. By her fifth year of marriage, she had three children: a daughter Lavon (born: 1913) and two sons Donald (born: 1915) and Harris (born: 1917). She had also launched herself into a writing career, becoming a reporter for the *Arizona Gazette* in Phoenix in 1918, and eventually publishing two original plays. In 1919, she and Thomas divorced.

An astronomical spectacle in 1921, however, transformed the direction of Makemson's life. The night of a picnic in the desert north of Phoenix, she was dazzled by a remarkable aurora (widely witnessed throughout the United States on 14 and 15 May), its streamers so bright that they cast enough light to read. The next day, newspapers noted the display had coincided with the appearance of large sunspots. Her curiosity aroused, Makemson began devouring popular books on astronomy. That September, she resigned her newspaper job, moved her children to Palmdale, California (near her parents' home in Pasadena), and supported herself teaching grade school while taking correspondence courses in trigonometry and astronomy from the University of California. In August 1923, Makemson enrolled full-time at the University of California at Berkeley, receiving her BA in 1925 at the age of 34. Over the next 5 years, she earned her MA (1927) and Ph.D. (1930) in astronomy (for work in celestial mechanics under **Armin Leuschner**), receiving several fellowships and research assistantships.

After a year at the University of California as an instructor of astronomy (1930/1931) and another of teaching mathematics and astronomy at Rollins College in Winter Park, Florida (1931/1932), Makemson became an assistant professor of astronomy and navigation at Vassar College. For the next quarter century, Makemson remained at Vassar College , the first astronomy faculty member there not to have been a student of **Maria Mitchell**. By her retirement in 1957, she was director of the college's observatory (from 1936), chair of the astronomy department (from 1941), and a full professor (from 1944).

At Vassar College, Makemson did yeoman work in practical celestial mechanics, calculating the orbits of comets, asteroids, and double stars, as well as teaching astronomy, history of astronomy, and meteorology. She also introduced the heavens to thousands of school children, high-school students, and scout troops who viewed celestial wonders through the observatory's telescopes.

Moreover, Makemson began to spread her intellectual wings farther afield, making use of her knack for languages to pursue what would now be called archaeoastronomy (although her work is not widely cited by archaeoastronomers today). During the summer of 1935, she worked at the Bishop Museum in Honolulu, Hawaii, beginning research on Polynesian astronomy (gaining some contemporary notoriety by suggesting that the legendary star Kokoiki, which allegedly appeared just before the birth of Hawaii's first king, Kamehameha I, might have been Halley's comet (IP/Halley) in 1758). In 1941, Yale University Press published Makemson's book *The Morning Star Rises: An Account of Polynesian Astronomy*, based on the writings of missionaries, Polynesian historians, anthropologists, as well as her own astronomical research (which used her familiarity with Polynesian languages to verify translations of ancient chants).

In 1941 and 1942, Makemson held a John Simon Guggenheim Memorial Foundation Fellowship for the study of Mayan astronomy. Some of her findings were published in 1946 in *The Maya Correlation Problems* (on her attempt at a correlation between the ancient Mayan calendar and the Julian and Gregorian calendars) and in 1951 in *The Book of the Jaguar Priest* (her translation of the Mayan calendar from the original hieroglyphs). In 1953/1954 she was granted a Fulbright Fellowship to teach in Japan.

Upon her retirement from Vassar College in 1957, Makemson returned to California and entered yet her third career, this time in the booming new field of space technology. From 1959 to 1964, she was research astronomer and lecturer at the University of California at Los Angeles [UCLA] and consultant to Consolidated Lockheed-California (1961–1963).

Makemson generally taught positional (navigational) astronomy, and managed to make it seem perfectly natural that a 70-year-old woman should be doing this at a university with no other female faculty in astronomy, mathematics, or physics. Her touch was light, and a characteristic final-examination question said, "you are lost on a desert island with a sextant, chronometer, carrier pigeon and your copy of Smart's *Spherical Astronomy*. Explain how you will save yourself."

At UCLA, Makemson met Robert M. L. Baker Jr., who in 1958 had just received his Ph.D. in engineering, the first of its kind to be granted in the United States with the specialty in astronautics. Although a handful of schools then were teaching astrodynamics – a newly coined word referring to the application of celestial mechanics to spacecraft in orbit around the Earth or on trajectories to the Moon or planets – no textbook on the subject yet existed. Aware of Makemson's experience in celestial mechanics, astronomical history, and book publishing, Baker invited her to coauthor *An Introduction to Astrodynamics*. Over the next decade, their text stood as the only one in the field, going through two editions and multiple printings.

In 1965, in the heyday of the manned space program, Makemson moved to Texas and worked as a consultant to the National Aeronautics and Space Administration [NASA] through the Applied Research Laboratories of General Dynamics in Fort Worth. By 1971, she had devised a technique for the Apollo astronauts to determine their selenographic latitude and longitude by photographing the positions of stars through a zenith telescope, allowing them to navigate around the Moon's surface without radio or radar (although her method does not appear to have been used).

Intellectually active well into her 80s, Makemson's last project was translating *The Astronomical System of Philolaus*, originally published in Latin by **Ismaël Boulliau** in 1645. It was still incomplete at her death in a nursing home. She was survived by one son (who had legally changed his name to Donald Worcester), seven grandchildren, and eleven great-grandchildren.

In addition to her two books, articles by Makemson were published in an eclectic variety of scholarly journals and semipopular magazines, ranging from *American Anthropology* to the *Astronomical Journal* to *The Sky* to the *Bulletin of the Seismological Society of America*.

Maksutov, Dmitry Dmitrievich

Born **Nikolayev (Mykolayiv, Ukraine), 11/23 April 1896**
Died **Leningrad (Saint Petersburg, Russia), 12 August 1964**

Dmitry Maksutov was a Soviet optician who is credited as a leading designer of astronomical optical instruments after World War II. A graduate (1913) of cadet school, he was enrolled in the Military Engineering College of Saint Petersburg, but his study was interrupted by World War I. Like other members of his family, he fought in that conflict, and after the 1917 Bolshevik Revolution, attempted to immigrate to the United States through China but failed. Maksutov continued his education at the Tomsk Technical Institute (Siberia) and worked in Saint Petersburg and Odessa, Ukraine, where in 1930 he was arrested but miraculously survived while every other randomly chosen "suspect" was shot. He was arrested for a second time during Stalin's Great Terror in 1937.

From 1930 to 1952, Maksutov worked in the State Optical Institute (Leningrad), where he founded and headed the laboratory for astronomical optics. After 1952, he worked at the Pulkovo Observatory. He was elected a corresponding member of the Soviet Academy of Sciences (1946). On two occasions (1941, 1946), Maksutov was awarded the highest scientific trophy of the USSR, the Stalin Prize, which was renamed the State Prize after Stalin's death. In spite of these honors and his international recognition, Soviet authorities never permitted him to travel abroad.

While not the first to consider melding the best attributes of a refractor and a parabolic reflector, in 1941 Maksutov proposed a meniscus optical system of exceptional performance (the Maksutov telescope). This compact type of a catadioptric telescope differs from the Schmidt design in that the correcting plate is a deeply curved, diverging meniscus lens. Since the primary mirror is also spherical, all three optical surfaces are simple to manufacture. The spherical aberration of the meniscus lens exactly balances that of the primary mirror, yielding a compact and well-corrected optical instrument, though stable and very precise alignment of the optical system is critical. Combining many advantages, Maksutov telescopes became very popular throughout the entire world, although they cannot have a large diameter. American optical engineer John Gregory popularized a variant of this system, foreseen by Maksutov, wherein an aluminized spot on the meniscus lens serves as a Cassegrain secondary. In the United States, a small coterie of amateur telescope makers founded the Maksutov Club, led by Allan Makintosh, and for many years published *Maksutov Club Circulars*.

During the era of slide rules and logarithm tables, Maksutov was actively involved in the design of many astronomical instruments, including the 6-m telescope (then the world's largest) called the Large Altazimuth Reflector [BTA] at the Special Astrophysical Observatory near Zelenchukskaya. He wrote several textbooks on astronomical optics. He is commemorated with a crater on the Moon's farside.

Malebranche, Nicholas

Born **Paris, France, 6 August 1638**
Died **Paris, France, 13 October 1715**

Nicholas Malebranche, a prominent natural philosopher who wrote on the metaphysical nature of the Universe, developed a synthesis of Cartesian rationalism with accepted Christian dogma. His replacement of the Cartesian subtle matter with miniature elastic vortices received its most elaborate mathematical treatment in the work of **Johann** and **Daniel Bernoulli**, who attempted to make it consistent with the work of **Johannes Kepler**.

Malebranche was the youngest of 13 children born to the prosperous family of Nicholas Malebranche and Catherine de Lauzon. Because of a spinal condition, he was educated at home until the age of 16. He then moved to the Collège de la Marche, where he received the degree of *Maître ès Arts* in 1656. Malebranche studied theology at the Sorbonne University for the next 3 years and then in 1660 entered the oratory, a papally approved Augustinian order dedicated to reform the Catholic Church from within. He would remain in the order until his death. In 1664 there occurred two events of particular importance in Malebranche's life. He was ordained a priest, and had his first encounter with **René Descartes**' physics. His reading of Descartes' *Traité de l'homme* (*Treatise on man*) would contribute to his adoption of the view that all natural phenomena are to be explained in terms of matter and the laws that govern its motions. In 1669 Malebranche was elected to the Académie royale des sciences for his *Treatise on the Laws of the Communication of Movement*.

A popular move in 17th-century science was to attempt to subsume natural phenomena under general laws. Despite the great success of this in the work of figures like **Isaac Newton**, an issue that still bothered philosophers was the cause of the adherence of bodies to these laws. Some, like the Cambridge Platonists Henry More and Ralph Cudworth, argued that God created immaterial viceregents to keep bodies in line. Even Newton worried about this issue; he flirted with the latter view, also with the view that God Himself acts on bodies to make them adhere to laws. Famously, at the end of the day, Newton opted to "feign no hypotheses" on the issue. Where Newton did not like the metaphysical and theological consequences of the view that God does each and everything, Malebranche embraced them and so was a full-blown occasionalist.

Although he held that God does each and everything, Malebranche did not think that scientific explanations ought constantly to appeal to God's activity. Instead, he argued that they ought to be given in terms of the laws that God has instituted, the laws in accordance with which He constantly acts. Malebranche's view was that since the divine attributes include order and simplicity, God's constant activity is in accordance with general laws. He appears to have been committed to the view that even miracles are in accordance with God's general laws and that we call something a "miracle" when it is anomalous with respect to what we mistakenly take to be the laws in place. (An alternate interpretation has Malebranche committed to the view that God acts in accordance with general laws except when performing miracles.) Nonetheless, Malebranche thinks that in "explaining" a particular event, we should not say that God brings it about; we should instead appeal to the general laws under which it is subsumed. Science, for Malebranche, is the search to uncover these laws. He thus contributed to the tendency in 17th-century science to offer explanations in terms of matter and the laws that govern its motion.

An interesting wrinkle in Malebranche's view arises from a consideration of his deeper metaphysics. He adhered to a representational theory of perception, holding that in sensory perception we perceive objects indirectly *via* our mental representations of them. When we observe an object, we are really just having a mental perception that might or might not correspond to an actual object. Since a perception, like everything else, is caused by God, the question for Malebranche was not whether or not our perceptions correspond to their causes but whether or not there is a material reality that God has created to correspond to these perceptions. In fact, Malebranche held that we cannot know that there are any material objects, except by faith. Malebranche could even hold that the material Universe is perfectly harmonious and orderly. A common maneuver for people like **Johannes Kepler** was to insist on the mathematical order of the Universe even when the astronomical data suggested something less. Malebranche's system allowed him to not take empirical data so seriously. Our perceptions might sometimes be of anomalies and irregularities, but Malebranche could insist that these perceptions do not tell us all about the actual material reality that corresponds to them. Since God's Universe would be maximally perfect and harmonious, Malebranche could ignore unhappy sensory perceptions and hold that our best idealizations of the Universe describe it exactly.

Mallius

➔ **Manilius [Manlius], Marcus**

Malmquist, Karl Gunnar

Born **Ystad, Sweden, 2 February 1893**
Died **Uppsala, Sweden, 27 June 1982**

Swedish astronomer (Karl) Gunnar Malmquist is eponymized in the Malmquist bias, the idea that a sample of distant objects will inevitably be dominated by the brightest ones, compared to a sample of nearby objects. He wrote down very useful equations for correcting this bias in the early 1920s, although the basic idea was already implicit in earlier work by **Jacobus Kapteyn**.

Malmquist was the son of Emil Vilhelm and Anne Alfrida (*née* Persson) Malmquist. By his first wife, Hanna Karola Gertrud Ingeborg (*née* Lundvall), he had two sons, Sten (a professor of statistics at Stockholm University) and Olle (a medical doctor). Hanna died in about 1951, and a second late marriage to Lisa Malmquist was childless.

Malmquist studied under **Carl Charlier** at the Lund Observatory where he developed methods of mathematical statistics for the analysis of astronomical data, receiving his Ph.D. in 1921. He moved to the Stockholm Observatory in 1931, participating in building the observatory at Saltsjöbaden. Malmquist was appointed professor at Uppsala University in 1939, where he continued his earlier theoretical work on observations of the Milky Way. In addition, he contributed to the founding of the Kvistaberg Observatory and the Uppsala Southern Station on Mount Stromlo in Australia. Malmquist was an active member of the Royal Academy of Sciences in Stockholm, the secretary of Royal Academy of Sciences in Uppsala from 1948 to 1963, and a member of numerous scientific societies.

Malmquist is best remembered for his description of the Malmquist bias, which plays a significant role in both stellar statistics and cosmology and about which an extensive literature exists. The classical Malmquist bias is that using a sample complete to some apparent brightness inevitably yields mean values for any measured quantity that are more and more dominated by the brightest objects at the largest distances. In general this is described by an integral equation incorporating several factors including the line-of-sight density and reddening distributions, the intrinsic properties of the observed sources, and the sensitivity of the detector. The equation has no simple solution. Malmquist showed, however, that under the simplifications of homogeneous space distribution, no absorption along the line-of-sight, and Gaussian distribution of absolute magnitudes with dispersion σ and intrinsic mean of $M\{o\}$, the mean value of $M\{m\}$, for any apparent magnitude m, is related to the intrinsic mean by his well known result:

$$M\{m\} = M\{o\} - 1.382\sigma^2.$$

Different forms of bias plague the measurement of many astronomical quantities, including number counts of sources, estimation of distances, and the motions of galaxies; properly correcting for biases is an important step in gaining knowledge about the Universe. Correct determination of the Hubble constant is particularly sensitive to Malmquist bias.

Other astronomical topics to which Malmquist made significant contributions include the large-scale inhomogeneities of the distribution of bright young stars in the galactic plane and the significance of interstellar absorption outside the plane. The asteroid (1527) Malmquista is named is his honor.

Ma'mūn: Abū al-ˁAbbās ˁAbdallāh ibn Hārūn al-Rashīd

Born **Baghdad, (Iraq), 14 September 786**
Died **near Tarsus, (Turkey), August 833**

Ma'mūn was the son of Caliph **Hārūn al-Rashīd**, a patron of the arts whose fame has come down to us in the tales of the *Thousand and One Nights*. Hārūn also supported a fine library in Baghdad, called "The Treasure House of Wisdom," as well as the translation of foreign works in various fields. So Ma'mūn, brought up in an educated environment, was not only learned in the traditional Muslim studies but also was aware of a wider world of foreign learning. When he came to the throne as the seventh caliph of the ˁAbbāsid Empire in 813, he was among the well-educated men of his time.

Ma'mūn spent his early years as caliph consolidating his reign and building internal unity in a diverse empire. It has been argued that part of that endeavor involved commissioning Arabic translations of important Persian documents, as part of a project of Arabicizing Persian learning. Since, in addition, many Persian intellectuals believed that Greek learning was in fact based upon older Persian learning, Ma'mūn commissioned translations of Greek material as well. Apart from these political considerations, however, there was undoubtedly a genuine interest on Ma'mūn's part in the learning of the Greeks. There is also a story of a dream in which Ma'mūn saw the Greek sage, **Aristotle**, reassuring him that religion and learning were not enemies and that Ma'mūn's support of foreign learning was not a threat to Islam.

Ma'mūn was zealous in his search for new material and sent the scholar Salm to Byzantine lands to buy manuscripts. (Salm also helped to improve an Arabic translation of **Ptolemy**'s astronomical classic, *The Almagest*.) According to some reports Ma'mūn founded, in the early 830s before his death, the Bayt al-Ḥikma, the House of Wisdom. However, some historians have argued that this was less a new foundation than an extension of the Treasury of Wisdom that was already in existence at the time of Hārūn. In any case we do know that Ma'mūn supported scholars of many nations and professing many faiths, who studied, translated, and disseminated wisdom and learning, particularly that of the Greeks.

In addition to his general interest in the learning of the ancients, part of Ma'mūn's support for astronomy was based on its utility for astrology, a subject with which it was to be closely associated for many centuries. Whatever the motives for his support, the result of these translation efforts was the translation into Arabic of a number of Greek astronomical works. These included the introductory treatises of **Theodosius,** Euclid, **Menelaus,** and **Aristarchus**, as well as all of Ptolemy's works.

In addition to supporting the intellectual climate in which this work could be done, Ma'mūn also sponsored two sets of observations. The first was done in Baghdad, in 828, in the Shammāsiyya area, by astronomers including **Yaḥya ibn Abī Manṣūr** and the noted mathematician **Khwārizmī**. (Two others were **Sanad ibn ˁAli** and **ˁAbbās al-Jawharī**.) The Shammāsiyya observations were conducted around the times of the solstices and equinoxes, and it appears that Ma'mūn took an active interest in them. **Bīrūnī** informs us in his *Taḥdīd* that Ma'mūn rejected the first set of observations of 828 because of the big difference between the values for the maximum and minimum altitudes of the Sun (at the summer and winter solstices, respectively) at those observations and at the latter ones.

Yaḥya died before Ma'mūn left on one of his campaigns against the Byzantines in the early 830s. After his death, Mā'mūn decided to do new observations at Dayr Murrān on a hill near Damascus. Accordingly, he charged **Khālid ibn ˁAbd al-Malik al-Marwarrūdhī** with the task of doing observations over the period of a year with a new set of instruments. The observations, done in two periods between 831 and 833, lasted more than a year. They pleased Ma'mūn sufficiently for him to order that astronomical tables be prepared on the basis of their results. Since the observations both in Damascus and Baghdad seem to focus entirely on the Sun and Moon, these tables must have reflected earlier material for planetary motions.

Quite apart from these undoubted contributions to astronomy, Ma'mūn furnished an example of the type of a ruler that found many echoes in medieval Islam. The result was the development of the observatory as a new scientific institution, a development directly inspired by Ma'mūn, and, more generally, a tradition of royal patronage of astronomy.

Manfredi, Eustachio

Born **Bologna, (Italy), 20 September 1674**
Died **Bologna, (Italy), 15 February 1739**

Eustachio Manfredi, a skilled observer of the heavens, a geographer, and a geodesist, oversaw the restoration and continued development of astronomy in Italy following the departure of **Giovanni Cassini** to Paris.

The son of Alfonso Manfredi, a notary from Lugo di Romagna, and Anna Maria Fiorini, Eustachio was the eldest of a family of scholars devoted to science and mathematics. Manfredi completed his early studies at the Jesuit school in Bologna, focusing on philosophy. In 1692, he graduated with a degree in civil and canon law, but never practiced. At Bologna, Manfredi studied mathematics and hydraulics with Domenico Guglielmini, and together with his childhood friend Vittorio Francesco Stancari, he became interested in astronomy.

After Cassini left for Paris and **Geminiano Montanari** for Padua, Italian astronomy in universities faded. Lecturers focused mainly on hydraulics and the science of numbers, and few studied astronomy. Cassini's meridian line of San Petronio was no longer in use. Manfredi and Stancari—who were essentially self-taught—conducted observations with the meridian, and at Stancari's house they set up a small observatory with a sextant and several telescopes. From 1698 to 1702, they undertook systematic observations of the relative positions of stars; studied planetary movements; and observed lunar and solar eclipses, the eclipses of Jupiter's satellites, and lunar occultations—doing so to determine accurately Bologna's geographical position.

In 1690, Manfredi, Stancari, and others, including the famous physician Giovanni Battista Morgagni, founded the *Accademia degli Inquieti*, which became a driving force for Bolognese culture. The institution turned its attention to the physical sciences, studying new systems such as those of **René Descartes**, **Gottfried Leibniz**, and **Isaac Newton**, focusing in particular on experimental and observational reality. The Accademia contributed decisively to the establishment of the *Istituto delle Scienze*, founded by Count Luigi Ferdinando Marsili, a member of one of Bologna's most illustrious families. Marsili, a valiant general and a scientist, believed that scientific research was the cornerstone of technological progress. His military experiences gave him opportunities to collect scientific and documentary material in order to establish a center in Bologna. Astronomy played a predominant role in the Accademia, representing the basic element of reform for a scientific alternative to Aristotelian thought; as a result, in 1702 Marsili appointed Manfredi and Stancari to oversee the construction of an observatory in Bologna, in his own *palazzo*. Instruments were ordered from the Lusverg family in Rome: two movable quadrants, a mural semicircle (currently exhibited at the Astronomical Museum of the University of Bologna), and a 3-ft. telescope.

During this period, Manfredi also studied sunspots, noting that there were far fewer than those observed by earlier astronomers. This phenomenon is now referred to as the Maunder minimum. In 1703, Manfredi wrote a pamphlet entitled *Descrizione d'alcune macchie scoperte nel Sole*, publishing his observations, from which he also calculated the value of the inclination of the rotational axis of the Sun on the ecliptic. In 1699, he was appointed lecturer in mathematics, and in 1704 he was appointed rector of a Pontifical College and was named Superintendent of Waters, a position he held until his death.

In 1712, Marsili donated all his instruments and his collections to the Bologna Senate, and on 13 March 1714, with the financial support of Pope Clement XI, the Istituto delle Scienze was inaugurated in Palazzo Poggi (now the seat of the University of Bologna). The Istituto incorporated the Accademia, with the name Accademia delle Scienze, and the Accademia delle Belle Arti. Manfredi was one of the inspirers of the institute and, in drawing up its program, he looked to Cassini, with whom he corresponded. A new observatory alongside the Istituto delle Scienze was planned, and construction began in 1712 under Manfredi's supervision, but was not completed until 1725; the main instruments were installed in 1727.

In 1715 Manfredi compiled the *Bolognese ephemerides* for the years 1715–1725, based on Cassini's tables, completed in Paris and previously unpublished. They included tables of the planets' transit time across the meridian, the eclipses of Jupiter's satellites, and the lunar conjunctions, as well as maps of the regions on Earth where solar eclipses would take place. The *Ephemerides*, considered among the best in Europe for several decades, were accompanied by a valuable book of instructions, *Introductio in Ephemerides,* detailing their use. The ephemerides for the period of 1726–1750 were subsequently published in 1725.

At this time, with the help of several assistants, including his two sisters, Manfredi undertook systematic observations to verify if there were perceptible shifts in the positions of the stars. If observed, these displacements would allow him to measure stellar parallax and confirm the Earth's annual revolution around the Sun; the issue of heliocentric and geocentric systems was still being debated. The initial observations revealed small shifts in the positions of the stars, yet they were not attributable to the parallactic displacement. The results were published in 1729 in *De annuis inerrantium aberrationibus*. That year, **James Bradley** offered the correct explanation for this phenomenon, later called "annual aberration of starlight," after the title of Manfredi's publication. Two years later, in Tome I of the *Commentarii dell'Accademia delle Scienze*, Manfredi published a treatise entitled *De novissimis circa fixorum siderum errores observationibus*, adding other observations to those of Bradley. Manfredi was the first to confirm Bradley's hypotheses. He did not explicitly express an opinion that would link him too closely to Bradley's explanations, due to the local political and religious situation. (Bologna was part of the Papal States.) Nevertheless, it was the first evidence of the Earth's movement around the Sun.

In 1736 Manfredi published *De gnomone meridiano Bononiensi ad Divi Petronii*, in which he included the history and description of Cassini's meridian, as well as all observations made since the instrument was created in 1655. His analysis of nearly 80 years of observations revealed a progressive decrease of one second per year in the obliqueness of the ecliptic. Although the actual value is approximately half a second, this nevertheless revealed and measured – for the very first time – a process that if continues unchanged would abolish the seasons in less than 2,000 centuries.

The following year Manfredi oversaw the publication of **Francesco Bianchini**'s *Astronomicae ac geographicae observationes selectae*. He had also previously organized and completed Stancari's notes, published as *Schedae mathematicae et observationes astronomicae*. His university lectures were collected into a considerable work, *Instituzioni astronomiche*, published posthumously in 1749.

In 1738 Manfredi asked Jonathan Sisson to make a new set of instruments. However, the astronomer died 2 years before the instruments were delivered. Sisson's instruments, installed and used by Manfredi's successor **Eustachio Zanotti**, are also exhibited at the Astronomical Museum. Because of his scientific merit, Manfredi was honored as a member of the Paris Académie des sciences and London's Royal Society.

Manfredi's manuscripts and the astronomical logbooks are in the Historical Archive of the Department of Astronomy, University of Bologna.

Manilius [Manlius], Marcus

Flourished **Rome, (Italy), 10**

Marcus Manilius, a citizen of Rome, authored *Astronomicon libri V*, the oldest and most widely cited work on ancient astrology. Nothing certain is known of his life, education, or related writings. Rediscovered in the Renaissance, the *Astronomica* soon developed a wide audience and an unparalleled tradition of scholarly editors, among them the foremost astronomers of their day. For the average reader, the *Astronomica* served as a literary introduction to the heavens and an advanced primer to astrology. Manilius' masterpiece, a Latin didactic poem in five books, unveils the cosmos in hexameter verse, explaining the celestial sphere and zodiac, "describing the stars, constellations, and planets," and above all, providing a Stoic vision of the celestial dance. It is not an introduction to astronomy – here even the basics are sometimes confused – and, indeed, astrological doctrine is often muddled. More significantly, the heavens for Manilius were a reminder to persist against fate, to trust divine reason. Influenced by **Ovid** and **Virgil**, Manilius opposed **Lucretiu**s' harsh view of civil society. For subsequent scholars, the *Astronomica* was an elegant and influential text, albeit beset with a bizarre style and complex history.

The traditional difficulty with the *Astronomica* stems from the absence of an archetype text and an abundance of corrupt copies. The longstanding debate concerning Manilius' manuscripts (and indeed the identity of the author) extends back to the 10th century, although it is now clear that Manilius lived during the reign of Augustus and Tiberius, and probably wrote the *Astronomica* between 14–27. The debate widened with the advent of the printing press (*circa* 1450), and since that time the *Astronomica* has had a remarkably rich publication history. The first notable printing (*circa* 1472) came from the celebrated Renaissance astronomer, **Johann Müller** (Regiomontanus), and by 1650 nearly a dozen printings had appeared. The first firm textual basis for the *Astronomica* was provided by the French scholar, J.-J. Scaliger (1540–1609), whose *Astronomica* (1579; Heidelberg 1590) was later reprinted by Johann Heinrich Boecler (1611–1672) in Strasbourg (1655) with commentary by the French astronomer **Ismaël Boulliau**.

Thereafter, interest in Manilius spread as the New Science took root in the Republic of Letters. Gerhard Vossius (1577–1649) and his son, Isaac Vossius (1618–1689), for example, corresponded with Boulliau (and others in his circle), each contributing to Manilius studies. This group included J.-F. Gronovius (1611–1671), Nicolaas Heinsius (1620–1681), Claude Saumaise (1588–1653), P.-D. Huet (1630–1721), and Edward Sherburne (1618–1702), professor of astronomy at Oxford. Sherburne's first English translation of Book I (*The Sphere*, London, 1675) was soon followed by the first complete English translation (Books I–V, London, 1697; 1700) published by Thomas Creech (1659–1700), also from Oxford. The Creech editions underwent several large printings and launched the modern popular tradition.

The modern scholarly tradition of the *Astronomica*, however, stems from Richard Bentley, the foremost classical scholar of his day, and here again classical studies and the New Science converged. Bentley's interest in Manilius began five decades before he published his *Astronomica* (London, 1739), and two years before he initiated his famous "Newton–Bentley Correspondence" (1692–1693). If that exchange epitomized Enlightenment it also echoed Antiquity. Ironically, Manilius' pagan concerns – Reason, Nature, Design – resonate throughout Bentley's "Confutation of Atheism" (1693), both texts claiming that the World was not a "fortuitous or causal concourse of atoms."

Two final editions of Manilius must be noted. As the Enlightenment drew to a close, the French astronomer **Alexandre Pingré**, celebrated for his work on comets, published an elegant edition of the *Astronomica* in Latin and French. The dean of Manilius scholars, however, is A(lfred) E(dward) Housman (1859–1936), the noted British poet, whose edition of the *Astronomica* is painstaking and pure. The best source for the modern reader, at once rigorous and readable, is edited by G. Goold.

Mañjula

➔ **Muñjāla**

Maraldi, Giacomo Filippo

Born **Perinaldo near Imperia, (Liguria, Italy), 21 August 1665**
Died **Paris, France, 1 December 1729**

As one of the earliest members of the Paris Observatory staff, astronomer and geodesist Giacomo Maraldi, sometimes identified as Maraldi I, conducted the first systematic observations of the surface features of Mars. The son of Francesco Maraldi and Angela Cassini (sister of **Giovanni Cassini**), Maraldi studied near his hometown until 1687 when, at his uncle's request, he moved to Paris and joined the observatory staff as an observer. Maraldi's main task was the production of a new stellar catalog that remained incomplete on his death; it was never published. He appears to have been a careful observer and was certainly a mainstay in the observatory's work. Maraldi observed a wide variety of phenomena, including planets, satellites, eclipses, and variable stars (including the discovery of R Hydrae). He observed six comets, calculating several orbits. It was he who first realized that the corona belongs to the Sun, not to the Moon.

Maraldi supported his uncle in the controversy with **Ole Römer** concerning the velocity of light, which the latter believed to be finite. Römer's theory, which he used to account for discrepancies between predicted and observed times of eclipses and occultations for the Galilean satellites of Jupiter as observed from Earth at various times of the year, was later shown to be correct.

One of Cassini's programs was a geodesic survey of France. Maraldi was brought into the operation to extend the Paris meridian south, working with **Jacques Cassini** (Cassini II), J. de Chazelles, and Pierre Couplet during 1701/1702. In 1718, he assisted in a survey of the Paris–Amiens meridian to Dunkirk with Cassini II.

During 1702/1703, Maraldi resided in Rome, where he worked on producing a meridian for the Church of the Carthusians and making observations.

Maraldi is best remembered for his Mars observations. He observed Mars at every opposition from 1672, eventually determining a rotational period of 24 hours 40 m. On the surface, Maraldi identified what later became named as Syrtis Major, Mare Sirenum, and Mare Tyrrhenum. He also monitored the polar caps. Late in his life Maraldi brought his nephew, **Giovanni Maraldi**, onto the Paris staff. Maraldi was associated with the Paris Academy of Sciences from 1694.

Maraldi I

➜ **Maraldi, Giacomo Filippo**

Maraldi, Giovanni Domenico [Jean-Dominique]

Born **Perinaldo near Imperia, (Liguria, Italy,) 17 April 1709**
Died **Perinaldo near Imperia, (Liguria, Italy), 14 November 1788**

As an observational astronomer at the Paris Observatory, Giovanni Domenico Maraldi made an accurate determination of the difference in longitude to the Greenwich Observatory and contributed important observations of comets and nebulae. He was related, though somewhat indirectly, to the famed Cassini family and the great astronomer **Giovanni Cassini** – indeed it seems he was likely named after his famous relative. But the Cassini family produced at least six astronomers and one somewhat well known botanist between the mid-17th century and the mid-19th century with no fewer than three using the name Giovanni Domenico or Jean Dominique (depending on whether the individual lived in France or Italy). Giovanni Maraldi was sometimes referred to as Maraldi II and was the nephew of **Giacomo Maraldi** (Maraldi I), who was, in turn, the nephew of Giovanni Cassini.

Maraldi II came to Paris in 1727 from his home, also the birthplace of his uncle and of Cassini. Perinaldo, though in Italy, was a mere 55 km from Nice, France. In 1731, Maraldi II was made a member of the Paris Academy of Sciences and was employed at the Paris Observatory, then home of his uncle Maraldi I and of several of the younger members of the Cassini clan including his cousin **Jacques Cassini**, with whom he performed some of his most memorable observations. Maraldi II retired in 1772 and returned to Perinaldo. There is actually mention of yet a third Maraldi (Giovanni Filippo: 1746–1797), sometimes referred to as Maraldi III, who observed planetary satellites at Perinaldo, but only one obscure source makes this reference.

When Maraldi II first arrived in Paris he was assigned the task of carrying out geodesic measurements using the eclipse times of Jupiter's satellites. Using this technique, he found a longitude difference between Paris and Greenwich of 9 min 23 s compared to the modern value of 9 min 20.93 s. Later Maraldi was to observe several comets, starting in 1742 and including the great comet of 1743/1744 (discovered by Dirk Klinkenberg and **Jean-Philippe Loys de Chéseaux**). Maraldi II also observed Halley's comet (IP/Halley) in 1759 and calculated several comet orbits. When not observing comets Maraldi observed the transits of Mercury and Venus and helped to publish 25 volumes of the *Connaissance des Temps* and **Nicolas de La Caille**'s catalog of southern stars, *Coelum Australe Stelliferum*. In September 1746, he observed comet C/1746 P1 De Chéseaux (which had been discovered by Loys de Chéseaux) along with his cousin Jacques Cassini. In the process of observing this comet, Maraldi discovered two globular clusters that would eventually be included in **Charles Messier**'s historic catalog: M2 in Aquarius and M15 in Pegasus.

Maraldi II

Maraldi, Giovanni Domenico [Jean-Dominique]

Marius

Mayr, Simon

Markarian, Beniamin Egishevich

Born **Shulaver, (Armenia), 29 November 1913**
Died **Yerevan, (Armenia), 29 September 1985**

Armenian observational astronomer Beniamin Markarian is remembered for the discovery of many hundreds of galaxies, the Markarian galaxies, characterized by more emission in the ultraviolet [UV] part of the spectrum than found in normal spirals or ellipticals. Many of them also have compact nuclei and are related to the quasars. Mkn 421 was the first object outside the Milky Way recognized as a source of photons as energetic as teraelectron volts.

Markarian graduated with a degree in mathematics from Yerevan State University in 1938 and began postgraduate work with **Viktor Ambartsumian,** defending his thesis in 1944 and beginning work with Ambartsumian at the Byurakan Astrophysical Observatory, where he remained until his death. He was elected to the Armenian Academy of Sciences in 1971, received a state prize in 1950, and served as president of the Commission on Galaxies of the International Astronomical Union (1976–1979), in which position he was eventually succeeded by his close colleague Edward Khachikian (1991–1994).

Markarian's early work was in spectroscopy, at relatively high resolution, of white dwarfs and stars in open clusters. But in 1965 Ambartsumian asked him to take over a project that was to obtain low-resolution (objective prism) spectra of a very large numbers of galaxies to look for faint blue ones with strong UV emission. Ambartsumian expected that these would be related to Seyfert and other active galaxies and fit into his (now obsolete) model that indicated diffuse material in the Universe, including gas and star clusters, was initially expelled from much denser material at galactic centers. Markarian primarily used an objective prism with an angle of 1.5° (producing a dispersion of about 2000 Å/mm) at the prime focus of the 1-m Schmidt telescope at Byurakan. By 1967 he had compiled a list of 70 UV-excess galaxies, eventually examining more than 2,000 plates, covering 17,000 square degrees of the sky and containing about 15,000 objects per plate. The final list of objects with strong UV continua took the numbers up to about 1,500. A second spectroscopic survey was begun by Markarian and his Byurakan colleagues in 1978; he continued to participate in the discovery and characterization of new Seyfert galaxies and quasi-stellar objects until his death. Markarian never traveled outside the Soviet Union, and some of the follow-up spectroscopy was carried out at Mount Palomar by his colleague Khachikian, who has continued work on UV galaxies since Markarian's death. Many of the objective-prism images from the 1960s were recorded on Kodak spectroscopic plates imported into Armenia with considerable difficulty.

Markgraf, Georg

Born **Liebstadt near Dresden, (Germany), 30 September 1610**
Died **São Paulo de Loanda, (Angola), 1643 or 1644**

Naturalist Georg Markgraf made the first systematic astronomical observations of the southern skies. At the age of 16, Markgraf began a tour of Central European universities including Strasbourg, Basle, Ingolstadt, Altdorf, Erfurt, Wittenberg, Leipzig, Griefswald, Rostock, and Stettin, before finally matriculating at the University of Leiden in September 1636. Markgraf officially studied medicine. One of his instructors there was Jacob Gool, the noted astronomer and arabist. Another Leiden astronomer, Samuel Kechel, was also a close associate. By June 1636 Markgraf was in Brazil, where he was to remain for the next 8 years, probably in the employment of Johan Maurits van Nassau-Siegen, who was expanding Dutch interests in South America. Markgraf busied himself in compiling detailed maps of the region, collecting specimens of flora and fauna, and making astronomical observations.

Markgraf's astronomical ambition may have been to become a New World equivalent of **Tycho Brahe**. Establishing an observatory in the Vrijburg Palace at Mauritsstad, he was almost certainly the first European to pursue systematic astronomy in the Southern Hemisphere. Markgraf recorded the meridian altitudes of stars and planets as well as a solar eclipse (13 November 1640) and a lunar eclipse (4 April 1642). He planned a treatise to be entitled *Progymnastica mathematica Americana* – intriguingly similar to Brahe's *Astronomia insauratae progymnasmata* – but apparently never produced as much as a rough draft. Sometime after August 1643 Markgraf left Brazil for São Paulo de Loanda in Angola, a new Dutch possession in Africa, where he soon contracted a tropical fever and died. Johan de Laet acquired Markgraf's natural history papers; this valuable material was published in *Historia naturalis Brasiliae* (1648). Markgraf's astronomical observations and calculations, including those for some 26 horoscopes, remain unpublished in collections of the Gemeentearchief (Municipal Archives) Leiden and the Observatoire de Paris.

Markov, Andrei Andreevich

Born **Ryazan, Russia, 14 June 1856**
Died **Petrograd (Saint Petersburg, Russia), 20 May 1922**

Russian mathematician Andrei Markov had the good luck to work with Pafnuty Chebyshev (of the polynomials) at Saint Petersburg (1874–1878). Many of his contributions were in the area of probability theory, including a refinement of the central limit theorem invented by **Pierre de Laplace**. He is best known for the Markov chains. Roughly these describe systems and processes whose future can be predicted from (completely known) current conditions with no knowledge of the past history of the system. Some astronomical systems, for instance clusters of stars (treated as point masses), can be thought of as Markovian. In practice, the precise knowledge of everything about the system at one time is never available. Markov's contemporary A. Lyapunov wrote down criteria for deciding when imprecise knowledge of a system would lead to its future behavior evolving in totally unpredictable directions. Such systems are called chaotic and can be recognized by the so called Lyapunov exponent.

Markowitz, William

Born **Mlec, (Austria), 8 February 1907**
Died **Pompano Beach, Florida, USA, 10 October 1998**

William Markowitz devoted most of his career to improving astronomical measurements for determining time, and then to establishing new time systems based on atomic standards rather than astronomical measurements. His efforts, as director of the United States Naval Observatory [USNO] Time Service Department, resulted in greatly improved international cooperation on matters related to time.

Markowitz was the son of Hyman and Rebecca (*née* Baumstein, from Poland) Markowitz. In 1910, he immigrated with his family to Chicago, Illinois, USA. His early interest in astronomy developed at Crane Technical High School in Chicago and Crane Junior College, where Markowitz took a course in astronomy. He entered the University of Chicago and obtained his B.S. (1927), M.S. (1929), and Ph.D. in astronomy (1931). Markowitz married Rosalyn Shulemson in 1943; they had one son, Toby.

After teaching at Pennsylvania State College, Markowitz joined the USNO in 1936, working under Paul Sollenberger and with **Gerald Clemence**. He later served as director of the USNO's Time Service Department from 1953 until his retirement in 1966. Markowitz's principal research interests concerned the rotation of the Earth and the motion of its pole. The polar motion occurring at decadal time scales is named the Markowitz wobble for him.

One of Markowitz's early duties was operating the Photographic Zenith Tube [PZT]. In 1949, he and Sollenberger designed an improved version for the observatory's new station near Miami, Florida. The variation of latitude, determined with the PZT, was one of Markowitz's chief research interests. Analysis of these data led to his contributions on the study of polar motion.

Markowitz directed the Time Service Department during a period of increasing demands for more uniform and accurate time. Ephemeris time, based on the orbital motion of the Earth, was proposed in the early 1950s to provide a more uniform time scale than that based on the Earth's rotation. Markowitz devised a practical means for its determination by inventing the dual-rate Moon camera bearing his name. The first Markowitz Moon camera was placed in operation at the Naval Observatory in June 1952, and 20 such cameras were used around the world during the International Geophysical Year (1957/1958). With data from these cameras, Markowitz worked with Louis Essen at the National Physical Laboratory in England to calibrate newly developed atomic clocks in terms of the Ephemeris second. The fundamental frequency of cesium atomic clocks, 9,192,631,770 Hz, which they determined, has defined the "second" internationally since 1967. At the International Astronomical Union [IAU] meeting in Dublin in 1955, Markowitz proposed the system of UT0, UT1, and UT2, which went into effect within months and remains today.

Markowitz participated in experiments synchronizing time using artificial satellites and atomic clocks transported by airplanes. He served as president of the IAU Commission on Time from 1955 to 1961, and was active in the International Union of Geodesy and Geophysics, the American Geophysical Union, and the International Consultative Committee for the Definition of the Second.

After retiring from the Naval Observatory, Markowitz served as professor of physics at Marquette University (1966–1972), and adjunct professor at Nova University in Florida.

Marrākushī: Sharaf al-Dīn Abū ˁAlī al-Ḥasan ibn ˁAlī ibn ˁUmar al-Marrākushī

Flourished **(Egypt), second half of the 13th century**

Marrākushī was one of the major astronomers in 13th-century Egypt. As his name indicates, he was originally from Maghrib, but his major astronomical activities took place in Cairo during the second half of the 13th century. It is not too surprising, given the turmoil affecting al-Andalus and Maghrib at that time, that a scholar from the westernmost part of the Islamic world would decide to emigrate to Egypt, whose capital Cairo was already established as the major cultural center of the Arab–Islamic world. Unfortunately, Marrākushī does not figure in any biographical sources, so we must rely on the scanty evidence provided by his own work in order to shed some light on his life.

Marrākushī is best known for his remarkable *summa* devoted to spherical astronomy and astronomical instrumentation, entitled *Jāmiˁ al-mabādi' wa-'l-ghāyāt fī ˁilm al-mīqāt* (Collection of the principles and objectives in the science of timekeeping), which is intended as a comprehensive encyclopedia of practical astronomy. This work is the single most important source for the history of astronomical instrumentation in Islam. It was the standard reference work for Mamluk Egyptian and Syrian, Rasūlid Yemeni, and Ottoman Turkish specialists of the subject.

This voluminous work (most complete copies cover 250 to 350 folios of text, diagrams, and tables) has occasionally been qualified as a mere compilation of older sources without original contents. While it is true that this synthetic work heavily depends upon the works of predecessors, it is definitively original and without any precedent. In fact, no single part of the work can be proven to reproduce the words of an earlier author, except for the few sections where Marrākushī clearly states from whom he is quoting. In those occasional cases where an earlier source is mentioned, Marrākushī's text always turns out to be either a major rewriting of the original or an independent paraphrase.

The *Jāmiˁal-mabādi' wa-'l-ghāyāt* is well written and logically organized, and employs a relatively literate style that is unusual for a work on technical topics. The author is clearly a very competent astronomer and also occasionally displays his knowledge of ancillary disciplines such as philosophy.

The *Jāmiˁ* is made up of four books on the following topics:

(1) On calculations, in 67 chapters. This book gives exhaustive calculatory methods (without proofs) concerning chronology, trigonometry, geography, spherical astronomy, prayer times, the solar motion, the fixed stars, gnomonics, *etc.*
(2) On the construction of instruments, in seven parts. The first part concerns graphical methods in spherical astronomy and gnomonics. The second through the seventh parts then treat the construction of portable dials, fixed sundials, trigonometric and horary quadrants, spherical instruments, instruments based upon projection, and observational and planetary instruments.
(3) On the use of selected instruments, in 14 chapters.
(4) The work ends with a "quiz" – *i.e.*, a series of questions and answers – in four chapters, whose aim is to train the mental abilities of the students.

An interesting confirmation of Marrākushī's Maghribi origin is provided by his geographical table: 44 of the 135 localities featured in the list of latitudes are written in red ink to indicate that the author visited these places personally and determined their geographical latitude *in situ* through observation. These 44 locations begin along the Atlantic coast of today's western Sahara, include numerous cities and villages in the Maghrib, two cities in al-Andalus (Seville and Cádiz), and continue along the Mediterranean coast *via* Algiers, Tunis, and Tripoli to end up in Alexandria, Cairo, Minya, and Tinnis. Marrākushī's western Islamic heritage is also apparent in the fact that his chapters on precession and solar theory depend upon the works of **Zarqālī** and **Ibn al-Kammād**.

Marrākushī appears to have written his major work in Cairo during the years 1276–1282. First, a solar table is given for the year 992 of the Coptic calendar (Diocletian era), corresponding to the years 1275/1276. Also, some examples of chronological calculations are given for the year 1281/1282, and his star table in equatorial coordinates is calculated for the end of the same year.

The arrival of Marrākushī in Cairo coincided with the establishment of the first offices of *muwaqqits* (timekeepers) in Egyptian mosques. His work can thus be seen as fulfilling a specific demand of Mamlūk Egyptian society (more specifically, the mosque administration, the muezzins and *muwaqqits*, instrument-makers, interested students, *etc.*). But the lack of any reference to the profession of the *muwaqqit* or to the milieu of the mosque would seem to indicate that Marrākushī was an independent scholar without institutional affiliation. The motive he gives for writing his *magnum opus* is the inadequate education of instrument–makers and their methodological failures. His introduction suggests that his target audience was instrument–makers, *i.e.* artisans and practitioners of applied science, who were not professional astronomers. However, this is somewhat contradicted by the technical level of the book, which certainly assumes the reader to know at least the basics of arithmetic, geometry, spherics, algebra, and trigonometry. Thus the *Jāmiˁ al-mabādi' wa-'l-ghāyāt* seems more likely to be a comprehensive reference work of intermediate to advanced level intended for active and apprentice *muwaqqits*, and for specialists of timekeeping and instrumentation who were associated with them.

Marrākushī must have died, most probably in Cairo, between the years 1281/1282 and *circa* 1320, since two early 14th-century sources refer to him as being deceased (an anonymous treatise on timekeeping entitled *Kanz al-yawāqīt*, datable to 723 H/1323 and preserved in MS Leiden Or. 468, f. 91r, and a treatise on instrumentation by **Najm al-Dīn al-Miṣrī** composed in Cairo *circa* 1330).

Marwarrūdhī: Khālid ibn ʿAbd al-Malik al-Marwarrūdhī

Flourished **Damascus, (Syria), 832**

Along with **ʿAlī ibn ʿĪsā al-Asṭurlābī** and a party of surveyors, Khālid ibn ʿAbd al-Malik al-Marwarrūdhī traveled to the Plain of Sinjār under orders of ʿAbbāsid Caliph **Ma'mūn** to determine the size of the Earth by making accurate measurements of one degree of latitude. Marwarrūdhī designed instruments, including an armillary and an astrolabe, for observations made in Baghdad. Following the death of **Yaḥyā ibn Abī Manṣūr**, **ʿAbbās ibn Saʿīd al-Jawharī** selected Marwarrūdhī to prepare appropriate instruments for placement at the Dayr Murrān monastery on Mount Qāsiyūn near Damascus. There, he led the yearlong series of solar and lunar observations *circa* 832, though he encountered considerable difficulties with the warping and expansion of the copper and iron instruments. The first of three generations of astronomers, he also took part in the project circa 843/844 in Baghdad concerning observations for determining the length of the spring season.

Māshā'allāh ibn Atharī (Sāriya)

Died ***circa* 815**

Māshā'allāh (from mā shā' Allāh, *i. e.*, "that which God intends") was a Jewish astrologer from Basra. Ibn al-Nadīm says in his *Fihrist* that his name was Mīshā, meaning Yithro (Jethro). Māshā'allāh was one of the leading astrologers in 8th- and early 9th-century Baghdad under the caliphates from the time of al-Manṣūr to **Ma’mūn**, and together with al-Nawbakht worked on the horoscope for the foundation of Baghdad in 762.

Ibn al-Nadīm lists some 21 titles of works attributed to Māshā’allāh; these are mostly astrological, but some deal with astronomical topics and provide us information (directly or indirectly) about sources (*i. e.*, Persian, Syriac, and Greek) used during this period. This valuable information also comes from the Latin translations of some of Māshā’allāh’s works, some of which are no longer extant in Arabic.

A selection of the works by Māshā’allāh includes *De scientia motus orbis* (On Science of the Movement of Spheres), preserved in Latin translation, containing an introduction to astronomy as well as a study of **Aristotle**’s *Physics*, both based on Syriac sources. **Ptolemy** and **Theon of Alexandria** are mentioned, but the planetary models are pre-Ptolemaic Greek and similar to those found in 5th-century Sanskrit texts, *Kitāb fī al-qirānāt wa-’l-adyān wa-’l-milal* (A book on conjunctions, Religions, and communities), an astrological history of mankind, attempts to explain major changes based on conjunctions of Jupiter and Saturn; a discussion of eclipses is preserved in a Latin translation by John of Seville and a Hebrew translation by **Abraham ibn ʿEzra**, and a commentary on the armillary sphere. (For other works, see Sezgin.)

Misattributions have sometimes occurred because of confusion between the works of Māshā’allāh, **Abū Maʿshar,** and Sahl ibn Bishr. Indeed, the authenticity of two treatises on the astrolabe attributed to Māshā’allāh and translated into Latin has been questioned by P. Kunitzsch.

Finally, according to E. Kennedy, Māshā’allāh’s son was an astronomer who composed a manuscript unifying the theories of **Khwārizmī** and **Ḥabash**.

Māshā’allāh ibn Atharī (Sāriya)

Maskelyne, Nevil

Born **London, England, 6 October 1732**
Died **Greenwich, England, 9 February 1811**

As Great Britain’s fifth Astronomer Royal and founder of the *Nautical Almanac*, Nevil Maskelyne made practical the finding of longitude at sea. Maskelyne was the third son of Edmund and Elizabeth Booth Maskelyne of Purton, Wiltshire, England. His father died when he was 11 years old. Maskelyne was educated at Westminster School and admitted to Trinity College, Cambridge University. He graduated seventh wrangler in mathematics in 1754, took Holy Orders in 1755, and became a fellow of his college. Maskelyne was elected a fellow of the Royal Society of London in 1758. He was appointed the fifth Astronomer Royal of England and director of the Royal Observatory at Greenwich in 1765; he held that office for 46 years. Maskelyne was also awarded his Doctor of Divinity (1777); he was named rector of Shrawardine, Shropshire (1775) and of North Runcton, Norfolk (1782). He married Sophia Rose in 1784; their only child, Margaret, was born the following year.

At the request of the Royal Society, Maskelyne traveled to the island of Saint Helena with Robert Waddington to observe the 6 June 1761 transit of Venus, but was defeated by clouds. On the same voyage, however, he was able to make longitude calculations using the so called "lunar distances" method advocated by Sir **Isaac Newton** and **Edmond Halley**, amongst others, and made possible by the improved lunar tables calculated by **Johann Mayer**. Maskelyne published the lunar distances method in *The British Mariner's Guide* (1763). While on Saint Helena, he carefully observed the tides, and the variation of the compass, and undertook measurements on the annual parallax of Sirius.

Finding longitude at sea was a major problem for sailors in the 18th century. Many ships had foundered as a result of not being able to determine their positions with accuracy. In 1714, the British Board of Longitude established a prize of £20,000 to facilitate the discovery of a reliable method for determining longitude at sea. It fell to Maskelyne (as Astronomer Royal) to examine the various solutions and inventions proffered to this problem. In 1763, he sailed to Barbados in order to test the reliability of John Harrison's fourth chronometer, H-4, and found its accuracy superior to the lunar distances method. Maskelyne also undertook longitude determinations by observing eclipses of Jupiter's Galilean satellites, and found this method was impractical on the deck of a ship at sea.

When Maskelyne succeeded **Nathaniel Bliss** as Astronomer Royal in 1765, he at last fulfilled the public function for which the Royal Observatory was founded by King Charles II in 1675, namely, the preparation of tables for ocean navigation. Maskelyne inaugurated publication of *The Nautical Almanac and Astronomical Ephemeris*, the first volume of which appeared in 1766 for the year 1767. It contained a compendium of astronomical tables and navigational aids, such as **James Bradley**'s tables of atmospheric refraction. Maskelyne had assisted Bradley in the preparation of such tables during the latter's tenure as the third Astronomer Royal in 1755. Maskelyne supervised publication of the *Nautical Almanac* for 50 years, from 1767 to 1816. He also published the cumulative Greenwich observations for the period from 1776 to 1811 in four volumes, containing positions of the Sun, Moon, planets, and selected reference stars. Maskelyne's work on the proper motions of several bright stars was used by Sir **William Herschel** to estimate the Sun's movement toward the constellation of Hercules.

In 1774, Maskelyne experimented with a plumb-line to determine the mean density of the Earth by measuring the gravitational deflection induced by a mountain. In the summer of the previous year, astronomer **Charles Mason** (of Mason–Dixon line fame) toured the highlands of Scotland and regions in the north of England in search of a suitable mountain. He eventually selected the peak of Schiehallion in the Cairngorm mountain range in Perthshire, Scotland. This mountain was reasonably isolated from other hills, had the desired east–west orientation (with a small north–south extent that Maskelyne sought), and had a relatively regular form to facilitate the calculation of its volume. In this experiment, Maskelyne investigated the principle and the constant of universal gravitation, confirming that the force of gravity acting between bodies is proportional to the inverse square of their separation. Charles Hutton analysed Maskelyne's data and calculated a value for the mean density of the Earth between 4.56 and 4.87 g cm^{-3}, as compared with the modern value of 5.52 g cm^{-3}. For this demonstration, Maskelyne received the Copley Medal of the Royal Society in 1775.

One of Maskelyne's correspondents was the Irish astronomer, James Archibald Hamilton, who operated a private observatory at Cookstown, County Tyrone. Hamilton communicated his observations of the 1782 transit of Mercury to Maskelyne, who commented favorably upon the results. Hamilton was later appointed the first astronomer of the Armagh Observatory in 1790. Maskelyne was requested to obtain precision clocks for the Armagh Observatory, and eventually recommended chronometer maker Thomas Earnshaw who subsequently produced two astronomical clocks for the Observatory. With Maskelyne's support, Earnshaw was awarded £3,000, under the new Longitude Act of 1774, for his innovative clock designs.

Maskelyne contributed to a number of fields of study, *e. g.*, he invented the prismatic micrometer, and edited Mason's improvements to Mayer's lunar tables. Yet, his most enduring legacy was his contributions toward the longitude problem and his establishment of the *Nautical Almanac*. Several lunar craters are named for him, Maskelyne W being the crater used as a finder by the crew of Apollo 11 during the lunar module's final descent onto the surface in 1969. The Maskelyne Islands in the Pacific Ocean are also named for our subject.

Mason, Charles

Born	**Wherr, Gloucestershire, England, 1730**
Died	**Philadelphia, Pennsylvania, USA, 25 October 1786**

Charles Mason, a surveyor and astronomer, worked with **Jeremiah Dixon** on several astronomical expeditions including surveying the Mason–Dixon line delineating the boundary between Maryland and Pennsylvania. Although his father was a miller and a baker, Mason was educated at a private school, and became a professional surveyor. His first wife, Rebekah Peach, is believed to have been responsible for Mason's introduction to Astronomer Royal **James Bradley**, who appointed him assistant observer at the Greenwich Observatory in 1756; when Rebekah died in 1759 in Greenwich, on her tombstone was carved: "Wife of Charles Mason, Junr, ARS" (assistant of the Royal Society).

With the transit of Venus of 1761 impending, Bradley chose Mason to lead an observatory expedition to Bencoolen, Sumatra. On the voyage he was accompanied by Dixon, a surveyor and astronomer with a private observatory. They departed in November 1760 aboard *HMS Seahorse* with orders to proceed to Bencoolen unless it was in the hands of the French, in which case they would divert to Batavia. While still in the English Channel the *Seahorse* was attacked by the French frigate *Le Grand.* After a violent battle, which lasted barely an hour, the captain was able to return the ship back to Plymouth. However, upon witnessing the casualties and damage to both the ship and some of the astronomical equipment, Mason and Dixon wrote of their desire of not going to Bencoolen. Instead, Mason suggested the eastern portion of the Black Sea, from where they would be able to observe first contact, but not the planet leaving the face of the Sun.

The Royal Society not only denied their request but threatened them with a law suit, so the voyage to Bencoolen was recommenced. However, by the time they were rounding the Cape of Good Hope, they received news that Bencoolen had been taken by the French. Arriving at the Cape of Good Hope in April 1761, Mason and Dixon prepared to observe the transit from there. As luck would have it, their observations at the Cape of Good Hope were the only successful ones for the South Atlantic region; everywhere else was clouded out.

Afterward, Mason and Dixon joined **Nevil Maskelyne** on the island of Saint Helena, assisting him in various measurements, such as for tides, longitude, and the gravitational constant.

In 1763, as a result of the successful collaboration with respect to the transit of Venus, Mason and Dixon were charged with the responsibility of surveying what is still referred to as the Mason–Dixon line. The language of the original land grants to William Penn (later Pennsylvania) and to Lord Baltimore (later Maryland) was sufficiently vague that, by the mid-18th century, the argument between their respective heirs required the appointment of a commission in 1760 to adjudicate the border dispute. Three years later, Mason and Dixon were hired to survey and establish the boundary. Arriving in America in November 1763, they set up their equipment: two transits, two reflecting telescopes, and a zenith sector. Within a month, the two had measured the southernmost latitude of Philadelphia: 39° 56′ 29.1″ N and began the survey proper.

During the first few months, Mason and Dixon followed the old "temporary line" surveyed in 1739 by Benjamin Eastburn. This brought them through small townships such as Darby, Providence, Thornbury, West Town, and West Bradford. From there they continued to travel westward, as they were directed, to continue along the parallel of latitude as far as the country was inhabited. The surveyors continued until September of 1767 where, at Dunkard Creek, their Indian guide informed them it was the will of the Six Nations that the survey be stopped. They returned to England a year later in September 1768.

Because of their experience and their quality observations in 1761, Mason and Dixon were again asked to participate in an expedition for the 1769 Venus transit. Mason did not wish to participate; at the last minute, he grudgingly agreed to travel to County Donegal in Ireland. Only Dixon was willing, and he observed from the island of Hammerfest, off the Norwegian coast.

After the transit, Mason returned to England and continued his professional association with Maskelyne and the Royal Society. He was charged with aiding in the solution to a problem Sir **Isaac Newton** had devised decades earlier: Whether large land masses, such as mountains, could draw a plumb line up to 2 min out of the true perpendicular. Maskelyne had been intrigued with this problem for many years, and upon receiving funding to test it, in 1773 he commissioned Mason to select a suitable hill. Traveling to Scotland, Mason chose Schehallien, in Perthshire. And then, quite suddenly, Mason returned to England, quitting what some believe could have been his greatest scientific feat. Apparently, he had remarried, and desired to remain in England, where he worked on the *Nautical Almanac*, cataloging fixed stars and determining precise positions for the Moon.

Unfortunately, Mason's health was failing; apparently, his years in America had left him in a weakened state. Also, his second marriage added six children to his original two, and he was feeling the strain of poverty. For reasons unknown, Mason and his entire family sailed to Philadelphia, where he died shortly after arrival and was buried in Christ Church Burying Ground, in an unmarked grave.

Mästlin [Möstlin], Michael

Born **Göppingen, (Baden-Württemberg, Germany), 30 September 1550**
Died **Tübingen, (Baden-Württemberg, Germany), 20/30 October 1631**

Michael Mästlin was a noted observer and mathematician himself, but is perhaps best known as the teacher of **Johannes Kepler**.

Mästlin was the son of Jakob Mästlin and Dorothea Simon (died: 1565), who were pious Lutherans; he had a younger brother and an older sister. Young Michael was sent to the monastic school in Königsbronn, and eventually he enrolled at Tübingen University in 1568. There, Mästlin studied mathematics and astronomy under Philip Apian (the son of the famous astronomer **Peter Apian**), whom Mästlin eventually replaced. Mästlin received his master's degree, *summa cum laude*, from Tübingen University in 1571. He tutored and taught there until he was called to be a deacon at the Lutheran Church in Backnang in 1576. There, Mästlin married Margarete Grüninger (1551–1588) in April 1577, who bore him three sons and three daughters; she died (possibly due to childbirth complications), with their sixth child. Mästlin then married Margarete Burkhardt, a daughter of a Tübingen professor, in 1589; they had eight more children.

Mästlin's publication of his careful observations of the comet of 1577 brought him fame as an astronomer. His reputation rose across Europe, leading to his appointment as a professor of mathematics at the University of Heidelberg in 1580. In 1584 Mästlin returned to the faculty at Tübingen, where he remained until his death.

For a while in the late 1570s, Mästlin was apparently the chief scientific advisor to his patron, Duke Ludwig III of Württemberg. Ludwig's successor, Duke Friedrich I, also relied on advice and opinions from Mästlin. At Tübingen, Mästlin was elected dean of the arts faculty several times. He was well liked by both his colleagues and his students. Mästlin was very generous both to his family and to others. He was a religious man; he followed the Lutheran line in opposing the Gregorian calendar reform partly because it was initiated by the pope. Mästlin had several students who became noted mathematicians, the most famous being Kepler. Mästlin also maintained interests in Biblical chronology and geography.

Mästlin was a prolific scholar of astronomy, writing extensively and corresponding with other astronomers throughout Europe. He can be considered the first astronomer to offer an orbit of a comet (though he did not use a proper procedure), putting the comet of 1577 in a heliocentric orbit just outside the orbit of Venus; he claimed that this supported the Copernican model of heliocentrism. Mästlin was an eager mathematician, working with spherical trigonometry to convert his observations to a useful format, and followed the published works of **Johann Müller** (Regiomontanus), Region Ontarus, Peter Apian, and **Caspar Peucer** in doing this. Mästlin read scholarly books very carefully, making extensive notes in many of his own books in a neat, small handwriting. For example, he heavily annotated his personal copies of **Nicolaus Copernicus'** *De revolutionibus* (noting, among many other things, numerous typographical errors in cataloged star positions), **Tycho Brahe's** *De mundi aetherei* on the 1577 comet (carefully assessing the positional observations), and **Johann Schöner's** 1544 treatise containing observations of Müller and **Bernard Walther** (where Mästlin seemed quite interested in eclipse measurements).

Through Mästlin's course on astronomy used his own textbook that followed Ptolemaic themes, this was likely due to the fact that basic astronomy (as taught at a low level at that time) did not need the technical aspects of Copernicus's heliocentrism and Müller's spherical trigonometry. In more advanced courses, these more technical aspects were evidently taught by Mästlin, who was widely known as a heliocentrist. That reputation had its origin in Mästlin's tract on the 1577 comet in which he placed the comet in a Venus-like orbit about the Sun, as did Brahe in his grand book on the same comet a decade later. Both Mästlin and Brahe credited the idea for such an orbit to **Abū Maʿshar**. Kepler credited Mästlin with having introduced him to Copernicus' philosophy during Kepler's student years at Tübingen (1589–1594). Kepler's mentor wrote an appendix entailing discussion of Copernican astronomy in the younger astronomer's first major publication, *Mysterium Cosmographicum* (1596, Tübingen). Mästlin maintained a long, productive correspondence with Kepler on astronomical matters. Kepler probably owed much of his own development of astronomical thought over the years to the training that he received from Mästlin.

In the late 1570s, Mästlin prepared for publication his *Ephemerides novae*, which were ephemerides of the planets based on Copernican theory (following the work of **Erasmus Reinhold**). Mästlin duly noted that the ephemerides needed correcting because the observations upon which they were based lacked accuracy, and he stated that Copernicus' theory is truer than older ideas. Following Regiomontanus, Peter Apian, and others from the previous 100 years, Mästlin joined his own generation of observers (including Brahe) in working carefully to obtain the best positional measurements possible of celestial objects and thereby improve the state of knowledge in astronomy.

Mästlin was known in his lifetime as a first-rate astronomical observer —his good eyesight is indicated by his drawing in 1579 of 11 stars in the Pleiades— and as an astronomer who was willing to challenge intelligently the old way of thinking about astronomy through the use of observations obtained in a more detailed and systematic fashion. In his early years, Mästlin improvised by using a thread to determine the position of transient objects (1572 supernova; comet of 1577) by checking their alignments with various stars. He impressed Brahe by finding that the supernova (B Cas) showed no parallax and must therefore be as distant as the other stars, attacking the Aristotelian position that the stellar region is unchanging. By 1577 Mästlin was using a clock to record times of observation; his was the first generation of astronomers where timekeeping was taken to be important, and times were noted often, despite the poor quality of timepieces then. Mästlin's tracts on comets and the 1572 supernova notably parallel Brahe's own tracts on these objects in that, unlike other typical treatises on such objects in that era, they concentrated on observations and reductions of observations while keeping astrological speculation to a bare minimum. Mästlin is also credited with being the first to publish his own finding that the unlit part of the crescent Moon glows faintly due to sunlight reflected off the Earth onto the Moon.

Though he was unable to undertake a huge observational program, such as Brahe did at Hven, Mästlin was an important influence on Brahe's work through his correspondence. Mästlin challenged his contemporaries to improve observational data rather than to just accept what had been passed down from the ancients through medieval times. He was also familiar with constructing sundials, celestial globes, quadrants, cross-staffs, and maps – all knowledge that was likely passed on to a large degree from his professor Philip Apian at Tübingen. Within 4 years of **Galileo Galilei**'s first pointing a telescope skyward, Mästlin had obtained two small telescopes which, though rather poor, showed him sunspots and the satellites of Jupiter. Mästlin remained an eager astronomical observer into his late years, making notes of his observations of the comets of 1618 and of a lunar eclipse in 1628.

Much of Mästlin's library now resides at the Municipal Library in Schaffhausen, Switzerland.

Mathurānātha Śarman

Flourished **Bengal, (India), 1609**

Mathurānātha Śarman composed the *Ravisiddhāntamañjarī* or *Sūryasiddhāntamañjarī*, an astronomical treatise consisting of four chapters and tables, in 1609. This work uses parameters belonging to the *Saurapakṣa*, one of the traditional schools of astronomy in India. The tables are for calculating the longitudes of the planets; there are also parallax tables for computing solar eclipses. He may have composed two other works, the *Pañcaṅgaratna* and the *Praśnaratnāṅkura* or *Samayāmṛta*.

Maudith, John

Flourished **1309–1343**

John Maudith produced astronomical tables in the early 14th century. In 1310 he compiled tables for the rising and setting times of stars. Maudith's tables were essentially Toledan tables recomputed for the Oxford meridian. He drafted a separate catalog of bright stars, epoch 1316, with stellar positions calculated according to **Thebit ibn Qurra's** theory of trepidation.

Very little is known of Maudith's life. Between 1309 and 1319 he was a fellow of Merton College, Oxford. The Merton *Catalogus vetus* describes him as a good astronomer and physician. After leaving Oxford, Maudith joined Richard de Bury's scholarly circle at Durham; **Thomas Bradwardine** was one of his colleagues there. Maudith later served John de Warenne, Earl of Surrey and Sussex, probably as a physician. He wrote a *Tractatus de doctrina theologica* dated to 1343.

Maunder, Annie Scott Dill Russell

Born **Strabane, Co. Tyrone, (Northern Ireland), 14 April 1868**
Died **London, England, 15 September 1947**

Solar astronomer Annie Russell joined her husband, **Edward Walter Maunder**, in supporting amateur astronomers in Britain by editing their journal and leading solar eclipse expeditions, while continuing her own solar research and popular writing on astronomy.

Russell was the first daughter of the Reverend William Andrew Russell, a minister of the Irish Presbyterian Church, and his second wife, Hester (*née* Dill). Annie had two half-brothers from her father's first marriage and two brothers and one sister from the second. For her secondary education, she attended the Ladies' Collegiate School, Belfast (renamed Victoria College in 1887), known as the premier institution for the education of girls in Ireland. Russell decided not to work for an Irish university degree but, instead, took the Girton College open entrance examination. By studying diligently, she overcame a deficit in her early training and upon graduation won the highest mathematical honor available to a woman, Senior Optime in the mathematical *tripos*. (When Russell graduated, women were allowed to sit for the Cambridge *tripos* examinations, although they were not granted a university degree.)

Upon leaving Girton College, Russell became a mathematics teacher at the Ladies' College, Jersey, but found teaching unrewarding. After learning of a possible vacancy for a "lady computer" at the Royal Greenwich Observatory, she applied for the position, even though the pay was much less than she earned as a teacher. She accepted the post and, while measuring daily sunspot photographs, met Maunder, head of the solar photography department. In 1890, Maunder had assisted a number of leading amateur astronomers in founding the British Astronomical Association [BAA] after the collapse of the Liverpool Astronomical Society. Together, Russell and Maunder worked on the association's journal. She was its first editor, from 1894 to 1896, and served an additional term, from 1917 to 1930.

In 1895, Russell married Maunder, and they worked together on numerous astronomical projects. Annie, however, was obliged to resign her position as Walter's paid assistant at Greenwich. Walter and Annie had no children of their own, but 45-year-old Walter was a widower with five children when he married the 27-year-old Annie. Although she continued with her astronomy, much time was spent in rearing her stepchildren. In another sense, her marriage to Walter proved fortunate for Annie Maunder's career. Through her husband, she was able to borrow instruments, establish contacts with other astronomers, and travel to various eclipse sites. Probably the most important factor was Walter's view that women deserved an important place in astronomy.

Maunder made many contributions to astronomy. Shortly after her marriage, she received the Pfeiffer Research Student Fellowship, established to upgrade the Girton College research potential. As the first recipient of this fellowship (1896), she used the money to undertake a photographic study of the Milky Way. At Greenwich, she was assigned to the solar department as a photographic assistant. Maunder's work involved photographing the Sun and examining the negatives with a micrometer. Recruited during the approach of a sunspot maximum, she noted the positions of the sunspots and worked on interpreting the phenomena.

Although much of her astronomical work was done in collaboration with Walter, Annie was an important contributor to astronomy in her own right. She published numerous papers and a book, *The Heavens and Their Story* (1908). Although Walter's name appeared as coauthor, he insisted that Annie had done all of the writing. Her professional level of competence was gained from formal university training, working as a paid assistant, and from informal training by her husband.

Maunder's prodigious output included theoretical work. She developed a theory that the Earth influences the numbers and areas of sunspots, and that sunspot frequency decreases from the eastern to the western edge of the Sun's disk (as viewed from Earth). With Walter and the BAA, she went on solar eclipse expeditions and became an expert eclipse observer. One of her photographs revealed a coronal streamer extending out to six solar radii – the longest then observed to that date. Maunder published numerous reports on these eclipses, and many papers on the history of astronomy, especially early accounts of the constellations.

Gender must be considered when examining Maunder's career. While she possessed all of the requisites to be a professional scientist, as a woman, she received less than full recognition of her qualifications and contributions from male professional astronomers. Fortunately, her husband recognized the importance of women to astronomy. Through a variety of channels including the BAA, she and other women astronomers were able to make their contributions.

Maunder's papers may be found in the Archives of the British Astronomical Association, the Archives of the Royal Astronomical Society, and the Archives of the Royal Greenwich Observatory.

Maunder, Edward Walter

Born **London, England, 12 April 1851**
Died **London, England, 21 March 1928**

Walter Maunder is chiefly remembered for his work in the field of solar studies. His plot of the latitude drift of sunspots is known as the Maunder butterfly diagram. The lapse in sunspot numbers during the interval from 1645 to 1715, which he investigated, has been termed the Maunder minimum.

The youngest of three sons of the Reverend George Maunder, a Wesleyan minister, Maunder's basic education was acquired at the school attached to University College in Gower Street, London, and supplemented with additional courses at King's College, London. He worked briefly in a City of London bank before taking the first-ever examination set by the British Civil Service Commissioners (1872), designed to fill vacancies created at the Royal Greenwich Observatory. With his appointment as photographic and spectroscopic assistant in 1873, the observatory entered the realm of astrophysics, or the New Astronomy, as it was called by **Samuel Langley**.

Maunder spent 40 years at Greenwich and became superintendent of the solar department, working chiefly under the direction of **William Christie**. Starting in 1874, Maunder operated the photoheliograph, taking daily photographs of the Sun (originally on wet plates, later on dry), then measuring and tabulating the numbers, areas, positions, and motions of sunspots. Data acquired over the next 30 years enabled Maunder to affirm what was known about the axis of solar rotation, the equatorial drift and periodicity of sunspots, and the Sun's differential rotation from the work of **Samuel Schwabe** and **Richard Carrington**. Another important finding was the observed correlation between solar activity and terrestrial magnetic disturbances, a subject discussed in a series of papers starting in 1904.

In 1887 and 1889, **Gustav Spörer** drew attention to a long continued absence of sunspot activity, from about 1645 to 1715. Maunder summarized Spörer's papers for the Royal Astronomical Society in 1890, and began his own search of historical records. Maunder published an article, entitled "A Prolonged Sunspot Minimum," which supported Spörer's conclusions. It attracted little attention. Nor did an article with a similar title, published in 1922. Only in the mid-1970s, after solar physicist John A. Eddy took a fresh look at the evidence, were Maunder's findings confirmed. This anomaly was named the Maunder minimum. Spörer's name is given to an earlier, similar epoch.

Maunder also undertook observations of solar prominences, the spectra of comets, planets, novae, and nebulae, and was a keen follower of total solar eclipses, observing those of 1886 (Carriacou, West Indies), 1896 (Vadsö, Norway), 1898 (India), 1900 (Algeria), 1901 (Mauritius), and 1905 (Canada). He was elected a fellow of the Royal Astronomical Society in 1875, served as a council member for several years, and was its secretary (1892–1897).

In 1890, Maunder and his brother, Thomas, played a central role in the formation of the British Astronomical Association [BAA], whose purpose was "to afford a means of direction and organization in the work of observation to amateur astronomers." He served as its third president (1894–1896), and was acting secretary (1914–1915). Maunder headed the Mars Section (1892–1893), the Star Colour Section (1900–1902), and the Solar Section (1910–1925). He likewise edited the association's *Journal* for a number of years, having previously edited *The Observatory* (1881–1887).

In all of these investigations, Maunder received invaluable help from his second wife, Annie, who was academically more qualified than her husband. **Annie Maunder** graduated from Girton College, Cambridge, as senior optime in the mathematical *tripos*, and joined the Royal Greenwich Observatory staff as "lady computer" in 1891. She and Walter were married in 1895 and worked closely together on the solar data, although Annie was obliged to resign her post as Maunder's paid assistant. Together, they provided leadership to a series of successful solar eclipse expeditions sponsored by the BAA.

Maunder retired from Greenwich at the end of 1913, but was recalled to maintain the sunspot record during World War I. Between 1914 and 1916, he served as secretary of the Victoria Institute, London, a society founded in 1865 to investigate questions of philosophy and science, especially those bearing upon religion.

Maunder and his wife published several books, including a history of the Royal Greenwich Observatory (1900), and many articles and papers in the *Monthly Notices of the Royal Astronomical Society*, and the *Journal of the British Astronomical Association*. They were frequent contributors to *Knowledge* and *Nature*.

Maupertuis, Pierre-Louis Moreau de

Born **Saint-Malo, (Ille-et-Vilaine), France, 28 September 1698**
Died **Basle, Switzerland, 27 July 1759**

In astronomy, Pierre de Maupertuis contributed to the understanding and diffusion of **Isaac Newton**'s theory in France and in continental Europe. He arranged for, and participated in, measurements to ascertain the shape of the Earth. In physics, Maupertuis was the first to formulate the least-action principle. He also made contributions to mathematics, biology, heredity, and moral philosophy. As a prolific intellectual, Maupertuis opened new roads in science.

Maupertuis' father, René Moreau, was a layperson. Maupertuis was raised by his overcautious mother and first educated at home. For philosophical instruction, he attended the Collège de la Marche in Paris in 1714. At his mother's request, he returned to Saint-Malo in 1716 and gave up his wish to go to sea. After a visit to Holland in 1717, Maupertuis moved back to Paris where he began musical studies, but switched to mathematics.

In 1718, Maupertuis joined the *Mousquetaires Gris* and in 1720, with the rank of lieutenant, was stationed in Lille. During his army period, he devoted all his free time to geometry. In the following year, he resigned his commission and returned to Paris. There Maupertuis joined a group of scholars, three of whom were members of the Académie royale des sciences, through whose intervention he was elected to the academy on 14 December 1723 as an *adjoint-géomètre*, the lowest position, despite having no publications.

In August 1725, a short time after the publication of his first paper devoted to the influence of shape on the properties of musical instruments, Maupertuis was promoted to *associé*. From 1723 to 1733, he published various memoirs concerning geometry, mathematics, and zoology; the memoir *Sur la question des maximis et des minimis* was the first step in his formulation of the least-action principle.

Maupertuis made his first foreign journeys, to London in 1728, to Basle – he registered there as a student – in 1729, and again to Basle the next year. These journeys played a major part in his future intellectual evolution. In London, Maupertuis was in the center of the Newtonianism, of observational science, and of watch and instrument making. He was admitted to the Royal Society on 27 June 1729 (O.S.). In Basle Maupertuis met **Johann Bernoulli**, from whom he received an excellent general scientific training and an introduction to **Gottfried Leibniz**' thought. Throughout his life, Maupertuis found friendship and support from the Bernoulli family.

During the 1730s, Maupertuis published many papers. 1731 was the year of both the publication, in England, of the *De Figuris*, his first astronomical paper, and his election as a *pensionnaire-géomètre* to the academy. The publication, in the following year, of his *Discours sur la figure des astres* is considered to be the first book promoting widely the Newtonian theory in France and continental Europe. While he presented Cartesianism and Newtonianism with some symmetry, Maupertuis did in fact support the latter.

The question of the exact shape of the Earth was of central importance, particularly to the academy, because **Jacques Cassini**'s and colleagues' measurements led to a prolate model of Earth, whereas Newtonians argued for an oblate Earth. During the period 1732–1735, Maupertuis studied the consequences of the law of attraction on the Earth's shape and other celestial bodies. Because of dissension, the academy ordered two expeditions to measure the length of a degree along a meridian at two very different latitudes. **Charles de la Condamine**, **Louis Godin**, and **Pierre Bouguer** led an expedition to Peru, while Maupertuis and **Alexis-Claude Clairaut**, who already worked together, led a second one to the Gulf of Bothnia. Before sailing to Lapland, both were trained in observing and measuring by Jacques Cassini. The abbé **Réginald Outhier,** a member of the Academy of Caen and an astronomer, accompanied them and chronicled the expedition in his *Journal d'un voyage au Nord, en 1736 & 1737*. This expedition may have been one wherein **John Hadley**'s octant was first used. Whereas the expedition to Peru lasted about 10 years, the Lapland team returned to Paris on 20 August 1737, just 16 months after departure. Their measurements confirmed the oblateness of Earth.

Maupertuis made two reports to the academy (1737 and 1738) but came under attack. He carried on his argument with Cassini in his *Examen désintéréssé des différents ouvrages qui ont été faits pour déterminer la figure de la Terre*, published in 1738 or 1739. Waiting for the return of the Peru mission, the Lapland astronomers reassembled in August 1739 and made a new measurement of the arc between Amiens and Paris, measured by **Jean Picard** in 1669. To support his position on the Earth's figure, Maupertuis published three works in 1740: *Éléments de géographie*, *Degré du méridien entre Amiens et Paris*, and *Lettre d'un horloger anglois à un astronome de Pékin*, this last an ironic literary piece attacking Cassini's followers in the academy. During this period, Maupertuis carried on a wide correspondence with leading European scholars. He also taught Mme du Chatelet geometry and calculus.

Maupertuis had been elected an *associé-étranger* of the Berlin Academy in 1735 and was so informed when he returned from Lapland. When Frederick II became King of Prussia in 1740, he wished to reform his academy and invited Maupertuis to come to Berlin. In September 1740, Maupertuis arrived there for the first time. Going to meet Frederick at Mollwitz, during the War of Austrian succession in the following year, Maupertuis was taken prisoner by the Austrians, but was well received by the court in Vienna. In 1745, he settled in Berlin and, in August, married Eleonor de Bork, a noblewoman he had met on an earlier visit. Maupertuis assumed the presidency of the Berlin Academy on 3 March 1746. Although he had been active in the Paris Academy (*sous-directeur* in 1735 and 1741, directeur in 1736 and 1742), he now had to resign. He was also a member of the Académie française.

In Paris, before his official installation in Berlin, Maupertuis penned his *Discours sur la parallaxe de la Lune pour perfectionner la théorie de la Lune et celle de la Terre* (1741), *Lettre sur la comète* (1742), and *Astronomie nautique* (1743). All dealt with Newtonian solutions to various questions.

In the later 1740s and 1750s, Maupertuis turned more to speculative and natural philosophy and to his routine work for the Berlin Academy. He published many of his ideas in letters. As president, he supported astronomical work, including the first precise measurement of lunar parallax thanks to observations by **Joseph-Jérome de Lalande** (another Berlin academician) at Berlin and by **Nicolas de La Caille** at the Cape of Good Hope.

Maupertuis was the first to formulate the least-action principle, which he considered as the summit of his work. He published on statics in *Loi du repos des Corps* in 1740; he applied the ideas to optics in a paper "*Accord de différentes lois de la Nature qui avoient paru incompatibles*" (1744). To extend the ideas to mechanics, Maupertuis assumed collisions of massive points. His full ideas appeared in *Essay de Cosmologie* in 1750.

Samuel König, a Berlin academician and long-time friend, claimed that Leibniz had indicated, in a letter, that he had been the first to formulate the principle. Although in poor health, Maupertuis fought to maintain his priority, and the fight drew in many from Berlin intellectual circles. As the Leibniz letter could not be found, the academy supported Maupertuis in a meeting of 13 April 1752, forcing König to resign. This resulted in much hostility towards Maupertuis, including a virulent attack by Voltaire, in his *Diatribe du docteur Akakia* (1752), which portrayed him as an arrogant fool.

In his last years Maupertuis produced works on reproduction, heredity, and pleasure, including *Dissertation physique à l'occasion du nègre blanc* (1744) and *Vénus physique* (1745). In the *Système de la nature* of 1751, Maupertuis speculated on parental heredity, anticipating some ideas of the following century. He left Berlin for the last time in June 1756. He was reinstalled in the Paris Academy on 15 June. A final journey in 1759 took him to Bernoulli's home in Basle, where Maupertuis died. At Saint-Roch in Paris, a marble funeral stele was erected by his friends in 1766.

Maurolico, Francesco

Born **Messina, (Italy), 16 September 1494**
Died **near Messina, (Italy), 21 or 22 July 1575**

Francesco Maurolico, in addition to doing original work, translated and commented on works by ancient authors such as Euclid, **Apollonius**, and **Archimedes**.

Maurolico spent nearly all of his life in Sicily, where he was ordained a priest in 1521, and held various ecclesiastical as well as civil posts. His astronomical writings include a criticism of **Nicolaus Copernicus**, and a treatise on the use of the principal astronomical instruments. Maurolico's observation of the supernova of 1572 in Cassiopeia (SN B Cas) appears to predate that of **Tycho Brahe** by five days.

Maury, Antonia Caetana de Paiva Pereira

Born **Cold Springs, New York, USA, 21 March 1866**
Died **Hastings-on-Hudson, New York, USA, 8 January 1952**

American spectroscopist Antonia Maury discovered a way of recognizing supergiant stars from their spectra, even when their distances could not be measured. She was the granddaughter of **John William Draper**, the first person to photograph the Moon, the niece of **Henry Draper**, another keen amateur astronomer, and the daughter of Mytton and Virginia (*née* Draper) Maury. Her father, an Episcopalian priest, edited volumes in natural history; a sister became a paleontologist and a cousin an oceanographer. Maury was taught largely by her father and uncle, going on to Vassar College, New York, where she was one of the last students of **Maria Mitchell**, and received a BA in 1887.

In 1888, Maury was employed by **Edward Pickering** at Harvard College Observatory as part of a program to determine the spectral types of stars. The program was funded by a memorial contribution from Henry Draper's wife in his honor, and eventually published as the Henry Draper Catalog. **Williamina Fleming** and **Annie Cannon** were also employed in this project. Maury was probably the most intellectually gifted of the three women. Although she had been employed to classify objective-prism spectra into the system defined by Pickering and Fleming, she instead set up her own system. It improved on the earlier system in two ways. First was a finer gradation by the temperatures of stars; Maury was the first to recognize that the temperature sequence should be O, B, A. Second, she noticed that in some cases the spectral features were unusually hazy (her type b) and in some cases unusually sharp (her type c). These and other details that Maury recorded were regarded by Pickering as a waste of time, and it was not until about 1907 that **Ejnar Hertzsprung**, who had independently discovered supergiants by another method, recognized the importance of Maury's class c. Her own catalog, with the a, b, and c characteristics and a variety of additional kinds of information including notes on composite spectra and emission lines, appeared in the *Harvard College Annals* in 1897. Many of Maury's "b" types were later recognized as rapid rotators, an interpretation she had herself suggested.

Maury was also a pioneer in the investigation of spectroscopic binaries. Pickering had discovered the first of these, Mizar, from the doubling of its calcium K line in 1889. Maury found the second, β Aurigae, the same year and was the first to measure the orbital periods of both. She was no longer formally employed by Harvard College Observatory after 1892 but continued to analyze spectra taken there until 1935, including a large number of plates of the very peculiar eclipsing binary β Lyrae. This work appeared periodically in the *Harvard Annals Bulletin* until 1935.

Maury lectured in several east-coast colleges and served for several years as curator of Draper Park Museum. She was also a recognized ornithologist and naturalist.

Maury was, somewhat ironically, the 1943 recipient of the Annie J. Cannon Prize of the American Astronomical Society, the only major recognition she ever received. Her relationship with Harvard College Observatory, though informal, became much smoother under the directorship of **Harlow Shapley**.

Maury, Matthew Fontaine

Born **near Fredericksburg, Virginia, USA, 14 January 1806**
Died **Lexington, Virginia, USA, 1 February 1873**

A naval officer best known for his wind and current charts and therefore considered one of the founders of oceanography, Mathew Maury was, in effect, the first superintendent of the Depot of Charts and Instruments, though **James Gillis** might more properly be considered its founder.

Maury became a midshipman in 1825 and had three periods of sea duty through 1834. Two years later he authored a widely used textbook, *A New Theoretical and Practical Treatise on Navigation*. Promoted to lieutenant in 1836, Maury suffered a leg injury in 1839 that confined him permanently to shore duty, a situation that would greatly affect the remainder of his naval career. In 1842 Maury was named officer-in-charge of the Depot of Charts and Instruments, founded in 1830 to centralize the Navy's navigational maps and technology. Maury became the first superintendent of a newly equipped depot established by Congress with a "small observatory" in 1844. That depot quickly grew into the United States Naval Observatory and Hydrographic Office, an agency Maury headed until he joined the Southern cause in the Civil War in 1861. Maury was promoted to the rank of commander in 1858, retroactive to 1853.

During his years as the superintendent, Maury struggled to balance astronomy and hydrography. His main achievements were in the latter; the wind and current charts, based upon data that sea captains submitted to the depot, greatly shortened ocean voyages. In astronomy Maury oversaw observations made with a variety of astrometric instruments, and produced widely praised star catalogs. He struggled with limited resources, but his undoubted achievement is that he turned a small depot into the first national observatory of the United States, on a par with the Greenwich Observatory in England and other national observatories around the world. Maury was often considered an outsider among the new breed of professional American scientists, and his legacy in the scientific establishment was complicated by strong feelings stemming from his role in the Civil War.

Maxwell, James Clerk

Born **Edinburgh, Scotland, 13 June 1831**
Died **Cambridge, England, 5 November 1879**

It was while competing for the fourth Adams Prize that James Maxwell wrote a paper on Saturn's rings, in which he proposed that they were made of small particles, and could not be solid.

Maxwell's father was John Clerk; Maxwell was added later for inheritance purposes. His mother was Frances Cay. Maxwell was brought up in the Scottish countryside on an estate at Middlebie, Galloway, in a house called Glenlair. His mother died when he was 8 years old, and after an unsuccessful spell with a private tutor, he was educated at Edinburgh Academy, from 1841. Maxwell wrote a paper on the geometry of ovals when he was 14.

Maxwell went to Edinburgh University in 1847, then to Peterhouse College, Cambridge, in 1850, transferring to Trinity College and graduating in 1854. In 1856 he took up the post of professor of natural philosophy at Marischal College, Aberdeen, to be close to his father who was ill.

Maxwell married Katherine Mary Dewar, the daughter of the principal of Marischal College, but this did not prevent him from losing his position when Marischal College and King's College in Aberdeen were merged in 1860. In 1861 he was elected a fellow of the Royal Society.

Maxwell was turned down for a chair at Edinburgh University, and was appointed chair of natural philosophy at King's College, London until 1865. He then divided his time between Glenlair and Cambridge, where he designed the Cavendish Laboratory, which opened on 16 June 1874.

In 1866, Maxwell formulated, independently of Ludwig Boltzmann, what is now known as the Maxwell–Boltzmann kinetic theory of gases. Later, Maxwell developed the famous equations describing electromagnetism that bear his name.

Mayall, Margaret Walton

Born **Iron Hill, Maryland, USA, 27 January 1902**
Died **Cambridge, Massachusetts, USA, 6 December 1995**

Over a period of 24 years, Margaret Walton Mayall led the American Association of Variable Star Observers [AAVSO] to a position of international leadership among variable star organizations while providing substantial support to professional variable star astronomers and for amateur and popular astronomy through her publications. Mayall studied at the University of Delaware, Swarthmore College (BA: 1924), and Radcliffe College Harward University, where she earned an MA in Astronomy in 1927. With the help of **Leslie Comrie** at Swarthmore, Mayall found employment at Harvard College Observatory [HCO]. From 1924 to 1954 she worked at HCO as a research assistant, and later as Pickering Memorial Astronomer. She spent the summers of 1925 and 1926 as first assistant to Margaret Harwood, director of the Maria Mitchell Observatory in Nantucket, Massachusetts, and it was there that she first became interested in variable stars. It was also Nantucket where she met Robert Newton Mayall. They were married in 1927, but had no children. During World War II and for a year beyond (1943–1946), Mayall served in the research staff of the Heat Research Laboratory, Special Weapons Group, Massachusetts Institute of Technology.

While at HCO, Mayall assisted **Annie Cannon** in the classification of the spectra of faint stars and the estimation of the brightness of catalogued stars. She worked with Cannon until the latter's death in 1941, and then completed Cannon's unfinished spectral work, editing the results for publication as the second volume of *The Henry Draper Extension—The Annie J. Cannon Memorial* in 1949. Mayall published many other technical monographs while working at HCO.

Early in 1949, HCO Director **Harlow Shapley** asked Mayall to consider taking over the position of AAVSO recorder from **Leon Campbell** when he retired. The AAVSO was founded in 1911 by **William Olcott** in response to HCO director **Edward Pickering**'s efforts to collect observations of variable stars. From about 1918 to 1954, the AAVSO was headquartered at and run under the auspices of HCO. In 1949, Mayall accepted the position and was named Pickering Memorial Astronomer at HCO and AAVSO recorder. (The title was later changed to director.) She remained director of the AAVSO for 24 years until her retirement in 1973.

When Shapley retired from the HCO directorship in 1952, AAVSO's position began to change. With an inadequate budget, aging telescopes and other facilities, and aspirations for a rather different type of organization, the new HCO director, **Donald Menzel**, was forced to reconsider observatory priorities. In 1954, he announced that the AAVSO would have to move out of the observatory, and the endowment that supported the Pickering Memorial Professorship would no longer be available. With a new title of director, Mayall oversaw the transition of the AAVSO to an independent, nonprofit scientific and educational organization. As the association struggled through severe financial hardship Mayall worked without salary for a number of years to ensure the future of the AAVSO.

Through her determination, persistence, and vision, and with substantial help from **Clinton Ford** and other AAVSO leaders, Mayall secured the future of the AAVSO in many important ways. During the critical early years of independence, she actively sought out new sources of funding from government, industry, and private donors. She communicated widely with the astronomical community to solicit both technical and moral support for the AAVSO from the professional community; she established an endowment fund to secure a firmer financial footing for the AAVSO; she expanded existing programs and committees and added new ones to attract a broader membership; she added more stars to the observing program and established new systems for correlating and publishing data for professional use; and in 1967 she introduced modern data processing methods at the AAVSO, with emphasis on machine computing and plotting for publication. Mayall retired as director emeritus of the AAVSO in 1973.

As a member of the International Astronomical Union [IAU], Mayall participated in the activities of two IAU commissions, Commission 27 on Variable Stars, and Commission 29 on Stellar Spectra. She was a fellow of the American Association for the Advancement of Science, and a member of Sigma Xi, the American Astronomical Society, and the Royal Astronomical Society of Canada.

Besides her professional work in astronomy, Mayall had a lifelong interest in promoting the work of amateur astronomers, and especially in encouraging popular interest in astronomy at all levels. Perhaps her most widely recognized contribution to popular astronomy was as the co-editor, with R. Newton Mayall, of the revised editions of Olcott's *Field Book of the Skies*. She was also co-author with her husband of *Skyshooting, a book on photography for amateur astronomers*, and *Sundials and Their Construction, Astronomical Contribution and Significance*. In addition, Mayall edited and revised a new edition of **Thomas Webb**'s *Celestial Objects for the Common Telescope* that has remained in print since 1962.

In all, Margaret Mayall worked with devotion and dedication to firmly establish the AAVSO as an independent research organization. It is today the largest organization of variable star observers in the world. In recognition of her efforts, the AAVSO, in 1974, established the Margaret W. Mayall Assistantship in her honor to provide variable star research opportunities for young people at AAVSO headquarters. In 1957, the Western Amateur Astronomers awarded their G. Bruce Blair Gold Medal to Mayall for her contributions to amateur astronomy. The following year, Mayall was the recipient of the American Astronomical Society's Annie Jump Cannon Award. The IAU named minor planet (3342) Fivesparks in honor of Mayall and her husband Newton.

Mayall, Nicholas Ulrich

Born **Moline, Illinois, USA, 9 May 1906**
Died **Tucson, Arizona, USA, 5 January 1993**

Nicholas (Nick) Mayall, a 20th-century observational astronomer, produced major advances regarding the motions and compositions of globular clusters, established the Crab Nebula as the remnant of the supernova of 1054 that was described by the Chinese, studied the internal motions of two galaxies, and contributed to the measurement of the rate of expansion of the Universe. Mayall was also an effective observatory director for the construction, commissioning, and early years of operation of the Kitt Peak National Observatory.

Mayall was the son of an engineer, Edwin L. Mayall, Sr., and his wife Olive (*née* Ulrich) Mayall. They moved to near Modesto, California, where Mayall attended elementary school, and then to Stockton, California where he completed high school. Mayall entered the University of California College of Mining in 1924 but had to shift to another field because of his extreme color blindness. He selected astronomy and graduated in 1928. Mayall lived with and supported his divorced mother during this period by working in the university library.

Mayall then worked for 2 years (1929–1931) as a computer at the Mount Wilson Observatory assisting **Edwin Hubble**, **Alfred Joy**, **Walter Adams**, and **Seth Nicholson** by measuring and reducing their observational data. After Pluto was discovered by **Clyde Tombaugh** in 1930, Mayall and Nicholson found earlier photographs of it in the archives and produced the first definitive elliptical orbit of the planet. Mayall decided, on the basis of his experience at Mount Wilson Observatory, that he would pursue a career in astrophysics specializing in nebular spectroscopy. He earned a Ph.D. from the University of California at Berkeley in 1934 for a thesis suggested by Hubble, a census of galaxies as a function of galaxy brightness and area in the sky. Mayall's thesis advisor was **William Wright** who arranged employment for his protégé as an astronomer at the Lick Observatory.

To work on diffuse galaxies and globular clusters, Mayall designed an UV-transmitting spectrograph for the 0.9-m Crossley telescope. Using that spectrograph he determined the radial expansion of the Crab Nebula and along with **Jan Oort**, established that it was a remnant of the supernova first observed by the Chinese in 1054. He obtained measures of the internal rotation of the Andromeda Galaxy (M31) and the large spiral galaxy (M33) in Triangulum. Mayall then collaborated with his graduate school colleague, theoretician **Arthur Wyse** on the analysis of that data in 1942.

During World War II Mayall worked at the Radiation Laboratory in Cambridge, Massachusetts, the Office of Scientific Research and Development project at the Mount Wilson Observatory headquarters in Pasadena, California, and the California Institute of Technology rocket project in Pasadena and Inyokern, California.

After the war Mayall was deeply involved in obtaining a 3-m reflector (now called the Shane reflector in honor of **Charles Shane**) for the Lick Observatory; the telescope was not completed until 1960. Mayall continued to use the Crossley reflector to determine the motions of 50 globular clusters and showed that they shared only partly in the rotation of the star of the Galactic disk. With **Milton Humason** and others, Mayall obtained the redshifts of 800 galaxies. Humason used the 100-in. (2.5-m) and 200-in. (5-m) telescopes for the fainter galaxies while Mayall observed the brighter ones with the Crossley reflector. Perhaps in compensation for his color blindness, Mayall was able to see fainter objects through a telescope than other astronomers, *e.g.*, $V = 16$th magnitude with the 0.9-m Crossley Reflector. The data gathered by Humason and Mayall were analyzed by Allan Rex Sandage (born: 1926) to give a Hubble constant of 180 km/s/Mpc, a significant milepost on the way from Hubble's original value of 530 km/s/Mpc to the currently accepted value near 65–70 km/s/Mpc.

In 1960 Mayall became the second director of the Kitt Peak National Observatory [KPNO]. He oversaw the development of the site and the construction of the 4-m telescope (now called the Mayall telescope in his honor). What Mayall lacked in administrative experience (at first a liability) he more than made up through his ability to attract a first-class scientific staff because of his personal reputation as an outstanding research astronomer. Importantly, that reputation had been developed on the large telescopes at Lick Observatory, Mount Wilson, and Mount Palomar. When the Association of Universities for Research in Astronomy [AURA], the managing corporation for KPNO, took over the project from the University of Chicago, Mayall assumed responsibility for the early development of the Cerro Tololo Interamerican Observatory [CTIO] in Chile and the construction of the 4-m CTIO telescope (now called the Blanco telescope in honor of the first CTIO director, Victor Blanco).

Perhaps the most important of Mayall's contributions at KPNO was his leadership of a transition in style for major observatory management. Over strong recommendations to the contrary by the directors and staff at the Mount Wilson and Palomar observatories, Mayall guided the implementation of an organization designed to facilitate use of the major facilities at KPNO as community assets. He was a gentle director, knew everyone of 300 employees by first name, and was particularly effective in relations with the university administrators and the appropriate federal and state officials who oversaw KPNO.

Mayall had long suffered from diabetes and arthritis, and retired from KPNO in 1971 at the age of 65. Throughout his research career of nearly 30 years at the Lick Observatory he was a meticulous and outstanding observer of galaxies and clusters, and proved equally capable as the administrator of a large scientific institution.

Mayer, Christian

Born **Meseritsch (Velké Meziříćí, Czech Republic), 20 August 1719**
Died **Heidelberg, (Germany), 17 April 1783**

The Jesuit astronomer Christian Mayer published the first catalog of stars that were close enough together, as seen through a telescope, that they might be considered double stars, and showed by comparison of some of these stars with **John Flamsteed**'s observations from the previous century that some possible orbital motion was detectable. Mayer could thus be considered to be the originator of the new and important field of double star astronomy. It was left to **William Herschel** to show, some two decades later, that some double stars might be linked gravitationally through his more accurate measures of stellar positions. Herschel demonstrated, with greater precision, possible motions on a shorter time frame.

Little is known with certainty of Mayer's early life except that in 1745 he entered the Jesuit order as a noviate in Mannheim, then capital of the Palatinate. Mayer taught languages and mathematics at the Jesuit school in Aschaffenburg and began active observational work in astronomy. In 1752, Mayer was appointed professor of mathematics and physics at Heidelberg University, and began publishing works in those fields but was soon concentrating his efforts on astronomy. Mayer's astronomical work eventually attracted the attention of Karl Theodor, Elector of the Palatinate, who was very interested in science. Karl Theodor first arranged for the construction of a small observatory at his summer residence in Schwetzingen and appointed Mayer state astronomer. A larger observatory was constructed in Mannheim, equipped with some of the finest instruments available from London instrument makers, the leaders in this field at the time. The new instruments included a great mural quadrant equipped with a telescopic site by Bird, installed in 1775, as well as other instruments by Dollond, Troughton, and Ramsden.

Mayer's work as an astronomer included much that was routine for the period, including participation in the measurement of a degree of the meridian with **César Cassini de Thury**, observation of the two transits of Venus from Russia, and the development of a map of the Russian Empire for Catherine II. But it was in his investigations of double stars that Mayer established his claim as a historical figure.

Ptolemy first applied the name double star to the bright naked eye pair ν^1 ν^2 Sagittarii, and in later years **Giambattista Riccioli** identified two such pairs in Capricorn and Hyades, while **Robert Hooke** noticed that γ Arietis was a telescopic double in 1665. **Jean Cassini** (Cassini I), **Giovanni Biachini**, and **Charles Messier** are all credited with recording the duplicity of one or more bright stars in subsequent years. By 1767, **John Michell** had concluded, on statistical grounds, that some of the many stars that appeared very close together telescopically might actually be gravitationally connected, but it was Mayer who first systematized the study of double stars. He first sent his lists of such stars to **Neville Maskelyne** for his comments, cataloging the right ascension and declination of various close pairs that to Mayer seemed candidates for closer observation.

Mayer published his first catalog of possible double stars in 1778. His claim that he had discovered stars with satellites was at first misinterpreted by astronomers and triggered a string of rebuttals from N. Fuss, **Maximilian Hell**, **Johann Bode**, and others who disputed the discovery of a planetary satellite of these stars. Herschel issued three catalogs of possible double stars in 1782, 1785, and 1821, listing a total of 848 examples of such pairs. Herschel's first catalogue was apparently published without prior knowledge of either Michell's or Mayer's previous efforts, but there was little overlap between the two lists of stars. It was not until Herschel reexamined his original catalog of double stars in 1802, and discovered that some of the companion stars had moved in such a way as to leave little doubt that the two stars were linked, that Michell's hypothesis and Mayer's empirical claims were given credibility. By then, also, Mayer had couched his terminology in such a way as to make clear that the coupling of stars and not planetary satellites was the object of his study. The English translation of his article in the *Transactions of the American Philosophical Society*, for example, discussed the companion stars as attendants rather than as satellites. In a table of 12 double stars in that article, Mayer supported his hypothesis by including Flamsteed's observations of eight stars from the previous century that seemingly demonstrated orbital motion had occurred over the intervening period.

Mayer, Johann Tobias

Born **Marbach near Stuttgart, (Germany), 17 February 1723**
Died **Göttingen, (Germany), 20 February 1762**

Selenographer Tobias Mayer prepared the earliest quantitative map of features on the surface of the Moon as well as lunar tables used by **Neville Maskelyne** in preparing early editions of the *Nautical Almanac*. Mayer was the son of a cartwright who left his trade in 1723 to work as foreman of a well-digging crew in Esslingen, Baden-Württemberg, where his family joined him a year later. Following the death of his father in 1731, Mayer was put into the local orphanage, and he taught himself mathematics from Christian von Wolff's *Anfangs-Gründe aller mathematischen Wissenschaften*. His mother found work in Saint Katharine's Hospital, which probably explains why Mayer came to prepare architectural drawings of the hospital at barely 14. His skill in this direction attracted the notice of a noncommissioned officer in the Swabian district artillery, then garrisoned in

Esslingen, under whose direction in 1739 Mayer produced a book on military fortifications; later that year he drew a map of Esslingen and its environs.

Mayer's first book, published around 1741, deals with the application of analytical methods to the solution of geometrical problems. His second, *Mathematischer Atlas* (1745), appeared in the period during which he briefly worked for the firm of Johann Andreas Pfeffel of Augsburg, Bavaria. Its choice of subject matter is a good index of the extent of Mayer's scientific knowledge at that time. On leaving Augsburg he joined the Homann Cartographic Bureau in Nuremberg, Bavaria, where he devoted 5 years to improving the state of mapmaking. Mayer collated geographical and astronomical data, and made observations of occultations and eclipses. He drew over 30 maps of which the Mappa Critica of Germany is considered the most significant, as it set new standards for handling geographical source materials and for applying astronomical data to the determination of latitude and longitude.

In 1747 and 1748 Mayer obtained a large number of meridian transits of the Moon, and made numerous measures of its angular diameter, to facilitate the lunar-eclipse method of fixing longitude. In addition to determining the selenographic coordinates of 89 major lunar markings, in doing so, he made allowance for the irregularity in the orbital motion and the libration of the Moon.

The *Kosmographische Nachrichten und Sammlungen auf das Jahr 1748* (Nuremberg, 1750), which Mayer edited for the newly formed Cosmographical Society, contains a description of his glass micrometer, his observations on the solar eclipse of 25 July 1748 and occultations of some bright stars, his major treatise on the lunar libration, and his consideration on why the Moon cannot have an atmosphere.

In early 1751, Mayer took a professorship at the Georg-August Academy in Göttingen. This was a nominal position, based solely on his reputation as a cartographer and practical astronomer. Shortly before leaving Nuremburg, he married Maria Victoria Gnüge, by whom he had eight children, of whom only three survived.

In 1752 Mayer drew up new lunar and solar tables, accurate to 1′. Comparing his positional values to historical observations (for instance, those made at all lunar and solar eclipses described since the invention of the telescope), he found that all discrepancies were attributable to errors in star places and the inferior quality of the instruments used. On the recommendation of **James Bradley,** Mayer's lunar tables, edited by **Nevil Maskelyne**, were used to compute the lunar and solar ephemerides for the early editions of the *Nautical Almanac*.

Mayer's further researches included elimination of errors from a 6-ft.-radius mural quadrant to be installed in Göttingen, the invention of a new method of calculating the circumstances of solar eclipses, the study of the proper motion of stars, and a catalogue of zodiacal stars. His works on each of these subjects were published posthumously in Georg Christoph Lichtenberg's *Opera inedita Tobiae Mayeri* (Göttingen, 1775). Appended to the book is a copper engraving of Mayer's map of the Moon. At 8 in. in diameter, it was the most accurate map of the visible lunar surface for half a century and was reproduced by **Johann Schröter** in his *Selenotopografische Fragmenten*.

Mayer's later work included efforts to improve land measurement, a method to find geographical coordinates independent of celestial observation. In 1765 his widow received £3,000 from the British government in recognition of her husband's claim, presented a decade earlier, for one of the prizes in connection with the quest to determine longitude at sea.

Much of the manuscript material relating to Mayer is preserved in Göttingen at the Niedersächsische Staats-und Universitäts-Bibliothek.

Mayer, Julius Robert

Born **Heilbronn, (Baden-Württemberg, Germany), 25 November 1814**

Died **Heilbronn, (Baden-Württemberg), Germany, 20 March 1878**

Julius Mayer independently established the principle of energy conservation, proposed a novel theory of the Sun's energy source, and considered the effects of tidal friction on the Earth–Moon system. Mayer was the youngest of three sons of the apothecary Christian Jakob Mayer and his wife, the daughter of a bookbinder. After attending Gymnasium at Heilbronn and an evangelical seminary at Schöntal, he began studies in the medical faculty at the University of Tübingen in 1832. Although he was expelled from the university in 1837 (for belonging to a secret student society), Mayer was allowed to take the state medical examinations and received his M.D. in 1838. After a short stay in Paris, he served as physician from 1840 to 1841 on a Dutch merchant ship that traveled to the East Indies. Following that experience, Mayer settled into a medical practice at Heilbronn. In 1842, he married Wilhelmine Regine Caroline Closs; the couple had seven children (only two of whom survived to adulthood).

During his oceanic voyage, Mayer undertook certain physiological observations that led him to speculate upon the conversion of food to heat in the human body, and on the resultant work that the body could perform. He concluded that heat and work are interchangeable, and this led him to reflect upon motion and heat as manifestations of a single, indestructible *Kraft* (force) in nature, which was quantitatively conserved in any conversion process. These ideas contained rudiments of the law of energy conservation. Soon afterward, Mayer extolled what later became known as the mechanical equivalent of heat. But he was not familiar with contemporary physical research and presented his ideas with a certain metaphysical style. Not surprisingly, his initial paper (1841) was rejected by the *Annalen der Physik und Chemie* (Annals of Physics and Chemistry). But after considerable reworking, Mayer's second paper, entitled "Bemerkungen über die Kräfte der unbelebten Natur" (Remarks on the forces of inanimate nature), was published in another journal, *Annalen der Chemie und Pharmazie* (Annals of Chemistry and Pharmacy), but went largely ignored. Nonetheless, Mayer anticipated to some extent the energy conservation principle later formulated by James Prescott Joule and **Herman von Helmholtz**, among others. Mayer's work was finally recognized after the former became engaged in a priority dispute. His views were later defended by Peter Guthrie Tait and some belated recognition at last came to him. In 1870, he was named a corresponding member of the Paris Academy of Sciences; in 1871, he received the Copley Medal of the Royal Society of London.

Mayer turned his theory of energy conservation upon two astrophysical problems. In 1846, he offered a novel explanation for the source of the Sun's heat. Mayer argued that its energy arose by the conversion of mechanical energy into heat, released during the Sun's continual bombardment by solid particles (meteors) attracted across interplanetary space. Though ultimately rejected, Mayer's idea may have influenced the creation of a successor theory of the Sun's heat by its gradual contraction.

Two years later, Mayer discussed the problem of tidal friction in his work, *Dynamik des Himmels* (Dynamics of the heavens, 1848). Here, he advanced a hypothesis by which the loss of energy and slowing of the Earth's rotation were roughly compensated by the planet's gradual contraction and acceleration. But like many of Mayer's speculations, this notion went largely unheeded by mainstream scientists. It is also wrong. Some of the energy heats the Earth, but the angular momentum is transferred to the orbit of the Moon, which is expanding at about 3 cm/year.

Mayer suffered bouts of depression that were exacerbated by family problems. But while he kept up his practice as a physician in Heilbronn, Mayer remained an outsider and dilettante when it came to his scientific work. He conducted few experiments and largely shunned mathematical analysis; he was primarily a conceptual thinker. Although his ideas regarding energy conservation were eventually accepted, they did not influence further developments in these subjects, which came from the works of others.

Mayr, Simon

Born **Gunzenhausen, (Bavaria, Germany), 20 January 1573**
Died **Ansbach, (Bavaria, Germany), 26 December 1624**

As court mathematician Simon Mayr was in charge of the Ansbach calendar, made the first telescopic observations of the Andromeda galaxy, and computed tables of the mean periods of the satellites of Jupiter more accurate than **Galileo Galilei**. Some sources state that his father Reichart Mayr was the *Burgermeister* (mayor) of Gunzenhausen, but most evidently Simon was from poor family, as in 1586 he went to the Margrave's school for talented poor boys. This school was established to train poor young men for the ministry. He stayed there until 1601 when he was appointed mathematician to the Margrave of Ansbach and was sent to Prague to study with **Tycho Brahe**. After Brahe's death he went to Padua to study medicine. Mayr returned to Germany in 1605 and was appointed mathematician and physician to the Margraves, Christian and Joachim Ernst, serving the rest of his life in that position.

An observatory was built for Mayr, but little is known about his instruments. According to Mayr's own account, he learned in 1609 from an artillery officer, Freiherr Hans Philip Fuchs, that a Dutchman had tried to sell him a telescope at the Frankfurt fair. Mayr grasped the concept and reproduced a telescope, which he used mainly to observe Jupiter. He claimed in a book printed in 1614, *Mundus Iovialis Anno M.DC.IX Detectus Ope Perspicilly Belgici* (The Jovian World, discovered in 1609 by means of the Dutch Telescope), that he had first observed Jupiter's moons in December 1609, a month before Galilei. Galilei fiercely accused Mayr of plagiarism. Disputes about the plagiarism case continued for centuries. In a long treatise by J. Klug, Mayr was accused as a plagiarist, while support for Mayr was presented by J. H. C. Oudemans and J. Bosscha. As a compromise, it was suggested by J. H. Johnson that Mayr probably saw the satellites of Jupiter before Galilei; however, he evidently did not comprehend their real nature until Galilei had published his account of their discovery and the explanation of their connection with the planet. Mayr discovered the variability of magnitudes of the satellites of Jupiter and gave them names – Europa, Io, Ganymede and Callisto – that are still in use.

Mayr was an independent discoverer of M31, the Andromeda nebula. *Mundus Iovialis* contains his telescopic observations of our neighbor galaxy. Mayr also published on the comet in 1596 (C/1596 N1) and was among the first to observe the "new star" in 1604.

McClean, Frank

Born **Glasgow, Scotland, 13 November 1837**
Died **Brussels, Belgium, 8 November 1904**

Frank McClean invested heavily in both laboratory and telescopic spectroscopy, comparing the solar spectrum with numerous terrestrial elements. His spectrographic survey of all stars brighter than 3.5 magnitude in both the Northern and Southern Hemispheres was a useful resource for astrophysicists for several years. McClean was the first astrophysicist to detect oxygen in the spectra of stars.

This wealthy civil engineer and amateur astronomer was the only son of John Robinson McClean, M.P., F.R.S., a renowned civil engineer, and Anna (*née*) Newsam McClean. Educated at Westminster School and the University of Glasgow, McClean graduated as 27th wrangler in the mathematical *tripos* at Trinity College, Cambridge in 1857. After working in his father's engineering firm, and later as a shipyard and railway engineer, McClean retired in 1870 in order to concentrate on his scientific and artistic interests. He maintained a private observatory and laboratory at Ferncliffe near Tunbridge Wells. Unlike many gentleman scientists, however, McClean engaged no laboratory assistants.

In his private laboratory McClean started experimenting with electricity in coils. After the completion of an attached observatory in 1875, he could extend his work to solar observation as well as stellar spectroscopy. McClean used a direct spectroscopic eyepiece of his own invention that was later commercialized by John Browning. Intrigued with the possibilities, McClean mounted a heliostat on his roof around 1879 to guide the light of the Sun to a fixed 4-in. refractor and spectroscopic bench in his attic laboratory. Using this apparatus, he undertook studies of the composition of the Sun as well as the effect of the Earth's atmosphere on the solar spectrum.

In December 1888, McClean presented to the Royal Astronomical Society a portfolio of photographs, enlarged 8.5 times, of the solar spectrum from the Fraunhofer line D to A, corresponding in representational mode and approximate dispersion to **Anders Ångström**'s lithographed normal map. In a subsequent publication, McClean continued Ångström's numbering sequence, labeling his plates VII to XIII, counting from the section containing D towards the violet.

Ångström's instrument had been a Nobert grating; McClean used a grating by **Lewis Rutherfurd** with 17,296 lines to the inch and with a ruled surface of about 1.74-in. width. His "Photographs of the Red End of the Solar Spectrum" covered that half of the Sun's visible spectrum not included in **Henry Rowland**'s photographic map. McClean's photographs also included "subsidiary" exposures displaying "in the same sections, both the red spectrum of the second order as before, and also the overlapping green-to-violet spectrum of the third order." The purpose of these double spectra was to act as a reference for spectroscopists in the red part of the spectrum with third-order spectra, for lack of overlappings in the same order. Commendable as was this extension of Rowland's photographic map into the yellow–red region of the spectrum (5,800 to 7,700 Å), it had the serious problem of not being sufficiently enlarged. One set of portfolio enlargements, deposited in the library of the Royal Astronomical Society, was accessible to the London-based scientific community and, to some extent, to visitors from other parts of Great Britain, but it was not easily available to researchers elsewhere. The only published part of this series of photographs was a small segment of the spectrum around the line A at 7,600 Å. Technically speaking, though, this plate was not a photograph but a lithographed sketch by the assistant secretary of the society and highly skilled lithographer William Henry Wesley (1841–1922) – "taken from the photograph." The plate is misleadingly labeled "The A group of the solar spectrum. Photographed by F. McClean," thus ignoring Wesley's lithographic drafting, and mentioning only the printing company (E. Stanford in London). Wesley did a superb job in bringing out the beautifully striated structure of this line group and the nearly plastic appearance of some of the split lines. Yet this mixture of techniques clearly did not meet the purpose, which was to complete the map photographically.

This became moot with the appearance of Rowland's second series in 1889, which included the red extreme of the spectrum. In spring of that year, McClean once again appeared before the Royal Astronomical Society to present exposures of the solar spectrum, with "parallel photographs" of iron, iridium, and titanium, produced in the same manner. However, his next two spectrographic publications adopted the contemporary photomechanical reproduction technique, even though this amounted to surrendering his do-it-yourself principle, which he had rigorously followed up to that point. In late 1890 he published "Comparative Photographic Spectra of the high sun and Low sun from H to A Showing the Atmospheric Absorption Bands" (in a sense, the photographic analogue of **Louis Thollon**'s contemporary lithographic comparative map). In November 1891 McClean completed comparative photographic spectra of the Sun and 15 metals (including platinum, iridium, osmium, palladium, rhodium, ruthenium, gold, and silver, as well as manganese, cobalt, nickel, chromium, aluminium, and copper) for the wavelength region 3,800–5,750 Å. This map of metallic spectra, compiled with the aid of a plane Rowland grating acquired in 1890, was especially useful because it was the first to include the rare metals palladium, rhodium, and ruthenium.

In 1895, McClean began a systematic study of the spectra of all stars brighter than 3.5 magnitude using a 20° objective prism. Grubb and Sons produced a special telescope for his purpose based on the telescopic cameras manufactured by the firm for the Astrographic Catalogue and *Carte du Ciel* project. McClean's survey for the northern heavens was published in 1896. The following year McClean was invited to the Royal Observatory at the Cape of Good Hope by **David Gill** to complete his survey of the whole sky. For his work at the Cape, McClean took only the objective prism and mounted it on the Cape's *Carte du Ciel* telescope. The southern skies survey was published in 1898. In reviews in The *Astrophysical Journal*, McClean's spectral charts were criticized by **Edwin Frost** as "unprofessional" because McClean failed to properly document the instrument, dates, times, and conditions under which the spectra were recorded, all details deemed necessary for the interpretation of the stellar spectra. Frost also observed that the photographic quality of the southern charts was improved over those from the north. Notwithstanding Frost's criticism, however, the McClean charts were a resource to which some astrophysicists could turn for comparative data, pending availability of the Henry Draper Catalogue. Based on his photographic spectral survey, McClean proposed a stellar spectral classification scheme similar to that of **Angelo Secchi**, but with Secchi's first class subdivided into three types corresponding to the B, A, and F stars in the Henry Draper classification, a scheme that was beginning to find favor. Thus, McClean's system was never widely adopted.

The spectral survey work produced two important results. First, because McClean arranged the survey in terms of galactic coordinates rather than in the conventional sidereal format, it clearly demonstrated that the stars in McClean's first type, which he recognized contained the spectrum of neutral helium, were concentrated near the galactic plane. Also, during his work at the Cape, McClean recognized that the spectrum of β Crucis and other stars in his Type 1, which he also identified as "helium" stars, contained the spectral lines of oxygen. Gill was able to verify the oxygen identification with the large Cape spectrograph. However, McClean's discovery of stellar oxygen was received with guarded caution by other astrophysicists who recalled the major controversy over **Henry Draper**'s earlier claim to have discovered oxygen in the spectrum of the Sun. It was for that reason that when McClean received the Royal Astronomical Society Gold Medal in 1899, it was primarily for his stellar spectral survey work, though the discovery of oxygen in the stars might equally have merited such recognition.

Aside from his scientific accomplishments, McClean also furthered the cause of scientific research by donating several expensive instruments to various institutions, including the 24-in. Victoria telescope to the Royal Observatory at the Cape of Good Hope. He also endowed the Isaac Newton studentships at the University of Cambridge for the encouragement of study and research in astronomy and physical optics.

McClean was honored with an honorary LL.D. by the University of Glasgow in 1894. Elected to membership in the Royal Astronomical Society in 1877, McClean served on its council from 1891 until his death from pneumonia. His wife, Ellen (*née* Greg), bore him two daughters and three sons.

McCrea, William Hunter

Born **Dublin, Ireland, 24 December 1904**
Died **Lewes, (East Sussex), England, 25 April 1999**

Irish–English mathematical astronomer Sir William McCrea is most widely known for work in modern, general-relativistic cosmology; he also helped to establish that the Sun and stars are made primarily of hydrogen and helium. McCrea was the eldest child of schoolmaster Robert Hunter McCrea and Margaret (*née* Hutton) McCrea. He attended elementary and grammar schools in Chesterfield, Derbyshire, winning an entrance scholarship in mathematics to Trinity College, Cambridge, and receiving a *tripos* degree in mathematics in 1926. McCrea's Ph.D. dissertation was completed under **Ralph Fowler** in 1930, after a year's visit at Göttingen University in Germany. His early work was largely on the application of mathematical methods to basic problems in quantum physics and relativity.

McCrea's academic appointments were as lecturer in mathematics at and the University of Edinburgh (1930–1932), reader in mathematics at Imperial College, London (1932–1936), professor of mathematics at Queen's University, Belfast (1936–1944). The last was interrupted by operational research in the British Admiralty, which he completed with the rank of captain. (The team was led by **Patrick Blackett**) McCrea was then Professor at Royal Holloway College, London (1946–1966), and, finally, the first research professor in theoretical astronomy at the recently established University of Sussex (1966–1972, and as an active emeritus professor for 25 years thereafter). Soon after the end of World War II, McCrea had been one of the strong advocates of a national center of theoretical astronomy. After much negotiation, the Astronomy Centre at the University of Sussex and the Institute of Theoretical Astronomy (under **Fred Hoyle**), which later merged into the overall Cambridge Institute of Astronomy, were the outcome of this. The best known of McCrea's students who remained in astronomy date from the Royal Holloway years and include Derek McNally, Gillian Peach, Michael

Rowen-Robinson, and Iwan Williams, most of whose careers were spent in London.

Two areas of McCrea's work had the longest, lasting impact on subsequent astronomical research. The first of these is cosmology. In 1933 he and **Edward Milne** of Oxford University showed that most general relativistic models of an expanding universe have close Newtonian analogs, which are somewhat easier to understand and within which approximate calculations can be done. McCrea was also the journal editor directly responsible for the acceptance of the first paper on steady-state cosmology (by Hermann Bondi and Thomas Gold) and was initially quite sympathetic to this alternative to an evolutionary universe; eventually he realized that it was in strong disagreement with observations. Late in life McCrea expressed doubts about all cosmological models (a trait he shared with **Grote Reber** and a number of other astronomers of his generation).

The other major area in which McCrea rightly receives credit is the demonstration that the Sun and stars are made mostly of hydrogen and helium. The 1925 Ph.D. thesis of **Cecilia Payne-Gaposchkin** reached this conclusion for K giants, but it was not widely accepted. Acceptance of the idea required calculations using more accurate treatments of the properties of hydrogen and other atoms and of the diffusion of radiation through ionized gases. European textbooks most often credit **Carl von Weizsacher**, American texts **Henry Russell**, British texts McCrea (particularly his work on the solar corona before 1931), and a case can perhaps also be made for **Bengt Strömgren**. The final step, showing that the main obstacle to the free passage of light through the outer layers of the Sun is due to hydrogen atoms with a second electron temporarily attached, was taken by **Ruper Wildt** in 1947.

McCrea was also an early proponent for a binary star model of the origin of blue stragglers (stars which appear to be younger than the populations around them) and came to be regarded as a source of last resort for mechanisms to explain or measure effects that otherwise defied the community, along the lines of, "Well, if Bill can't think of a way to measure the cosmological constant independent of the other cosmological parameters, perhaps it can't be done." (Actually it can.) Some of the ideas McCrea put forward, for instance accounting for the most massive stars by accretion of gas onto ones like the Sun, and mechanisms for formation of hydrogen molecules, were indeed prompted by observations most of his contemporaries thought inexplicable.

Knighthood came relatively late in McCrea's life, in 1985, long after honorary degrees from universities in Ireland, England, and Argentina, and academy memberships in Belgium, Italy, Scotland, and England. His service to the Royal Astronomical Society [RAS] (whose Gold Medal he received in 1976) was remarkable. McCrea held all four of the major offices, secretary (1946–1949), president (1961–1963), foreign Secretary (1968–1971), and treasurer (1976–1979), as well as editorships of the RAS's *Monthly Notices* and *Observatory* Magazine. He married Marian Nicol Core Webster in 1933, and was a lifelong communicating member of the established Anglican Church.

McIntosh, Ronald Alexander

Born **Auckland, New Zealand, 21 January 1904**
Died **Auckland, New Zealand, 17 May 1977**

An accountant, and then journalist by profession, Ronald McIntosh distinguished himself as an amateur observer of meteors and also as a computer of meteor orbits and radiants. He was self-trained in mathematics and celestial mechanics. An internationally recognized authority, McIntosh's published papers (numbering over 100) served as the standard reference works on Southern Hemisphere radiants and meteor rates between 1925 and 1945, and still remain, along with more recent radar studies, among the most reliable sources of such information. The importance of his contributions was frequently acknowledged by **Charles Olivier** of the American Meteor Society. Elected a fellow of the Royal Astronomical Society, and of the International Astronomical Union's Commission 22 on Meteors, McIntosh twice was awarded a Donovan Prize and Bronze Medal from Australia for his contributions to astronomy. He was also a popular lecturer at the Auckland Planetarium for a number of decades and served as secretary of the Auckland Observatory and Planetarium Trust Board. McIntosh was married and had two children.

McKellar, Andrew

Born **Vancouver, British Columbia, Canada, 2 February 1910**
Died **Victoria, British Columbia, Canada, 6 May 1960**

Canadian stellar astronomer Andrew McKellar is best remembered today for his accidental discovery (not at the time understood) of the cosmic microwave background, which is perhaps the strongest evidence for a Big-Bang universe (one that had a very hot, dense state about 15 billion years ago). The discovery came in the form of the measurement of the temperature of CN molecules (really radicals) in the interstellar medium. He found this to be about 2.3 K, with the result being confirmed the next year by **Walter Adams**.

Andrew McKellar was the son of John Hamilton McKellar and Mary Littleson of Scotland. Andrew married Mary Belgrave Crouch in 1938, and they had two children, Andrew Robert and Mary Barbara.

McKellar took an honors BA in mathematics and physics at the University of British Columbia in 1930, followed by graduate work in physics at the University of California (MA: 1932, Ph.D.: 1933). During this time, he was a student assistant at the Dominion Astrophysical Observatory. With a fellowship from the United States National Research Council, he spent 2 years at the Massachusetts Institute of Technology (1933–1935). During World War II, McKellar taught physics at the University of British Columbia (1941/1942), followed by service in the Royal Canadian Navy in operational research (1944/1945), for which he was awarded an MBE in 1947. He also spent a year as visiting professor of astronomy and physics at the University of Toronto (1952/1953). Most of McKellar's career, from 1935 until his death, was at the Dominion Astrophysical Observatory.

McKellar was an associate editor of the *Astrophysical Journal*. He served as president of the Royal Astronomical Society of Canada (1959/1960), the Astronomical Society of the Pacific (1955–1957), and the International Astronomical Union Commission on Comets. He was also active in the American Astronomical Society and was a fellow of the Royal Society of Canada.

McKellar was a leading figure in the development of molecular spectroscopy in astronomy. He determined the $^{12}C/^{13}C$ ratio in carbon stars to be 5:1, very different from the terrestrial ratio; this evidence supported the idea of a CNO- cycle hydrogen fusion is stars. He detected the molecules CH, CN, and NaH in interstellar space in 1940, realizing that their spectra in space is altered from the laboratory form due to extreme conditions. His analysis of cometary spectra showed that solar radiation is the cause of excitation of cometary molecules. Before his death, McKellar studied the chromospheres of giant stars spectroscopically by observing eclipsing binaries.

At the time of McKellar's death, the importance of his measurement of the interstellar temperature had not yet been appreciated. Both he and his contemporaries would have agreed with the judgement of **Gerhard Herzberg** that it had "of course a very restricted meaning."

McLaughlin, Dean Benjamin

Born **Brooklyn, New York, USA, 25 October 1901**
Died **Ann Arbor, Michigan, USA, 8 December 1965**

American stellar spectroscopist Dean McLaughlin participated in the discovery that stars in general rotate like the Sun and that members of close binary systems are often rapid rotators. He was the son of Michael Leo Benjamin and Celia Elizabeth Benjamin McLaughlin. In 1927, he married Laura Elizabeth Hill, with whom he had five children. McLaughlin received all his degrees from the University of Michigan, BA (1923), MS (1924), and Ph.D. (1927), the last for the analysis of spectra of eclipsing binaries, under the guidance of **Ralph Curtiss** and **Richard Rossiter**. They recognized that, just before the brighter star is fully eclipsed, rotation will give the uneclipsed segment of the star an additional motion away from us, leading to an asymmetrical line profile. This is still sometimes called the McLaughlin effect or the Rossiter–McLaughlin effect.

McLaughlin served as an assistant in the Michigan astronomy department from 1922 to 1924 and then became instructor of mathematics and astronomy at Swarthmore College, from 1924 to 1927. In 1927 he returned to Ann Arbor as assistant professor of astronomy, was promoted to associate professor in 1934 and professor in 1941, and remained at Michigan for the remainder of his career. He participated in the Swarthmore College solar eclipse expedition to Sumatra in 1926 and in the Michigan expedition to Fryeburg, Maine in 1932. When World War II broke out, the McLaughlins moved to Massachusetts for 3 years while he served in the Radiation Laboratory of the Massachusetts Institute of Technology, working on radar problems. In 1940, 1951, and 1958 he was a guest observer at the Mount Wilson, Mount Palomar, and Lick observatories. McLaughlin had a great interest in field geology, and from 1951 until 1965 his summers were spent as a cooperating geologist in the Pennsylvania Topographic and Geologic Survey.

McLaughlin was a fellow of the American Association for the Advancement of Science, the Geological Society of America, and the American Astronomical Society, which he served as secretary from 1940 to 1946. He also belonged to the International Astronomical Union, the Astronomical Society of the Pacific, the Michigan Academy of Science, Arts, and Letters, the Michigan Geological Society, the Pennsylvania Academy of Science, and Sigma Xi.

After the death of Curtiss in 1929, McLaughlin directed the Michigan spectrographic programs. A careful, diligent spectroscopist, McLaughlin used Michigan's 37.5-in. reflecting telescope and spectrographs for 40 years under increasingly difficult circumstances, as the university and city encroached on the observatory. His research continued Curtiss's work on the atmospheres of Be stars, bright stars with emission lines of hydrogen in their spectra, and on peculiar variable stars. McLaughlin also became an authority on the spectral characteristics of novae; he devoted much time to unraveling their problems after an unprecedented run of good weather and seeing allowed him to create an excellent photographic record of Nova Herculis 1934. McLaughlin's expertise allowed him to observe and measure many obscure lines on the plates. He also combined spectroscopic with photometric observations.

McLaughlin was known for his good humor and gifts as a teacher and colleague. He also took part in efforts to popularize astronomy and wrote many general articles for *Popular Astronomy*, beginning as an undergraduate at Michigan. In 1961 he published an introductory textbook based upon his courses, and in 1965 he coedited a standard handbook on astrophysics with his Michigan colleague **Lawrence Aller**. The textbook was the immediate precursor of those written starting about 1970 and meant specifically for nonmajor courses in astronomy, and was widely used for general astronomy courses in the 1960s.

In the 1950s McLaughlin's geological researches led him to propose a new theory to explain the appearance of the surface features of Mars, based upon the effects of wind and volcanic activity. His ideas have found more favor in recent years, thanks to observations from space-borne vehicles. His geological researches in the United States led to studies of Triassic era rocks in Pennsylvania and New Jersey and of the pre-Cambrian in Canada.

The University of Michigan observatories had established a tradition of careful observational spectroscopy, beginning with Curtiss and W. Carl Rufus. McLaughlin and his students continued that tradition, specializing in peculiar stars, variables, and novae. McLaughlin chose important problems that lay, however, within the capabilities of the Michigan equipment; he developed a large and consistent body of observations, and he wrote studies that included not only the observational data but also shrewd interpretations. With his colleagues, Curtiss at first and later with Aller, he kept the Michigan graduate program going strong. He was a productive, respected, and significant astronomer throughout his 40-year career.

A number of records are in the Michigan Historical Collections, Bentley Library, The University of Michigan.

McMath, Robert Raynolds

Born **Detroit, Michigan, USA, 11 May 1891**
Died **Bloomfield Hills, Michigan, USA, 2 January 1962**

As the founder and long-time director of the McMath–Hulbert Solar Observatory [MHSO], Robert McMath enjoyed a second career in astronomy following a successful career in engineering and industrial management. Organizational skills learned in his business career served McMath and astronomy well as he led the American Astronomical Society as its president, and guided the foundation of the Association of Universities for Research in Astronomy [AURA]. McMath served as the first president and as chairman of the AURA board of directors during the early phases of the development of the Kitt Peak National Astronomical Observatory.

McMath, the son of Francis Charles and Josephine (*née* Cook) McMath, enjoyed a privileged childhood earning nearly a full year of advanced standing credits at the prestigious private Detroit University High School. He received his BCE from the University of Michigan in 1913. During and immediately after college McMath worked as a draftsman with the Canadian Bridge Company and in 1914 joined the Saint Lawrence Bridge Company as an assistant engineer; both companies were founded by his father. Anticipating the importance of aviation in World War I, already raging in Europe, McMath took flying lessons and qualified as a pilot before volunteering for service as a commissioned officer in the army. His assignment, however, was as a civil engineer building air bases for the Army Signal Corps's fledgling Air Service. Discharged with the rank of major but in poor health and on the verge of a nervous breakdown from overwork during the war, McMath recuperated for a period, before becoming general manager of Biltmore Forest Estates Company, a North Carolina real estate venture in which his father was an investor. There, during 1921 he met and married a young widow, Mary Ridgley (*née* Rodgers) Garrison, daughter of a vice president of the DuPont Company. They had a daughter, Madeline.

McMath joined Motors Metal Manufacturing Company [MMMC] the next year as assistant manager with explicit instructions from his father, a major stockholder in the firm, to assist in the liquidation of the nearly bankrupt company. McMath's preliminary assessment was that the firm could be salvaged, so he returned the company to profitability, remaining with MMMC or its successors for the remainder of his business career. McMath rose successively to vice president and general manager (1922), president (1925), and chairman of the board (1928–1954).

At an early age, McMath developed an interest in photography that coincided with a long-term family interest in astronomy. His father and grandfather both pursued astronomy as an avocational interest that spun off their training as surveyors in their careers in civil engineering. At the urging of his father, McMath took up astronomy intending to combine that interest with photography. As amateur astronomers, they participated in a solar-eclipse expedition on 24 January 1925, planning to observe the eclipse from a balloon with Detroit probate judge Henry Schoolcraft Hulbert (1869–1959). This plan had been recommended by **William Hussey**, then director of the University of Michigan's Observatory. Although the balloon ruptured during the inflation process, high winds would likely have otherwise prevented the proposed flight. This aborted attempt was only the first of an extended series of astronomical projects undertaken by the McMaths with Judge Hulbert.

In August, 1928 McMath made his first effort combining photography with astronomy. Holding a spring-driven camera between his stomach and the eyepiece of a 4-in. refracting telescope guided manually, he attempted to photograph sunrise in the Moon's craters. While the resulting frames showed decreasing shadow lengths, the quality of the images was not what McMath desired. When, at Judge Hulbert's suggestion, the University of Michigan astronomy department came to MMMC for help in fabricating the mounting for a new telescope, McMath met **Ralph Curtiss**, the new director of the University of Michigan's Detroit Observatory and chair of the astronomy department. Curtiss was impressed by the lunar sunrise film; he decided to join with the McMaths and Hulbert in creating time-lapse motion pictures of celestial objects. They designed a special 10.5-in. Newtonian reflecting telescope mounted on essentially the same mounting that MMMC fabricated for the Detroit Observatory that was completed in 1930 and housed in a dome at McMath's summer place on Lake Angelus near Pontiac, Michigan. At the suggestion of **Heber Curtis**, who was appointed head of the astronomy department following the untimely death of Curtiss, this observatory was named the McMath–Hulbert Observatory with Robert as director, a position he held until 1961.

The 10.5-in. telescope, which utilized the best mechanical and electrical engineering practices of the time, was designed to make time-lapse celestial motion pictures. It was likely the first equatorially mounted telescope that used continuously changing driving rates in both hour angle and declination. The highly refined tracking system eliminated annoying sudden motions of the image caused by manual tracking of an astronomical object during time-lapse photography. By 1931, the telescope could accurately follow the Moon or any other astronomical object smoothly without manual tracking. Curtis arranged to have McMath present films of the Moon and the satellites of Jupiter at a meeting of the National Academy of Sciences held in Ann Arbor in 1932. The films were widely acclaimed as educational tools and were distributed for many years by the *Encyclopedia Britannica*.

In December, 1931 the McMath–Hulbert Observatory was formally deeded to the University of Michigan. McMath, his father, and judge Hulbert were declared honorary curators for the new asset of the university's astronomy department. The telescope was then modified to take time-lapse photographs of solar prominences in the light of, for example, the K-line of calcium. The human eye cannot easily follow the slow changes on the Sun. But the McMath–Hulbert time-lapse technique speeded up the action by some 300 to 600 times, thus giving for the first time a dynamic presentation of solar activity. It was in these films that astronomers became aware that solar prominences originated above the surface of the Sun and flowed back into the Sun, rather than the reverse as had previously been believed.

To further pursue this work, McMath designed and constructed a 50-ft. solar tower telescope that was completed in 1936, with technical assistance from the Mount Wilson Observatory. **Edison Pettit** of the Mount Wilson staff spent three summers at the McMath–Hulbert Solar Observatory using these innovative new instruments. Later McMath designed and had built a 70-ft. tower telescope and a 24-in. Cassegrain reflector. These were not quite ready for operation when World War II broke out. Funding for these projects came from a variety of sources including family members, industry, private foundations, and the university.

Efforts at the McMath–Hulbert Observatory from 1942 until 1946 were devoted to various wartime projects. McMath worked principally with the Office of Scientific Research and Development and was awarded the President's Medal of Merit in 1948 for his accomplishments. Among the developments at the observatory was an instrument that McMath designed and built to observe in the near infrared with a Cashman lead-sulfide photocell, a product of World War II research, or a lead-telluride photocell. By connecting each to a recorder, McMath and the observatory staff were able to conduct spectral investigations in the infrared to study conditions in the atmospheres of both the Earth and Sun. In 1945, McMath was appointed professor of solar physics in the University of Michigan Astronomy Department.

After the war, research at the McMath–Hulbert Observatory continued with a vacuum spectrograph to make highly refined Doppler velocity measurements of motions within various solar features. The observatory staff included **Leo Goldberg**, **Orren Mohler**, Helen Dodson-Prince (1905–2004), and Austin Keith Pierce (1918–2005). McMath was appointed professor of astronomy in 1951, and retired as professor emeritus of astronomy, from the University of Michigan in 1961.

As president of the American Astronomical Society (1952–1954), McMath was asked to chair the National Science Foundation's [NSF] advisory panel for the National Astronomical Observatory [NAO]. It was an inspired choice on the basis of McMath's eclectic interests in business, engineering, and science, and his government service. From his wartime governmental service, McMath was acquainted with many influential individuals in Washington. Among his friends were Alan Waterman, the director of the NSF, former Michigan congressman Joseph Dodge, director of the Bureau of the Budget, and Paul Klopsteg, associate director of the NSF.

Prior to the first meeting of the NAO panel, McMath developed detailed plans for site surveys using 100-ft. towers to automatically record seeing at possible sites for the new observatory. Both daytime and nighttime seeing was considered reflecting McMath's hope that the site might include a large, modern solar telescope. By the fourth panel meeting in February 1956, site selection was well underway and a lengthy discussion of the observatory's organization took place. Additional details were discussed a year later when seven universities joined forces to form AURA. The association, selected by the National Science Board in May 1957 to construct and operate a national optical observatory, was officially incorporated on 28 October 1957 with McMath as its first President. When ill health caused him to relinquish many of his responsibilities, McMath was appointed chairman of the AURA board.

The need for a very large solar telescope was debated in the following year. At a meeting in September 1958, the AURA executive committee approved McMath's action in sending a revised solar telescope proposal to NSF. By late November, some 9 months after the decision to build the observatory on Kitt Peak, the solar telescope project, with Keith Pierce in charge, was added to the ongoing construction program.

McMath died before the solar telescope dedication in November 1962, when by resolution the AURA board, the instrument was officially named the Robert R. McMath Solar Telescope. Some 30 years later it was rededicated as the McMath–Pierce Solar Telescope.

At the 1961 annual AURA meeting, McMath suggested that plans be made for the construction of a 150-in. optical telescope. The resulting 158-in. reflector was dedicated in 1973 as the **Nicholas Mayall** telescope in honor of Mayall's long service as the second director of Kitt Peak National Observatory.

McMath served the American astronomical community ably and well during this crucial time, in which the emphasis was changing from individual projects to those of a team, and received many honors recognizing that service. He was awarded an honorary AM by his *alma mater* in 1933, and honorary DSc's in 1938 by Wayne State University, and by Pennsylvania Military College 3 years later. McMath received the John Price Witherill Medal of the Franklin Institute, Philadelphia in 1933, the Rittenhouse Medal of the Rittenhouse Astronomical Society in 1936, and the Society of Motion Picture Engineers Journal award, 1940. Two years later he was elected a fellow of the American Philosophical Society and of the National Academy of Sciences in 1958.

Many of McMath's papers are held among the Michigan Historical Collections of the University of Michigan's Bentley Historical Library. A valuable autobiography exists in the personal file at the National Science Foundation in Washington, DC.

McVittie, George Cunliffe

Born **Smyrna (Izmir, Turkey), 5 June 1904**
Died **Canterbury, Kent, England, 8 March 1988**

British mathematician and relativist George C. McVittie made important contributions toward the problem of comparing the predictions of different general relativistic models of the Universe with observations. He was the son of a British merchant father and an Alsatian mother, born in a largely immigrant community that also included Jason Nassau (later director of the Warner and Swasey Observatory, CaseWestern Reserve University, Cleveland, Ohio, USA). With his brother, McVittie was home-schooled, developing an interest in both astronomy and Turkish archaeology. The family was on holiday in England in the summer of 1922 when a change in government in Turkey led to the sacking of Smyrna and the destruction of their home. None of them ever returned. After a spell helping his father, McVittie won a bursary and entered Edinburgh University in 1923 to study mathematics and natural philosophy. Profiting from the excellent teaching of Sir **Edmund Whittaker** and Charles Darwin, he progressed with high honors and scholarships to his master's degree.

In 1927, McVittie started research on the Maxwell–Einstein equations under the supervision of Whittaker. In 1928, he moved to Cambridge University where he received his only formal training in astronomy and, working under **Arthur Eddington,** completed a Ph.D. dissertation on unified field theories (the attempt to unify electromagnetism and general relativity, the theory of gravity, into a single set of equations) in 1930. He failed, but as did Einstein, who persisted in the attempt until near his death. In 1930, McVittie began work (part of it in collaboration with **William McCrea**) on the fate of density perturbations in a nearly homogeneous, static universe and then turned to the fate of condensations in an expanding universe, which grow more slowly than those on a static matrix – but still grow, so that galaxies indeed do form!

McVittie, held academic positions at Leeds (1933/1934), Liverpool (1934–1936), and London (a readership at King's College 1936–1948 and a professorship at Queen Mary College 1948–1952). Between 1939 and 1945 McVittie was seconded to Bletchley Park to work on deciphering of meteorological information from enemy territory and to attempt to restore accurate weather forecasting of the sort that had previously depended on international cooperation. The work of his group was enormously successful; he visited both the United States and Canada (an essential collaborator in receiving and decoding Japanese meteorological information) helping to establish their programs. McVittie was awarded the OBE for this work. Some of it was later published in meteorological journals.

During his London years, McVittie was one of the editors of *The Observatory* and of the *Quarterly Journal of Mechanics and Applied Mathematics*. He also gave some attention to **Edward Milne**'s theory of kinematical relativity, but soon concluded that the Einsteinian theory had a better chance of describing the observed universe. McVittie's 1937 book, *Cosmological Theory*, began the process of asking how valid comparisons between data and theory might be made on the scale of the whole Universe. At London, he was an inspiration to the young Arthur C. Clarke (among many other students) and served on the council of the Royal Astronomical Society.

In 1952, McVittie made big changes in both his personal and professional life, when he and his wife Mildred moved to Urbana, Illinois, USA. He became professor and head of a moribund Department of Astronomy at the University of Illinois. In the 20 years he was in Urbana, McVittie built the department into a thriving research school, with both optical and innovative radio telescopes. This suited his interest in comparing astronomical and cosmological theory with experiment; he kept in close touch with the wealth of new ideas and observational discoveries that emerged in the discipline during his time at Urbana.

McVittie's monograph *General Relativity and Cosmology* (1955, 1964) belongs to the Urbana period. Comparison of the two editions is particularly interesting. The first had described cosmological observations in terms of time and distance, using formulae that were linear approximations to the equations of general relativity and appropriate only for nearby objects. The advent of radio astronomy and discovery of much more distant galaxies and quasars prompted him to recast the entire discussion in terms of exact equations in the only directly measurable quantity, redshift, in the second edition.

In 1961, McVittie became secretary of the American Astronomical Society, holding the office until 1969. He was the last person to run the society on a part-time basis. Toward the end of his tenure, he helped oversee a number of difficult transitions, including the establishment of subdisciplinary divisions, transfer of the ownership of the *Astrophysical Journal* from the University of Chicago to the society, and the transformation of the Annie J. Cannon Prize to a research award. In curious irony given his birthplace, McVittie was by then a conservative voice counterbalancing the "young Turks." He also managed a series of publications on steady-state cosmology (which he never really believed in), stellar statistics, gravitational collapse, and the redshift-distance relationship.

On his retirement in 1972, the McVitties moved to Canterbury, England, where the University of Kent welcomed him as honorary professor of theoretical astronomy. The word "honorary" rapidly became a misnomer; he began teaching astronomy for the natural scientists and general relativity for the applied mathematics group, which he joined. McVittie supervised several mathematics doctoral students, including D. L. Wiltshire, R. P. A. C. Newman, and G. G. Swinerd, who produced important results. Also, 50 years after his 1933 paper, he published a solution of the nonlinear differential equation [NLDE] arising from a cosmological model. It is a quirk of history that his 1983 paper has eventually led to the formation of a very strong NLDE group within applied mathematics at Kent.

Some books on differential geometry offended McVittie's sense of orderliness and clarity of thought, and in the last year of his life McVittie turned to Clifford algebra as a vehicle for understanding gravitation at elementary-particle level. Up to a week before his death in March 1988, he was working on a fourth-order generalization of Einstein's equations, based on the Clifford algebraic approach.

In Canterbury, McVittie rediscovered his love for archaeology and played an active part in the Canterbury Archaeological Trust, of which he was treasurer from its foundation in 1976. He was elected to the Royal Society of Edinburgh (but not that of London). Minor planet (2417) McVittie was named for him.

Méchain, Pierre-François-André

Born **Laon, (Aisne), France, 16 August 1744**
Died **Castellón de la Plana, Spain, 20 September 1804**

Pierre Méchain discovered and computed orbits for many comets and participated in important surveys and other geodesic work in France. As the son of a humble architect, Méchain spent his formative years in his native town. His talents eventually led him to attempt a course of study at the prestigious École des Ponts et Chausées. Because of lack of funds Méchain was forced to leave the school in order to earn his living as a private tutor. A small telescope that he handed over to his father to help the latter through some financial embarrassment brought the young man to an astronomer's attention. His father sold the telescope to **Jérôme Lalande** who then took the younger Méchain under his wing. Méchain owed his career as an astronomer to Lalande. Thanks to this patronage, Méchain obtained his first scientific employment in 1772, being appointed hydrographer in the Dépot de la Marine, the French navy's cartographic service, at first in Versailles and then in Paris. During the course of this work he gained experience in drawing maps, as well as in the determination of latitudes and longitudes on land.

Méchain also specialized privately in the search for comets. This met with success with the discovery of two comets in 1781 and the suggestion that **William Herschel**'s planet, initially taken to be a comet, had a circular orbit. The following year, by calculating the orbits, he showed that two comet apparitions, those of 1532 and 1661, did not correspond to the same comet, as had been the general opinion until then. This work earned Méchain an award from the Académie des sciences and his election as a member of that institution.

Once started on the pursuit of comets, Méchain soon became the most famous comet-hunter in France, securing his reputation by the discovery of up to nine more comets in subsequent years, and also through the calculation of the orbits for all comets for which he had sufficient knowledge. Based on his reputation as an orbital calculator, Méchain took charge of the preparation of the *Connaissance des Temps*, the French yearbook of astronomical ephemerides, which he edited between the years of 1788 and 1794. His work as a cometary observer necessarily led him to discover other new nebulous objects, which were included by **Charles Messier**, also a famous comet-hunter, in his well-known catalogue.

Méchain's experience in cartography and his status as a member of the Académie des Sciences, led to his selection, with **Jean-Dominique Cassini** and a young mathematician, **Adrien-Marie Legendre**, for a major geodetic task, linking the Paris Observatory and Greenwich Observatory by a great triangulation chain. This operation resulted in a confrontation between two different methods of geodetic surveying. The British, under general Roy, used the well-known portable quadrant, whereas the French tried a new instrument, invented by another academician, **Jean Charles de Borda**, which later became known as the repeating circle. Publication of the results, which was delayed until 1791 by the bellicose tension between France and Britain, was to be Méchain's first major astronomical/geodetic work.

When the French National Assembly decided to create a new standard of measurement, based on nature, and accepted the definition of the meter proposed by the Académie des sciences, Cassini, Legendre, and Méchain were again selected to undertake a major geodetic operation, the measurement of the arc of the meridian between Dunkerque and Barcelona.

In the end, it was Méchain and **Jean Delambre** who were in charge of the operation, which was, in time, to lead to Méchain's death. Between 1792 and 1798, Méchain and Delambre carried out both geodetic and latitude measurements on both French and Spanish territory. These they presented at the International Conference that met in Paris in 1799 to establish the decimal metric system; the results were published in *Base du système métrique décimal* (Paris, 1806–1810).

In 1798, Méchain was elected a member of the Bureau des longitudes, the organization set up to oversee French astronomical observatories and operations; he went on to hold the most important institutional positions in astronomy in France. On 10 September 1798, the bureau appointed him as as *Capitaine Concierge* of the Paris Observatory. On 8 June 1801, he was entrusted with the functions of the director of the observatory, and on 5 December of that year he was nominated as president of the Bureau des longitudes. Méchain remained in this post until 31 August 1802 when the bureau decided to extend geodetic operations in Spain to link the Balearic Islands with the Spanish coast and extend the Dunkerque–Barcelona arc by 3° towards the south.

Appointed as the person responsible for this work, Méchain left Paris on 26 April 1803. He carried out various subsidiary projects and made numerous terrestrial and latitude determinations both on the mainland and in the Balearic Islands. Méchain's death from malaria interrupted the work, which was completed between 1806 and 1808 by **Jean Biot** and **François Arago**.

Mee, Arthur Butler Phillips

Born **Aberdeen, Scotland, 21 October 1860**
Died **Cardiff, Wales, 15 January 1926**

Amateur astronomer Arthur Mee, an author, journalist, and educator, combined an interest in planetary observation with organizing and coordinating astronomical activities, particularly in Wales. He was the son of George S. Mee, a pastor in the Baptist Church, and of Elizabeth (*née* Phillips) Mee. His father left the ministry to become a journalist, eventually settling in Llanelli in Wales, where Arthur spent his early years. Mee followed his father into journalism, first in Llanelli, where he married Claudia Thomas in 1888. He moved to Cardiff in 1892 to work in the *Western Mail* newspaper, for which he continued to work until his death, serving for many years as an assistant editor. He was best known professionally as a newspaper columnist.

Mee developed an early interest in astronomy and was active as an observer from the age of 17. He was noted for his visual observations with his 8-in. reflecting telescope, particularly of the Moon and Mars. He made many drawings of lunar features; these and his other observations, especially those of sunspots, meteors, and eclipses, were regularly published in amateur scientific journals. **Camille Flammarion** included some of Mee's drawings in his book *La Planète Mars*. On 11 March 1892, Mee observed Saturn with his 8-in. telescope. He was surprised to see the shadow of Titan on the disk and the satellite itself in transit a short distance away; he claimed to have been the first person to observe both simultaneously.

Shortly after moving to Cardiff, Mee founded the Astronomical Society of Wales, becoming its first president. For two decades, he edited its journal, its almanac, and later its magazine, *The Cambrian Natural Observer*. For a time, the society had over 200 members, with its publications relatively widely distributed. Through these activities, Mee was noted for his efforts to coordinate the activities of amateur astronomers and to publish their observations. He consequently had a pivotal role in Welsh amateur astronomy for the three decades preceding his death.

Mee encouraged amateur astronomers, and was prominent in popularizing astronomy as a public lecturer and as a writer. He published the book *Observational Astronomy* and the booklet "The Story of the Telescope." Mee was instrumental in arranging the gift of a 12-in. reflector as a public observatory to the city of Cardiff. He later donated his own telescope to the astronomical society in the nearby town of Barry.

Arthur Mee was known as a quiet, diffident man, short in physical stature. He was noted for his sense of humor, as is clear from his own entry in the book *Who's Who in Wales*, which he himself edited. He stated that in his early years he was intended for the medical profession, but "saved many lives by becoming a journalist." Mee developed widespread interests alongside astronomy, including history, natural history, languages, literature, and geography. He published several books, pamphlets, and articles on a diverse range of subjects, often writing under the *nom-de-plume* "Idris." He has occasionally been mistakenly confused with the English author Arthur Henry Mee, editor of the *Children's Encyclopaedia*.

Arthur B. P. Mee was suddenly taken ill and died of heart failure, survived by his wife. The crater Mee in the southern uplands of the lunar nearside commemorates him.

Megenberg, Konrad [Conrad] von

Born **probably (Germany), *circa* 1309**
Died **Regensburg, (Bavaria, Germany), 14 April 1374**

Konrad von Megenberg translated **John of Holywood's** (Sacroboscö's) *Sphere*, the standard primer on astronomy and cosmology from the early 13th to the 17th century in the Latin West, into German. His *Die deutsche Sphaera* and his *Buch der Natur*, a translation of the influential *De natura rerum*, one of the earliest works of natural philosophy to appear in German, established him as an important figure in the transmission of early scientific literature into the vernacular and an influential source in the development of scientific terminology in German. Also an observer of comets, Megenberg was a prominent scholar in German lands of the mid-14th century. He was one of the major figures at Saint Stephan's School, the predecessor to the University of Vienna, and thus he was a forerunner of such later astronomers as **Georg Peurbach** and **Johann Müller** (Regiomontanus).

Von Megenberg's exact birthplace is unknown, though he spent some of his early years in Erfurt before studying at the University of Paris, where he received his Master of Arts in 1334. At Paris he would undoubtedly have studied and then probably taught (as a lecturer in the Cistercian College of Saint Bernard) Sacrobosco's *Sphere*. While at Paris Megenberg observed the comet of 1337 (C/1337 M1), which he described briefly in his *Buch der Natur*. Megenberg is known to have been active in administration as Procurator of the English Nation, and twice a delegate to the Papal Curia at Avignon. He was listed in the Faculty of Arts at Paris until 1342, when Megenberg moved to Vienna as rector of Saint Stephan's School, where he appears to have introduced astronomy as part of the curriculum. In 1348 Megenberg took the post of Canon at the Cathedral of Regensburg, where he remained for the rest of his life.

Arnold summarizes the known biographical evidence for Megenberg's life and career. He goes on to discuss and analyze Megenberg's German *Sphaera* and also judges him the author, identified in the manuscript as Chunradus de Monte Puellarum, of a Latin commentary on Sacrobosco entitled *Super spera questiones*, although Thorndike (1949) does not draw that connection.

James M. Lattis

Alternate name

Chunradus de Monte Puellarum

Mellish, John Edward

Born **Madison, Wisconsin, USA, 12 January 1886**
Died **Medford, Oregon, USA, 13 July 1970**

As an amateur astronomer, John Mellish discovered six comets. In his later years as an optical worker, he manufactured many telescopes and optical components for American observatories and astronomers. Raised on a farm near Cottage Grove, Wisconsin, Mellish received a limited education before taking full responsibility for his mother's farming operations. With a strong native curiosity, he invested his spare time in intense investigations of nature including the night sky. After making his own 6-in. Newtonian reflector in 1907, Mellish discovered several comets. He then published a description of the telescope making process in the *Scientific American*. The response to that article, together with his notoriety from the comet discoveries, launched Mellish on a career as an optical worker though he longed for an alternate career in observational astronomy.

Mellish languished in that indeterminate state as farmer, part-time optical worker, and amateur astronomer for 8 years before a major opportunity emerged for him. A shortage of technical staff at Yerkes Observatory prompted director **Edwin Frost** to take a closer look at Mellish on the urging of the aging **Edward Barnard**, who had himself once been an amateur discoverer of comets. When Mellish discovered his third comet in winter 1915, Frost offered him a position as an unpaid observer. A grant to Mellish from the Watson Fund of the National Academy of Sciences paid for a hired hand to work the family farm while Mellish was away. Mellish's arrival at Yerkes Observatory was delayed for over a month by his hasty courtship and marriage to 18-year-old Jessie Ruth Wood of Glencoe, Illinois.

Soon after his arrival at Yerkes, Mellish discovered what he took to be a comet in the rapidly fading dawn twilight. Although the discovery was announced to the international astronomical community by a telegram from Harvard Observatory, the object was soon shown to be a previously catalogued nebula, NGC 2261. Mellish redeemed himself within a few weeks by discovering his fourth comet. After the erroneous comet discovery was announced, **Edwin Hubble**, then a graduate student at Yerkes, studied NGC 2261 photographically. Within a year Hubble announced that, as Mellish had contended, the nebula had apparently changed in appearance. NGC 2261 has since been known as Hubble's variable nebula.

Mellish remained at Yerkes for 15 months, during which he continued to observe regularly with the Yerkes comet seeker as well as other available telescopes. Another early morning session, this time with the 40-in. Clark refractor, resulted in a second controversial Mellish observation. In the post-dawn sky in November 1915 Mellish observed what he described as craters on Mars, although Mars was many weeks beyond opposition and presented a comparatively small image. Mellish was convinced of his observation and discussed the matter with Barnard. Mellish claimed that Barnard showed him his own drawings of Mars. Those drawings displayed circular objects that Mellish took to be craters. However, Barnard's advice was that other astronomers were unlikely to believe such observations and that Mellish would be well advised not to discuss his own observations with others. In his later years, Mellish ignored Barnard's advice and discussed his observations as well as his discussion with Barnard with many other astronomers. The matter was not resolved satisfactorily until the Barnard drawings were discovered in a trunk at Yerkes Observatory in the early 1990s. The three circular markings that Mellish described were actually displayed in Barnard's drawings. However, those markings have now been identified with the Martian volcano *Olympus Mons* and two smaller nearby volcanoes known to exist in the region of Mars that Barnard observed. More recently, careful examination of modern photographs of Mars in connection with an accurate ephemeris of the planet for November 1915 indicates Mellish likely observed the giant impact crater Argyre, the mountains surrounding that crater, Neridium Montes, and the super canyon Valles Marineris, which Mellish described as a crack.

In November 1916, after the Mellish family's first child was born, Mellish accepted an appointment as the director of the Harrold Observatory in Leetonia, Ohio. He discovered his fifth comet in April 1917, but otherwise Mellish's astronomical observing from Leetonia was unproductive. Instead, during this period Mellish faced the reality that he was unlikely to succeed as an observational astronomer and shifted his interest back to optical work. With strong support from Leetonia machine tool manufacturer Elmer A. Harrold (1864–1931), Mellish perfected the telescope mountings for his telescopes. He advertised regularly to the amateur astronomy market and aggressively solicited optical work from professional observatories as well. By the time the Mellish family moved to Illinois from Leetonia in 1923, Mellish had a substantial backlog of orders for telescopes and had become well established as a supplier of optical windows, small lenses, and mirrors for use in professional observatory photometers and spectrographs. Mellish visually discovered a possible sixth comet that later was suggested as being an accidental rediscovery of comet 6P/d'Arrest.

For the remainder of his life, Mellish continued to practice recreational astronomy while maintaining a productive business in optics. His small telescopes, both refracting (up to 10 in. in aperture) and reflecting (many in apertures up to 16 in.), were inexpensive and sustained his business as a continuing workload. In addition, Mellish took on larger mirrors for professional telescopes up to 30 in. in aperture, for example a Pyrex mirror for the University of Illinois. Mellish was asked by **Otto Struve** to produce an unusual set of Schmidt system optics (20-in. × 20-in.) for the McDonald Observatory in 1939. The collapse of his second marriage (also to Jessie) and Struve's impatience with the resultant delays thwarted that effort.

During World War II, Mellish capitalized on skills he learned while making optical windows for observatory instruments by manufacturing rock-salt optics sets for infrared spectrophotometers. He was apparently responsible for 90 percent or more of the optics for these important new instruments for chemical laboratory and refinery process control analyses. He supplied rock-salt optics sets to Shell Development, Pure Oil, Dow Chemical, the University of Michigan, and many other institutions in addition to his regular optics work.

The Mellish family eventually included ten children, but both of Mellish's marriages to Jessie ended in disastrous divorces. The first of these occurred in 1933 in Saint Charles, Illinois, the culmination of a prolonged legal battle as Jessie suffered an extended period of depression. After the first divorce, Mellish moved to Escondido, California, where he reestablished his business with the help of Clarence Lewis Friend (1878–1958). The second divorce occurred in 1939 in Escondido as Jessie's struggle to reestablish herself once again failed. Mellish gave Friend two telescopes and showed him how to search for comets. Friend eventually made independent discoveries of at least four comets.

Mellish was a productive contributor to astronomy for most of his life, with six comet discoveries to his credit and as a telescope maker who supplied inexpensive telescopes for both amateur and professional applications. The International Astronomical Union named a crater on Mars in Mellish's honor.

Melotte, Philibert Jacques

Born **Camden Town, (London), England, 29 January 1880**
Died **Abinger, Surrey, England, 20 March 1961**

English astrometrist Philibert Melotte discovered the eighth satellite of Jupiter, Pasiphae, and some southern nebulae carry his name. He was the son of a (Belgian-born, hence the names) lecturer at the Royal Naval College, who enrolled him at the Roan School in Greenwich, where Melotte completed his formal education at age 15. He then joined the staff of the Royal Observatory (Greenwich) as a supernumerary computer, remaining on the staff there for his entire career. At the time, it was the custom of the Royal Observatory to recruit the bulk of its staff members for observation and data reduction from local schools. This was an ideal opportunity for Melotte, as those students who showed particular talent (and were able to pass a set of fairly challenging examinations) were allowed to take up permanent posts when they fell vacant. Melotte was one of these students who, by exceptional talent, rose within the observatory to be a department head.

In his first 10 years at Greenwich Melotte made hundreds of astrometric observations of a wide range of astronomical objects. His most celebrated discovery occurred in 1908 while he was engaged in systematic observations of Jupiter and the known Jovian moons. Melotte had set out to confirm the existence of satellites numbers six and seven (Himalia and Elara), discovered at Lick Observatory (Mount Hamilton, California) by **Charles Perrine** in 1904 and 1905. In the course of these observations he found a "moving object" that, through subsequent investigation, he demonstrated to be a satellite of Jupiter. The discovery of the eighth satellite of Jupiter brought Melotte considerable recognition and the 1909 Royal Astronomical Society's Jackson–Gwilt Medal.

Most of his first decade as an astronomer was, however, spent in measuring the photographic plates for the Greenwich zone of the *Carte du Ciel*. As a result, Melotte was the obvious person to undertake the remeasurement of the astrographic plates taken about 1905 by **John Franklin–Adams** and the compilation of a Royal Astronomical Society edition of the Franklin-Adams star charts (on a much smaller scale of 1° = 20 mm than the *Carte du Ciel* charts). In collaboration with **Sydney Chapman,** Melotte also used these plates for faint star counts, and, still later with **Knut Lundmark,** he examined the obscured regions of the plates. A 1926 catalog of southern nebulae found there includes objects still referred to by their Melotte numbers.

Melotte's early work had been supervised by H. P. Hollis, who was head of the astrographic department, and upon Hollis's retirement in 1920, Melotte succeeded him, though his appointment to appropriate rank was considerably delayed. In 1933, Sir **Harold Spencer Jones** returned from the Cape Observatory to become Astronomer Royal and director at Greenwich. He brought with him some 2,847 photographic plates, taken at a number of observatories during an observing campaign aimed at minor planet (433) Eros with the purpose of improving knowledge of distance scales within the Solar System. Most of the rest of Melotte's career was devoted to measuring and reducing these plates, some of the work being done at Abinger, where the observatory staff was moved at the start of World War II. After the war, Melotte returned to Greenwich, where he remained until retirement in 1948. He had served at the observatory for 53 years.

Melotte was well-known to support the efforts of amateur astronomers, and he willingly provided his expertise in celestial photography to many projects. He was also active in several organizations and served as the secretary of the Royal Astronomical Society's Photographic and Instruments Committee from 1913 to 1950 and secretary to the British Astronomical Association from 1913 to 1921 and again from 1926 to 1930, finally becoming its president in 1944. He was a Freemason of high rank, serving as Treasurer of the Trafalgar Chapter for 30 years, and he was a member of the Royal Naval College Lodge of Mark Master Masons. Melotte was survived by his wife and son.

Menaechmus

Flourished **(Turkey), *circa* 350 BCE**

Menaechmus, the Greek mathematician who supposedly told Alexander the Great that there is no royal road to geometry, was a pupil of **Eudoxus**, the founder of Greek mathematical astronomy. Menaechmus is said to have added more homocentric spheres to the Eudoxean planetary models, which had already been enriched by **Callippus**. But his greatest achievement was the discovery of the conic sections, which takes pride of place in **Johannes Kepler**'s *Astronomia Nova* (New astronomy) (1609).

Menaechmus defined the conic sections as the intersection of a cone of revolution with a plane perpendicular to one of the cone's generators. He distinguished three kinds, which arise, respectively, by cutting a right-angled, an acute-angled, or an obtuse-angled cone. (**Apollonius** later gave them the names parabola, ellipse, and hyperbola, by which we call them still.) The conic sections occur in Menaechmus' two solutions to the Delian problem of duplicating the cube, which can be readily explained using modern mathematical lore and notation.

Menelaus of Alexandria

Born **Alexandria, (Egypt), *circa* 70**
Died ***circa* 130**

Menelaus is best known for his development of spherical trigonometry.

Little is known about the life of Menelaus. It appears that he spent his early years in Alexandria, and was probably born there; after that, he seems to have moved to Rome. **Pappus** and **Proclus** both referred to him as Menelaus of Alexandria. **Ptolemy** noted astronomical observations made by Menelaus in Rome on 14 January 98. In addition, **Plutarch** related a conversation about optics involving Menelaus as an adult in Rome around the same time.

Ibn al-Nadim's *Fihrist* (a register of mathematicians, written *circa* 950) mentions six books by Menelaus, some of which were said to have been translated into Arabic at the time. They included *The Book of Spherical Propositions*, *On the Knowledge of the Weights and Distribution of Different Bodies*, three books on the *Elements of Geometry*, and *The Book on the Triangle*. The only book by Menelaus that can be found today is the first in the list above, generally referred to as the *Sphaerica*.

That book documents Menelaus' major contribution to astronomy, which was the development of spherical trigonometry. For example, the first known definition of a spherical triangle appears at the beginning: The Greek term that he used for a spherical triangle, *tripleuron*, was not commonly used by other mathematicians to refer to triangles (although it does occasionally appear in Euclid), and suggests that Menelaus was aware of the originality of his topic. In short, he appears to have been the founder of spherical trigonometry. He is best known today, within that field, for Menelaus' theorem, which has applications to astronomy.

In addition to his theoretical work, Menelaus made many astronomical observations and attempted to organize them and make estimates relating to the movement of the stars. Several 10th-century Arab astronomers (**al-Battani**, **al-Sufi**, and Hajji-Khalifa) allude to a catalog of fixed stars composed by Menelaus; this was apparently not a full catalog, and was largely based on his observations. Based on Menelaus' observations, Ptolemy suggests that Menelaus was able to estimate that the equinox was moving westward at the rate of 1° per 100 years. (A more accurate figure given today is about 1° per 72 years.) Pappus also mentions a treatise by Menelaus on the settings of the signs of the zodiac. (The calculations in this treatise would have involved the use of trigonometry.)

Menzel, Donald Howard

Born **Florence, Colorado, USA, 11 April 1901**
Died **Boston, Massachusetts, USA, 14 December 1976**

Donald Menzel combined astronomy and atomic physics to revolutionize our understanding of the physics of the Sun and gaseous nebulae. He founded three observatories and brought the Smithsonian Astrophysical Observatory to Harvard College Observatory to enrich the scientific cultures of both institutions.

Menzel, the son of Charles Theodor and Ina Grace (*née* Zint) Menzel, was raised in Leadville and Denver, Colorado. In Leadville, his father worked as a telegrapher, clerk, and ticket salesman before becoming the proprietor of the city's largest general store. By 1916, the financial success of the store allowed Charles to retire, and the family moved to Denver, where Donald completed high school. As a schoolboy Menzel pursued numerous hobbies, suggested by his insatiable scientific curiosity. These in turn provided an outlet for an almost boundless energy that was to characterize his entire professional life. One such interest, in particular, was to have important consequences later in his life. After his father taught him the Morse code at an early age, Menzel combined this skill and his interest in the emerging field of radio technology to become an amateur radio operator (W1JEX), a hobby he retained for most of his adult life.

Menzel earned BA and MA degrees from the University of Denver, where he carried out observations of eclipsing variable stars under the benign guidance of professor Herbert Alonzo Howe. Through these efforts he established contacts with Princeton University's **Raymond Dugan**, which eventually led to his enrollment for graduate study at Princeton, University in the fall of 1921. Once at Princeton, the new astrophysics being pioneered by **Henry Norris Russell** drew Menzel's attention. During the summers, Russell dispatched Menzel to the Harvard College Observatory, where he identified a few thousand star clusters near the periphery of the Large Magellanic Cloud for **Harlow Shapley**. For his Ph.D., awarded in 1924, Menzel endeavored to establish a stellar temperature scale by using the recent theory of **Alfred Fowler** and **Edward Milne** on application of **Meghnad Saha**'s equation to stellar spectra.

After graduating from Princeton, University Menzel spent a few years on the faculties of the University of Iowa and the Ohio State University before landing a solid appointment at the Lick Observatory. At Lick, he honed his talent in the application of atomic physics to the interpretation of solar and nebular spectra. Menzel's scientific apogee remains his seminal treatise on the solar chromosphere, based on his exhaustive analysis of **William Campbell**'s collection of photographic plates of the so called flash spectrum. This work, published in 1931, stands as a milestone in theoretical astrophysics. It is one of the earliest examples of quantitative astronomical spectroscopy. Menzel's findings revealed that the chromosphere was not in thermodynamic equilibrium, and that helium and hydrogen were the dominant solar chemical components. His work foreshadowed the spectacular conclusion of **Walter Grotrian** and **Bengt Edlén** that the temperature of the solar plasma increased outward into the overlying tenuous solar atmosphere. Menzel also began studies of planetary nebulae at Lick Observatory.

In the fall of 1932, Menzel accepted Shapley's invitation to join the staff of the Harvard Observatory. There, he soon organized the second outstanding example of his facility with astrophysical spectroscopy. With his students and other collaborators, Menzel authored a series of 16 papers on the physics of gaseous nebulae between 1937 and 1945. This systematic study is as valid and valuable today as when it was written. Menzel's collaborators included **James Baker**, **Leo Goldberg**, Malcolm H. Hebb, George H. Shortley, and **Lawrence Aller**. Menzel's other original contributions to the physics of gaseous nebulae included his observation that under some circumstances, light passing through a gas may be amplified through fluorescence, presaging the phenomena now known as lasers and masers. Further, Menzel's observations regarding the dependence of the visual appearance of a gaseous nebula on the three possible combinations of the opacity of the gas to Lyman continuum and Lyman α radiation served as a useful heuristic for several generations of astrophysicists.

Encouraged by the progress made in France by **Bernard Lyot** with his coronagraph, Menzel undertook to develop a similar device for observing the solar corona whenever the Sun was visible. Menzel's coronagraph, which ultimately became much like Lyot's, was installed in an observatory at Climax, Colorado in late 1940 and manned by Harvard graduate student Walter Orr Roberts (1915–1990).

When the United States entered World War II, Menzel suspended his astronomical work to teach cryptography at Radcliffe College, but was soon commissioned as a lieutenant commander in the navy. He coupled his knowledge of radio and solar physics to become an expert on radio and radar transmission. Assigned to the Office of the Chief of Naval Communications, Menzel arranged for frequent advice on solar activity from Roberts at Climax to be transmitted to the Carnegie Foundation's Department of Terrestrial Magnetism, Washington, DC, for use in radio propagation forecasts for the military services. The forecasts were made using methods of analysis Menzel helped to develop. In this effort, Menzel not only demonstrated the critical practical importance of knowledge of the

Sun and solar activity, he also established relationships with key government scientists and administrators that would later prove useful to his observatory construction programs.

Menzel remained at Harvard for the rest of his career, serving as the director from Shapley's retirement in 1952 until 1966, when he was succeeded by his own student Goldberg. In the years immediately following his assumption of responsibility for the observatory, Menzel was faced with some difficult choices. Physical facilities were deteriorating, and the staff was depleted. Menzel was eventually successful in raising funds to modernize the observatory office buildings. To make immediate room for expanding the staff, Menzel severed long-standing relationships with the American Association of Variable Star Observers [AAVSO] and *Sky & Telescope* magazine, which had previously occupied space in the observatory. In addition, he began destruction of the Harvard plate collection, seen by most astronomers as a priceless resource for research. Eventually Menzel abandoned that plan in the face of protests from many astronomers. In addition, **Bart Bok** and a few other key staff members moved on to other observatories. After this difficult period, Menzel was successful in restoring the vigor of both the academic and research programs at Harvard.

In addition to being one of the leading intellectual figures of American astrophysics, Menzel also distinguished himself as a potent scientific entrepreneur in the fine tradition of **George Hale**. During his career, Menzel established three solar observatories: The High Altitude Observatory in Colorado, the Sacramento Peak Observatory in New Mexico, and the Harvard Radio Astronomy Observatory in Texas; he also brought another, the Smithsonian Astrophysical Observatory, to Harvard.

Menzel served as a consultant to various federal agencies, notably the National Bureau of Standards, the Air Force Office of Scientific Research, and the Office of Naval Research, and as a director of the Association of Universities for Research in Astronomy that organized the National Optical Astronomical Observatories. He had a natural talent for popularizing current scientific discoveries and wrote extensively for newspapers, magazines, and even for film. He authored nearly a dozen books ranging from a practical field guide to the stars and planets and a handbook on radio transmission to scholarly monographs on quantum spectroscopy, stellar structure, and mathematical methods in physics.

Curiously, another source of Menzel's fame was his writings on Unidentified Flying Objects [UFOs]. Like Edward U. Condon who looked into this same issue, Menzel concluded that there was no solid evidence to support the claims of those who believed that extraterrestrials were routinely visiting this planet. While completely serious in his belief that there was no evidence supporting the existence of the UFOs, Menzel also exhibited his sense of humor well in this area. Colleagues came to cherish his frequent cartoons of imaginary intruders from other planets.

During the late 1960s Menzel's activity was slowed by a serious circulatory problem. He stepped down from the directorship, but continued his researches as time permitted. Menzel also continued his pilgrimages to solar eclipses often with his wife Florence whom he married in 1926. The final eclipse he observed, on 24 December 1973, was his 16th expedition.

➔ **Kauffman, Nicolaus**

Merrill, Paul Willard

Born **Minneapolis, Minnesota, USA, 15 August 1887**
Died **Pasadena, California, USA, 19 July 1961**

American stellar spectroscopist Paul Merrill discovered the presence of the short-lived radioactive element technetium in the atmospheres of a few cool, highly evolved stars, proving that these stars must have nuclear reactions going on in their interiors at the present time. He also discovered the diffuse interstellar bands.

Merrill's father was a Congregational minister, and throughout his life the son adhered to this religion. Most of his life was spent in California. Merrill attended Stanford University, earning the AB degree in physical science and mathematics in 1908, and then joined the United States Coast Survey for a short time before entering the University of California in 1909 as assistant and fellow at Lick Observatory, achieving the Ph.D. in 1913. He then taught astronomy at the University of Michigan, 1913–1916.

After leaving the University of Michigan Merrill accepted an appointment with the United States Bureau of Standards from 1916 to 1918. He experimented with treating photographic plates with dicyanin to make them sensitive to red light. Merrill arranged with professor **Edward Pickering**, director of the Harvard College

Observatory, to use Harvard's 24-in. refractor and an objective prism to photograph the spectra of stars on dicyanin-sensitized plates. Whereas ordinary photographic plates reached into the red only slightly beyond the hydrogen Hβ line at 4,861 Å, the sensitized plates reached beyond 8,000 Å. From them he was able to identify several molecules not previously known to occur in stellar spectra.

Finally, in 1919, Merrill went to the Mount Wilson Observatory where he remained not only until his retirement in 1952, but as a volunteer the rest of his life. During his lifetime he published some 260 articles and four books. While at Lick Observatory, Merrill and **Charles Olivier** jointly published two articles on the great January comet C/1910 A1. That same year Merrill published a note on the "Spectrographic Orbit of β Capricorni." Thenceforth the bulk of his publications dealt with stellar spectroscopy and variable stars, in which he did considerable original research. Merrill was also a pioneer in red and infrared photography of stellar objects.

Merrill was particularly interested in wartime advances of photographic techniques that could also be applied to astronomical work. In a 1920 article, "Progress in Photography Resulting from the War," he wrote that the government, which usually considered scientific work an unnecessary luxury, "under the stress of a great emergency acknowledged its value and supplied funds as never before." As a result, certain aspects of research were pursued with unprecedented vigor during the war. Photographs of the ground taken from aircraft had been seriously handicapped by the fact that blue light is scattered in the atmosphere, resulting in blurred photographs on blue-sensitive plates. Red wavelengths, on the other hand, are less affected by scattering. Hence Merrill's experiments with dicyanin-sensitized plates were extended for military purposes. During World War I he designed special airborne cameras and took numerous airplane flights from Langley Field to test his equipment.

At Mount Wilson Observatory Merrill's primary topics of investigation were stellar spectroscopy, infrared photometry, stars with emission lines, and variable stars, especially the spectra of long-period variables. For many years, he edited the publications of the Mount Wilson Observatory written by his colleagues as well as publishing his own work.

Besides his many research papers Merrill published four treatises. The first, in 1938, *The Nature of Variable Stars*, was intended primarily for amateurs and laymen interested in astronomy. In the preface Merrill expressed that his purpose was not only to outline current knowledge of variable stars, but also to clarify for the non-technical reader the general nature of modern astrophysics.

Merrill's second book, *The Spectra of Long Period Variable Stars* (1940), is a scholarly text giving the history of the interpretation of stellar spectra, work to which he contributed extensively. His third book, *Lines of the Chemical Elements in Astronomical Spectra* (1956), not only identified all the elements found in stellar spectra but included over 1,060 references to their discovery and identification. Merrill's final book, *Space Chemistry* was published in 1963, nearly 2 years after his death.

Among Merrill's achievements are his identification of zirconium in S-type stars as well as technetium. He was also the first to suggest that red stars form three distinct branches of the giant red stars. Progressing toward the red side of the HR giant diagram from spectral classes G or K, the most prevalent red stars are class M, showing titanium oxide in their spectra; another branch consists of R and N carbon stars; and finally the S types show zirconium oxide. The variable stars with these spectral classes also show hydrogen lines in emission. Merrill found that 88% of the long-period variables showed M-type spectra, 5% N type, 5% S type, and 2% K or R types, and clarified that the differences in spectral appearance derive from (1) temperature, (2) the ratio of carbon to oxygen, and (3) the ratio of elements around zirconium to those around titanium in the periodic table. The latter two differences are a result of nuclear reactions in the stars themselves and mixing of the products to the surfaces. Other Merrill contributions include (1) the determination of the absolute brightness of the long-period variables with **Ralph Wilson**, using the method of statistical parallax; (2) classification of stars with extended atmospheres with **Roscoe Sanford**; (3) demonstration of turbulence in interstellar gas with **Olin Wilson**; and (4) probably most importantly, the recognition that certain diffuse features, commonly found in stellar spectra (especially those centered around 4430 Å), are actually produced in the interstellar medium. Most of these features probably arise from absorptions by carbon–hydrogen bonds, but the precise substances involved are not yet certain.

Merrill received many honors during his career. He was a member of the National Academy of Sciences and received its Draper Medal in 1945. In the American Astronomical Society [AAS] he served as councilor (1931–1934), vice president (1947–1950), and president (1956–1958), and was the AAS Russell Lecturer in 1955. Merrill was elected to the Council of the Division of Physical Sciences of the National Research Council for 1941–1944, and to the Council of the Astronomical Society of the Pacific, whose Bruce Medal was conferred upon him in 1946. He was a fellow of the American Philosophical Society. Additionally he was a member of the American Association for the Advancement of Science [AAAS], and of the honorary societies, Phi Beta Kappa and Sigma Xi. In 1922 Merrill was elected a fellow, and in 1948 associate member of the Royal Astronomical Society.

In 1913 Merrill had married a school classmate, Ruth Currier. She and their son, Donald, survived him.

Mersenne, Marin

Born **Oizé, (Sarthe), France, 8 September 1588**
Died **Paris, France, 1 September 1648**

An avid astronomical correspondent, Marin Mersenne provided vital communication links between practicing scientists of his era. He made important contributions in time keeping, experimental practice, and the philosophical approach to science by religion, the latter at some personal risk. Merseene was born into a family of laborers. He spent 5 years at the Jesuit collège at La Flèche beginning in 1604, followed by 2 years of theology at the Sorbonne University in Paris. In 1611 he joined the Franciscan Order of Minims, so named because they considered themselves the least of all the religious orders. Mersenne became a priest in Paris in 1612, and from 1614 to 1619 he taught philosophy at the convent at Nevers. In 1619 Mersenne moved to the Minim convent de l'Annonciade near the Place Royal (now Place de Vosges). Other than for a few short trips, he remained there until his death.

Mersenne's greatest contribution was his continual correspondence and meetings with scientific leaders, developing an informal network for disseminating information well before the inception of scientific journals. It was said "to inform Mersenne of a discovery meant publishing it throughout the whole of Europe." After Mersenne's death, letters from nearly 100 correspondents were found in his cell. Those who visited or corresponded with Mersenne included **René Descartes**, Gérard Desargues, Pierre Fermat, Thomas Hobbes, **Christiaan Huygens**, John Pell, **Galileo Galilei**, Blaise Pascal, and **Nicholas Torricelli**.

Mersenne viewed the question of Earth's motion as undecided and encouraged the search for more scientific evidence to settle the issue, yet he defended Galilei and published his work in French (*Les Méchanique de Galilée* 1634, as well parts of Galilei's *Dialogo* and *Discorsi*). Mersenne felt the church should censor some opinions, but urged moderation because he believed that "true philosophy never conflicts with the belief of the church." Mersenne was a careful experimenter who insisted on precision and repetition. "One should not rely too much only on reasoning," Mersenne wrote, as he questioned whether or not Galilei actually carried out some of the experiments on acceleration down a plane that Galilei described.

In 1636 Mersenne proposed a design for a reflecting telescope using a concave paraboloidal primary and a convex paraboloidal secondary arranged so that their focal points coincide. The electro-optics branch at the National Aeronautics and Space Administration's Marshall Space Flight Center uses an off-axis Mersenne telescope in a lidar (light detection and ranging) system.

Mersenne was the first to discover that the frequency of a pendulum is inversely proportional to the square root of its length, and it was Mersenne who proposed the use of a pendulum as a timing device to Huygens, inspiring him to invent the pendulum clock.

In other fields, Mersenne is often credited with developing the system of tuning musical instruments called equal temperament, and he experimentally developed three important principles in the acoustics of stringed instruments. Mersenne also published results on the cycloid, reported on the chemistry of tin, discussed a "sensitive plant" from the West Indies, and sought a perfect language that was natural and universal for communication of scientific ideas.

Messier, Charles

Born **Badonviller, (Meurthe-et-Moselle), France, 26 June 1730**
Died **Paris, France, 12 April 1817**

Charles Messier, the first astronomer to search systematically for comets, published memoirs of his astronomical observations on solar-system phenomena, including his observations of 44 comets. He made independent discoveries of 20 comets. However, Messier is best known today for his catalog of the 103 brightest nebulous objects in the skies visible from the Northern Hemisphere.

Messier was the tenth of twelve children of Nicolas Messier, a catchpole, and Françoise B. Grandblaise. Six of his brothers and sisters died at young age; his father died in 1741. Messier was educated by his older brother, Hyacinthe, who was working in the administration of the princes of Salm, reigning in Badonviller at that time. When the princes gave up Badonviller in 1751, Hyacinthe left for Senones, and Charles Messier went to Paris. Messier's interest in astronomy originated when he saw the great six-tailed comet (C/1743 X1) independently discovered by **Jean-Philippe Loys de Chéseaux** and Dirk Klinkenberg (Haarlem, the Netherlands). The annular eclipse of 25 July 1748 was also visible from his hometown.

In 1751 in Paris, the astronomer of the navy **Joseph Delisle** employed Messier, because of his fine handwriting, as a clerk. In addition to a small salary, Delisle provided a room for Messier at the Hôtel de Cluny. Delisle's secretary introduced Messier to the astronomical observatory on Hôtel de Cluny and instructed him to keep careful records of his observations. Messier's first documented observation was the Mercury transit of 6 May 1753. Delisle convinced Messier of the necessity of measuring exact positions for all observations – one of the most important preliminaries to his success as an observational astronomer. In 1754, Messier was regularly employed as a depot clerk of the navy.

In 1757 Delisle directed Messier to search for a comet expected to return in 1758. At that time, the return was no more than a prediction by **Edmond Halley**. Because of an error in Delisle's calculations, Messier looked at wrong positions for months. However, in August 1758, he discovered another comet (which had been discovered previously) and a comet-like patch in Taurus. The latter was not moving and was thus not a comet, but a nebula. Now known as the Crab Nebula, the remnant of the 1054 supernova, it became the first entry in Messier's catalog of such comet-like objects. Messier later reported that it was this pair of discoveries that prompted him to continue looking for comets with telescopes and to compile his catalog of nebulous objects that might be mistaken for comets.

Messier finally succeeded in finding comet 1P/Halley in January 1759, 4 weeks after its recovery by **Johann Palitzsch**. The secretive Delisle witheld the announcement of Messier's discovery until April; other astronomers were then skeptical about the late announcement. In 1760, Messier made his first independent comet discovery. He continued searching for and observing comets with telescopes over the decades, making original discoveries for a total of 13, and independently codiscovering another seven up to 1801.

Though Messier discovered more nebulous objects that could be mistaken for comets during his comet searching, he had little interest in these objects *per se*. In 1764, he undertook a serious scan of the skies, and compared his results to all the catalogs and lists available to him (those of Halley, **William Derham**, **Johannes Hevel**, **Nicolas de La Caille**, **Giovanni Maraldi** and **Guillaume le Gentil de la Galazière**) to compile a catalog of all such comet-like objects.

His catalog had grown to 45 objects when Messier decided to publish it in 1769, in the *Memoirs* of the French academy for 1771.

When Delisle retired in 1765, Messier continued to work at the Hôtel de Cluny, but it was not until 1771 that he was reclassified as astronomer of the navy. Because of his numerous comet discoveries, his fame spread. French King Louis XV nicknamed Messier "The Comet Ferret." He was elected to most scientific academies existing at that time, including the Academy of Haarlem (1764), the Royal Society (London, 1764), the Royal Academy of Sweden (1769), the Royal Academy of Prussia (1769), and the academies of Belgium (1772), Hungary (1772), and of Russia (1777). Although a proposal to elect Messier to the Royal Academy of Sciences in Paris had failed in 1763, on 30 June 1770 he was finally honored in his own city. He became good friends with the astronomer/mathematician **Jean Bochart de Saron**, who evaluated Messier's observations and calculated orbits of his comets to help him find them after perihelion.

At the age of 40, Messier married Marie-Françoise de Vermauchampt, who was 37; they had known each other as astronomical observers for about 15 years. On 15 March 1772, Madame Messier gave birth to a son, who was christened Antoine-Charles. Tragically, both the mother and the infant died within 11 days.

Messier started a most fruitful cooperation with a younger astronomer, **Pierre Méchain**, whom he met in 1774. Together, they produced a second version of Messier's catalog in 1780; they added 23 new objects to bring the catalogue of nebulae and star clusters to 68 entries. Their vigorous effort increased the number of entries to 103 in the third version published in 1781. Both the second and third editions of the catalog were published in the French almanac, the *Connaissance des Temps*. Twentieth-century astronomers added seven more objects from Messier's and Méchain's notes, expanding their catalog to 110 objects. Messier himself originally discovered 44 and independently codiscovered about 20 of them: 11 nebulae, 27 open star clusters, 29 globular star clusters, 44 galaxies, and 3 other objects (star cloud M24, double star M40, and M73, an asterism of 4 stars).

On 6 November 1781, Messier was severely injured when he fell about 25 ft. into an ice cellar while walking in a park with Bochart de Saron. It took Messier more than a year to recover. In November 1782, Messier resumed his assiduous observing activities, again concentrating on comets.

As a result of the French Revolution, the Royal Academy of Sciences was closed in 1793. Among the many victims of the revolution was Messier's friend Bochart de Saron, who was guillotined on 20 April 1794. In 1795, Messier entered the Bureau of Longitudes and the new National Institute of Sciences and Arts, which succeeded the academy. In 1806, he received the Cross of the Legion of Honor from Napoleon Bonaparte. Suffering from failing eyesight, Messier made his last comet observation of the great comet C/1807 R1. In 1815, Messier suffered a stroke that left him partially paralyzed. He passed away in his home in Hôtel de Cluny.

A lunar crater and the minor planet (7359) are named Messier, in his honor. The 1775 proposition of **Joseph-Jérôme de Lalande** to name a constellation for him, *Custos Messium*, was soon rejected. However, his most obvious honor is certainly the common naming of deep-sky objects for him, with their catalog numbers, for example Messier 42 or M42 for the Orion Nebula, and M31 for the Andromeda Galaxy.

Metcalf, Joel Hastings

Born **Meadville, Pennsylvania, USA, 4 January 1866**
Died **Portland, Maine, USA, 23 February 1925**

Joel Metcalf enjoyed three simultaneous and challenging careers: a pastoral career of considerable intensity; a career as a very successful amateur astronomer with the discoveries of 41 asteroids, 5 comets, and at least 10 variable stars to his credit; and a third career as an outstanding optical designer and craftsman, with four important instruments to his credit.

Metcalf was the son of Lewis Herbert and Anna (*née* Hicks) Metcalf. Lewis, a Civil War veteran, lost a leg at the first battle of Bull Run and was held at Libby Prison, Richmond, Virginia. After marrying and settling in Meadville, Lewis served as a newspaper editor and as county treasurer.

At about age 13, Joel Metcalf read **Richard Proctor**'s book, *Other Worlds Than Ours*, which triggered his lifelong interest in astronomy, an interest that was further stimulated by the close conjunctions of Jupiter and Mars in 1879 and 1881. Metcalf acquired his first telescope, a 2-in. French spyglass, in 1882. This was replaced in a few years by a 3.6-in. Fitz refractor. Metcalf graduated from Meadville Theological Seminary in 1890, continued his education for a year at Harvard Divinity School, and completed a Ph.D. at Allegheny College, Meadville, in 1892. He married Elizabeth S. Lockman, of Cambridge, Massachusetts, in September 1891. They had a son and a daughter.

Metcalf was ordained as a Unitarian minister in 1890. After organizing a church in Roslindale, Massachusetts, Metcalf accepted his first formal pastorate in Burlington, Vermont in 1893. That same year, Metcalf began to perfect his techniques for designing and polishing lenses.

In 1901, Metcalf acquired a 7-in. Alvan Clark & Sons equatorial from the estate of Elisha Arnold, a wealthy amateur astronomer of Keesville, New York. The telescope and its heavy mounting, a one-ton granite pier, and the dome were all transported across the frozen Lake Champlain, New York, in February. The dome and granite pier were nearly lost when the ice cracked and the horses bolted.

The load straddled the crack perilously, supported only by the edges of the dome, before neighbors helped Metcalf complete the transportation. After the observatory was reassembled in Burlington, Metcalf apparently limited himself to recreational observing; he published no formal scientific papers during this 10-year period of his career. The observatory was eventually donated to the University of Vermont.

After a decade of intense community service in Burlington, and exhausted to the point of a nervous breakdown, Metcalf took a leave of absence to spend a year at Oxford University in England. There, he attended an average of 24 lectures weekly on philosophy and religion. Oxford's Radcliffe Observatory director **Herbert Turner** became aware of Metcalf's intense interest in astronomy, and gave him keys to the observatory. Metcalf observed furiously in addition to his vigorous classroom participation. He published one project in the *Monthly Notices of the Royal Astronomical Society*, the astrometric positions and magnitudes of 90 stars in Cygnus. Although stressed by this dual occupation, it provided welcome relief for Metcalf; he returned to the United States exhausted but mentally refreshed.

After his return from England, Metcalf served at the First Congregational Church in Taunton, Massachusetts from 1904 to 1910. As a minister, he was very active in the social issues of the time, child labor, low wages, and social injustice, and called for slum elimination. Metcalf belonged to the Taunton Science Club, was elected president of the Ministerial Association, and in April of 1906 was elected to the Executive Committee of the Channing Conference of Unitarian churches in Rhode Island, Southern Massachusetts, and Eastern Connecticut.

By late 1905 Metcalf had reestablished himself in astronomy with a new roll-off roof observatory. In addition, he completed a 12-in. photographic telescope with which he could record a field of stars over 4° in diameter on an 8-in.-by-10-in. photographic plate. It was in Taunton, using the 12-in. camera, that Metcalf's career as a discoverer of asteroids, comets, and variable stars ignited. Following a suggestion by **Solon Bailey**, Metcalf developed a new photographic asteroid search procedure. In a reversal of the normal process, Metcalf guided his telescope so it would track the retrograde motion of an asteroid as it drifted slowly against the background of stars. The consequence of this change was that stars appeared on photographic plates as lines, but any asteroid in the field appeared as a single spot. The asteroid was not only easy to identify, but much fainter asteroids were detected because their light was all concentrated in one spot. Metcalf took two exposures one half hour apart, shifting the plate slightly between them, to avoid misidentification of plate flaws. Within 3 months Metcalf discovered three new asteroids, in late 1905 and early 1906. He described his new procedure for the information of other astronomers in the *Astrophysical Journal*. In a second *Astrophysical Journal* paper he demonstrated how the procedure could be used to study short-term light variations in asteroids. Metcalf discovered 31 asteroids from Taunton using this procedure. He also discovered six variable stars photographically, AK Her, RW Leo, SS Tau, UU Tau, UV Tau, and NSV04158 Cnc. On 15 December 1906, while searching for asteroids photographically, Metcalf discovered the short-period comet now known as 97 P/Metcalf-Brewington.

Metcalf accepted a call to a new pastoral assignment at the Unitarian Society in Winchester, Massachusetts in 1910. He made his 32nd asteroid discovery, his first from Winchester, in November 1911. In the next 3 years Metcalf discovered nine more asteroids bringing his total to 41. During his stay in Winchester, he also discovered one more variable star, NSV 04891 Leo.

Metcalf's work in optics was conducted mainly as recreation during Unitarian summer camps at South Hero, Vermont. In addition to the 12-in. photographic doublet, he developed a 7-in. folded *f*/10 refractor for use as a comet seeker. Sweeping the sky from a hill near their summer cottage with this telescope in August 1910, he discovered comet C/1910 P1 (Metcalf). His third comet, C/1913 R1 (Metcalf), was also discovered from South Hero. Other optical work computed and polished by Metcalf at South Hero included a 10-in. triplet for photographic patrol work at Harvard's Oak Ridge Observatory. The 10-in. triplet went into service at the Boyden Observatory, University of the Orange Free State, Bloemfontein, South Africa. The 12-in. doublet used for so many asteroid, comet, and variable star discoveries in Taunton, and Winchester, is now located at Oak Ridge Observatory, as is a 16-in. *f*/5.25 photographic doublet that Metcalf designed and polished under contract to Harvard.

When the United States entered World War I, Metcalf volunteered to serve the troops through the Young Men's Christian Association. Assigned to the front lines with the 3rd division, 7th infantry, he saw action at Château Thierry and the battle of the Marne, delivering letters, cigarettes, and candy to the troops, and even carrying wounded soldiers and/or their equipment during frequent 25-mile marches. He received a citation for bravery in action, and recuperated in Paris after experiencing shell shock and being exposed to mustard gas. After returning to the United States in 1919, Metcalf volunteered to go with the Unitarian Church to Transylvania (Hungary) to help with the reconstruction of 100 churches in that country.

Metcalf's last pastoral assignment was in Portland, Maine, where he served until his death. While vacationing in South Hero, he discovered two more comets, including 23P/1919 Q1 (Brorsen–Metcalf) and C/1919 Q2 (Metcalf). This was the second recorded apparition of comet 23P, a comet with an orbital period around 72 years. Metcalf also made an independent rediscovery of comet 22P/Kopff in 1919, and discovered two more variable stars, SV Hya and WZ Oph. Thus, although the rigors of Metcalf's war service had taken a severe toll on him, he was still making contributions to astronomy. At the time of his death, Metcalf was making a 13-in. photographic triplet lens of his own design. The triplet lens was later completed by C. A. Robert Lundin of Alvan Clark & Sons and used in the discovery of the planet Pluto by **Clyde Tombaugh** at Lowell Observatory.

A further appreciation of Metcalf's importance in astronomy may be gained in several quite different ways. Metcalf was chair of the Visiting Committee for Harvard College Observatory and a member of the Visiting Committee for the Ladd Observatory at Brown University, serving as chair of a search committee when Brown University needed a new observatory director. **Edward Pickering** nominated Metcalf to serve on both the Comet and Asteroid Committee of the American Astronomical Society.

Metcalf died of an aneurysm. About 900 persons attended his funeral in Portland including several justices of the Supreme Court.

Metochites [Metoxites], Theodore [Theodoros, Theoleptos]

Born **Nicaea, (Iznik, Turkey), 1260/1261**
Died **Constantinople, (Istanbul, Turkey), 1332**

Son of George Metochites, a cleric of the Eastern Orthodox Church during the imperium of Emperor Michael VIII Paleologos, Theodore Metochites grew up in the cultural center of Constantinople. However, because his father George favored union with the Latin Church, the family was exiled. Theodore, nevertheless, received a good education and completed his *enkyklios paideia* by the time he was 20. Favored by Emperor Andronikos II, he became a close collaborator and counselor. In this capacity he made several important diplomatic missions to Cyprus, Serbia, and Thessaloniki, among others, and was appointed to several successively more important public offices. In 1304, Metochites was appointed to the highest position of the Byzantine administration, *megas logothetes*, or Grand Deputy, with duties equivalent to chancellor or prime minister, which he held until 1321.

Metochites's career ended when the emperor was deposed, and he was exiled by the new Emperor Andronikos III Paleologos. He died, as the monk Theoleptos, in 1332 at the Chora monastery in Constantinople to which he had donated his extensive library, and whose restoration work he had personally supported. Metochites's mosaic portrait in the monastery where he offers the Church of Chora to the enthroned Christ commemorates his extensive gifts to the institution.

Metochites was an exceptionally prolific writer and scholar, leaving behind works of rhetoric (royal eulogies and discourses), 20 poems, a literary testament in verse, a collection of philosophical texts, and two works on astronomy. His collection of texts, *Hypomnematismoi kai semeoses gnomikai* (Annotations and gnomic notes or Personal comments and annotations), an astonishing collection of essays and texts on history, literature, and thinking, includes material on over 70 Greek authors. It contains the most extensive commentary on Aristotelian philosophy of the late Byzantine period. Metochites's commentaries on the *Dialogues of Plato* had an important influence on the Platonic renaissance of the 15th century.

Metochites's work associated with astronomy includes his paraphrases of **Aristotle**'s works on natural philosophy and his comprehensive introduction to Ptolemaic astronomy. His *Stoicheiosis Astronomike* (Elements of astronomy) revived Ptolemaic studies in Byzantium and gives evidence of the significance of contacts with Persian and Arabic science in astronomy as practiced in the period of the early Paleologai. In this work, Metochites described earlier astronomical studies and made a clear argument for the importance of astronomy over the other branches of mathematics. He clearly distinguished between astronomy and the then popular apotelesmatics (astrology), which he condemned. In his *Semeoses gnomikai* (Annotations), Metochites provided an important critique of Aristotle.

Meton

Flourished **Athens, (Greece), *circa* 432 BCE**

An early careful and quantitative observer, Meton is known for his calendrical discoveries, some of which are still in use today.

Meton was the son of Pausanias, but little is known of his life apart from a few probably apocryphal stories, such as the tale, found in **Plutarch**, that he simulated madness to avoid military service. Meton was a contemporary of the famous Greek playwright Aristophanes, who characterized him in his still popular comedy *The Birds*, as a ridiculous geometer. The picture of Meton given here is, of course, a caricature, but it indicates that he was well known to contemporary Athenians, as he himself avers in the play, and it probably contains more than a grain of truth. He is shown wearing soft boots, typical of women and effeminates, and he makes a show of publicly carrying out his researches.

Like most other ancient Greek astronomers, however, Meton is known essentially for his contributions to science. He may well be the first astronomer who moved away from an approach to astronomy tied up with magic and came to conclusions based on serious, scientific investigations. He is certainly the first personality on whom those pillars of ancient astronomy, **Hipparchus** and **Ptolemy**, relied as a collector of reliable and usable data.

Meton, probably along with others (notably **Euctemon**), carried out careful observations to detect the solstices, by determining when the shadow cast by a gnomon was at its maximum and minimum. He observed that 235 lunations, or synodic months, amount approximately to 6,939 days and 16.5 hours, while 19 solar years amount to 6,939 days and 14.5 hours – a difference of only two hours. Now 19 years of lunar months amount to 228; by intercalating 235–228 = 7 months over the course of the 19-year cycle, it is possible to synchronize lunar months and solar years.

This observation has no relevance to the Gregorian calendar (which is based on the Sun) or to the Muslim calendar (which is based on the Moon, and hence runs perpetually about 11 days shorter than the solar year). Meton's observation has, however, had continuing relevance for the Jewish calendar, which determines how all Jewish festivals fall. These are observed to this day by Jews throughout the world.

The ancient Hebrew calendar was basically lunar, but the festivals such as Passover had to fall at the appropriate season of the year. Originally this calendar was *ad hoc*. When the New Moon was sighted, the Jerusalem Sanhedrin declared the new month, which might occur after 29 or 30 days (since the mean synodic month is slightly over 29.5 days long), and the message was relayed by beacons on high places to persons living at a distance. When the spring month in which Passover would be celebrated was approaching, yet there were no signs of spring, the authorities would announce the intercalation of a full month, in order to "catch up" with the Sun. Such a calendar is self-correcting, since a dubious call in respect of the sighting of the Moon or the intercalation of the month, would be corrected next time around. On account of political changes, such a system gradually became unworkable, and around the 7th century Meton's cycle was used to substitute a perpetual calculated calendar, still in use today. In it, some slight modifications known as "postponements" were introduced, in order to avoid the coincidence of certain religious celebrations on or near the Sabbath, with attendant religious problems. This calendar was more accurate than the Julian calendar, despite its relatively large swings, but will ultimately require correction (to allow for the slight error in the ancient calculation of the mean lunation period).

The Metonic cycle also determines the Christian festival of Easter. Easter was originally fully dependent on the Jewish Passover, but, beginning with the Council of Nicaea in 325, the Church attempted to fix an independent, agreed date. In the west this was eventually settled on as the first Sunday after the paschal moon occurring on or after the Vernal Equinox, reckoned as 21 March. But the determination of the paschal moon is based on Meton's cycle and does not necessarily correspond to the astronomical Full Moon, any more than the beginning of a Jewish month necessarily corresponds with the New Moon.

The Metonic cycle has its place in the Julian Period proposed in 1583 by Joseph Justus Scaliger, and named by him for his father Julius. This consists of numbered days in a period of 19 × 28 × 15 = 7,980 years, beginning on 1 January 4713 BCE. The figure was arrived at by multiplying together the numbers of years in the Metonic cycle, the solar cycle of the Julian calendar, and the ancient Roman cycle of indiction. The starting point was the nearest past year in which the cycles began together. Julian dates are still in use by astronomers.

Another place where the Metonic cycle figures is in the calendrical ciphers known as clog almanacs, found on boards or sticks, used in western Europe for hundreds of years until the 17th century. These present the so called golden number, which gives the position of a particular year within the Metonic cycle. They were first noticed in England by Richard Verstegan in his book *A Restitution of decayed intelligence* (London, 1634) p. 58:

> They used to engrave upon certaine squared sticks about a foot in length the courses of the Moones of the whole yeere, whereby they could al waies certainely tell when the new Moones, full Moones, and changes should happen as also their festival daies.

Metrodorus of Chios

Flourished **Chios (Khíos, Greece), *circa* 325 BCE**

Metrodorus of Chios formulated the first theory of the origin of the Universe and made several early contributions to astronomy and cosmology. He is often confused with Metrodorus of Lampsacus, but the two have no relation to each other. Metrodorus of Chios (hereafter referred to as Metrodorus) was most likely born in the fourth century BCE, though Smith suggests the date 500 BCE is more probable. However, Freeman (1966) indicates that his father was put to death during the reign of Antigonus Gonatas between 323 and 301 BCE, putting his (Metrodorus' father's) birth date between 400 and 380 BCE. This means Metrodorus could not have been born earlier than 380 BCE.

Metrodorus was the son of Theocritus, who was a well-known statesman in Chios. Theocritus was, oddly enough, the student of yet another Metrodorus, who some have suggested is the younger Metrodorus' namesake. Theocritus was also a leader of an anti-Macedonian democratic party in Chios, but these political interests do not seem to have been inherited by his son, who was largely interested in the physical sciences and epistemology. Metrodorus was thought to have studied under **Democritus**, though some scholars have argued that Metrodorus simply learned the teachings of Democritus from Nessas. This latter point makes sense in light of the likely dates of his life, for Democritus died in 359 BCE and Metrodorus most likely was born well after 380 BCE, making him too young. Once Metrodorus had established himself as a philosopher, his pupils included Diogenes of Smyrna, who later taught Anaxarchus.

Metrodorus' views on the physical sciences are described in his book *On Nature*. Metrodorus espoused the view that the stars, like the Moon, were lit up by the Sun, and that the Milky Way marked the line of passage of the Sun. Meteorites were sparks caused by the collision of clouds drawn up by the Sun. The Sun's heat also apparently caused the winds to form. This latter fact is due to his view that the Sun was a "sediment" of the air and was constantly quenched and ignited. This occurs when air condenses, forms a cloud (of water), and descends on the Sun, which puts out the fire. However, it is reignited when the water dissipates. Metrodorus extended this concept to describe some processes of the early Universe. He said that this process of quenching and reigniting continued until the fire of the Sun dominated the water vapor around it. The stars then formed from portions of this water vapor. (Basically they were ignited clouds.) He also extended the quenching and igniting aspect to explain night and day, as well as eclipses. This concept is fascinating, as it is one of the earliest scientific (albeit completely incorrect) explanations of the formation of the Universe.

Meotrodorus' views on cosmology also contained another progressive viewpoint. It was his opinion that the world was only one of many, since "it is as unlikely that a single world should arise in the infinite as that a single ear of corn should grow on a large plain" (Guthrie, 1965, 405). In terms of the ordering of the cosmos, Metrodorus held that the Sun was the highest object in the sky, with the Moon next and beneath them the planets and stars. Metrodorus also contributed several noteworthy arithmetical puzzles, including some that dealt directly with astronomy.

Michell, John

Born **Nottinghamshire, England, 1724**
Died **Thornhill, (West Yorkshire), England, 21 April 1793**

Reverend John Michell demonstrated the existence of binary stars and physical star clusters, predicted the existence of black holes, and made the first realistic estimate of the distance to a star, all major intellectual achievements for an 18th-century English scientist – clergyman.

Michell is thought to have been born in Nottinghamshire, perhaps on Christmas Day 1724, but that is uncertain. There are no portraits available, and only a brief description of him as "a little short man, of a black complexion, and fat" exists in a contemporary diary. It is known that he married a Sarah Williamson in 1764 but that she died the next year.

In 1742 Michell became a student at Queens' College, Cambridge University, from which he received his MA (1752) and BD (1761) degrees. During this time he held the first of several rectorships at churches in the region.

In 1767 Michell published a paper on double stars and clusters, arguing that they were far more common than would be the case if stars were randomly scattered over the celestial sphere. For example, he estimated that there was only about one chance in 496,000 that random placement would result in a cluster like the well-known Pleiades. Consequently, he argued that most close pairs of stars must be physical binary star systems and most clusters must be physically close groups of stars, probably held together by the gravitational force. This was apparently the first use of statistical arguments in astronomy, and the result was confirmed when **William Herschel** measured the motion of the stars in a few binary pairs around each other.

Michell was also a telescope builder; he built his own reflector with a 30-in.-diameter primary mirror and a focal length of 10 ft. After his death, this telescope was purchased by Herschel, who built a newer but similar reflector.

In May 1783 Michell wrote a fascinating letter to **Henry Cavendish** (1731–1810), which Cavendish read before the Royal Society on 27 November 1783 and had published in the *Philosophical Transactions*, 1784. Starting from **Isaac Newton**'s corpuscular theory of light, published in his *Opticks*, Michell pointed out that light particles leaving an astronomical object such as a star would slow down like any other objects in a gravitational field, and that this decrease in speed might be used to provide information about the mass and distance of stars. For example, the images through a prism of different stars would be offset differently depending on the speeds of their light, and from this one could recognize differences in mass.

Michell also pointed out that if a star was massive enough, its escape speed might exceed the speed of light from the star, so that light could not escape, rendering the star invisible – the first known description of what we now call a black hole. He also tried to determine the mass of such a star on the assumption that it had the same density as the Sun, and estimated that it would have 497 times the diameter of the Sun, stating that "a body falling from an infinite height towards it, would have acquired at its surface a greater velocity than that of light, and consequently, supposing light to be attracted by the same force in proportion to its *vis inertiae*, with other bodies, all light emitted from such a body would be made to return towards it, by its own proper gravity." Such a classical Newtonian black hole star would be incredibly more massive than the Sun, of course, far more than is required by the modern theory of black holes. However, his calculation of the mass-to-radius ratio was correct.

Michell apparently did not think it likely that many such unseen stars would exist, but he pointed out that the presence could be detected by their gravitational influence on nearby objects. For example, a binary system with a black hole would seem to have a star revolving around nothing. Indeed, black holes can be detected in this fashion today.

The following year, 1784, Michell made the first realistic assessment of the distances to the stars. Reasoning by means that are analogous to modern photometric parallaxes, he used the apparent diameter and brightness of Saturn, and its known distance from the Sun, to infer that Vega, with approximately the same brightness as Saturn, must be some 460,000 astronomical units from the Sun. The actual distance is more than four times that much but Michell could not have guessed that Vega is intrinsically much brighter than the Sun. It was over 50 years before **Friedrich Bessel** measured the first stellar parallax to confirm the enormous distances that Michell had been the first to realistically estimate.

In his later years Michell addressed the problem of determining the density of the Earth. Since the radius of the Earth was well known, this was equivalent to determining the mass of the Earth and also the value of *G,* the constant in Newton's law of gravitation. For this purpose Michell devised a truly beautiful experiment to measure the force of gravitation between small lead spheres affixed to the ends of a 6-ft. wooden beam and large lead spheres placed nearby. The beam was to be suspended from a single metal fiber acting as a torsional balance, which Michell invented independently of, and perhaps before, Charles de Coulomb. Measuring the angles of rotation of the fiber with the large sphere first on one side of the beam and then the other, the force between the lead spheres could be compared with the gravitational force of the Earth on the spheres, allowing determination of the density or mass of the Earth.

Michell died before carrying out this experiment, but his apparatus was given to Cavendish, who rebuilt the apparatus and carried out the experiment. This well-known Cavendish experiment (more appropriately, the Michell–Cavendish experiment) produced a value of 5.48 for the specific gravity of the Earth, compared to the modern value of 5.52. Cavendish's 1798 paper on this experiment begins with a long description of Michell's apparatus and experimental design.

In geology, Michell carried out seminal studies of earthquakes, earning him the title "father of seismology." The great Lisbon earthquake of 1755 intrigued Michell, who developed a theory of earthquakes, read to the Royal Society of London in 1760 and published in *Philosophical Transactions*. He suggested that earthquakes were produced when two different layers of rocks rubbed against each other at a particular location many miles beneath the surface of the Earth (now referred to as the epicenter), perhaps caused by steam produced by volcanos. The earthquakes were wave motions of the solid material of the Earth, which traveled from their source to other parts of the Earth. Michell distinguished between two different types of waves of different speeds, which he expected would enable the location of the epicenter to be determined.

While at Cambridge Michell wrote a *Treatise of Artifical Magnets* (1750), describing for the first time in print how to make strong artificial magnets. He also reported experiments that showed the forces between magnets were consistent with an inverse-square law between individual poles of the magnets.

Michell's work on earthquakes and seismology led to his election in 1761 as a fellow of the Royal Society of London, a position he had coveted. It also merited him the Woodwardian Chair of Geology at Cambridge University, which he held from 1762 to 1764. In 1767, apparently in order to earn a better living, Michell became rector of the Church of Saint Michael and All Angels in Thornhill, near Leeds, Yorkshire, England, where he remained the remaining 26 years of his life, and where he was buried.

Michelson, Albert Abraham

Born **Strenlo (Strzelno, Poland), 19 December 1852**
Died **Pasadena, California, USA, 9 May 1931**

Albert Michelson made the first measurement of a star's diameter and many measurements of the speed of light. His longevity, extraordinary skills of observation, and his enthusiasm for research (which he often expressed as "It is such good fun!") allowed him to make significant other contributions to the fields of optics, astronomy, and the study of light.

Michelson came to the United States as a child in 1855, living with his parents first in New York and then in the western states of Nevada and California. He attended high school in San Francisco, California, where his science teacher encouraged him to continue his formal education after matriculating in 1869. Michelson was able to secure a position at the United States Naval Academy, at Annapolis, Maryland (the first Jew to be admitted) and graduated in 1873. Following this he served as a midshipman in the navy for 2 years and then was appointed to the position of instructor of physics and chemistry at the Naval Academy from 1875 to 1879. While this is an impressive start to his career, it is even more so when it is noted that there were no vacancies at the Naval Academy when Michelson was applying for admission. It was only through the favorable impression made on President U. S. Grant and high-ranking navy officials at the meeting he arranged in Washington, DC, that he was able to secure the appointment.

Michelson married Margaret McLean Heminway in 1877, and they had three children. They eventually divorced, and Michelson later married Edna Stanton in 1899; they had three children. In 1879, Michelson took up a post at the United States Naval Observatory Nautical Almanac Office in Washington to work with **Simon Newcomb**. The following year he received a leave of absence to travel to Europe, where he studied at the Collège de France and the universities of Heidelberg and Berlin. On his return to the United States in 1881 Michelson resigned from the navy.

Michelson received an appointment as professor of physics in the Case School of Applied Science in Cleveland, Ohio, in 1882, which he held until 1889 when he accepted a similar position at Clark University at Worcester, Massachusetts. Michelson was offered the position of professor and head of the Department of Physics at the University of Chicago in 1892, which he accepted, and he remained there for the rest of his career.

Throughout his career, Michelson's research focused on experimental optics, and most of his 78 papers concerned light. Some of his major accomplishments were the measurement of the velocity of light, ruling of diffraction gratings, development of one kind of interferometer, null detection of the Earth's motion through the "ether," development of the echelon spectrometer, measurement of stellar diameters, and an investigation of the metallic colorings in nature. His research influenced other eminent scientists. **Albert Einstein**, for example, probably knew about Michelson's results on the speed of light and its constancy when he formulated his Special Theory of Relativity, in which such constancy was postulated.

Michelson's lifetime of research into the nature of light began as an instructor at the Naval Academy when he was ordered to construct an experiment to measure its velocity. Using what was essentially "home built" equipment, he found he was able to make the measurements. Most surprising was that his measurements proved more accurate than any that had been previously obtained! Michelson continued to work on making more accurate measurements of the velocity of light while he was at the Case School of Applied Science, and in 1883 he reported a value of 299,853±60 km/s.

In 1887 Michelson and **Edward Morley** collaborated in investigating the motion of the Earth through hypothetical ether using the Michelson interferometer. The presence of the ether was expected to produce a 0.4 fringe difference for two heams of light travelling the same distance parallel and perpendicular to the Earth's direction of motion. However, the measured difference was less than 0.01 fringe, or in other words the effect of the ether was not detected.

Also in 1887 Michelson and Morely showed that they were able to accurately define the length of the standard meter using measurements of the wavelength of light. Using the interferometer and the red cadmium light line, they were able to determine that 1,553,163.5 wavelengths of this light made up a meter. Since the wavelength of light remains constant over a wide range of conditions, they proposed that it would be a better way to define the standard length of a meter rather than the then used "metal bar" standard for the meter. The use of light to define the meter was generally adopted in 1960.

In 1882 Michelson published the theory of his "differential-refractometer," which today is referred to as an interferometer. Much of Michelson's research time at Clark University was spent in pursuing the uses of the interferometer. The interferometer was one of Michelson's most famous inventions and can be simplistically described as a device that splits a beam of light into two parts traveling in different directions and then recombines them such that the difference in their path lengths traveled can be detected. In 1891 Michelson published his technique for using the interferometer to measure stellar diameters and also used the approach to measure the diameters of some of the Jovian satellites. It took until 1920, in collaboration with **Francis Pease** at the Mount Wilson Observatory, for Michelson's dream of measuring stellar diameters to be realized. Together they found the diameter of the star α Orionis (Betelgeuse) to be 47 milli-arcseconds.

Michelson's interest was also caught by Pieter Zeeman's discovery of how magnetic fields influence spectral lines. To explore this effect in greater detail, Michelson invented the echelon spectrometer to provide the resolving power needed to study the effect.

Michelson became a research associate of the Carnegie Institution of Washington in 1924 at the invitation of **George Hale**. At the Mount Wilson Observatory Michelson once again began his experiments in determining the velocity of light. Using projection apparatus located on Mount Wilson, light was reflected back from a receiver on Mount San Antonio some 22 miles away, to determine its velocity. Using this technique he determined the speed of light to be 299,798 km/s. The piers used for this experiment at the Mount Wilson Observatory still stand to this day on a south ridge of the mountain, and a plaque commemorating his experiments is located nearby.

Michelson was not only a man of science but also a Freemason, and he had a well-developed artistic side with many varied interests. He was an avid sketcher and often took his watercolor kit when he went on vacation. Michelson was known to play the violin, enjoy a good game of billiards, and – as a measure of the quality of his health – play tennis until he was past 70 years of age.

Michelson was able to view the beauty of art and nature through science. In a paper he wrote, "On the Metallic Coloring in Birds and Insects," he explored the nature of the metallic colors seen in hummingbirds and certain butterflies. Michelson was able to conclude that their iridescent colors were due to the same effects as the colors reflected from thin metallic films.

Michelson's final experiment was on the same topic on which he began his career, the measurement of the velocity of light. By 1926, he had made more than a thousand measurements of the speed of light using a variety of approaches. Even though the results of these experiments were the best that had ever been made, Michelson was not quite satisfied. For his final experiment he developed a completely new apparatus including a mile long, 3-ft. diameter pipe that could be evacuated of air. The results of this experiment were published in the *Astrophysical Journal* in 1935 by Pease and William Pearson, with Michelson listed as the first author. In this paper they describe the need for the new experiment, which provided a reflective light path through the pipe of eight or ten miles under a vacuum of 0.5 to 5.5 mm of mercury. The result was a measure of the speed of light in a vacuum of 299,774 ± 11 km/s.

To mention just two of Michelson's notable honors, and there are many more, he received the Nobel Prize for Physics in 1907 (the first American to do so in science) for his measurements of the speed of light; he also served as the president of the National Academy of Sciences from 1923 to 1927. Michelson's awards include honorary degrees, medals of merit in science, and membership in scientific societies. There is little doubt that he will continue to be remembered as one of the finest experimental physicists.

Mikhailov, Aleksandr Aleksandrovich

Born **Morshansk near Tambov, Russia, 26 April 1888**
Died **Pulkovo near Leningrad (Saint Petersburg, Russia), 29 September 1983**

Alexsandr Mikhailov oversaw the reconstruction of the Pulkovo Observatory. For decades after World War II, Alexsandr Mikhailov was the capable and authoritative leader of the Soviet Union's astronomical community. He was the author and editor-in-chief of numerous publications and a participant in many scientific expeditions.

Mikhailov graduated in 1911 from Moscow University with a Gold Medal. He served as an astronomy professor at this university from 1918 to 1947. Concurrently, Mikhailov was a geodesy professor at what is now the Geodetic University. From 1947 to 1964 he served as director of the world-famous Pulkovo Observatory – the Central Astronomical Observatory of the Soviet Academy of Sciences. In 1964 Mikhailov was given the title academician.

Mikhailov was decorated with a plethora of Soviet and foreign awards, including the highest Soviet decoration, the Medal of a Hero of Socialist Labor (1978). Living permanently under the pressure of his high social status, especially during the Stalin regime, he – unlike many others of his rank at that time – nonetheless never volunteered to harm his colleagues, associates, and subordinates in the style of the political situation of the time.

The area of Mikhailov's personal scientific interests was very broad: astrometry (positional astronomy), stellar astronomy, gravimetry and the theory of Earth's figure, the theory of eclipses, and space research involving the Moon. He was an active solar-eclipse observer and designed several new astronomical devices for eclipse study. A great erudite, Mikhailov wrote much on the history of astronomy and was notable as a popularizer of astronomical knowledge.

An amazingly hardworking person who was fluent in several European languages, Mikailov was an illustrious communicator of Soviet science to the international astronomical community. He was elected as a member of many scientific bodies abroad. Mikailov served as a vice president of the International Astronomical Union (1946–1948), and as a vice president of the International Academy of Astronautics (1967–1977).

It was Mikhailov who oversaw the reconstruction of the glorious Pulkovo Observatory, which had been completely destroyed by the Nazis during the siege of Leningrad during World War II. The observatory was successfully restored as a great symbol of Russian science. Unfortunately, decades later Mikhailov himself became an eyewitness to the slow decline of this internationally acclaimed scientific institution.

Mikhailov married Zdeňka Kadlá in 1946. The couple had a son, Georgij Aleksandrovich Mikhailov.

Milankovitch [Milankovič], Milutin

Born **Dalj, (Croatia), 28 May 1879**
Died **Belgrade, (Serbia), 12 December 1958**

Yugoslavian mathematician and geophysicist Milutin Milankovitch is best known for his presentation of the theory that Earth's paleoclimate resulted from interactions of three long-term astronomical cycles affecting the amount of solar energy received by Earth.

Milankovitch was awarded a doctorate in technical sciences from the Technical High School (later the Institute of Technology) in Vienna in 1904. For the next 5 years, he served as a chief engineer in the construction industry, working with reinforced concrete. In 1909, he was appointed to a professorship in physics and celestial mechanics at the University of Belgrade in Yugoslavia, where he remained until his retirement some forty-six years later. Milankovitch was a member of the Serbian Academy of Sciences and other professional organizations.

Starting around 1912, and for the next thirty years, Milankovitch convincingly demonstrated that variations in (1) the eccentricity of Earth's orbit around the Sun and (2) the obliquity of Earth's axis of rotation, along with (3) the precession of the equinoxes, all contributed to cyclical changes in climate experienced over the past 600,000 years, most notably during the Pleistocene glaciation. Because the three variations have different periods (the best-known is the 26,000 years of precession), they sometimes reinforce and sometimes nearly cancel each other, producing large swings in the amount of sunlight reaching the northern hemisphere. These long-term astronomical and climatological cycles are known as Milankovitch cycles and have gained widespread acceptance.

Millman, Peter Mackenzie

Born **Toronto, Ontario, Canada, 10 August 1906**
Died **Ottawa, Ontario, Canada, 11 December 1990**

Peter Millman developed several pioneering programs to observe meteors and to record their spectra. He was the son of Robert M. Millman and Edith Middleton. In 1931, Millman married Margaret B. Gray with whom he had two children, Barry and Cynthia.

Millman spent most of his youth in Japan, where his parents were missionaries. His interest in astronomy developed during his secondary education at the Canadian Academy in Kobe. Millman returned to Canada to enter the University of Toronto, where he took his B.A. in astronomy with the Royal Astronomical Society of Canada Gold Medal in 1929. As an undergraduate, he worked as a summer student at the Dominion Astrophysical Observatory, Ottawa. During his graduate training at Harvard Observatory, **Harlow Shapley** suggested Millman analyze meteor spectra in the observatory's collection. After taking his M.A. (1931) and Ph.D. (1932), he remained another year at Harvard as an Agassiz Fellow.

In 1933, Millman joined the Astronomy Department at the University of Toronto. With the opening of the David Dunlap Observatory in 1935, he participated in the routine radial velocity program but also initiated visual meteor observations and developed a meteor spectra program. Millman joined the Royal Canadian Air Force in 1941; after teaching navigation to pilots, he moved to London to work in operational research. On his return in 1946, he moved to the Dominion Observatory, where he became chief of the Stellar Physics Division and developed a visual meteor program.

From the late 1940s, Millman worked with D. W. R. McKinley of the National Research Council [NRC] of Canada on visual and radar tracking of meteors by triangulation. In the early 1950s, two stations with super-Schmidt cameras were erected in Alberta in a joint United States–Canadian project to study the upper atmosphere. Millman's meteor spectrographs in Alberta and Ottawa produced a steady stream of data. In 1955, Millman joined the NRC as head of its Upper Atmosphere Research Section.

Millman was active in the Royal Astronomical Society of Canada (president: 1960–1962), president of the Meteoritical Society (1962–1966), president of Commission 22 of the International Astronomical Union [IAU] (1964–67), chair of the IAU Working Group for Planetary System Nomenclature (1973–1982), and first secretary of the Canadian Astronomical Society (1971–1977). He was also a fellow of the Royal Society of Canada and a councillor of the Smithsonian Institution. Millman was awarded the J. Lawrence Smith Medal of the United States National Academy of Sciences in

1954, awarded the Gold Medal of the Czechoslovak Academy of Science (1980), and a minor planet (2904) was named for him.

Millman was the world's leading authority on meteor spectra, being the first to undertake systematic spectroscopic studies. Beginning in his Toronto days, he organized visual meteor programs. After World War II, radar and photographic recording of meteor showers were added. During the International Geophysical Year, this became a North America-wide project, providing solid statistics on meteors. Millman was a pioneer in using aircraft for observing meteors and solar eclipses. He collaborated with **Carlyle Beals** on meteorite impact structures, and later devised a program for meteorite recovery.

Milne, Edward Arthur

Born **Hull, England, 14 February 1896**
Died **Dublin, Ireland, 21 September 1950**

British mathematician Edward Milne contributed many of the ideas that have made it possible to analyze the spectra of stars and determine the temperatures, densities, and chemical compositions of their atmospheres, some of those ideas carrying his name. However, he is perhaps more often remembered for a unique cosmological model in which gravitation and electromagnetism followed two different kinds of time.

Milne was the eldest of three sons (all eventually scientists) of a headmaster of a Church of England school, Sidney Milne, and a teacher, Edith Cockcroft. After completion of studies at Hymers College in Hull, Milne won a scholarship at Trinity College, apparently having achieved the highest score to date on the entrance examination. His eyesight made him ineligible for active duty in World War I, but a year and a half after beginning work (in 1914) at Cambridge, he withdrew to work on antiaircraft ballistics research for the duration of the war. Shortly after returning in 1919, Milne was elected a fellow of Trinity College (precluding the need for an advanced degree) and, in 1920, became assistant director of the Solar Physics Observatory under Hugh Frank Newall, the founder of astrophysics at Cambridge. Milne was appointed to the Beyer Professorship of Applied Mathematics at the University of Manchester in 1925 and, in 1929, became the first Rouse Ball Professor of Mathematics at Oxford University, where he and **Harry Plaskett** founded another school of astrophysics.

Milne's work of greatest lasting importance was done at Cambridge and Manchester. He showed that a star in which energy was transported by radiation could not rotate like a solid body, and that the pressure of radiation on atoms with very strong absorption lines (like the violet pair of ionized calcium) would be enough to lift atoms off the surface of a star into its chromosphere. Such "line driving" is now recognized as the cause of winds from cool, bright stars. Working with **Ralph Fowler,** Milne showed that these strong lines are produced very high in the atmospheres of the Sun and stars, and used the Saha equation to calculate the temperature at which lines would be strongest. This, in turn, led to a theoretical explanation of why some spectral features of ionized atoms look stronger in giants than in dwarfs, providing the physical underpinning of stellar luminosity criteria, including an explanation of what the light coming from the Sun ought to look. He pioneered the idea of detailed balance in stellar atmospheres (the idea that the number of transitions between a pair of levels going up and down must have a fixed ratio), leading to what were then called the Milne relations, and derived a form of the equation describing how radiation propagates through stellar gas that also carries his name. His approximation for the opacity of gas to that propagation is still used in calculations to show what the dominant effects must be in the appearance of stellar spectra. And the Milne–Eddington approximation describes absorption features and the stellar continuum as it is being formed together in all layers of the atmosphere.

At Oxford, Milne turned his attention to cosmology, as did many astronomically inclined British mathematicians, in light of **Edwin Hubble**'s discovery of the redshift–distance relation and the increasing familiarity of **Albert Einstein**'s general theory of relativity. Milne and **William McCrea** in 1934 published a set of Newtonian cosmological models that had many of the features of the relativistic ones, but were much easier for most people to understand and are still used as analogies in modern discussions of cosmology. But Milne felt that his most important contribution was what he called kinematic relativity. He started with homogeneity and isotropy (so that every fundamental observer would see not only the same physics but the same history of the Universe) as a basic assumption, not as an observation. Milne believed that he could follow this assumption to a single-model universe that would be the only self-consistent possibility, requiring certain laws for gravitation and so forth. This was not published in final form until his 1948 book, *Kinematic Relativity*. By then he had also incorporated different timescales for gravitational and electromagnetic time, the former a natural logarithm of the latter. Others have returned from time-to-time to these ideas, but so far without much impact on understanding of either the structure of the Universe or the physics in it.

Also at about the time he went to Oxford University, Milne suggested that nova explosions might be caused by the collapse of a normal star to a white dwarf. They are in fact explosions on the surfaces of white dwarfs with close companions, but the suggestion meant that the idea of collapse as a source of rapid energy release was "in the air" when **Walter Baade** and **Fritz Zwicky** put forward the (correct) idea of powering supernovae with collapses to neutron stars.

Milne was elected to the Royal Society (London) in 1926, and received medals from the Royal Astronomical Society (London), the Astronomical Society of the Pacific, and other scholarly organizations. He served as president of the London Maths Society (1937–1939) and suffered a fatal heart attack during a meeting of the Royal Astronomical Society, which he had served as president from 1943 to 1945.

Milton, John

Born **London, England, 9 December 1608**
Died **London, England, 8 November 1674**

Although in no technical sense an astronomer, John Milton, the greatest epic poet of the English language, engaged the new world picture of **Nicolaus Copernicus**, **Galileo Galilei**, and **Johannes Kepler** and imaginatively stretched the boundaries of the canvas upon which it was painted.

Milton's birth coincided roughly with the invention of the telescope. The son of a well-off middle-class Puritan father, he received a rich religious and classical education at Saint Paul's School in London and at Cambridge University. After leaving university, Milton pursued a further period of personal study, and in 1638 embarked on an almost 2-year Grand Tour; this took him to Italy, where he was granted an audience with the aging Galilei. This encounter, in addition to stimulating his awareness of astronomical issues, reinforced Milton's sense of identity as a free Englishman and a Protestant: "I found and visited the famous *Galileo* grown old, a prisoner to the Inquisition, for thinking in Astronomy otherwise than the Franciscan and Dominican licencers thought" (*Areopagitica*, 1644; in Flannagan, p. 1014b).

In the 1640s and 1650s, Milton was an active defender of the antiroyalist position in the English Civil War and the Commonwealth under Oliver Cromwell, writing the official defense of the 1649 execution of King Charles I (*Defensio pro populo Anglicano*, 1651). Soon thereafter, Milton became completely blind, and some of his enemies saw the latter state as divine punishment for his regicidal propaganda. After the restoration of the monarchy in 1660, Milton narrowly escaped with his life, and the rest of his years were spent in relative seclusion. It was principally in this period, from 1660 until his death in 1674, that he produced the greatest of his poetic works, the epic *Paradise Lost* (1667), and *Paradise Regained* and *Samson Agonistes* (published together in 1671).

The narrative of *Paradise Lost* encompasses not only the fall of humankind into sin but also extensive probing of astronomical issues. In Milton's exercise of cosmological imagination, Galilei's influence can be traced in a number of ways. Galilei is the only contemporary of Milton's to be explicitly named in *Paradise Lost*, and his discoveries provided Milton with an abundant store of both poetic and scientific material. For example, Satan's shield is described as being

> like the moon, whose orb
> Through optic glass the Tuscan artist views
> At evening from the top of Fesole,
> Or in Valdarno, to descry new lands,
> Rivers or mountains in her spotty globe. (*PL* 1.287–1.291.)

Milton thus not only alludes to Galilei's telescopic examination (in *Sidereus Nuncius*) of the Moon's surface, but also uses the simile to suggest that Satan's armor, when viewed up close, may, like the Moon, appear less perfect and "celestial" than one had previously thought. Milton again references Galilei's telescopic discoveries – and again associates Satan with the word "spot," implying blemish – in calling the fiend, in his solar journey, "a spot like which perhaps / Astronomer in the sun's lucent orb/Through his glazed optic tube yet never saw" (*PL* 3.588–3.590). Milton nods in the direction of yet a further discovery of Galilei's – that the Milky Way consists of multitudinous stars – when the angel Raphael, speaking to Adam, the first man, refers to "the Galaxy, that Milky Way/Which nightly as a circling zone thou seest/Powdered with stars" (*PL* 7.579–7.581).

Because of suggestions in *Paradise Lost* that the Earth may be in the center of the world, Milton's astronomical position is often wrongly thought to be basically Ptolemaic. However, Milton undermines this premature conclusion in two main ways. One includes the Copernican references and vocabulary that he and his authoritative characters (such as Raphael) employ, even if these appear in the context of similes or surmises. Speaking to Adam, Raphael asks, "What if," in addition to the six planets, "seventh to these/The planet earth, so steadfast though she seem,/Insensibly three different motions move?" (*PL* 8.128–8.130). Earth's status as a planet and its three motions are clearly Copernican, as is Raphael's further reference to Earth "as a star/Enlight'ning her [*i. e.*, the Moon] by day, as she by night/This earth" (*PL* 8.142–8.144).

A final feature of the narrative of *Paradise Lost* that places it in the tradition of Copernicans such as Kepler and **John Wilkins** is its envisaging of the transport of living bodies across astronomical space. As Robert Burton had pointed out in 1638, the dissolution of the Aristotelian "hard and impenetrable" crystalline spheres opened up the prospect of space travel: "If the heavens then be penetrable, … it were not amiss in this aerial progress to make wings and fly up" (*The Anatomy of Melancholy,* Part 2, p. 50). In *Paradise Lost* Satan does just this, though his flight is not upwards from Earth toward the stars, but down through the stars toward the Sun and the Earth. From the rim of the Universe, downward Satan "throws"

> His flight precipitant, and winds with ease
> Through the pure marble air his oblique way
> Amongst innumerable stars, that shone
> Stars distant, but nigh hand seemed other worlds. (*PL* 3.563–3.566.)

J. Tanner has called *Paradise Lost* "perhaps the greatest description of space travel in highbrow fiction." Yet what enabled Milton to produce such a description – and so to contribute to the genre of science fiction, then in its infancy – was his immersion in the cosmological ferment of his day.

Much more cosmologically radical than these generally Copernican themes, however, was Milton's imaginative depiction of our universe of stars, Sun, and planets as itself a mere speck within an immensely larger, perhaps infinite, physical "creation" dominated by the unformed matter of chaos. In Milton's extracosmic chaos, even normal categories of time and space do not apply. It is

> a dark
> Illimitable Ocean without bound,
> Without dimension, where length, breadth, and highth,
> And time and place are lost. (*PL* 2.891–2.894.)

Moreover, these dark, chaotic materials, which are nevertheless of divine origin, may be, or may become, the stuff of new or other "worlds" (*PL* 2.916).

In any case, in the picture presented in *Paradise Lost*, the entire known stellar Universe – regardless whether its internal structural features be Ptolemaic or Copernican – is enclosed in a sphere that hangs down from the walls of heaven. And when Satan, on his journey across chaos, beholds this Universe from afar, it appears as a mere speck, "in bigness as a star/Of smallest magnitude close by the moon" (*PL* 2.1052–2.1053). Such, in the decades just before the advent of **Isaac Newton**'s cosmology, was Milton's imaginative poetic expansion of cosmography outward toward the infinite.

Mineur, Henri Paul

Born **Lille, Nord, France, 7 March 1899**
Died **Paris, France, 7 May 1954**

Mathematician Henri Mineur played an important role in the development of astrophysics in France. His 1944 recalibration of the zero-point of the Cepheid period–luminosity relationship was unnoticed at the time but presaged the later work of **Walter Baade**. Mineur was the son of Paul Mineur, a mathematics teacher who taught in Lille and later at the Lycée Rollin in Paris, and Léonie Jacquet. Henri was a pupil at the Lycée Rollin along with **Jean Dufay**, who became director of the Lyon Observatory and Haute-Provence Observatory. At 18, Mineur received entry to the École Polytechnique in a good rank, and entry at first rank to the École Normale Supérieure. He chose the latter, but with France engaged in World War I, he went instead into the army. At the war's end in 1919, Mineur returned to his studies, and passed the examination (*l'agrégation*) to teach secondary-school mathematics 2 years later. After passing his doctoral thesis (on the analytic theory of continuous finite groups) in 1924, he spent the following year teaching mathematics at the Lycée Français in Düsseldorf, Germany. In 1925, he took a position as an *astronome adjoint* at the Paris Observatory, directed then by **Benjamin Baillaud**. Mineur was already familiar with the observatory, having served there in 1922/1923 as a trainee under **Paul Couderc**.

After serving various departments at the Paris Observatory, Mineur became involved in the *Carte du Ciel* project, launched in 1887 by **David Gill** and **Ernest Mouchez**. Mineur also researched stellar statistics, a topic that influenced his astronomical career and developed his skills in various domains of astronomy. He earned good reports about his research from others at Paris, including from **Ernest Esclangon**, director at that time.

In 1931, Mineur directed the work of several students, including Li Heng (1898–1989), whose work led Mineur to study stellar fields and clusters. Li Heng worked on the determination of the zero-point of the period–luminosity relationship for Cepheid variables, studied their spatial and velocity distributions, and in 1932 submitted a dissertation on his statistical researches on Cepheids. After Li Heng's departure from France, Mineur pursued and developed this line of research; in 1944, he published a paper giving corrections for the zero-point for classical Cepheids and for RR Lyrae variables. He also noted in a later publication that this result served to multiply the distances to such stars by a factor close to 1.8.

The elections of 1936 in France had given power to the Popular Front, one of whose innovations related to scientific research and led to the appointment of both Irène Joliot-Curie and Jean Baptiste Perrin as Undersecretary of State for Scientific Research. This subsequently led to the creation of a service for research in astrophysics, which comprised the Haute-Provence Observatory (near Manosque in the south of France) and an associated laboratory in Paris. The observing station and the laboratory would later be attached to the Centre National de la Recherche Scientifique [CNRS], established in October 1939. Mineur played a large role in this effort along with **Daniel Chalonge**, an *aide-astronome* at the Paris Observatory after 1933, whom Mineur had previously known as an assistant in the Sorbonne. Mineur later obtained the positions of general secretary of the service and director of the laboratory. Mineur was removed from his position in 1941 by the Vichy government, while he was engaged in the resistance; the laboratory was removed to several different locations. A part of the domain of the Paris Observatory was allotted to it. After World War II, a new laboratory building, constructed in 1952, hosted the newly named Institut d'Astrophysique de Paris. Mineur, still an assistant astronomer at the Paris Observatory, served as its director until his death. He played a large part in centralizing this hitherto widely dispersed astrophysical research, giving France an important role within it.

Mineur, an astrophysicist concerned with the Milky Way, its constituents, and stellar absorption, was also a mathematician who studied relativity, celestial mechanics, and pure mathematics. He was especially engaged with general problems relating to the treatment of data, and wrote a clear, well-written, and widely used book on the technique of least squares. He trained many students, and his courses in stellar astronomy and lectures on the expansion of the Universe enjoyed large audiences.

Mineur was a talented popularizer, helping amateur astronomers mostly through the articles he published in *L'Astronomie,* the magazine of the Société Astronomique de France, which he had joined in his youth. In declining health by 1952, Mineur attended a meeting in Rome during which Walter Baade announced and **Andrew Thackeray** confirmed, that the calculated distances in the Universe had to be multiplied by a factor of 2; on that occasion, **Clabon Allen** recalled Mineur's 1944 paper that had presented a similar result, also from consideration of Cepheid and RR Lyrae variables. Mineur's early death was a deep loss within the ranks of his generation of researchers.

Mineur married twice, to Suzanne Fromant in 1926 and to Gabrielle Cloche in 1929.

Minkowski, Hermann

Born **Aleksotas, Russia (now Kaunas, Lithuania), 22 June 1864**
Died **Göttingen, Lower Saxony, Germany, 12 January 1909**

German mathematician Hermann Minkowski introduced the concept of "space–time." The Minkowski metric or geometry is the one appropriate to **Albert Einstein's** special theory of relativity.

Minkowski, Rudolph Leo Bernhard

Born **Strasbourg, (Bas-Rhin, France), 28 May 1895**
Died **Berkeley, California, USA, 4 January 1976**

Rudolph Minkowski made significant contributions to the understanding of gaseous nebulae, was codiscoverer of the two principal types of supernovae, and participated in the early identification of radio sources with their optical counterparts. Son of Oskar Minkowski, a professor of pathology, Minkowski attended German schools in Cologne, Greifswald, and Breslau. He began to study physics at the University of Breslau (1913) and hoped to go to Berlin the following year. These plans were disrupted by war; from 1914 to 1918, Minkowski served in the German army. After that conflict ended, he studied in Berlin, then returned to Breslau, and completed his doctoral thesis under the supervision of Rudolf Ladenburg (1921). After working at Göttingen University for a year with James Franck and Max Born, Minkowski relocated to Hamburg in 1922 and taught at University of Hamburg until 1935, when he was forced to immigrate to the United States.

In 1933, Adolf Hitler seized power in Germany; his National Socialist Party subsequently forbade persons from "non-Aryan" backgrounds to retain employment in official places like universities. In 1935, Minkowski lost his title as professor and was no longer allowed to teach. His father-in-law, judge Alfons David, had been dismissed from the court at Leipzig in 1933. But through the assistance of **Walter Baade**, who had left Hamburg for the Mount Wilson Observatory in 1931, Minkowski first secured a 1-year appointment at Baade's new institution. His position on the Mount Wilson staff was made permanent after his formal dismissal (1936) was received from the University of Hamburg. Thus, from 1935 until 1960, Minkowski worked as a research astronomer at the Mount Wilson and Palomar observatories and (after compulsory retirement) from 1961 to 1965 at the Radio Astronomy Laboratory of the University of California in Berkeley. In 1926, Minkowski married Luise Amalie David; the couple had two children.

Minkowski's research career can be divided into two phases. Prior to his emigration, he had worked chiefly on laboratory spectroscopic problems. His principal subject of investigation was the width of spectral lines, and how they were broadened by pressure and self-absorption. Minkowski published related papers on the behavior of electrons in metallic vapors and the process by which electrons pass through atoms (with Hertha Sponer). His final Hamburg paper (with **Hermann Brück**) described the atomic-beam method of determining the fine structure of spectral lines.

Yet, as early as 1933, Minkowski had turned his attention towards astrophysical problems, including features observed in the spectrum of the Orion Nebula. Upon settling in the United States, his knowledge of spectroscopy proved most useful for studying a variety of astronomical objects. Minkowski's collaboration with Baade led to a rapidly growing number of publications. These included studies on the internal motions of gaseous nebulae and the discovery of almost 200 new planetary nebulae. He and Baade also collaborated on the study of supernovae in other galaxies and supernova remnants in our Milky Way. Minkowski and Baade distinguished supernovae of two types (I and II), based upon their light curves and the presence/absence of hydrogen in their spectra. Their classification scheme also proved useful as a tool for estimating cosmological distances in space (supernovae as "standard candles"). Shortly after the Crab Nebula was recognized as a supernova remnant, Minkowski and Baade identified its small central star (later found to be a neutron star/pulsar). Minkowski also worked on the distribution of emission nebulae in our Galaxy and on the spectral features of comets.

After 1949, Minkowski became intrigued with the new field of radio astronomy. Together with Baade, he began to locate the optical counterparts of newly discovered radio sources. One of the first extragalactic counterparts identified (1954) was the radio source Cygnus A. Minkowski likewise studied the distribution of galaxies and in 1960 identified the galaxy (3C 295) having the highest known redshift (Z=0.45) at the time (prior to the discovery of quasars).

Minkowski was also responsible for the wide-field photographic sky survey conducted by the National Geographic Society and known today as the "Palomar Observatory Sky Survey" [POSS]. This work was done with the 48-in. Schmidt camera on Palomar Mountain and covered the Northern Celestial hemisphere down to a declination of –33°. The POSS has proven to be an invaluable tool for countless astronomers.

Minkowski was chosen a member of the Royal Astronomical Society and the United States National Academy of Sciences (1951). He was awarded the Bruce Gold Medal of the Astronomical Society of the Pacific in 1961 and an honorary doctorate from the University of California at Berkeley in 1968.

Minnaert, Marcel Gilles Jozef

Born **Bruges, Belgium, 12 February 1893**
Died **Utrecht, the Netherlands, 26 October 1970**

Marcel Minnaert pioneered new techniques in the measurement and understanding of spectral line strengths and chemical abundances in the Sun and stars. Minnaert was the son of Jozef and Jozephina (*née* Van Overberge) Minnaert. Both of his parents were teachers at normal schools. Ever since his birth, Minnaert's father meticulously kept a diary on his only child's education, which provides a clear insight into the intellectual development of young Minnaert. Just before his father's premature death in 1903, Minnaert and his parents relocated to Ghent. In 1910, Minnaert enrolled at the University of Ghent, where he studied biology. Four years later, he was awarded his doctoral degree after completing a thesis on the effects of light on plants, entitled "Contributions à la étude de la photobiologie quantitative."

During his studies, Minnaert associated himself with Flemish students, who wished to change the language of instruction at the university from French to Dutch. This measure was introduced during the German occupation of Belgium during World War I and resulted in an urgent need for teachers at the Dutch-language university. Minnaert then went to Leiden, the Netherlands in 1915 to take up physics. He attended the lectures of leading scientists, especially **Hendrik Lorentz** and Paul Ehrenfest. After his return to Ghent in 1916, Minnaert was appointed as an associate professor of experimental physics.

In 1918, Minnaert had to flee his country, to escape prosecution by the Belgian government. He had been one of the language activists at the University of Ghent and was now accused of collaboration with the Germans. Afterwards, he was sentenced *in absentia* to 15 years of penal servitude. Minnaert moved again with his mother to Utrecht, the Netherlands. Thereafter, his main interest became photometry, or the precise measurements of light intensity. He secured a position at the Heliophysical Institute of the University of Utrecht, which, under the direction of Willem Julius, was engaged in developing new photometric techniques related to solar spectroscopy. Minnaert became an observer at the institute; by 1925 he obtained a second doctoral degree (in physics), having written a thesis on anomalous dispersion, entitled "Onregelmatige Straalkromming" (Irregular ray curvature).

Minnaert applied himself to research in solar physics, especially the formation of the Fraunhofer absorption lines in the solar spectrum. Following **Albertus Nijland**'s death in 1936, Minnaert was chosen his successor in 1937 as professor of astronomy and director of the University of Utrecht Observatory. He converted the observatory into a prominent astrophysical institute for research in solar and stellar spectra.

Minnaert's chief contributions lay in his foundation of the "curve of growth" technique in determining solar chemical abundances by spectral analysis. Along with his concept of "equivalent width" (introduced simultaneously by Harald von Kluber in 1927), this methodology established Minnaert's reputation as an outstanding astronomer. The intensities of spectral lines originate from several different broadening mechanisms, which allows them to exhibit characteristic profiles, with a residual intensity being left at the center. Minnaert introduced the measurement of line intensities in terms of the fraction of energy removed from the adjacent continuum by absorption, a quantity which he expressed as the "equivalent width" of a rectangular (*i. e.*, fictitious) absorption feature.

In 1929, Minnaert investigated how the equivalent width increases with the number of absorbing atoms. By first calibrating **Henry Rowland**'s spectral scale in terms of equivalent width, and then applying an earlier technique of **Henry Norris Russell**, he obtained an empirical result by plotting the equivalent width against the number of absorbing atoms. This relationship was called by Minnaert the "curve of growth," a term reminiscent of his earlier biological studies. Following Wilhelm Schütz's theoretical extension of the "curve of growth" in 1930, Minnaert and his students were able to analyze solar equivalent widths, which yielded explanations for the broadening of solar spectral lines and renewed theoretical understanding of line formation.

By the late 1930s, Minnaert's love of nature and his ability to popularize physics were combined into the three-volume work *De natuurkunde van 't vrije veld* (Physics of the outdoors), which appeared from 1937 to 1940. At the same time, his extensive research on solar physics, in collaboration with Jacob Houtgast and Gerard F. W. Mulders, culminated in publication of the voluminous *Photometric Atlas of the Solar Spectrum* (1940). For several decades, this proved to be a standard reference work. During World War II, Minnaert was imprisoned by the Germans for his vocal left-wing opposition to fascism.

After World War II, Minnaert investigated a variety of subjects, including the temperatures of cometary nuclei, gaseous nebulae, the atmospheric homogeneity of Venus, and lunar photometry. For over 20 years, he revised the photometric atlas of the solar spectrum, initially with a several of young astronomers, later with Houtgast, and in the final stages, with **Charlotte Moore-Sitterly**. This publication, *The Solar Spectrum*, was completed in 1966. Minnaert officially retired in 1963, but remained active as a member of the International Astronomical Union [IAU] commission that established the nomenclature of features on the Moon's farside. He also published a laboratory manual, *Practical Work in Elementary Astronomy* (1969).

During his career, Minnaert received honorary degrees from the universities of Heidelberg, Moscow, and Nice. He was a member of various academies, among which are the Koninklijke Nederlandse Akademie van Wetenschappen, the Koninklijke Academie voor Wetenschappen, and the Letteren en Schone Kunsten van België. For his research in solar and stellar photospectrometry, Minnaert received several international awards, the Gold Medal of the Royal Astronomical Society in 1947 and, in 1951, the Bruce Medal of the Astronomical Society of the Pacific. His engagement in cooperative astronomical research enabled Minnaert to hold the positions of president and vice president of several commissions within the IAU.

In 1928, Minneart married Maria Boergonje Coelingh; the couple had two sons.

Mīram Čelebī: Maḥmūd ibn Quṭb al-Dīn Muḥammad ibn Muḥammad ibn Mūsā Qāḍīzāde

Born **Istanbul, (Turkey), 1475**
Died **Edirne, (Turkey), 1525**

Mīram Čelebī, one of the most important Ottoman mathematicians and astronomers, attempted to reconcile the mathematical (Ptolemaic) and natural philosophical (Aristotelian) traditions concerning astronomy, while writing astronomical texts that were widely used in the Ottoman Empire.

Mīram Čelebī's grandfather Muḥammad was **Qāḍīzāde**'s son; he married **ʿAlī Qūshjī**'s eldest daughter in Samarqand. His father, the scholar Quṭb al-Dīn Muḥammad, came with his grandfather ʿAlī Qūshjī to Istanbul, where Quṭb al-Dīn married Mīram Čelebī's mother, who was the daughter of Khōja-zāde, a famous scholar and philosopher of that time. His father, who had been a teacher at the Manāstır *madrasa* (school) in Bursa, died at a young age, and so Mīram Čelebī was raised by his grandfather Khōja-zāde. Mīram was educated not only by his grandfather but also by other leading scholars of the time such as Sinān Pasha. Upon his graduation, he taught at several *madrasas* (the Gelibolu, the Edirne ʿAlī Bey, and the Bursa Manāstır), becoming the most prominent figure of his time in the mathematical sciences. Indeed Sultan Bāyazīd II (died: 1512) asked him to be his teacher. Mīram Čelebī was appointed as Qāḍī ʿaskar (a high official in the Ottoman judiciary) of Anatolia during the reign of Yavuz Sultan Selīm I (reigned: 1512–1520); however, shortly thereafter he was dismissed from his post and retired. Towards the end of his life, he went on the pilgrimage to Mecca; upon his return he settled in Edirne. He was buried in the courtyard of the Qāsīm Pasha Mosque.

Mīram Čelebī, most famous for his many works in astronomy, optics, and astrology, was also well known in the fields of history and literature. (He even wrote an important work on hunting.) He wrote in Arabic and Persian (the scientific languages of his time) as well as in Turkish. Among his many students were **Muṣṭafā ibn ʿAlī al-Muwaqqit** and the famous philosopher and historian Ṭashköprülüzāde.

Mīram Čelebī inherited the scientific tradition of the Samarqand School of mathematics and astronomy represented by his great-grandfathers Qāḍīzāde and ʿAlī Qūshjī. He was also greatly influenced by **Ibn al-Haytham**'s methodology in the field of optics (*ʿilm al-manāẓir*) and tended to favor his approach of combining mathematics and natural philosophy over the more mathematical approach of both great-grandparents. In addition, Mīram Čelebī was well informed of the opinions of Kamāl al-Dīn al-Fārisī, **Ibn Sīnā**, and **Fakhr al-Dīn al-Rāzī**, among others.

One of Mīram Čelebī's most important astronomical works is his commentary on the Persian *Zīj-i Ulugh Beg,* also known as *Dustūr al-ʿamal fī taṣḥīḥ al-jadwal*, which was completed in 1499 and dedicated to Sultan Bāyazīd II. Mīram Čelebī incorporated findings from **Jamshīd al-Kāshī**'s *Zīj-i Khāqānī* and ʿAlī Qūshjī's *Sharḥ Zīj-i Ulugh Beg*. The work, written in a didactic style, provided five examples of solutions for calculating the sine of 1°. More than 30 extant copies of the *Dustūr* attest to its widespread use by Ottoman astronomers. Mīram Čelebī's mathematical bent is also indicated by a work in which he calculated the ratio of the highest mountain in the world to the diameter of the Earth, a problem going back to **Naṣīr al-Dīn al-Ṭūsī**.

The most noteworthy work written by Mīram Čelebī on the subject of theoretical astronomy is a commentary on ʿAlī Qūshjī's work *al-Fatḥiyya fī ʿilm al-hay'a.* Unlike his great-grandfather, who sought to eliminate Aristotelian natural philosophy from astronomy, Mīram Čelebī sought to reconcile the mathematical and the natural philosophical in astronomy as he had done in optics. He completed it in 1519 following the request of many of Mīram Čelebī's students when he was teaching *al-Fatḥiyya.* The commentary was both practical and theoretical and was used as a supplementary textbook in the Ottoman *madrasas*. Mīram Čelebī stated his intention to write an appendix to his commentary in which he would analyze the problems pertaining to the models of Mercury and the Moon. Although there is no extant copy of this appendix, it is an indication of the importance of the subject as well as an example of a continuous astronomical tradition to solve difficulties related to **Ptolemy**'s planetary models.

Many of Mīram Čelebī's other astronomical works deal with instruments, including a variety of quadrants. His *Risāla dar Shakkāzī wa Zarqāla az ālāt-i raṣadiyya* (in Persian) examines two astronomical instruments invented by **Zarqālī** and their use in astronomical observations. He also wrote on the calendar, the determination of the direction to Mecca (*qibla*), and various other astronomical problems. His *Risāla fī samt al-qibla* is a comprehensive study on the determination of the *qibla* using astronomical and mathematical calculations. Moreover, in accordance with the tendencies of his time, he wrote original works in the field of astrology, such as *al-Maqāsid fī al-ikhtiyārāt* and *Masā'il-i Mīram Čelebī* (in Turkish).

Throughout his work, Mīram Čelebī placed great importance on rational and empirical evidence for the subjects he investigated. His work in theoretical astronomy was an extension of the Samarqand tradition that his great-grandfather ʿAlī Qūshjī continued with his colleagues and students in Istanbul. Mīram Čelebī especially enriched its mathematical character. His relationships with other members of the Samarqand School who came to Istanbul (such as Sayyid Munajjim and **ʿAbd al-ʿAlī al-Birjandī**) await further research. More information is also needed on his contribution to studies on observations conducted in Istanbul at the time of Sultan Bāyazīd II.

Mitchel, Ormsby MacKnight

Born **Morganfield, Kentucky, USA, 28 July 1809**
Died **Beaufort, South Carolina, USA, 30 October 1862**

Ormsby Macknight Mitchel, the founder and first director of the Cincinnati Observatory (which briefly housed the largest telescope in the United States), established the first exclusive astronomical periodical in the United States, served as second director of the Dudley Observatory, and became nationally famous as an inspirational lecturer on astronomy. He also enjoyed a distinguished United States army career during the Civil War, reaching the rank of major general.

Born in 1809 in Kentucky on what was then the American frontier, Mitchel was the youngest child of John Mitchel; both his father and his grandfather were surveyors. As a child in Lebanon, Ohio, Ormsby was tutored by his widowed mother, Elizabeth (*née* MacAlister) Mitchel, and a brother-in-law, until he entered a school opened by an elder brother, becoming an active member of the school's Thespian Society and Debating Club. In 1825, Mitchel entered the United States Military Academy at West Point, New York, studying surveying, civil engineering, and practical astronomy in addition to military subjects. After graduating in 1829, he taught mathematics at West Point, meanwhile meeting and marrying a young widowed mother, Louisa (*née* Clark) Trask, in 1831.

In 1832, Mitchel resigned his commission and went to Cincinnati, Ohio, then the fourth largest city in the United States and the most important metropolis not on the Atlantic seaboard. There, he studied law and was admitted to the Ohio bar while working as chief engineer of the Little Miami Railroad, one of the key railway lines being constructed across booming Ohio. In 1836, the newly founded Cincinnati College hired Mitchel to teach mathematics, mechanics, machinery, and astronomy; he also established a civil engineering program, one of the first in the country.

Although slightly built (5 ft. 6 in. and 130 lbs), Mitchel was a charismatic teacher and public speaker who held every audience spellbound. In 1841 and 1842, Mitchel gave a series of public lectures on the solar system to crowds of 2,000 Cincinnati residents. After the last lecture, Mitchel announced he would devote the next 5 years to founding a major astronomical observatory in Cincinnati. He also proposed a novel financing scheme: public subscription of shares of stock at $25 apiece – more than a month's wages for many laborers – for which subscribers would have the privilege beholding the heavens through the observatory's grand telescope. Within a month (on 24 May 1842), the Cincinnati Astronomical Society was formed, announcing more than $6,500 worth of stock had been subscribed. After visiting the finest telescope makers in Europe, Mitchel contracted with the firm of Merz & Mahler of Munich, Bavaria, to buy a 12-in. refractor. When it was mounted in 1845, it stood as the largest telescope in the United States and second largest in the world (surpassed only by the Pulkovo 15-in. refractor in Russia) until 1847, when another 15-in. Merz refractor was installed at Harvard College Observatory.

Having secured the telescope, Mitchel's next challenge was to construct the observatory within which to mount the telescope. He did so, meeting the deadline established in the deed for the property, but only by calling upon volunteer labor from Cincinnati citizens and with a complete dedication of his own time and energy to the project.

By the observatory's completion, however, Mitchel had big problems. As the fledgling institution had no endowment, in 1844 he had promised to serve as its director for a decade without pay beyond his college professor's salary. However, in January 1845, 4 days before the telescope arrived, Cincinnati College burned to the ground, and up in smoke went Mitchel's sole source of support for his wife and seven children as well as for the Cincinnati Observatory.

As a result, Mitchel launched himself into a career as a professional itinerant lecturer in astronomy. His timing was fortunate, as the mid-19th century was a golden age for circuit lecturers. Over the next decade, Mitchel became nationally famous for speaking without notes or visual aids aside from diagrams drawn in the air with a wand; his lectures riveted thousands of listeners in Boston, New York City, Philadelphia, New Orleans – some audiences (according to contemporary accounts) leaping to their feet and cheering as at a sporting or political event. Each year, he toured the nation from November through March when Ohio's observing conditions were poor, further augmenting his income by writing several popular books based on his lectures, among them *Planetary and Stellar Worlds* (1848), *Popular Astronomy* (1860), and *Astronomy of the Bible* (1863).

Less well-known was Mitchel's astronomical research during Ohio's clearer, warmer months. He remeasured the positions of the 2,700 double stars in **Friederich Struve**'s 1827 catalogue, especially those south of the celestial equator that never rose high above Pulkovo's horizon; he resolved many stars Struve had not marked double or triple, discovering the greenish companion to the red giant Antares (possibly his most original scientific discovery). Mitchel also determined the rotation period of Mars, monitored the position of the newly discovered planet Neptune, counted sunspots, measured the positions of planetary satellites, and observed comets and nebulae; in short, routine work typical of visual astronomers in mid-19th century observatories.

More significantly, by 1848, Mitchel was involved in early trials (conducted by the United States Coast Survey under **Sears Walker** and **Alexander Bache**) of the American method of longitudes, using the telegraph to compare local times at observatories hundreds of miles apart to determine their differences in longitude. He also proposed and experimented with a telegraph-type system within the Cincinnati Observatory itself to automate the recording of right ascension and declination for ordinary positional astronomy – the so called American method of transits. For both purposes, he invented an early chronograph, which recorded timings on a rotating flat disk, installing working prototypes at the Cincinnati and Dudley observatories.

Lastly, Mitchel founded the first exclusive astronomical periodical in the United States, the *Sidereal Messenger*. Published monthly from July 1846 through October 1848 (when publication ceased for lack of funds), it was a hybrid research journal and popular magazine, summarizing major findings by astronomers in Europe and the United States, plus detailing work at the Cincinnati Observatory.

In 1857, Mitchel's wife, who had also long been his observing assistant, was paralyzed by a series of strokes. In 1859, weighed down by her care, Mitchel reluctantly accepted an offer to become the second director of the Dudley Observatory in Albany, New York. He replaced **Benjamin Gould** after several years of controversy between the latter and the board of Albany citizens responsible for overseeing the observatory. The position included the luxuries of a house and a regular salary. But in 1861, with the start of the Civil War, Mitchel reentered active military service as a brigadier general in charge of volunteers from Ohio; the day after his departure, his wife suffered her last stroke and died.

Affectionately known in the army as "Old Stars," Mitchel served in several campaigns, the most famous being "the great locomotive chase" in Alabama, in which his men took possession of a train to cut telegraph wires and destroy bridges to disrupt the Confederate army's supply lines. His services earned him the rank of major general of volunteers. Mitchel was placed in command of the Union's Department of the South, at Hilton Head, South Carolina; however, a month later, he was stricken with yellow fever and died.

According to contemporary and later biographers, Mitchel's enduring contribution to astronomy was his oratorical eloquence that inspired hundreds of thousands of listeners and readers with wonder for the heavens – a powerful influence in inspiring wealthy philanthropists and the general populace to found scores of observatories in later 19th-century America.

Mitchell, Maria

Born **Nantucket, Massachusetts, USA, 1 August 1818**
Died **Lynn, Massachusetts, USA, 28 June 1889**

Maria Mitchell, the first woman astronomer in the United States, paved the way for women in science. She trained an entire generation of women astronomers who followed her into research as well as teaching. Mitchell played a vital role in the 19th century's more enlightened attitudes about the role of women in American society and science.

One of ten children born to William and Lydia (*née* Coleman) Mitchell, Mitchell was raised in a favorable environment with the intellectual lives of her parents. As members of the Nantucket Quaker Meeting, they encouraged each of their children to read extensively and engage in thoughtful dialogue about what they were learning. At an early age, Mitchell began to help her father with his astronomical observation and computing. Her father was well-known as an astronomer who could be trusted to rate chronometers for the whaling vessels and merchant ships calling at Nantucket. Using a platform on top of their home, and later a similar structure on top of the Pacific Bank where William served as a teller, their observing was not limited to time-keeping work but included various objects in the Solar System and sweeping for comets.

Mitchell's formal education was limited to a few years in a school run by her father, followed by a few years at the Reverend Cyrus Peirce's school. She showed a special aptitude for mathematics from an early age, and learned under Peirce's guidance to the extent of his ability. For several years Mitchell assisted Peirce in the operation of his school before starting her own career as a teacher in a school she organized in 1835.The following year she accepted an additional role as librarian of the new Nantucket Athenaeum.

Mitchell experienced more frequent contact with women in the community as a librarian, but also enjoyed more time for her own studies. She taught herself to read French and German and then mastered the mathematical works of **Pierre de Laplace**, **Joseph Lagrange**, and **Karl Gauss** while continuing astronomical observations with her father when weather permitted. While sweeping the skies on the night of 1/2 October 1847, she discovered a comet near Polaris, now known as C/1847 T1 (Mitchell). This was her fourth independent discovery but the first for which the priority was properly hers. Her father immediately reported it to **William Bond**, director of the Harvard College Observatory. There were other independent discoveries of the same comet within days by others, including the director's son **George Bond** who conceded he had narrowly missed making the discovery himself on the same evening. However, William's immediate action in posting the letter to Bond ensured that the comet was credited to his daughter. The discovery by the young American woman brought her substantial notoriety in Europe as well as America. Mitchell was awarded a gold medal by King Frederich of Denmark.

The fame gave Mitchell the opportunity to increase acquaintances among leading American scientists like **Alexander Bache**, director of the United States Coast Survey [USCS], and **Charles Davis**, newly appointed superintendent of the United States Navy's Nautical Almanac office in Boston. Within 2 years, Davis offered her additional employment as a computer for the new *American Ephemeris and Nautical Almanac.* Mitchell computed ephemeris data for the planet Venus from her home in Nantucket. Bache invited Mitchell to spend one summer in Maine working with USCS observers. She continued in that dual employment as librarian and astronomical computer from 1849 until 1865. With her additional income, Mitchell traveled in the United States, learning first hand how privileged her special position on Nantucket was in comparison with women in other parts of the country. Female self-development and self-reliance was encouraged at the peak of whaling and maritime activity in Nantucket, like no where else in the United States at the time.

Mitchell had more travel opportunities when she was asked to travel as a tutor and chaperone for a Chicago banker's daughter in 1857. Mitchell accompanied the young woman to England where she was welcomed as a visitor to the Greenwich and Cambridge observatories. When the banker's daughter was forced to return to Chicago by her father's crisis during the financial panic of 1857, Mitchell stayed in Europe and visited many noteworthy astronomers including **Angelo Secchi**, **Caroline Herschel**, and **Mary Somerville**.

On her return to America, Mitchell received a 5-in. Clark refractor equipped with a micrometer as a gift "from the women of America" in recognition of her achievements as a woman astronomer. This fine instrument intensified Mitchell's desire to continue in her chosen career as an astronomer. After her mother died, Mitchell and her father moved to Lynn, Massachusetts. She was soon interviewed by a trustee for Matthew Vassar's endowment to establish the first women's college in the United States. As one of the best known women in America, Mitchell was a natural choice for the Vassar College faculty, New York, even though she lacked any formal educational credentials. Mitchell quickly accepted the position and moved with her father to the campus near Poughkeepsie, New York in 1865.

The Vassar College Observatory was equipped with a 12-in. Fitz refractor, one of the largest telescopes in the United States. Mitchell was eager to use the new instrument and valued the opportunity to have an influence in the higher education of women. Her classes in astronomy, though rigorous, were popular and well attended. Her astronomy classes and night observing sessions with the telescope created opportunities for education unlike that available to women in any other institution. With the help of her students, Mitchell conducted visual observation of double stars and planets. Thus, Mitchell's later career in astronomy was primarily as a teacher who empowered women in astronomy and the sciences rather than as a researcher.

Several of Mitchell's students were employed in the field of astronomy. The most noteworthy of these include **Antonia Maury**, **Caroline Furness**, Margaretta Palmer, and Mitchell's successor at Vassar College, Mary Whitney (1847–1921). More importantly, her students who chose to pursue careers in astronomy were important assets for the expansion of American astronomy through the first few decades of the 20th century. Working for **Edward Pickering** as "computers" at Harvard College Observatory, and later at Lick and Mount Wilson Observatories, they contributed greatly through their interpretation, classification, and measurement of spectra, as well as the more routine computations necessary for observational-data reduction.

Mitchell took a second tour in Europe in 1873, but while she visited noteworthy astronomers, she was more interested in the status and education of women. The trip had a marked influence on her subsequent life decisions, and she became more involved in improving the status and opportunities for women in the United States. She helped organize and served as president of the American Association of Women, assumed leadership roles in organizations such as the Social Sciences Association, and was the first women accepted as a member of the American Association for the Advancement of Science.

After she resigned in 1888 from Vassar College, Mitchell returned to her home, where she died. During her lifetime, Mitchell was honored by her election to the American Academy of Arts and Sciences and to the American Philosophical Society.

Mizzī: Zayn al-Dīn [Shams al-Din] Abū ʿAbd Allāh Muḥammad ibn Aḥmad ibn ʿAbd al-Raḥīm al-Mizzī al-Ḥanafī

Born **probably al-Mizza near Damascus, (Syria), 1291**
Died **Damascus, (Syria), 1349**

Mizzī was a *muwaqqit* (*i. e*., an astronomer appointed to a mosque who is responsible for regulating the times of prayer), an instrument maker, and the author of numerous treatises on astronomical instruments. He studied in Cairo under the well known physician and encyclopedist Ibn al-Akfānī. He was first appointed as a *muwaqqit* in al-Rabwa, a quiet locality near Damascus, and then at the Umayyad Mosque in Damascus, a position he held until his death. Mizzī authored treatises on the use of the astrolabe, the astrolabic quadrant, and the sine quadrant. In particular his treatises *al-Rawḍāt al-muzhirāt fī al-ʿamal bi-rubʿ al-muqanṭarāt* (On the astrolabic quadrant) and *Kashf al-rayb fī al-ʿamal bi-'l-jayb* (On the sine quadrant) were popular. He also wrote on the use of less common instruments, such as the *musattar* (concealed) and the *mujannaḥ* (winged) quadrants.

Although he made few original contributions to instrument making in particular or to astronomy in general, Mizzī was nevertheless an important and influential authority in the field, whose didactic treatises were appreciated by students of applied astronomy dealing with timekeeping (*ʿilm al-mīqāt*). The instruments he made were highly praised as being the best of his times and sold for considerable prices, namely 200 dirhams or more for an astrolabe, and at least 50 dirhams for a quadrant. Some five quadrants of his fabrication are extant, dated between the years 1326/1327 and 1333/1334. According to the 15th-century astronomer Ibn al-ˁAṭṭār, he also made astrolabes with mixed projections (*i. e.*, with markings obtained by a combination of stereographical projections about the North Pole and South Pole, respectively). According to his biographer al-Ṣafadī, Mizzī also excelled in oiling bows (*baraˁa fī dahn al-qisī*) and impressed his contemporaries by constructing mechanical devices such as those of **Banū Mūsā**.

Moestlinus

➤ **Mästlin [Möstlin], Michael**

Mohler, Orren Cuthbert

Born **Indianapolis, Indiana, USA, 29 July 1908**
Died **Ann Arbor, Michigan, USA, 17 September 1985**

Orren Mohler served as director of the University of Michigan Observatories from 1961 until 1970 and continued as director of the McMath–Hulbert Solar Observatory [MHO] until 1979.

Mohler received his AB in 1929 from Michigan Normal College, followed by an MA (1930) and Ph.D. (1933) from the University of Michigan. From 1933 to 1940, Mohler taught astronomy at Swarthmore College, Pennsylvania, and worked as an astronomer at the private observatory of amateur astronomer Gustavus Wynne Cook (1867–1940). While working for Cook, Mohler conducted observing programs on the spectrographic binary star TX Leonis and on Nova Herculis 1934. He also attempted to improve the quantum efficiency of the Geiger–Muller counter so it could count individual protons.

In 1940, Mohler became the first full-time professional astronomer at MHO of the University of Michigan at Lake Angelus near Pontiac, Michigan. During World War II, Moher worked at MHO on military research and development, including development of the Cashman PbS infrared detector. He later exploited this experience by fitting such a detector to the MHO spectrograph. Working with **Robert McMath**, Mohler was able to extend infrared spectroscopy to well beyond previous limits, but it was apparent that local seeing was preventing full exploitation of the resolution of the excellent grating available. This prompted McMath to seek funding for the first astronomical vacuum spectrograph which, when completed, fully rewarded their effort. Mohler then published an atlas of the solar spectrum from 11,984 Å to 25,578 Å with approximately 100 times greater resolution than any previous spectrum in this region. Mohler was appointed professor of astronomy in 1956. Mohler became director of the McMath–Hulbert Observatory, and in 1962 was appointed as chairman of the Astronomy Department and director of the University of Michigan Observatories.

Mohler's primary interests were instrumentation and the history of astronomy. He was awarded the Naval Ordnance Development Award for his contributions to military research and development, and was a Fulbright Scholar.

Molesworth, Percy Braybrooke

Born **Colombo, (Sri Lanka), 2 April 1867**
Died **Trincomali, (Sri Lanka), 25 December 1908**

Percy Molesworth, one of the notable British amateurs in the late 19th century, contributed much of our pre-spacecraft knowledge of Jupiter. Molesworth was the son of Sir Guildford and Mary Elizabeth (*née* Bridges) Molesworth. His father, a noted civil engineer, served as a colonial officer in Ceylon. Molesworth was educated in England at Winchester College, Winchester and received a commission in the Corps of Royal Engineers of the British army in 1886. After further education at the Royal Military Academy at Woolwich and Chatham, he served in England and Hong Kong before requesting a return to Ceylon. As captain (later major), Molesworth was stationed in Trincomali. This gave him an ideal location for observing Mars and Jupiter, using a 12.5-in. reflector, in the garden of his house high above the sea.

Molesworth was the most assiduous of all observers of Jupiter. His observations (visual transit timings, especially from 1898 to 1903) contributed greatly to establishing the patterns and permanence of the various currents. In 1900, for example, he recorded 6,758 central meridian transit timings on Jupiter! Molesworth's individual reports were published in the *Monthly Notices of the Royal Astronomical Society*. As a result of his and others' work, all the permanent slow currents that control large circulations on Jupiter had been identified by 1901. Molesworth also noted several phenomena whose importance for the atmospheric dynamics on Jupiter has become recognized in the era of spacecraft: The start of a great south tropical disturbance (discovered in February 1901), the turbulent bright spots west of the Great Red Spot, one of which he saw erupting within less than an hour, and the 90-day oscillation of the Great Red Spot itself. Molesworth also contributed substantial observations and drawings of Mars to the *Monthly Notices*; those that were not published in 1903 are still in the archives of the Royal Astronomical Society.

With his health failing, Molesworth retired in 1906 at the age of 39, intending to continue astronomical observations from his estate in Trincomali; however, he fell ill again and died of dysentery.

Moll, Gerard

Born **Amsterdam, the Netherlands, 18 January 1785**
Died **Amsterdam, the Netherlands, 17 January 1838**

Dutch astronomer Gerard Moll directed the Utrecht Observatory for 26 years. The son of Gerard, a wealthy Amsterdam merchant, and Anna (*née* Diersen) Moll, he became a junior clerk in an Amsterdam mercantile house around 1800. It was a job he undertook with reluctance but performed satisfactorily. His spare time was devoted to mathematical and scientific studies, including astronomy. After several years, Moll's father allowed him to undertake academic studies at the University of Amsterdam. Moll was awarded a Ph.D. in 1809, and afterwards studied at the University of Paris.

In 1812, Moll was appointed director of the Observatory at the University of Utrecht. Following that institution's reorganization in 1815, Moll was also appointed professor of mathematics and natural philosophy, a post which he held until his death. The university, however, failed to provide much in the way of support or maintenance for the observatory.

In 1825, Moll was offered a chairmanship at the University of Leiden. But he declined the offer after Utrecht administrators evidently agreed to provide substantially greater support. Moll used this opportunity to acquire an improved collection of astronomical instruments and a substantial library. During his Utrecht career, he observed an annular eclipse of the Sun (7 September 1820), a transit of Mercury across the Sun's disk (5 May 1832), and an occultation of Saturn (8 May 1832).

Besides astronomical observations, Moll conducted research in several areas of physics (then called natural philosophy). He extended the work of Hans Christian Øersted after the latter's 1820 discovery of electromagnetism. Moll repeatedly measured the speed of sound and arrived at a value very near the currently accepted figure.

Moll was given further responsibilities by the Kingdom of the Netherlands, concerning flood protection and the observation of tides along the Dutch coast. His comparative study of the British and French systems of weights and measures earned Moll a knighthood of the Order of the Belgian Lion. He was awarded honorary doctorates by the universities of Edinburgh and Dublin.

Mollweide, Karl Brandan

Born **Wolfenbüttel, (Germany), 2 February 1774**
Died **Leipzig, (Germany), 10 March 1825**

Astrometrist and mathematician Karl Mollweide is best known for his spirited defense of the Newtonian theory of color. The son of Christoph Mollweide, Karl Mollweide studied mathematics at Helmstadt University beginning in 1796, and in 1800 started teaching mathematics and physics in Halle/Saale, while continuing his studies at the University of Halle. After his graduation from the university in 1811, he became an observer at the university observatory in the old castle of Pleissenburg, and lectured in astronomy. Mollweide was elected professor of astronomy in 1812 and became a professor in mathematics at the University of Leipzig in 1814. From 1820 to 1823 he was dean of the philosophical faculty.

In 1814, Mollweide married the widow of the gatekeeper Knorr, of the hospital gate in Leipzig. Mollweide's wife was sister to the wife of another assistant at Pleissenburg Observatory. After his wife's death in 1821, his sister-in-law took care of his household. Mollweide had a stepson but no natural children by marriage.

Mollweide lived in the tower of the Pleissenburg until 1816. He worked on problems in spherical astronomy (*e. g.* stellar aberration) and astronomical position finding, as well as interpretations of various text passages from astronomers of classical antiquity.

Before his appointment in Leipzig, Mollweide was publicly engaged in defending **Isaac Newton**'s theory of colors. In that regard, he was a dedicated opponent of Johann Wolfgang von Goethe and his *Farbenlehre* (Theory of colors); Goethe never accepted Newton's theory.

Mollweide also wrote mathematical essays on the construction of magic squares, the application of **Carl Gauss**' addition and subtraction logarithms, and on the largest ellipse contained in a square. Two of his outstanding discoveries are still of great mathematical importance today. He calculated the Mollweide projection, which is often applied in the field of cartography when the whole Earth is depicted. He studied Cartesian trigonometry and developed the Mollweide formulae of plane trigonometry or sky, which are used in the calculation of the triangle.

Molyneux, Samuel

Born **Chester, England, 18 July 1689**
Died **Kew, (London), England, 13 April 1728**

Samuel Molyneux, noted as an instrument maker and observational astronomer, assisted **James Bradley** in the latter's studies that led to the discovery of the aberration of light. The only son of the astronomer **William Molyneux** and Lucy Domville, Molyneux was raised by his uncle, Thomas after both parents died while he was a young boy. Educated at Trinity College, Dublin (BA: 1708, MA: 1710), Molyneux studied meteorology and was elected to the Royal Society in 1712. He became a member of parliament in 1715 (elected again in 1726 and 1727).

In 1717 Molyneux married Lady Elizabeth Capel, who inherited money and an estate at Kew, to which the couple moved. Caught by the enthusiasm of **John Hadley** for optics, Molyneux turned his scientific interests to making optical components and instruments. His design for a Newtonian reflector set the standard of construction for such instruments. He conducted experiments to find the best alloy for speculum metal by testing 150 alloys of varying compositions. Between 1723 and 1725, Molyneux worked on reflecting telescopes with **James Bradley**, then Savilian Professor at Oxford (later Astronomer Royal).

In 1725, with Bradley, Molyneux ordered a large zenith sector from instrument maker **George Graham**, in order to investigate the large parallax of γ Draconis reported by **Robert Hooke**. Molyneux and Bradley set the telescope up in Molyneux's house in Kew, looking through holes in the roof. They observed γ Draconis in December 1725 and found a large shift in position as the month progressed. However, it was in the wrong direction to be a parallactic shift; as the two continued observing through the year they saw a large annual circular motion. Bradley ordered a larger, more versatile zenith sector from Graham and erected this one at the house of Molyneux's aunt in Wanstead in August 1727. By December, Bradley had made accurate measurements by which he inferred the phenomenon of the aberration of light.

Meanwhile, Molyneux's political interests took more of his time. He became a member of the Irish Parliament in 1727 and a lord of the admiralty, ceasing work in astronomy. Molyneux died at a young age of a stroke, presumably as a result of a medical problem inherited from his mother who also died early of a brain disease.

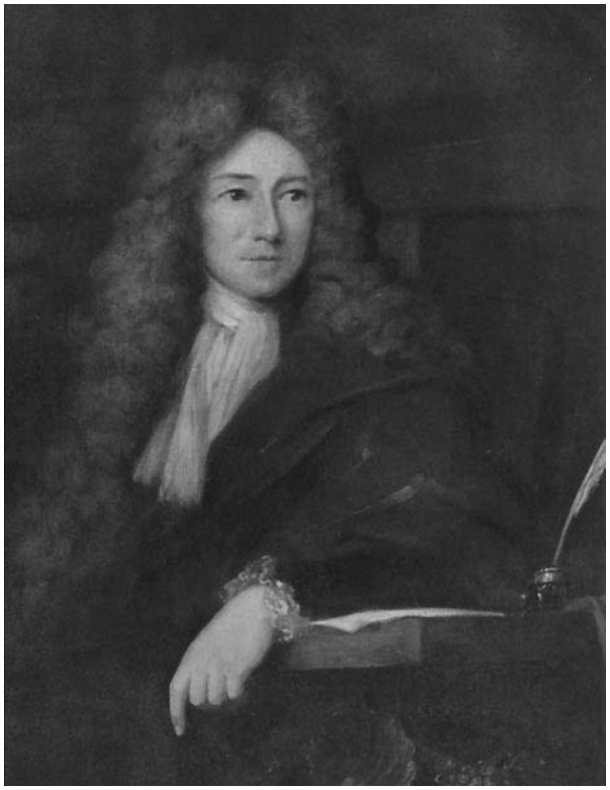
Molyneux, William

Born **Dublin, Ireland, 17 April 1656**
Died **Dublin, Ireland, 11 October 1698**



William Molyneux, an influential figure in the scientific affairs of Dublin in the late 17th century, gained the respect of **Edmond Halley** and **John Flamsteed** as an astronomer and wrote *Dioptrica Nova*, the first major book in English on optics.

William was the eldest surviving son of Samuel Molyneux and Margaret, daughter of William Dowdall, of Dublin. The Molyneuxs became part of the protestant establishment that dominated Dublin social and political life. Samuel, trained as a lawyer, was a skilful artillery officer, experimenting with gunnery for many years. William received a good schooling and entered Trinity College, Dublin, at the age of 15. After graduating he went to London in 1675 to study law. However, law did not interest Molyneux greatly, and he devoted most of his time to applied mathematics and science. He returned to Dublin in 1678 and married Lucy, the youngest daughter of Sir William Domville, Attorney General of Ireland. Only 2 months later, she became ill, becoming blind and suffering from constant headaches until her death 13 years afterwards. After a vain search in England for medical relief for his wife, Molyneux settled down in Dublin and passed the time by translating **René Descartes**'s *Méditations*, published in London in 1680. He also translated **Gallileo Galilei**'s *Discorsi* from Italian for his own use.

Molyneux's wife's affliction probably led him to pose the Molyneux problem, which assumes that a man blind from birth who gains his sight is confronted by a sphere and a cube that he had previously learnt to distinguish by touch. Can he identify at first sight which is which? Molyneux believed not. John Locke, George Berkeley, and other philosophers discussed the problem.

Molyneux's first important achievement in astronomy was to record the lunar eclipse seen in Dublin on 1 August 1681. He sent his observations to a friend in London, Charles Bernard, who passed them on to Flamsteed, the Astronomer Royal, whom Molyneux had previously visited at Greenwich. This led to a correspondence between Flamsteed and Molyneux that continued for the next ten years in which problems of optics, astronomy, ballistics, and tides were discussed. Molyneux learned a great deal about optical instruments from Flamsteed's letters; the exchanges were remarkable for their cordiality, as Flamsteed was reputed to have a short temper.

In 1684 Molyneux became involved in a controversy between **Robert Hooke** and **Johannes Hevel**. In his *Machina coelestis* (1673), Hevelius had claimed that open sights were better than telescopic sights. Hooke vigorously disputed the claim and, in 1679 Halley went to Danzig to test the rival theories. Halley supported Hevelius and gave him a written testimonial to that effect. Hevelius repeated his claim in 1685, in his *Annus Climactericus* which Molyneux reviewed, showing Halley's conclusions were invalid and telescopic sights were more accurate.

In October 1683 Molyneux and some colleagues from Trinity College formed a society on the model of the Royal Society of London. It was called the Dublin Philosophical Society; it met in rooms owned by an apothecary and included a garden for plants and a laboratory. Sir William petty was the first president, and Molyneux was secretary. The society exchanged minutes with the Royal Society and the Oxford Philosophical Society. Papers read in Dublin were frequently published in the *Philosophical Transactions of the Royal Society*. The society was the forerunner of the Dublin Society (1731) that became the Royal Dublin Society (1820), promoting the utilitarian aims of the original society.

In 1685 Molyneux was elected a fellow of the Royal Society. That same year he visited his brother Thomas (afterwards Sir Thomas) who was studying medicine in Leiden, the Netherlands. The brothers visited **Christiaan Huygens** at The Hague where he showed them a telescope in his garden and a planetary clock. In Paris they visited **Jean Cassini** and saw a clockwork device for driving a telescope.

Returning through London, Molyneux visited Flamsteed, and he also ordered the construction of a combined dial and telescope of his own design, to which he gave the name *Sciothericum telescopicum*. Flamsteed later examined the device and was not impressed. The following year Molyneux published a book describing the instrument.

When James II arrived in Ireland in 1688, Molyneux fled to England, settling in Chester. There, his son **Samuel Molyneux** was born; he was a source of great interest and pride to his father and became an astronomer.

During his 2-year stay in Chester, the elder Molyneux wrote *Dioptrica Nova,* which was the first book on optics published in English. The book was received favorably and became a standard text. In a dedication to the Royal Society he made a complimentary reference to Locke, which led to a long and friendly correspondence between the two men.

After the defeat of James II in July 1690, Molyneux returned to Dublin and became involved in politics. He was elected as one of the university representatives in the new Irish parliament in October 1692 and was reelected in 1695. As a result of his concern about the effect of the English parliament's legislation on the linen and woolen industries in Ireland, early in 1698 he published the work by which he is generally best known: *The Case of Ireland's being bound by Acts of Parliament in England*, *stated.* It was an attempt to prove the legislative independence of the Irish parliament, and it provoked strong opposition from the English parliament.

Despite the unfavorable reaction to his book in England, Molyneux went to London in July 1698 to fulfill a long-standing promise to visit Locke. Upon his return in September, he soon suffered a recurrence of a kidney complaint and died.

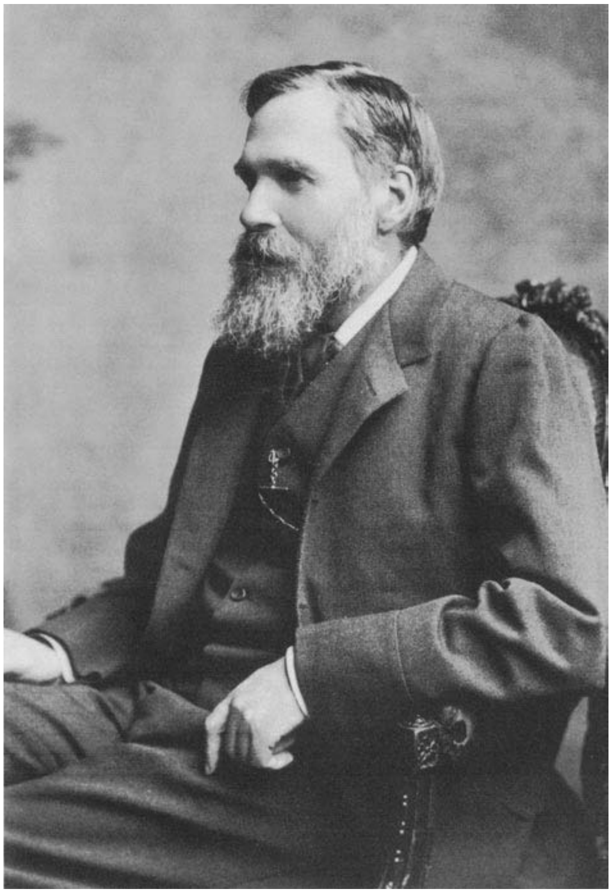
Monck, William Henry Stanley

Born **Skeirke near Borris-in-Ossory, (Co. Laois), Ireland, 21 April 1839**
Died **Dublin, Ireland, 24 June 1915**

Although trained as a lawyer and philosopher, William H.S. Monck was a highly proficient amateur astronomer who was among the first to realize the existence of dwarf and giant stars. With the assistance



of Stephen M. Dixon, Monck made the first astronomical photoelectric measurements of light in Dublin in August 1892.

Monck was the third of four sons of the Reverend Thomas Stanley Monck (1796–1858) and his wife Lydia (*née* Kennedy). His childhood was spent in a rural community 16 miles southeast of Parsonstown (now Birr), King's County, where **William Parsons**, the Third Earl of Rosse, completed the great 72-in. reflecting telescope in 1845. The sight of the Leviathian of Parsonstown may well have kindled Monck's interest in astronomy.

The Anglo–Norman family Monck that settled in Ireland descended from William Le Moyne (living in 1424) of Devonshire and his son Robert. From 1705 the Monck family was associated with the Charleville estate near Enniskerry, County Wicklow. William's grandfather, the Reverend Thomas Stanley Monck, was a younger brother of Charles Stanley, the First Viscount Monck. Charles, the Fourth Viscount Monck, was Governor General of Canada from 1861 to 1868.

William Monck was educated at home by tutors. He distinguished himself on entry to Trinity College Dublin, and in 1861 he obtained the first scholarship in science with a gold medal and a first class honors degree in logic and ethics; he also received the Wray Prize for the encouragement of metaphysical studies. He studied divinity with distinction for several years. However, instead of following his father and grandfather into the Anglican Church of Ireland, Monck turned to law and was called to the bar in 1873. He was later appointed chief registrar in bankruptcy in the High Court in Dublin. In 1878 Monck returned to academic life and was professor of moral philosophy in Trinity College (the chair formerly occupied by George Berkeley) until 1882. He wrote *An Introduction to Kant's Philosophy* (1874) and a well-received *Introduction to Logic* (1880).

In 1886 Monck became a fellow of the Royal Astronomical Society [RAS] and a member of the Liverpool Astronomical Society. On 12 July 1890 he wrote a letter to the *English Mechanic* advocating the formation of an association of amateur astronomers to cater for those who found the RAS subscription too high, or its papers too technical, or who, being women, were excluded. Moves toward setting up such a society had already been made by **Edward Maunder**, and the British Astronomical Association was established at a meeting in London on 24 October 1890.

Monck was a prolific writer, and from 1890 onwards many of his letters and articles appeared in the early volumes of the *Publications of the Astronomical Society of the Pacific*, *The Sidereal Messenger,* and *Astronomy and Astro-Physics* (the forerunner of the *Astrophysical Journal*), as well as the *Journal of the British Astronomical Association* and the *English Mechanic*. In 1899 he published *An Introduction to Stellar Astronomy,* which consisted mainly of articles that had previously appeared in *Popular Astronomy.*

In 1891 Monck purchased a 7½-in. refractor designed by **Alvan Clark** that had been owned previously by the Reverend **William Dawes**, Frederick Brodie, and Dr Wentworth Erck. Monck erected the telescope in the back garden of his residence at 16 Earlsfort Terrace, Dublin. Shortly afterward he received a request from his old college friend, George M. Minchin (1845–1914). Minchin, a professor of applied mechanics at the Royal Indian Engineering College at Cooper's Hill, London, wanted to test "on the stars" some selenium photocells that he had developed. Using a quadrant electrometer borrowed from Trinity College to record the voltage produced by the cell, Monck and his neighbor, professor Dixon, succeeded in measuring the relative brightness of Jupiter and Venus on the morning of 28 August 1892. They failed to obtain "certain" results from the stars on account of instrumental drift and other difficulties. Minchin continued to improve his cells. Working with professor **George FitzGerald** of Trinity College and William Edward Wilson (1851–1908), Minchin made measurements of stellar brightness in April 1895 and January 1896 using the 24-in. reflector operated by Wilson at Daramona Observatory in County Westmeath. These observations were reported by Minchin in *The Proceedings of the Royal Society.*

In 1894 Monck suggested that there were probably two distinct classes of yellow stars – one being dull and near, the other being bright and remote. He based this on his examination of several catalogs that displayed the early Harvard Observatory spectral classifications as well as proper motions for large numbers of stars. What Monck noticed was that those stars comparatively close to the Earth (and therefore exhibiting the largest proper motions) were not also the brightest stars. In fact, the 92 stars he identified as Capellan (modern spectral classes F and G) and the 59 Arcturian stars (modern spectral class K) had large proper motions and were about equal in brightness to the Sirian stars, of which there were only 11 of the same brightness and proper motion. Monck concluded, properly, that this meant that the Sirian stars were likely intrinsically brighter but farther away on average. This clue to the existence of dwarf and giant stars was taken up by his friend **John Gore** who estimated the size of Arcturus. If better data had been available to Monck, his discussion of proper motions and spectra might have led him to the relationship between luminosity and color later discovered by **Ejnar Hertzsprung** and **Henry Norris Russell**.

Monck may have been the first to suggest the parsec as a unit of distance. In his *An Introduction to Stellar Astronomy* (1899), he wrote:

> If we adopted as our unit of distance that of a star with a parallax of one second (in other words 206,265 times the distance of the Sun), the distance of any other star will be 1/p, where p is the parallax expressed as a fraction of a second. This would, I think, be a more convenient unit of distance than that usually adopted by astronomers; *viz*., a year's light passage, or the distance which light travels in a year.

Monck was greatly interested in meteors; he corresponded with **William Denning** for many years. Monck wrote 39 articles or letters related to meteors in the current journals over 3 decades (1885–1914).

David DeVorkin has described Monck as a "brilliant amateur astronomer," but probably very few of his contemporaries realized the potential impact of his astronomical studies. Quiet and reserved in manner, he was an authority on politics, history, and legal matters. Monck took a great interest in educational matters and supported all schemes for improving the lot of the underprivileged. He was a formidable chess opponent but took more pleasure in solving problems than in the cut and thrust of games.

Monnier, Pierre-Charles le

Born **Paris, France, 23 November 1715**
Died **Herils, Calvados, France, 3 April 1799**

Pierre Le Monnier, an outstanding observational astronomer, brought English astronomical ideas and instrumentation to France. Le Monnier's father (also named Pierre) was professor of philosophy at the Collège d'Harcourt and member of the Académie royale des sciences. His brother, Louis Guillaume Le Monnier, also an academician, was professor of botany at the Jardin du roi, physician (*premier médecin ordinaire*) to King Louis XV and King Louis XVI, and a physicist. In 1763, Pierre-Charles married a daughter of the wealthy Norman family of Cussy, with whom he had three daughters, one of whom married **Joseph de Lalande**, another who married Pierre Charles' brother Louis.

Le Monnier began his astronomical career early with the assistance of his father. As early as 1731, when Le Monnier was still quite young, he indicated his skill with observations of the opposition of Saturn. In 1732, he was allowed to observe in Paris. In 1735, Le Monnier presented an elaborate lunar map to the academy and was admitted as *adjoint géomètre* on 23 April 1736. By 1746, he rose to *pensionnaire* and became professor of physics at the Collège royal (Collège de France). He was eventually elected to the Royal Society of London, the Berlin Academy, and the Académie de la Marine.

Mainly as an observer, Le Monnier greatly advanced astronomical measurement in France. He was a favorite of Louis XV, who procured for him some of the best astronomical instruments in France. Le Monnier studied the Moon, determined the positions of many stars, conducted extensive research in terrestrial magnetism and atmospheric electricity, and wrote about astronomical navigation.

Le Monnier's career accelerated with the geodesic expedition of 1736 to Lapland. He accompanied **Pierre de Maupertuis**, **Alexis Clairaut,** and the Swedish astronomer–physicist **Anders Celsius** to measure a degree of an arc of meridian at high latitude. The equipment of the expedition included a 9-ft. zenith sector, a transit instrument, and a clock, all by **George Graham**, the leading English maker of the day. In addition to surveying the degree of meridian, Le Monnier made observations of atmospheric refraction at various latitudes and in different seasons.

In 1741, Le Monnier published his *Histoire céleste* as a review of observations made in France from the founding of the Académie royale des sciences. The transit instrument he describes there and illustrates in detail was designed by Graham. Le Monnier introduced his *Description* by relating it to that previous account of the transit instrument, to Maupertuis' account of the zenith sector, and to the general textbooks written by Nicolas Bion in France and Robert Smith in England. Le Monnier thought that the mural quadrant was capable of being a universal instrument for all fundamental measurements in astronomy. Intimately familiar with the English mural quadrants, having acquired one of 5-ft. 4 in. radius from Jonathan Sisson in 1743, Le Monnier had also examined the original Graham quadrant in detail at Greenwich in 1748, and obtained a similar instrument of 8-ft. radius from John Bird in 1753. It was clear that, as the mural quadrant was becoming the principal instrument in the observatories of Europe, so London makers were moving into a position where they dominated the market in precision instruments. Le Monnier played an important part in this process, especially in relation to France, and his *Description* is one of its most impressive monuments.

Then Le Monnier published *La théorie des comètes* (1743), which was largely a translation of **Edmond Halley**'s *Cometography* but with several additions, and constructed the first transit instrument in France at the Paris Observatory and the great meridian at the Church of Saint Sulpice, Paris, also during the year 1743.

In 1748, Le Monnier travelled to England and observed an annular eclipse of the Sun in Scotland. An indefatigable observer, he undertook a star catalog and in 1755 produced a map of the zodiacal stars. He made several observations of Uranus before it came to be recognized as a planet by **William Herschel** in 1781. In fact, the third Astronomer Royal, **James Bradley**, recorded Uranus as a star in 1748, 1750, and 1753, while **Tobias Mayer** sighted it in 1756. But Le Monnier recorded Uranus 12 times between 1764 and 1771, including six observations in January 1769. Apparently he did not recognize Uranus, which was near its stationary point in the sky at the beginning of 1769, so its movement among the stars would not have been obvious.

Le Monnier introduced two constellations, now obsolete. The Reindeer (*Le Renne* or *Tarandus Vel Rangifer*) was created in 1743 for commemorating Lapland. Some faint stars between Camelopardalis and Cassiopeia formed it. The Solitary Thrush (*Le Solitaire* or *Turdus Solitarius*) was an Indian bird created in 1776 near the tail of Hydra.

Le Monnier's work on lunar motion was the most extensive and the most important of his time. In the first edition of the *Principia*, **Isaac Newton** had shown that the principal inequalities of the Moon could be calculated from his law of universal gravitation; in the second edition Newton applied these calculations to the observations of **John Flamsteed**. His methods, however, added little to the theory that **Jeremiah Horrocks** had suggested long before. Flamsteed calculated new tables based on Horrocks' theory incorporating Newton's corrections, but he did not publish them. They appeared for the first time in *Institutions astronomiques* (1746), Le Monnier's most famous work. It was basically a translation of **John Keill**'s *Introductio ad veram astronomiam* (1721), but with important additions and with new tables of the Sun and the Moon. The textbooks of Lalande and **Nicolas de La Caille** later largely replaced this book, which was the first important general manual of astronomy in France.

Le Monnier supported the view of Halley that the irregularities of the Moon's motion could be discovered by observing the Moon regularly through an entire cycle of 223 lunations, which is the Saros cycle of approximately 18 years and 11 days, with the assumption that the irregularities would repeat themselves throughout each cycle. Le Monnier and Bradley each began such a series of observations; Le Monnier continued this work for 50 years.

During the 1740's Clairaut, **Jean d'Alembert**, and **Leonhard Euler** were racing to create a satisfactory mathematical lunar theory, which demanded an approximate solution to the difficult three-body problem. In the ensuing controversy, Le Monnier seconded d'Alembert who used Le Monnier's *Institutions astronomiques* as the basis for his tables. In 1746, Le Monnier presented a memoir to the academy describing his observations of the inequalities in the motion of Saturn caused by the gravitational attraction of Jupiter. His results were important for improving the lunar theory, because a good explanation of the perturbations of Saturn also required a treatment of the three-body problem.

The best lunar tables of the 18th century were those of Tobias Mayer, which were based on Euler's theory but with the magnitude of the predicted perturbations taken from observations. Although Le Monnier admired English methods in astronomy, he adhered to the task of correcting Flamsteed's tables even while confessing the superiority of Mayer's.

As a regular correspondent with Bradley, Le Monnier was apparently the only astronomer with a sufficiently long and sufficiently accurate enough series of stellar observations to verify Bradley's discovery of the nutation of the Earth's axis in 1748. Le Monnier was the first to apply nutation in correcting solar tables.

Le Monnier's most prominent pupil was Lalande, who attended his lectures in mathematical physics at the Collège Royal. To determine lunar parallax, Lalande, on Le Monnier's strong recommendation, went to Berlin in 1751 to take measurements of the Moon for comparison with those taken by La Caille at the Cape of Good Hope.

Monnig, Oscar Edward

Born **Fort Worth, Texas, USA, 4 September 1902**
Died **Fort Worth, Texas, USA, 3 May 1999**

Oscar Monnig functioned as an active amateur astronomer as well as a publisher of an astronomical newsletter that provided an important link between members of the North American community of amateur astronomers. As a collector of meteorites, he assembled one of the largest and most diversified collections in the world.

Monnig was one of three sons of William and Alma (*née* Wandry) Monnig. His father and uncle, George B. Monnig, founded Monnig Wholesale, Inc., a successful dry goods business that eventually grew to include five retail department stores in the Fort Worth area. Monnig finished his formal education at the University of Texas at Austin earning an LL.D. degree in 1925. After practicing law for 5 years, Monnig joined the family business. He succeeded his brother Otto in 1974 as chief executive officer of the company, continuing in that capacity until the business was sold in 1983, by which time his health had begun to deteriorate.

Monnig's first love was astronomy. He always insisted on calling himself an "amateur," having had no formal training in any related field. He once signed up for a course in astronomy in college, but the class was cancelled for lack of enrollment; therefore his knowledge was all from individual study. Monnig was part of a small band of dedicated observers that included Robert Brown, James Logan, Sterling Bunch, and Blakeney Sanders. Together, they founded the Las Estrellas Observatory under dark skies south of Fort Worth. Work at the observatory emphasized variable star and meteor observing, photographic observation of comets and planets, and lunar occultation timing. With the advice of Canadian astronomers **Peter Millman** and Ian Halliday, gained during a solar eclipse expedition in August, 1932, Monnig successfully captured early spectrographic images of meteors by placing a prism in front of a camera lens. The group's meteor work was so regular and of such high quality that **Charles Olivier** began identifying them as the "Texas Observers", and the title was adopted by the group.

In 1928, Sterling Bunch published two issues of a newsletter that he titled *The North Texas Astronomical Bulletin*, but his effort floundered for lack of writers. In 1931, Monnig restarted the publication, but titled it *The Texas Observers Bulletin*, as an informal newsletter that carried various observations about astronomical subjects "of interest to amateurs." Monnig continued the publication of this bulletin until 1947. It was mimeographed and mailed in standard business envelopes to more than 200 subscribers around the United States and Canada. In some issues, Monnig would include photographic prints of interest in the envelope, but would leave space on the mimeographed page for the photograph to be pasted in after it was received by the subscriber. The *Texas Observers Bulletin* was recognized favorably by such professionals as **Otto Struve** and **Bart Bok**, who encouraged similar efforts on the part of other amateurs.

Over time, Monnig's astronomical interest became strongly focused on meteoritics, a field that he chose because "it was a small area where he could find joy." His most lasting legacy is the internationally recognized meteorite collection that he amassed. The Monnig Meteorite Collection is now housed in the Department of Geology at Texas Christian University in Fort Worth. His collecting started in the early 1930s when meteorites were mere curiosities and the idea of making a collection of these objects was alien to most people. Because the family business required his visiting large areas of the United States southwest, Monnig left word that he would buy any "strange rock that turned out to be a meteorite" as he traveled. As a result he bought many "hen-house door stops" from ranchers and farmers. Also, an important opportunity to collect fresh meteorites occurred when newspapers or radio would report a "fireball." Monnig would try to establish where a possible fall would have occurred and would then go there at the first opportunity, sometimes successfully finding meteorites. Over time and his travels, he built up a network of observers and meteorite hunters around Texas, Oklahoma, and Arkansas. Monnig encouraged others to get involved by publishing a small but well-written brochure describing the appearance and physical characteristics of a meteorite together with information on how to contact him when a suspected meteorite was found. When Monnig could not visit the area of a possible fall, he frequently solicited the help of Robert Brown who traveled to the area to coordinate a search. When a new discovery was made, Monnig often teamed up with **Harvey Nininger**, one of the few other meteorite collectors in the early days. Because his duties as a businessman were primary, Monnig's impact on science exists largely in his collection of many rare meteorites that otherwise might have been lost.

Monnig was one of the charter members of the Society for Research on Meteorites (later known as the Meteoritical Society). In addition to being a fellow of the society, he served as a councilor from 1941 to 1950 and from 1958 to 1966; he also served as the society secretary from 1946 to 1950. In 1984, Monnig was honored as the first recipient of the Texas Lone Star Gazer Award.

On 2 January 1941, Monnig married Juanita Mickle whom he met while pursuing a meteorite fall in East Texas; they had no children.

Montanari, Geminiano

Born **Modena, (Italy), 1 June 1633**
Died **Padua, (Italy), 13 October 1687**

Geminiano Montanari was the first to recognize the variability of Algol. The son of Giovanni Montanari and Margherita Zanasi, he was left fatherless at age 10. Montanari began his studies in Modena. After an agitated youth, at 20 he went to Florence to study law; he remained there for 3 years. After one of the frequent and violent quarrels he had during his life (to testify a strong character), Montanari left Florence and moved to Salzburg, Austria, where he took a law degree in 1656.

During a stay in Vienna, where he carried on legal practice, Montanari befriended Paolo del Buono, **Galileo Galilei**'s pupil and Florentine diplomat at the imperial court. With his help Montanari took up mathematical and scientific studies, which always interested him.

After a long journey in Austria and the eastern Carpathians, Montanari returned to Italy in 1658, dropped law, and became astronomer to the Grand Duke of Tuscany. In 1661, he returned to Modena as astronomer to Duke Alfonso IV d'Este. There

Montanari married Elisabetta, who collaborated actively with him. Montanari also met the Marquis Cornelio Malvasia, the duke's military chief who was interested in astronomy. In 1649 Malvasia had called the young **Gian Domenico Cassini** to Bologna. Montanari observed with Cassini in Malvasia's private observatory at Panzano, near Bologna. The collaboration produced a large volume, the *Ephemerides novissimae motuum coelestium*, published by Malvasia in 1662.

Montanari became skilled in the design and construction of astronomical instruments including good objective lenses. (One, dated 1666, is in the Museo della Specola in Bologna.) He was one of the first to invent the bifilar micrometer, which he used to draw a lunar map for Malvasia's *Ephemerides*. A device for the exact positioning of telescopes was described in *La livella diottrica* (The leveling diopter) of 1674.

In 1664, with Malvasia's assistance, Montanari obtained the chair of mathematics at the University of Bologna, where Cassini had been teaching astronomy since 1650. His Bologna years were the happiest of his life; he became a promoter of Bolognese cultural development.

In 1667, Montanari discovered that the star Algol (β Persei) was fainter than usual. Between 1668 and 1677 Montanari followed the variability of Algol, sending his results to the Royal Society of London. He also gave a description of Algol's variability in his 1671 *Sopra la sparizione d'alcune stelle ed altre novitá celesti* (On the disappearance of some stars and other celestial novelties), in which he also reported his suspicion of the variability of the star now known as R Hydrae. Montanari perceived neither the regularity nor the period of variation of Algol because of the deterioration of his eyesight, which prevented regular observation. These observations by Montanari struck another blow against Aristotelian immutability, still in contention decades after Galilei's *Sidereus Nuncius*. Montanari's ideas on this phenomenon, which were contrary to popular opinion, were thus violently attacked. Montanari's observational diaries, including his Algol observations, passed to **Francesco Bianchini** and **Eustachio Manfredi**, who recorded them in Bianchini's *Astronomicae ac geographicae observationes* (Verona, 1737); unfortunately the diaries were later lost.

Montanari was also a keen observer of comets and other celestial phenomena, as demonstrated by the observations he made of the meteor that crossed the sky of central Italy in 1676 or those of the comet of 1682, the same observed by **Edmond Halley**. He believed comets to be above the Moon, *pace* the Aristotelians, because he was able to measure the parallax (with a telescope equipped with a micrometer) and the distance, confirming **Tycho Brahe**'s and Cassini's observations. He mistakenly maintained that meteors are similar to lightning and that rocks sometimes found at impact sites are terrestrial in origin.

Typical of natural philosophers of this period, Montanari was also interested in many other natural phenomena. In physics, Montanari experimented on the behavior of liquids in capillary tubes, ascribing it to the major or minus capacity of liquid to stick to the matter of a vessel, which became the topic of a decade-long polemic against Donato Rossetti. Montanari also undertook biological and medical experiments, including blood transfusion between animals in 1668 at Udine. Interested in meteorology, Montanari studied tornados and was the first to use the term "atmospheric precipitation." He noted the utility of the barometer for weather forecasting and as an altimeter. Montanari also devoted himself to ballistics, writing a short manual in which the gunners could find tabulated values for elevations corresponding to gun-ranges. He also worked in hydraulics, leaving the results of his work to his pupil Domenico Guglielmini. With the help of Bolognese and Paduan intellectuals Montanari published several tracts intended to discredit astrological prognostication.

Montanari organized and promoted the Accademia della Traccia (derived from the Florentine Accademia del Cimento), important for scientific debate and for instruction that he gave to his best pupils. It is clear from his works that he was an authentic Galilean, and he maintained a position based on a clear distinction between "metaphysics" and "natural philosophy."

In 1678 Venice created a chair of astronomy and meteors at Padua. Lured by a large salary, Montanari took the position. In addition to teaching, for which he was famous for clarity and scientific rigor, he performed other duties for the Republic, from inspection of rivers and the protection of the lagoon of Venice, to fortifications, artillery training, and organization of the mint and monetary problems. Due to all these duties, some dangerous to his health, Montanari became blind. He died suddenly of an apoplectic stroke.

Moore, Joseph Haines

Born **Wilmington, Ohio, USA, 7 September 1878**
Died **Oakland, California, USA, 15 March 1949**

American stellar spectroscopist Joseph Moore has as his monuments a catalog of the radial velocities of all northern stars brighter than visual magnitude 5.51, compiled with **William Campbell**, and the third, fourth, and fifth editions of the definitive catalog of orbital elements of spectroscopic binaries. He was the only child of John Haines and Mary Ann (*née* Haines) Moore. In 1907, Moore married Fredrica Chasa, a Vassar College, New York, graduate who had come to Lick Observatory as a computer; they had two daughters, Mary Kathryn (Gates) and Margaret Elizabeth (Matthews). Moore received his postsecondary education at Wilmington College, whence he graduated AB in classics in 1897, and at Johns Hopkins University, from which he received his Ph.D. in 1903. He was elected to the United States National Academy of Sciences in 1931 and was a fellow (and in 1931 vice president) of the American Association for the Advancement of Science. Moore twice served as president of the Astronomical Society of the Pacific (1920 and 1928) and was vice president of the American Astronomical Society in 1942.

Moore came from a Quaker family and remained a lifelong member of the Society of Friends. Although he began his postsecondary education in the field of classics, Moore was influenced in his last year at Wilmington College by W. W. Bennett, who taught

astronomy there and encouraged him to use the 12-in. reflector belonging to the college. At Johns Hopkins University, Moore studied astronomy under **Simon Newcomb** and physics under **Henry Rowland**, J. S. Ames, and **Robert Wood**. His doctorate was awarded for studies of the spectroscopy of the fluorescence and absorption of sodium vapor. At graduation, Moore was offered by Ames the choice of instructorships in physics at Harvard, Yale, or the University of California (Berkeley), or the position of assistant in spectroscopy at Lick Observatory under Campbell. He chose the latter although the salary was lower, and joined the staff of Lick Observatory on 1 July 1903. Moore was promoted to assistant astronomer in 1906. From 1909 to 1913, he was astronomer-in-charge of the Lick Obervatory's southern station in Chile. On his return, he was promoted to associate astronomer in 1913, and astronomer in 1918. He held the position of assistant director from 1936 to 1942 and was director from 1942 to 1945. Although Moore relinquished the directorship, for medical reasons, in November of 1945, he continued as astronomer and also taught courses at Berkeley until 1948.

Moore's first major task at the Lick Observatory was to assist Campbell in the determination of the radial velocities of all stars brighter than visual magnitude 5.51 that were observable from the Lick Observatory. This resulted in a major catalog in Volume 16 of the *Publications of Lick Observatory*. In 1932, he published *A General Catalogue of the Radial Velocities of Stars, Nebulae, and Clusters* (the predecessor of **Ralph Wilson**'s later catalog). Moore was author or joint author of three of the five *Catalogs of Spectroscopic Binaries* published by the Lick Observatory – a task that the present writer, although he never met Moore, eventually inherited from him. The last catalogue of which Moore was an author (with F. J. Neubauer) was published shortly before Moore's death. All these catalogs remained important reference works to other astronomers for several decades.

Moore took part in five expeditions from the Lick Observatory to observe total solar eclipses. Three were within the United States, one in Mexico, and one in Australia. All but the Mexican expedition, for which the weather was poor, were successful and produced useful results. Moore was in charge of the last two expeditions, in California in 1930 and to Maine in 1932. Moore's special interest in eclipses was the study of the spectrum of the solar corona. This spectrum had been first observed by **Charles Young** during the eclipse of 1868. Until 1931, when **Bernard Lyot** succeeded in observing the corona without waiting for a total eclipse, its spectrum could be observed only during the brief moments of totality. Moore's work thus helped to lay the foundations of our knowledge of the solar corona and of the physical conditions of the matter within it. Campbell and Moore also discovered the doubling of the emission lines in spectra of some planetary nebulae, which they attributed to rotation, but which is now understood as evidence for expansion of the nebulae.

Moore-Sitterly, Charlotte Emma

Born **Ercildoun, Pennsylvania, USA, 24 September 1898**
Died **Washington, District of Columbia, USA, 3 March 1990**

Spectroscopist Charlotte Emma Moore-Sitterly devoted her professional career to atomic spectroscopy, providing a wealth of vitally needed basic astrophysical data. Moore obtained a BA degree in mathematics from Swarthmore College, Pennsylvania, USA, in 1920. (She would be awarded an honorary doctorate in 1962.) After graduation, Moore moved to Princeton University Observatory, where she became a computational assistant to **Henry Norris Russell**, the director. She also attended graduate courses at the university. Thus began a lifelong association with Russell, until his death in 1957, and Moore's work in two broad, largely separate, fields of fundamental astrophysics.

Russell was engaged in the determination of physical properties of binary stars and on the analysis of stellar spectra based on laboratory data. The first centered on the analysis of eclipse light curves and radial velocity variations for binary stars with the aim of determining accurate masses and radii with which to compare stellar models. The data also yielded dynamical parallaxes for many of the systems (over 1,700) that supplemented trigonometric parallax determinations, especially those compiled at Yale University. The summary monograph resulting from this extended study (1940) served for decades as the standard compilation of fundamental dynamical properties for stars.

The second, atomic spectroscopy, is the field with which Moore is most closely associated. On her arrival at Princeton, she was put to the task of identification of atomic lines in stellar spectra. Laboratory spectroscopy saw a rapid advance in the last quarter of the 19th and first quarter of the 20th centuries. The introduction of electric furnaces, improved vacuum technology, broad wavelength sensitivities of photographic plates, and availability of high-resolution diffraction gratings and long-focus cameras paralleled improvements in sample purity produced for laboratory analysis. In astrophysics, however, quantitative analysis of stellar spectra had not yet started. Progress was hampered by low resolution and poor sensitivity, and by barely developed theoretical means for handling line formation in stellar atmospheres.

This began to change around the time of Moore's arrival at Princeton. By 1920, line identifications were available for a significant number of lines in the solar spectrum and, by extension, to a broad range of stellar spectra. Although lacking a firm theoretical basis with which to explain the appearance of these spectra, the still nascent quantum theory – represented by the Bohr atom and Sommerfeld's explanation of fine structure – at least provided some organizing principles. The analysis was extended to the Stark effect and Zeeman effect, all of which showed that similar groups of lines could arise from coupled energy levels. The recognition of the spin quantum number in 1925, and rapid progress on a vector model of the atom by Alfred Lande, set the stage for Moore's most valuable contributions. (The vector mode was elaborated by Russell and **Frederick Saunders** – so called spin-orbit or L–S coupling.) These were the multiplet table of the elements and compilation of atomic energy levels.

There were two critical steps involved here. First, accurate ionization energies were required to provide a zero point to the energy levels for each element and the identification of the ground-state (resonance) transitions. By the early 1930s, extensive laboratory intensity and wavelength tables were available through Massachusetts Institute of Technology, California Institute of Technology, and other laboratories; the largest sets were the so called Harrison and Paschen tables. But these were limited by the relatively low temperatures that could be achieved in sparks and furnaces. In contrast, the Sun has been used as a standard for spectroscopic measurements, since the discovery of the absorption spectrum by **William Wollaston** and **Joseph von Fraunhofer** early in the 19th century.

Spurred by the accumulation of laboratory data, particularly by **Robert Bunsen**, **Gustav Kirchhoff**, **Norman Lockyer**, and others, **Henry Rowland**, between 1895 and 1897, published the first wavelength list of the photosphere on the Ångstrom scale with identifications for 39 elements (of which several were later shown to be spurious) between 2,975 Å and 7,350 Å. This served as the benchmark list.

The construction of the Snow telescope at Mount Wilson, the first dedicated observatory in the United States for solar spectroscopy and imaging, provided an opportunity to update the list as new spectra covering the same wavelength range became available. Moore was hired by **Charles St. John** to assist with the task. She remained at Mount Wilson from 1925–1928, holding the job title of "computer."

Laboratory standards had by then produced an absolute scale, and this was adopted for the line list. The published list contained identifications for 57% of the detectable lines and assignment of 57 elements. Moore continued her work at Mount Wilson through 1932, and obtained her Ph.D. from the University of California at Berkeley in 1931 with a thesis on sunspot spectra. This represented a major step in the analysis of the solar spectrum, since both magnetic-field data and lower-temperature species (including molecules) were observed. The list was published in 1932 and 1933.

Moore returned to Princeton in 1931 as a research assistant (1931–1936) and then as a research associate (1936–1945), working mainly with Russell and remaining until 1945 when she moved to the National Bureau of Standards [NBS] to work in the spectroscopy section that was headed by William Frederick Meggers. During her second sojourn at Princeton, she married the physicist Bancroft Sitterly and was awarded the second Cannon Prize of the American Astronomical Society for her thesis work.

The product of this period of Moore's life, *A Multiplet Table of Astrophysical Interest*, became the fundamental reference for all astrophysical line identifications. It assigned spectroscopic terms and energy levels to almost 26,000 lines for up to the second ionization state of elements through thorium. First appearing in 1933 in the *Princeton University Observatory Publications* (under the title "Spectrum Lines of Astrophysical Interest"), it was revised twice, in 1945 and again in 1972. The last was issued by the NBS and received very wide circulation. It was soon followed by *An Ultraviolet Multiplet*, which extended the line lists and analyses into the vacuum ultraviolet [UV]. Also resulting from this effort was a series on atomic energy levels, which went through several revisions after first issue by NBS in 1949, a compilation that served as a basic reference for all spectrum predictions.

The utility of these publications extends far beyond their original intention – without these lists, modern stellar atmospheres analyses would be impossible. After Moore's death, they were merged with critically evaluated atomic energy levels and quantum mechanical line strengths to become the National Institute of Science and Technology [NIST] electronic database of atomic line identifications. When the UV spectral window opened after World War II, through the use of sounding rockets and (ultimately) satellites, the UV multiplet table became an indispensable guide to the new territory. Although frequently mentioned as a critical need in her publications, no similar multiplet table was produced for the infrared during Moore's lifetime. Her tables still are widely cited by atomic physicists and chemists, as well as astronomers.

The final step in the evolution of Moore's analyses of the Sun came in 1966 with the publication of the line strengths and wavelengths in the combined solar spectrum using equivalent widths based on the intensity-calibrated tracings obtained at the University of Utrecht, the Netherlands. The work, which was sponsored by a resolution of the International Astronomical Union [IAU], formed the basis for the determination of elemental abundances in the Sun. By its completion, around 24,000 lines were measured with identifications for almost 73%.

Moore remained at NBS, now the NIST, until her retirement in 1968. Thereafter, she joined the Naval Research Laboratory [NRL] and remained affiliated with NRL until her death. She was awarded the Meggers Prize of the Optical Society of America (1972) and the Bruce Medal of the Astronomical Society of the Pacific (1990). She served as vice president of the American Association for the Advancement of Science (1952) and IAU Commission 14 (1961–1967).

Morgan, Augustus de

Born **Madura (Madurai, Tamil Nadu, India), 27 June 1806**
Died **London, England, 18 March 1871**

Though not an astronomer, Augustus de Morgan, one of the most notable British mathematicians and logicians of the 19th century, served the Royal Astronomical Society in leadership positions for over 3 decades, including his service on the council, and as secretary and editor of the *Monthly Notices*. His influence on the organization and its members was substantial and positive.

De Morgan's father John was a lieutenant colonel in the British Army in India. Born with only one eye, de Morgan was raised in England. Though he did poorly at school, at the age of 16 de Morgan entered Cambridge University where he studied under George Peacock, professor of astronomy and geometry, and **William Whewell**, with both of whom he remained friends. Peacock, along with **John Herschel** and Charles Babbage, formed the Analytical Society famous for introducing to Cambridge advanced German and French methods of calculus and helping to develop a purely symbolic algebra. De Morgan took his BA in 1826, but because of his strong objections to the theological test required at Cambridge, he did not get a fellowship or proceed to the MA. He read for the bar in London but, in 1828, with no mathematical credentials, he was awarded the first professorship of mathematics at the new University College, London. De Morgan held the post until 1831 when he resigned on a matter of principle; he held the post a second time from 1836 to 1866, when he resigned, again on a matter of principle, once again on theological strictures, but now applied to others rather than to himself.

The publication of de Morgan's *Elements of Arithmetic* (1831) was a significant advance in providing a mathematically rigorous yet philosophically sophisticated treatment of number and magnitude useful for scientific applications. De Morgan coined the term "mathematical induction" to differentiate once and for all the purely formal technique of advancing from number n to $n+1$ (used in mathematical proofs) from the purely empirical method of hypothetical induction in science. He saw the far-reaching applications of algebraic and numerical analysis to science, and was himself fascinated by purely algebraic and numerical applications to purely empirical problems; it was he, for instance, who produced the first almanac of Full Moons (from 2000 BCE to 2000) and showed how probability theory can be used, for instance, in predicting catastrophic events in life, a technique in use today by insurance companies throughout the world. His *Trigonometry and Double Algebra*, first published in 1849, provided the first thoroughly geometric interpretation of complex numbers, which further extended their application in engineering and astronomical calculations.

De Morgan also made important contributions to symbolic logic; he saw, more than any other British luminary of the time (except, perhaps, George Boole), that logic as it had been passed down from **Aristotle** was severely handicapped in scope, due in large part to a paucity of rigorous mathematical symbolism. He showed that many more valid inferences are possible than were envisioned by Aristotle, using formulas such as the ones now known as De Morgan's Law:

$$\sim (p \vee q) = \sim p \wedge \sim q, \text{ and } \sim(p \wedge q) = \sim p \vee \sim q.$$

These laws of converses and contradictions state, in English, that the truth value of the negation, or contradictory, of the disjunction of two propositions, is the same as the conjunction of the negation of each of the propositions; likewise, the truth value of the negation, or contradictory, of the conjunction of two propositions is the same as the disjunction of the negation, or contradictory, of each of the propositions. In his *Formal Logic*, de Morgan uses the important new concept of quantification of the predicate to solve problems that were simply unsolvable in classical Aristotelian logic; when Sir William Hamilton accused him of stealing the idea from him, de Morgan replied that it was Hamilton who was the plagiarist, a charge that seems to have been settled in de Morgan's favor. His *Budget of Paradoxes*, published in 1872 and reprinted in 1954 with a new introduction by the great philosopher of science, Ernest Nagel, is a paradigm debunking book; in it, de Morgan shows step by step the fallacies by which frauds, cranks, and pseudoscientific tricksters continue to this day to titillate the public with extraordinary but ultimately false claims.

De Morgan became a fellow of the Royal Astronomical Society in 1828, joining the council in 1830. He was twice secretary of the society (1831–1838, 1848–1854). Though he was asked to become president of the society, he declined on the basis that, in his view, only practicing astronomers should assume that responsibility. In 1837 de Morgan married Sophia Elizabeth Frend, daughter of a mathematician/actuary.

Morgan, William Wilson

Born **Bethesda, Tennessee, USA, 3 January 1906**
Died **Williams Bay, Wisconsin, USA, 21 June 1994**

American spectroscopist William Wilson Morgan gave his name both to the Morgan–Keenan–Kellman [MKK] system of classification of spectra of stars and to the Johnson–Morgan [UBV] system of measuring stellar colors. Both are still in use.

Morgan's town of birth no longer exists. He was the son of Protestant home missionaries, and as a result of the family's itinerant life style, received his schooling at home, in Florida, Colorado, and Missouri, before finishing high school in the nation's capital. A Latin teacher in Missouri first turned his attention to astronomy with a view of the Moon through a theodolite mounted near a library window. Morgan, whose mother had been born in Virginia, started college at Washington and Lee University (Lexington, Virginia) in 1923 and had planned to complete a degree in English there. But his physics and astronomy professor, Benjamin Q. Wooten, spent the summer of 1926 at Yerkes Observatory and learned that the director, **Edwin Frost** (a spectroscopist who had been nearly blind for some years), needed an assistant to obtain daily spectroheliograms as part of the observatory's routine work.

Morgan was offered the job, and took it up, over his father's objections, in fall 1926. He remained at Yerkes Observatory the rest of his life. Morgan completed a BS in mathematics and physics (largely by correspondence) at the University of Chicago in 1927, and a Ph.D. in 1931, working with **Otto Struve** (who had succeeded Frost as director at Yerkes), with a thesis on the spectra of type A stars displaying a variety of spectral peculiarities, now called Ap stars and known to have strong magnetic fields that facilitate concentrations of rare elements like europium on their surfaces. Morgan was appointed an instructor in 1932 and progressed to full professor, becoming department chair at Chicago for 1960 to 1966 and director of both Yerkes Observatory and McDonald Observatory (1960–1967). He held a distinguished service professorship (1966–1974) and an emeritus position the rest of his life. He served as editor of the *Astrophysical Journal* from 1947 to 1952. Morgan's own Ph.D. students at Chicago included at least 16 who became professional astronomers, including J. Allen Hynek and **Armin Deutsch**.

Morgan's approach to stellar classification and measurement was an innovative, morphological, process-based one. He did not seek to calibrate any particular features in terms of stellar temperature, density, or composition. Rather, working with **Philip Keenan** and Edith Kellman, he chose specific stars to be standards of each type, and other stars were typed by comparing their spectra (obtained with similar telescopes and spectrographs) with a set of images of the standard ones. Their *Atlas of Stellar Spectra with an Outline of Spectral Classification* was published in 1943, with revisions in 1951 and 1973 by Morgan and Keenan. In the early 1950s, together with Harold L. Johnson (died: 1980), Morgan developed a three-color system for stellar photometry. The V color was nearly equivalent to the traditional visual magnitude, B was a blue color (but longward of the Balmer jump), and U (for ultraviolet) was shortward of the Balmer jump. The spectral classes and the color system together were an extraordinarily powerful tool for stellar astrophysics. The spectral type revealed what the intrinsic color and brightness of a star must be, and then the measured UBV brightness revealed the distance to the star, how much reddening and absorption of light had occurred along the way, and something about the abundances of heavy elements in the star.

With graduate students Stewart Sharpless and Donald Osterbrock, Morgan applied these techniques to measure the distances to clusters and associations of hot (OB) stars in the plane of the Milky Way. They announced in 1951 that these associations were concentrated in a few spiral arms, showing clearly for the first time that the Milky Way is a spiral galaxy, as had been suggested half a century before by **Cornelis Easton**. The discovery of a spiral pattern in the distribution of hydrogen gas in the galactic plane from its radio emission at 21 cm both confirmed and unfairly eclipsed their work.

Beginning in the 1950s, Morgan also turned his attention to galaxies. He and **Nicholas Mayall** were able to show that the integrated spectrum of a galaxy contains a good deal of information about the kinds of stars that contribute most of the light (typically populations of giants and supergiants of different ages and compositions). Morgan also worked on a more morphologically based system for the classification of the appearance of galaxies, independent of that evolved by **Edwin Hubble**. An important aspect of the system was the recognition of the special status of the very large galaxies found at the centers of some rich clusters, to which he assigned the types N (meaning nucleated) and cD (meaning supergiant, diffuse; the letter c having been the label given to supergiant stars by **Antonia Maury** some 60 years before).

Morgan received medals or other awards from the United States National Academy of Sciences, the Royal Astronomical Society, the American Astronomical Society (serving as vice president; 1968–1970), and the Astronomical Society of the Pacific. He was a member or associate of scientific academies in the United States, Denmark, Belgium, and Argentina and of the Pontifical Academy of Sciences. He married in 1928 Helen Barrett (died: 1963), the daughter of Yerkes astronomer Storrs Barrett, and, in 1966, Jean Doyle Eliot.

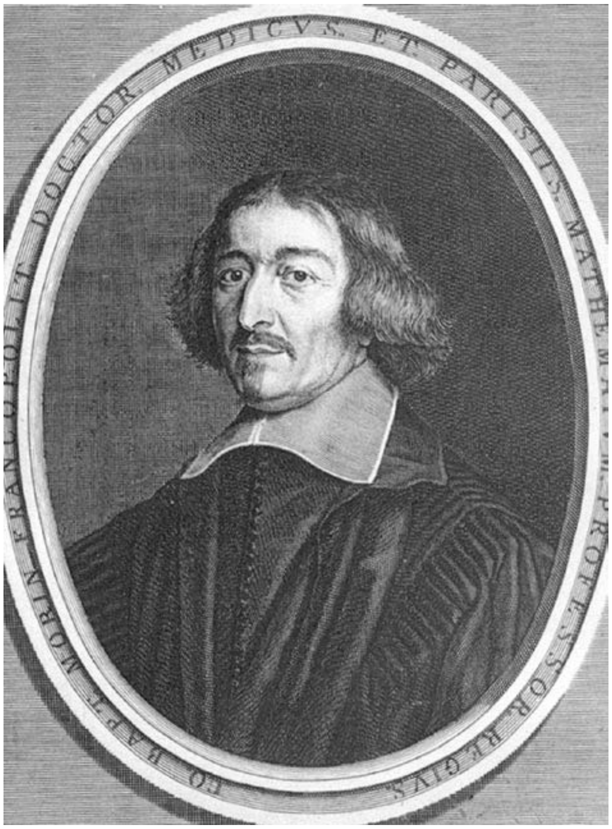
Morin, Jean-Baptiste

Born **Villefranche-sur-Saône, (Rhône), France, February 1583**
Died **Paris, France, 6 November 1656**

Jean-Baptiste Morin, a noted astrologer and notorious controversialist, defended **Johannes Kepler**'s elliptical orbits while at the same time attacking **Nicolaus Copernicus**'s heliocentric cosmology. Baptized on 23 February 1583, his birthdate is unknown. Little is known of Morin's family origins, and he never married. After studying philosophy with Marc Antoine at Aix-en-Provance (1609–1610), Morin took degrees at Avignon (BA: 1611, MD: 1613) where he likely met **Pierre Gassendi** and began his studies with the provincial astronomer **Joseph Gautier**. Always successful in attracting patronage, Morin was first supported by Claude Dormy, Bishop of Boulogne, who sent him to Germany and Hungary to visit mines and to conduct research on metals. Thereafter, Morin received patronage from Leon d'Albert, Duke of Luxembourg, before finally being appointed professor of mathematics at the Collège royal, a post he held from 1630 until his death. It is likely Morin received this appointment through Cardinal Richelieu, no doubt due to his skill in astrology. Quarrelsome in his disputes, Morin consistently opposed Copernicanism and the New Science.



As an astronomer, Morin is chiefly remembered for his efforts to determine longitude at sea. The ensuing debate – like the whole of Morin's career – was surrounded by bitter controversy. His first public pronouncement came in 1633 in a conference at Théophraste Renaudot's Bureau d'adresse, and thereafter a string of pamphlets added fresh fuel to a debate that dominated the decade. Morin's method was sound in principle but impractical. Derived in part from the methods of **Gemma Frisius** (employing spherical triangles but rejecting the use of clocks), it differed in emphasizing the measurement of lunar distances from a fixed star. But the method required especially accurate ephemerides and precise observations of angular distances. The controversy involved the most celebrated astronomers of the day, and given the influence of Richelieu, several commissions were established that included Abbé Chambon, Claude Mydorge, Étienne Pascal, Pierre Hérigone, and later Jean de Beaugrand. Despite receiving 1,000 livres to develop a suitable quadrant, Morin failed to demonstrate his theory. For his part, Morin boasted he had discovered new methods for finding parallaxes and refractions, the equation of time, the height of the pole, the obliquity of the ecliptic, and for determining the more subtle lunar motions.

Morin's public humiliation soon spawned new controversy. Shifting the debate from longitude, Morin launched a barrage of attacks against Copernicanism and atomism, sometimes defending **Aristotle** (1624) against the mechanical philosophy. Morin railed against **Galileo Galilei**, **René Descartes**, and a dozen others, particularly Gassendi and **Ismaël Boulliau**. Significantly, Morin's arguments against Copernicanism were rooted in astrology, and here he endorsed the Tychonic model. As astrologer and champion of the anti-Copernicans, Morin nevertheless embraced **Johannes Kepler**'s elliptical orbits, further asserting he had improved Kepler's methods and the accuracy of the Rudolphine Tables. **Thomas Streete** and **Nicolaus Kauffman** (Mercator) apparently agreed.

Driven by ambition and animosity, Morin's career tells us a good deal about the troubled context of the New Science. The most important polemicist of his generation, Morin seemed to pick his battles on the basis of political advancement, not scientific merit. As a *caractère mélancolique,* he frequently called his opponents "imbeciles," "imposters," and "ignorant buffoons" as well as "plagiarists," "pygmies," and "pathetic pretenders." Vehement and vulgar, his attacks wreak with scatological references. For himself, Morin reserved the rarified title "Complete Restorer of Astronomy." Boulliau, who did his best to ignore Morin, called him the *astronome papier* (paper astronomer). But Morin's published attacks soon escalated from simple incivility to public charges of impiety and atheism. Unpublished evidence suggests Morin wrote Cardinal Mazarin to expose Gassendi's heresies, he advised that Bernier be arrested, he urged that his enemies and their books be burned, and he maliciously predicted the death of Gassendi and Boulliau. Opinion varied. Gui Patin thought Morin "touched in the head", Pierre Bayle thought him a "fake savant" touched with genius. In any case, Morin broke unspoken rules, and his opponents destroyed his reputation. His methods, theories, and judgment were publicly condemned, his astrology was ridiculed, and his Latin was lampooned. Morin was attacked, avoided, and finally ignored.

Morin's often ugly career in astronomy was supported handsomely by astrology. Good evidence suggests he maintained strong ties with the court of Louis XIII, and by tradition, he was present at the birth of Louis XIV. Morin dedicated a number of publications to Richelieu and regularly cast horoscopes for king, queen, and the royal family. Mazarin awarded him an annual pension of 2,000 livres in 1645, and he reportedly earned 4,000 livres per year as astrologer, a princely sum. Following his death, Morin's *magnum opus*, the *Astrologia gallica* finally came to press in 1661, a large folio edition of some 850 pages. The most influential work of its kind, Morin extended principles pioneered by **Johann Müller** (Regiomontanus), boasting new astrological theories of elections and astrological houses. The volume appeared posthumously with assistance from the Queen of Poland, Louise-Marie de Gonzague, who supplied 2,000 thalers toward publication. The recommendation came from her secretary, Pierre Desnoyers, a major correspondent of Gilles Personne de Roberval and Boulliau. An advocate of both astrology and the New Science, Desnoyers, like many contemporaries, used the terms "astronomer" and "astrologer" interchangeably.

Morin was buried at Saint-Étienne-du-Mont. A decade later, in 1666, J.-B. Colbert proclaimed academics could no longer publish on astrology, and in 1682, by royal proclamation, astrological almanacs were forbidden in France. In the end, if Morin was the last great astrologer, he has yet to receive the historical attention he legitimately deserves.

Morley, Edward Williams

Born **Newark, New Jersey, USA, 29 January 1838**
Died **West Hartford, Connecticut, USA, 24 February 1923**

American chemist Edward Williams Morley is best known for his collaborative experiments with physicist **Albert Michelson**, which failed to detect an "ether-drift" effect on the speed of light measured in different directions relative to the Earth's motion. The negative result of the Michelson–Morley experiments may have helped inspire **Albert Einstein'**s special theory of relativity.

The son of a Congregational Minister, Morley received his BA (1860) and MA (1863) from his father's *alma mater*, Williams College, Williamstown, Massachusetts. There he studied with astronomer Albert Hopkins, who, during Morley's postgraduate year, guided his mounting of a transit instrument with which Morley then measured the college's latitude from observations of stars. In 1865, Morley read a paper about his results before the American Academy of Arts and Sciences and published it in their *Proceedings*. His work on these observations and their reduction has been credited with instilling in him the careful experimental nature that later led to his greatest successes. (Williams College's Morley Science Center was named for him in 2000.)

Intending to follow in his father's professional footsteps as well, Morley studied at Andover Theological Seminary, where he earned a license as a minister of the gospel in the Congregational Church (1861–1864). Morley spent the final months of the Civil War as a relief agent in the United States Sanitary Commission at Fort Monroe, Virginia, attending convalescing Union soldiers. He then returned to the seminary, where he studied until he was appointed teacher at South Berkshire Academy, Marlboro, Massachusetts.

In 1868 Morley moved to Ohio, where he briefly served as pastor of a Congregational Church in Twinsburg. Preaching did not agree with him, however, and he accepted an appointment to the faculty of Western Reserve College (1869), where he began a program of chemistry teaching and research, and where he served as chairman of the chemistry and natural history programs (1882–1906). Morley also taught chemistry and toxicology at the Cleveland Medical School (1873–1888). His interest in chemistry dated back to his boyhood, when he devoured not only popular works but also textbooks.

In 1887, he gave a series of lectures on Charles Darwin, natural selection, and evolution, which he preferred to call "development".

Over the course of his career, Morley focused on three significant problems. In the 1870s, he refined the techniques of gas analysis to demonstrate that colder air contained less oxygen than warmer air, thus proving the theory of Yale meteorologist **Elias Loomis** that attributed winter cold snaps to cold air falling from high altitudes.

In the 1880s, in order to evaluate the hypothesis of English chemist William Prout that all the elements were based on hydrogen, Morley developed procedures to determine the precise relative atomic weights of oxygen and hydrogen that eliminated impurities in the gases he tested, as well as every likely source of experimental error. Morley's determination in 1895 that the relative atomic weight of oxygen was 15.789 led him to conclude that Prout's hypothesis was invalid. In recognition of Morley's apparent resolution of a long-lived problem, Morley's colleagues elected him to the National Academy of Sciences (1897) and to the presidencies of the American Association for the Advancement of Science (1895–1896) and of the American Chemical Society (1899).

Yet Morley is best remembered for his work in the 1880s in collaboration with physicist A. A. Michelson of the Case School of Applied Science (later the Case Institute of Technology and then part of Case Western Reserve University), which failed to detect any "ether drift," taken as a given by all the contemporary wave theories of light. One way in which Morley improved Michelson's techniques was to eliminate sources of optical distortion by mounting his interferometer on a stone platform floating in mercury. Neither scientist, however, believed the null result of their efforts, and after Michelson's departure from Case in 1888, Morley continued to search for ether drift in collaboration with Michelson's successor, Dayton C. Miller.

Miller, who did not give up easily, reported a positive result at the December/January 1924–1925 meeting of the American Association for the Advancement of Science, for which he received a prize designated for the best paper of the meeting. Corecipient was **Edwin Hubble**, for his paper on the discovery of Cepheid variables in spiral nebulae, establishing their nature as separate galaxies, well outside the Milky Way.

Morley was married to Isabel Ashley Birdsall; they had no children. After Morley's retirement to West Hartford, Connecticut, in 1906, he stayed active by analyzing, in the chemistry laboratory at his home, geological samples collected in Indonesia by a neighbor. He traveled to England to accept the Davy Medal of the Royal Society in 1907 at the hands of Lord Rayleigh.

Morrison, Philip

Born **Somerville, New Jersey, USA, 7 November 1915**
Died **Cambridge, Massachusetts, USA, 22 April 2005**

American theoretical physicist and astrophysicist Philip Morrison is most often mentioned in connection with the 1959 suggestion, with Guiseppe Cocconi, that the most natural means of communication across interstellar distances would be radio waves, probably at a wavelength close to the 21 cm emitted by neutral atomic hydrogen gas.

Born to Moses and Tilly (*née* Rosenbloom) Morrison, Philip attended high school in Pittsburgh, Pennsylvania, and received a BS in physics in 1936 from the Carnegie Institute of Technology (now Carnegie Mellon). He earned a Ph.D. from the University of California (Berkeley), working in theoretical physics with **Robert Oppenheimer**, in 1940 and moved quickly through teaching positions at San Francisco State College (1940–1941) and the University of Illinois (1941–1942), where he was recruited by fellow Oppenheimer student Robert F. Christy for the Metallurgical Lab (atomic bomb project) at the University of Chicago.

Morrison worked initially on the design of the reactors to be built in Hanford, Washington, for producing plutonium from uranium. By 1944, as the Manhattan Project became more intense, he and many others moved to Los Alamos, New Mexico, site of the laboratory under Oppenheimer's direction. Morrison and Marshall Holloway were responsible for the final readiness and assembly of the plutonium bombs, both the one tested at the Trinity site on 13 July 1945 and the one dropped over Nagasaki on 9 August (for which he traveled to the Tinian Island take-off point). They and colleagues **Luis Alvarez** and Robert Serber wrote a letter, also to be dropped over Japan, which they hoped would reach a Japanese colleague and make clear the United States could deploy additional bombs if necessary. Morrison was also part of the assessment team sent to Japan soon after. The experience left him a life-long opponent of nuclear war, and indeed war in any form. He was for many years active in the Federation of American Scientists (serving as its chairman: 1972–1976), a group supporting peaceful uses of science.

After another year at Los Alamos (directing a plutonium reactor that he dubbed Clementine, because of its location "in a cavern, in a canyon . . .") Morrison took up an associate professorship at Cornell University. While there, he initially remained engaged in nuclear physics, coauthoring with **Hans Bethe** a classic text in the field. Morrison moved from Cornell to the Massachusetts Institute of Technology in 1965, officially retiring in 1986, but remaining actively engaged in physics research and teaching until shortly before his death.

Morrison's interests gradually shifted to astrophysics, initially the propagation of cosmic rays in the Solar System – he rightly associated the variation of the flux reaching Earth with solar effects – and their origins (which he associated with supernova remnants like the Crab Nebula and active galaxies). He wrote the first review article on γ-ray astrophysics, before the first source had been seen, predicting in 1958 that supernova remnants and active galaxies should be sources – but so should be interstellar space if sufficiently high-energy cosmic rays hit neutral gas making pions. All indeed are, though not such bright sources as Morrison had hoped.

It is worth noting that in 1959 when Cocconi and Morrison suggested the 21-cm search wavelength, it lay in an accessible region between the short-wave emission by the Earth's atmosphere and the longer wavelength emission by the Galaxy. The 3-K microwave background radiation had not yet been discovered. The suggestion led to the first modern search for radio signals from extraterrestrials, by Frank Drake in 1960.

Morrison guided a couple of dozen future physicists to and beyond Ph.D.s. Those who remained in cosmic-ray physics or astrophysics included Howard Laster, Kenneth Brecher, James Felten, Leo Sartori, Alberto Sadun, and Minas Kafatos.

Morrison and his students had for many years a remarkable record of bringing concepts of fundamental physics to bear on new astronomical results very quickly. This included:

(1) cooling of stellar remnants by neutrino emission (with Hong-Yee Chiu);
(2) calculation of X-ray production by various mechanisms (with James Felten), which permitted a calculation of how much hot gas would be required to produce the X-rays discovered to be coming from rich clusters of galaxies even as they were finishing the calculation – it turned out to be comparable with the total amount of mass needed to hold the clusters together gravitationally – the modern number is 30% of that;
(3) a fluorescent theory of supernova light emission (which shared some of the virtues with the radioactive decay mechanism that was ultimately adjudged correct);
(4) an analogy between active galaxies and pulsars as soon as the latter were discovered;
(5) a prediction of X-ray emission from the Crab Nebula and radio galaxies (later seen, though the mechanism is probably different);
(6) the suggestion with Brecher that the emission from γ-ray bursts must be beamed into a narrow cone;
(7) the association of a subset of active galaxies (including M 82) with star formation fueled by recent infall of new gas rather than with a central black hole; and
(8) a shadowing mechanism to account for the jet found to be sticking out of the edge of the Crab Nebula in the 1980s.

In spite of all these remarkable theoretical achievements, Morrison may well have made his greatest impact as a communicator of science. For decades, thousands of students in introductory astronomy courses have begun the term by watching a film he coproduced with his wife and Charles and Ray Eames, *Powers of Ten*, which illustrates the enormous range of length scales from subatomic physics to the cosmos. (The book version of 1980 was in collaboration with Phylis Morrison.) He was the narrator and guiding spirit of several educational television programs (*e. g.*, *Whisper from Space*, on the cosmic microwave background radiation, and *Ring of Truth*, a series dealing with how science works), and from 1968 to 1994 wrote virtually all of the book reviews that appeared in *Scientific American*, the December issue always featuring children's books, coreviewed by the Morrisons together. His first marriage, to Emily Morrison of Boston, ended in divorce in 1983, and his second wife and collaborator, Phylis Singer Morrison, died in 2002.

Morrison received honorary degrees from Case Western Reserve, Rutgers, and Denison universities, and medals and prizes from the American Physical Society, the American Chemical Society, and several other organizations. He was elected to the United States National Academy of Sciences.

It is probably useful in understanding Morrison's career to know that a childhood attack of polio left his legs considerably weakened, so that he was dependent on canes for getting around from midlife onward and later on a wheelchair.

Möschlin, Michael

➜ **Mästlin [Möstlin], Michael**

Mouchez, Ernest Amédée Barthélémy

Born **Madrid, Spain, 21 August 1821**
Died **Wissous near Paris, France, 25 June 1892**

Ernest Mouchez, a notable hydrographer and cartographer, directed a rejuvenation of the Paris Observatory and helped initiate the *International Carte du Ciel and Astrographic Catalogue* project. Mouchez's parents were French: His father, Jacques Barthélémy Mouchez, was a perfumer and wig maker to the spouses of the Spanish King Ferdinand VII. He was a widower when he married Mouchez's mother, Louise Cécile Bazin. Mouchez was sent to Paris for his studies, living with family friends. After attending the lycée in Paris and Versailles, he entered the École Navale.

After graduation, Mouchez served in the marine as an officer, rising to the rank of *contre-amiral* by 1878. During this period, he produced nearly 150 coastal maps of Asia, South America, and Algeria. (These last maps were the only ones available to Allied troops when they landed in Algeria during World War II.) Mouchez explored some 4,000 km along the Brazilian coast. Mouchez's work in hydrography and geographic astronomy contributed to the training of navigators, particularly for the determination of longitudes. He directed one of the voyages to observe the transit of Venus of 9 December 1874 at Saint Paul Island in the Indian Ocean, obtaining high-quality visual and photographic data.

In 1862, Mouchez married Carlota Finat (born: 1843), the second daughter of his half-sister Sophie, who was 7 years older than him. They had six children; their older daughter later married **Camille Guillaume Bigourdan**.

Mouchez succeeded **Urbain Le Verrier** as director of the Paris Observatory in 1878. In this position, he managed to liberate the astronomers from administration, opened the observatory to foreign exchanges and was a patron, along with Sir **David Gill** of the Cape of Good Hope Observatory, of the *Carte du Ciel*, inaugurated in 1887. This often-criticized enterprise of 18 observatories from all over the world found its value a century later: The accurate proper motions of almost one million stars from the *Carte du Ciel* catalog formed the first epoch for comparison with the "Brahe" catalog produced by the astrometric Hipparcos mission (1989–1992).

Under Mouchez's directorship, the observatory built the coudé equatorial from **Maurice Löwy**'s plans, with which the famous lunar map was obtained, along with **Henri Deslandre**'s spectroheliograph, which long provided standard references. In 1885, Mouchez formed a section on Astronomie physique, combining it with sections for Météorologie and Physique du Globe and placing them all under **Charles Wolf**. In 1890, he asked Deslandres to direct a section called Spectroscopie stellaire. This service, related to the new field of astrophysics, was discontinued when Deslandres moved to the Observatoire d'astronomie physique in Meudon, near Paris. Mouchez was also responsible of the first complete network of synchronous clocks in Paris, of the creation of the Paris Observatory museum, and the organization of regular visits for the public, still in existence. In 1884 he founded the first periodical devoted to astronomy in France called *Bulletin astronomique*. A few hours after presiding over a meeting of the Paris Observatory Council, Mouchez died suddenly at his cottage.

Mouchez was a remarkable organizer, having inherited a difficult situation from Le Verrier. Mouchez developed the Paris Observatory along the lines that **Friedrich Struve** had suggested to Le Verrier when the latter was thinking about reorganizing French astronomy. Mouchez was a member of the Bureau des longitudes from 1873 and of the Académie des sciences from 1875.

Moulton, Forest Ray

Born **Osceola County, Michigan, USA, 29 April 1872**
Died **Wilmette, Illinois, USA, 7 December 1952**

Forest Moulton is perhaps best remembered for his collaboration with **Thomas Chamberlin** on what became known as the Chamberlin–Moulton hypothesis.

Moulton was born in a log cabin built by his father Belah Moulton, a Civil War veteran, on the family's 160-acre homestead in Michigan. His mother, Mary (*née* Smith) Moulton, was impressed by rays of sunlight filtering through the surrounding forest; hence her son's name. Moulton was educated at home by his mother, next in a one-room school, and then at Albion College, from which he received his B.A. degree in 1894. He attended the University of Chicago as a graduate student in 1895, was appointed assistant in astronomy in 1896, received his Ph.D. in astronomy and mathematics in 1899, and then joined the university's faculty.

Moulton rose to full professor in the astronomy department. His field was celestial mechanics, including the three-body problem and its application to the motion of the Moon under the influence of the Earth and Sun. His 1902 text, *Introduction to Celestial Mechanics*, later revised in 1914, was widely utilized. More elementary texts were his *Introduction to Astronomy*, published in 1906, and *Descriptive Astronomy*, in 1912. With his colleagues at Chicago, Moulton developed a survey course and the accompanying text, *The Nature of the World and Man*, was published in 1926. It was reissued in 1937, and revised in 1939, as *The World and Man as Science Sees Them*. Moulton also wrote *Consider the Heavens*, a popular book, in 1935. Always interested in popularizing astronomy, Moulton acted as an informal advisor to Frederick Charles Leonard (1896–1960) and his Society for Practical Astronomy that enjoyed some success nationally in the period from 1910 to 1916. Leonard went on to found the astronomy department at the University of California at Los Angeles and established himself as an authority in meteoritics.

During World War I, Moulton was commissioned a major in the Army and placed in charge of the Ballistics Branch of the Army Ordnance Department at Aberdeen, Maryland. There, he developed new methods for calculating the trajectories of artillery projectiles. In 1926, he published *New Methods in Exterior Ballistics*. Also of a technical nature was Moulton's 1930 textbook, *Differential Equations*.

Moulton was a member of an interdisciplinary research team headed by Chamberlin, the chairman of the Geology Department at the University of Chicago. The team investigated mutual problems in geophysics and astronomy. Beginning in 1903, half of Moulton's salary was covered by Chamberlin's grant from the Carnegie Institution of Washington.

In his studies on the Earth's changing climate in the geological past, Chamberlin had begun to question the plausibility of **Pierre de Laplace**'s nebular hypothesis. Laplace had postulated that a hot fluid had cooled, condensed, and gradually shrunk to the present size of the Sun; rings of gas shed by the shrinking Sun had condensed into the planets of the Solar System. Chamberlin, however, realized that glaciation and salt deposits indicated a colder and more arid climate in the past, incompatible with the warm and moist conditions postulated by Laplace's theory.

More troubling was the fact that a majority of the Solar System's angular momentum resided in the orbits of the jovian planets, while its mass is heavily concentrated in the Sun—an unlikely occurrence within Laplace's nebular hypothesis. This unsymmetrical distribution of matter and angular momentum suggested to Chamberlin that the Solar System had been formed by the near-collision of a nebulous cloud and the proto-Sun. From his analysis of the dynamic considerations, Moulton concluded that the original solar nebula had perhaps been similar to a spiral nebula. Astronomers have since abandoned the Chamberlin–Moulton hypothesis, and have assumed an alternate version of the nebular hypothesis, despite its unsolved dynamical problems.

Moulton served as a private consultant to the directors of the Meteor Crater Exploration and Mining Company (1929/1930), organized by **Daniel Barringer**, and produced the most thorough analysis regarding the probable size, mass, and speed of the incoming projectile. His calculations cast serious doubt on the existence of a still-buried meteoric mass.

By the early 20th century, the calculation of orbits as practiced by Moulton had become somewhat obsolete. Observational astrophysics held much greater research promise than did theoretical astronomy. The booming business and stock market of the 1920s, in which Moulton's younger brothers were participating, offered an alluring alternative career, and Moulton resigned his position at the University of Chicago in 1926 to become director of the Utilities Power and Light Company in Chicago, where he remained until 1937. His company barely survived the Great Depression. Moulton also served as a trustee and director of concessions for Chicago's Century of Progress Exposition (1933/1934). He closed the concession's books in 1936 with a profit.

In the 1930s, after leaving the University of Chicago, Moulton retained his interest in popularizing astronomy. He conducted a weekly radio broadcast of interest to aspiring amateur astronomers that was heard throughout the midwestern United States. On each broadcast, Moulton offered copies of his books as a prize for the best weekly essay he received. More than a few of the recipients of these books went on to pursue careers in science and engineering, including Hugh M. Johnson who had a distinguished career as an X-ray astronomer.

Afterwards, Moulton undertook another major career move, serving as Permanent Secretary of the American Association for the Advancement of Science [AAAS] from 1937 to 1946, and as Administrative Secretary from 1946 to 1948. Under his direction, the Association doubled its membership and gained control of the Association's journal, *Science*, from the J. McKeen Cattel family. The archives of the AAAS contain records of Moulton's work there from 1937 to 1948.

Moulton was twice married and divorced: to Estelle Gillete, from 1897 to 1938, with whom he had four children; and to Alicia Pratt, from 1939 to 1951.

Mouton, Gabriel

Born **Lyon, France, 1618**
Died **Lyon, France, 28 September 1694**

Gabriel Mouton is most widely known for his work on a universal standard of length based on a "geometric foot" or one-thousandth of a *mille*. Mouton lived his whole life in Lyons. After obtaining a doctorate in theology he became, in 1646, a Vicar of Saint Paul's Church in that city. In spare time from his clerical duties he studied mathematics and astronomy.

Mouton's *mille* was proposed as a minute of longitude on the Earth's surface, a distance that eventually became known as a nautical mile. In 1670 Mouton developed a system of decimal divisions for his length standard. In order for this standard to be reproducible, Mouton proposed a pendulum of the standard length and measured the number of oscillations in 30 min. His value of 3959.2 oscillations was to be an easy way to verify that the pendulum was of proper length. A similar concept, but based on a pendulum with a period of 1 s in Paris, was later proposed as the basis for a universal system of measurement. However, the metric system as originally devised was not based on the length of a pendulum, but on a meter as one ten-millionth of the distance between the Earth's pole and Equator. Several of the principles used in Mouton's system were incorporated into the International System of Units [SI].

Mouton's astronomical accomplishments included determining the apparent diameter of the Sun at apogee. As an experimentalist, he constructed an astronomical pendulum. And, as a calculator, he was able to present a practical way to compute ordered tables of numbers such as logarithmic tables of trigonometric functions.

Mouton's work includes *Observationes diametrorum soles et lunae apparentium,* published in Lyons in 1670.

Mrkos, Antonín

Born **Střemchoví, Moravia, (Czech Republic), 27 January 1918**
Died **Prague, Czech Republic, 29 May 1996**

Antonín Mrkos is remembered as a discoverer of comets and minor planets, and for measuring the precise astronomical coordinates of these objects. The son of farmers, Mrkos studied at several secondary schools, including an ecclesiastical gymnasium, before entering the Technical University in Brno in 1938. His studies were interrupted by the onset of World War II, and during 1939–1943, he taught at primary schools at Nové Město and Ždárec in Moravia.

After a short stay in Austria, Mrkos took a position in 1945 under director **Antonin Bečvář** at the Skalnaté Pleso Observatory in Slovakia. There, Mrkos participated in the famous visual comet-hunting program using 25 × 100 Somet–Binar binoculars, as well as the cometary astrometric program with the 0.6-m reflector. Following his successful visual discovery of three comets (including 45P/Honda–Mrkos–Pajdušáková) in 1948, he made photographic recoveries of three periodic comets during 1949/1950. Mrkos was the principal observer with the 0.6-m reflector during 1946–1956.

Noting that the observatory's location (on the eastern slope of the second highest mountain, Lomnicky' Štít) in the High Tatras made it impossible to hunt for evening comets in the western sky, Mrkos decided to observe from the 2,634-m peak, to which he would regularly climb, shunning the more convenient cable cars. He also worked as a meteorologist for the weather station there. During a 4-year interval starting in early 1952, Mrkos visually discovered six more comets, including 18D/Perrine–Mrkos, an accidental rediscovery of a comet lost since the beginning of the century. With his private 0.5-m reflector, he recovered the intermediate-period comet 13P/Olbers in 1956.

Mrkos's most famous discovery, of C/1957 P1 (Mrkos) on 2 August 1957, was of one of the century's brightest comets, whose tail he detected while measuring the night sky glow at Lomnicky' Štít. Shortly afterwards, Mrkos traveled to Antarctica for 2 years with a Soviet expedition as part of the International Geophysical Year (1957/1958).

On his return to Slovakia, Mrkos made his 11th and final visual comet discovery in late 1959. During 1961–1963, he participated in another Soviet Antarctic expedition, working at Molodeznaya and Novolazarevskaya, after which he spent a year on the staff of the Geophysical Institute of the Czechoslovak Academy of Sciences in Prague, before taking a position (which he held until his retirement) in the astronomy department of Charles University. In addition, Mrkos was made director of the observatory at České Budéjovice in southern Bohemia, and this led to the establishment of a planetarium and of the new observatory he was to direct on Kleť Mountain.

Mrkos made the first photographic observations of comets with the 1-m reflector and 0.4-m Maksutov at Kleť Mountain in 1968, and the 1969 recovery of his comet 45P was an early success. The Kleť activity was extended to cover minor planets in 1977, and for many years it was the most regular contributor of data to the International Astronomical Union [IAU] Minor Planet Center. It was Mrkos's habit to spend 20 days each month at the observatory and 10 days in Prague reducing and typing up the observations prior to mailing.

Because of the dedication of Mrkos and assistants such as Růžena Petrovičová and Zdeňka Vávrová, at the time of his death, the program ranked as the sixth most successful ever launched for the discovery of minor planets that had been numbered. At that time, Mrkos was listed as the 11th most prolific discoverer. Two photographic discoveries of comets were credited to him at Kleť, bringing his lifetime total to 13. Among Mrkos's more interesting discoveries of minor planets is the near-earth object (5797) 1980 AA, later named "Bivoj." Mrkos was elected president of IAU Commission 6 during the triennium 1985–1988.

Following his retirement on 31 December 1991, Mrkos had hoped to continue his photographic astrometric work from a site closer to Prague. He located a small camera at an abandoned geodetic observatory near Ondřejov and planned to put it to use. An extended stay in the hospital in 1994/1995 delayed these plans, and on a subsequent visit to the remote site, he found that it had been vandalized. Particularly sad was the theft of his Somet–Binar binoculars, which had played a role in the visual discovery of 11 comets, and which Mrkos always had nearby when he was observing.

Muʿādh

➔ **Ibn Muʿādh: Abū ʿAbd Allāh Muḥammad ibn Muʿādh al-Jayyānī**

Mukai, Gensho

Born **Hizen (Saga and Nagasaki Prefectures), Japan, 1609**
Died **Kyoto, Japan, 1677**

Gensho Mukai introduced Western astronomical ideas in Japan during the early Edo period; however, he retained a traditional Chinese cosmology. At age five, he moved to Nagasaki, where he learned astronomy under Kichiemon Hayashi and became a Confucian scholar as well as a physician. In 1658, Mukai moved to Kyoto, where he practiced medicine and remained until his death. Though little seems to have been written about his life, Mukai no doubt found his place among the intelligentsia of Confucian scholars in Kyoto in the early Edo Period (1603–1867). He is probably remembered as much for what was seen as his personification of Confucian ideals as he is for specific works that he wrote. Mukai's comparison of Eastern and Western concepts also seems to have had an influence not only on scholars who immediately followed him, but on Japanese society as a whole. He inspired his children, who exhibited notable intellect and creativity. Mukai's second son, Kyorai (1651–1704), was a poet and student of the famous *haiku* master, Basho Matsuo.

Mukai is probably best known in the context of Japanese science for introducing concepts of Western astronomy in the early Edo era, a time of growing isolation from the outside world. Under *Tokugawa* policies of seclusion, Nagasaki was the only link to the West, and indirect contact with European sources allowed some acquisition of western astronomical knowledge. This contact led to what has been termed *Nanban* astronomy, a scholarship that involved translation, commentary, and comparative evaluation of European and Chinese-derived epistemologies. As a part of such activity, Mukai completed a set of commentaries around

1650 titled *Kenkon Bensetsu* (Western cosmography with critical commentaries). This work was based on a translation by Christopher Ferreira, whose Japanese name was Chuan Sawano, of what no doubt were several European works, but most especially **Christoph Clavius**'s *In Sphaeram Ioannis de Sacro Bosco*, *Commentarius* (1607).

In Mukai's commentaries, for perhaps the first time in Japan, sphericity of the Earth was explicitly recognized. However, while Mukai was instrumental in introducing such concepts into Japan, his commentaries show a disdain if not outright antagonism at times for what he saw as contradictions to classic Chinese precepts such as the theory of five elements (wood, fire, earth, metal, and water). He never abandoned his beliefs in Neo-Confucian principles, and with his strong contrasts of European and Chinese models, was no doubt influential in making such principles central to intellectual thought in early Edo Japan.

Mukai saw the Earth as inextricably related to the sky, and the European view of nature was simply something he could not recognize. Although he did accept western astronomical knowledge as it related to enhance the classical concerns of traditional far-eastern astronomy, Mukai continually denounced physical theories based on the Aristotelian four elements. For example, whereas **Tycho Brahe** showed that trepidation was really a matter of observational error, Mukai dismissed the theory of north–south oscillation as an explanation for trepidation not because of observational discrepancies but because the idea of such oscillation did not fit within what he felt was the harmony of the five-elements theory.

Müller, Johann

Born **Königsberg, (Bavaria, Germany), 6 June 1436**
Died **Rome, (Italy), 8 July 1476**

Johann Müller (Regiomontanus) published valuable astronomical ephemerides and mathematical texts and devised new instruments and methods of observation. He was to 15th-century astronomy as **Nicolaus Copernicus** and **Tycho Brahe** were to 16th-century astronomy.

Johann Müller himself used the scholarly name "Johannes de monte regio" or similar names. Though he evidently never used it himself, since the 16th century he has been known as Regiomontanus, from the Latin for Königsberg (King's mountain).

Young Johann was a child prodigy and was sent off to the University of Leipzig at the age of 11. Three years later, he visited Vienna and stayed on as a student under **Georg Peurbach** at the university there, receiving his bachelor's degree in 1452 (at age 15); upon receiving his master's degree in 1457, Regiomontanus was appointed to the University of Vienna's faculty. He was tremendously knowledgeable about ancient, medieval, and contemporary scholarly works, and he knew Latin and Greek.

A visit by Cardinal Bessarion to Vienna in 1460 led to Regiomontanus traveling to Rome and many other places in Europe, before settling in Nuremberg in 1471, where he set up a print shop to publish scholarly works with technical diagrams. As was typical of the astronomers of his day, Regiomontanus was very much both an astrologer and an astronomer, though he seemed to spend more time in his later years on astronomical science and mathematics than on astrology. He was also a religious man, and his personal trademark sign was a cross on a hill with a background of stars. Regiomontanus was supposedly called by the Pope to Rome in 1475 or 1476, where he died of unknown causes (though the plague has been suggested as a possibility), suddenly terminating an increasingly productive career in revolutionizing astronomy.

Johann Gutenberg had published the first printed astronomical calendar in 1448, and while at Leipzig, young Regiomontanus was drawn toward checking the accuracy of that calendar, finding errors between the predicted positions of the planets and their true locations in the sky. This led him on an intense astronomical career to build an improved astronomy that would forever hold him as the foremost astronomer of 15th-century Europe. During his lifetime, Regiomontanus created much impact by traveling to visit astronomers elsewhere, by corresponding with astronomers in technical discussions, by seeking out classical writings on astronomy and encouraging publication of new translations of them, and by writing and publishing his own widely consulted works on astronomy. Among those with whom Regiomontanus dealt was **Paolo Toscanelli** of Florence, who made perhaps the most accurate positional observations of comets in the 15th century. One of the problems that Regiomontanus eagerly attacked was that of a comet's position, size, and distance, and his "Sixteen Problems" regarding these unknown quantities became a much-cited work after **Johann Schöner**'s publication of the manuscript in 1531, upon the appearance of Halley's comet, (IP/Halley)

Regiomontanus' *Ephemerides* were heavily used in Europe because they were seen as authoritative in predicting eclipses, phases of the Moon, positions of the Sun, Moon, and planets, and church calendar information.One of the reasons that ephemerides such as these were so popular was the strong European adherence to astrology in that era. Copernicus and Christopher Columbus both annotated their own copies of *Ephemerides*, and it has been argued that both Columbus and **Amerigo Vespucci** must have used Regiomontanus' almanacs on their voyages overseas; Columbus likely used his copy for impressing the American natives in Jamaica by successfully predicting the lunar eclipse of 14 September 1494. Copernicus was heavily influenced by Regiomontanus' *Epitome* and *Ephemerides* in his writing of *De revolutionibus*.

Regiomontanus wrote an impressive book, *De triangulus omnimodis* (On triangles), a treatise on plane and spherical trigonometry that was first published in 1533. This book was much used by European astronomers in the 16th and 17th centuries to determine celestial positions. Regiomontanus wrote this organized text on geometry and trigonometry specifically for use by astronomers, realizing that astronomers needed these mathematical tools to advance their knowledge of the motions of celestial objects. Even though his treatise was built on the work of ancient and medieval mathematicians, Regiomontanus added his own theorems and employed algebraic techniques for solving geometric problems; he utilized his geometric procedures in his other astronomical work, as can be seen in his treatise on comets.

Regiomontanus was also interested in making astronomical instruments for improved astronomical observations – one of the essential ingredients for building a better astronomy. Making better clocks seems to have been a part of these endeavors, as he attempted to construct a planetary clock. Had Regiomontanus lived to old age, his impact on astronomy would doubtless have been much greater, given his talents and enthusiasm. He envisaged publishing many more books on astronomy – translations into Latin of historical works and also many of his own new works on the subject.

Numerous manuscripts and letters written by Regiomontanus are extant in various libraries, attesting to a prolific career of correspondence and writing on topics astronomical and mathematical. His instruments, books, and papers passed to **Bernard Walther** of Nuremberg at the death of Regiomontanus. Walther kept these estate items to himself, unwilling to share them, until his death in 1504, when they began to be scattered through various sales. Schöner purchased much of the estate material on astronomy belonging to Peurbach, Regiomontanus, and Walther around 1522, eventually publishing much of the unpublished materialof the three men. Even the famous artist **Albrecht Dürer** eventually purchased Regiomontanus' copy of Euclid's *Elements* at auction.

Müller, Karl

Born **1866**
Died **22 October 1942**

With **Mary Blagg**, Viennese selenographer Karl Müller wrote the definitive reference *Named Lunar Formations* (1935), sponsored and adopted by International Astronomical Union Commission 17.

A formation on the Moon is named for him.

Selected Reference

Chong, S. M., Albert Lim, and P. S. Ang (2002). *Photographic Atlas of the Moon*. Cambridge University Press.

Müller, Karl Hermann Gustav

Born **Schweidnitz (Swidnica, Poland), 7 May 1851**
Died **probably Potsdam, Germany, 7 July 1925**

Karl Müller's career, devoted to photographic photometry, produced valuable contributions in the form of catalogs of both photometric data and of variable stars.

Educated at Leipzig University and Berlin University, Müller worked briefly for **Arthur von Auwers** and then assisted **Hermann Vogel** at the Astrophysical Observatory at Potsdam from its beginning in 1877. During 1917–1921 he served as that institution's Director.

From early in his career, Müller pursued the study of terrestrial lines in the solar spectrum. His investigation of the Sun's brightness over its disk resulted in several expeditions to climb high mountains (including Tenerife at age 59). Müller's planetary and asteroid work recorded changes in brightness as a function of phase. He began in 1886, assisted by **Paul Kempf**, the construction of the *Potsdam Durchmusterung*, giving visual magnitudes and colors of all stars in the northern sky down to magnitude 7.5. (With **Ernst Hartwig**, Müller compiled a catalog of more than 1,600 variable stars from 1916 to 1921.)

Muñjāla

Flourished **Deccan, (India), possibly 900**

Muñjāla was the author of a remarkable work, the *Laghumānasa*, which is an abridged version of a larger work called *Bṛhanmānasa*. Very little is known about the life of Muñjāla, except that he was a *brāhmaṇa* belonging to the *Bhāradvājagotra*, and that he lived in Deccan.

The *Laghumānasa* was very popular among the astronomers from Kerala, and it is mentioned by **Bīrūnī**. **Parameśvara** wrote a commentary on it, and quotations from it are found in the works of Bhāskaracārya and Munīśvara.

The *Laghumānasa* appears to be the first siddhāntic text to treat the precession of the equinoxes. Muñjāla gives the number of "ayana" revolutions to be 199,669 in a kalpa, and the "ayanāṃśa" to be 6° 54′ in 932 and the year of zero "ayanāṃśa" as 522. Muñjāla was the first Indian astronomer to introduce corrections to the Moon's equation that account for what today is called evection. Muñjāla anticipates Bhāskaracārya in understanding that the sine and cosine are related in a way that we would express today by saying the derivative of a sine function is a cosine function.

Muñoz, Jerónimo

Born **Valencia, Spain, *circa* 1520**
Died **Salamanca, Spain, 1592**

Jerónimo Muñoz, a leading Spanish astronomer and geographer of the 16th century, observed the supernova of 1572 (SN B Cas) and speculated upon its cosmological significance. Muñoz began his studies at the University of Valencia, from which he received his Bachelor of Arts degree in 1537. He continued studies at other European centers and received a Master's degree. Two of his principal instructors were **Oronce Finé** and **Gemma Frisius**. Being an expert Hebraist, Muñoz for some time was professor of Hebrew at the University of Ancon. He returned to Valencia sometime before 1556; in 1563, he was appointed to the chair of the Hebrew Department in Valencian General Studies. In 1565, Muñoz was also named head of the Mathematics Department. In 1578, he accepted the chair of mathematics at the University of Salamanca. Muñoz was also awarded the chair of that institution's Hebrew Department.

In Valencia and Salamanca, Muñoz taught arithmetic, geometry, and trigonometry, geometrical optics, astronomy and its applications, astronomical instruments, cartography, geography, and astrology. Although Muñoz did not publish many works, his personal manuscripts, and students' copies of notes and texts prepared for his classes, are preserved at the libraries of Salamanca, Barcelona, Madrid, Munich, the Vatican, Naples, and Copenhagen.

In Spain, Muñoz enjoyed a wide reputation as mathematician, astronomer, geographer, Hellenist, and Hebraist. His fame at other places in Europe was due primarily to his published work on the supernova of 1572 entitled *Libro del Nuevo Cometa* (Book of the new comet) (Valencià, 1573). This account of the "comet" was prepared at the request of Phillip II. It was then translated and reprinted in French (1574). Muñoz corresponded about the "comet" with several astronomers, including the Viennese doctor and mathematician Bartholomaeus Reisacherus, and the imperial doctor of Bohemia, **Tadeá Hájek z Hájku** (Hagaecius). From the latter, but especially through the work of **Cornelius Gemma** (*De Naturae Divinis Characterismis*, 1575), which included an extensive account of Muñoz's observations, his own data and conclusions eventually reached **Tycho Brahe**. Brahe then dedicated a chapter with commentary in his *Astronomiae Instauratae Progymnasmata* (1602) to the work of Muñoz.

As an observational astronomer, Muñoz achieved the highest precision in determining stellar positions. He should likewise be counted among the astronomers who exposed the cosmological implications of the "comet," recognizing that maintenance of the Aristotelian dogma regarding an incorruptible sky (violated by the supernova's appearance) was untenable. Although Muñoz called the object a comet, he recognized that it looked more like a star than a comet. His reason for classifying it as a comet had much to do with his desire to find natural causes for the phenomenon, without calling upon divine omnipotence (*potentia dei absoluta*), which other astronomers and mathematicians such as Frisius, **Thomas Digges**, Hagaecius, or Brahe himself did invoke.

Muñoz's work on the supernova of 1572 must be placed in the context of his ambitious scheme to revise Aristotelian cosmology and Ptolemaic astronomy. This can best be seen by Muñoz's comments about the second book of **Pliny**'s *Natural History* and in his translation (with numerous additions) of the *Commentary on the mathematical composition of Ptolemy* by **Theon of Alexandria**. Within his comments on Pliny, read at the University of Valencia in 1568, Muñoz presented some cosmological ideas similar to the Stoic tradition. He rejected the idea of the sphere of fire and considered the cosmos to be a continuous medium that became progressively more rarified as one moved away from the center (the Earth) and eventually trailed off into an immense vacuum. Using various arguments, Muñoz also rejected the idea of crystalline spheres and thought that the planets moved through the cosmic medium upon their own natures.

Muñoz clearly showed that the discipline of astronomy could successfully address questions from natural philosophy. On the other hand, his astronomical observations and comparisons to available planetary predictions, gleaned from **Ptolemy** to **Nicolaus Copernicus** and **Erasmus Reinhold**, led him to doubt the viability of Ptolemy's parameters, those of subsequent astronomers, and his own contemporaries. But the reform in astronomy required a radical transformation in the realm of instrumentation and a systematic program of observations – things that remained out of reach for a modest university professor. As for cosmology, Muñoz never accepted the Copernican system. Instead, he proposed a cosmology consisting of a fluid heaven and a theory of planetary movements resulting from different sources. That cosmology's qualitative features were described without the use of mathematical astronomy.

Muñoz was a successful geographer and cartographer; these were subjects to which he further applied his mathematical knowledge. He determined precise geographic coordinates (*e. g.,* latitudes) of numerous places on the Iberian Peninsula, of which he then drew a map. He applied geodetic methods of triangulation, which he learned from his teacher Frisius and which he taught in his own classes with practical examples. The oldest surviving map of the Kingdom of Valencia, appearing in Abraham Ortelio's atlas, *Theatrum Orbis Terrarum* (1570), was prepared from Muñoz's data.

Muñoz trained a large number of students including prominent military engineers and treaty writers such as Diego de Alava, university professors, and several leading cosmographers from the late 16th to the early 17th centuries who were in service to the Spanish monarchy.

Naburianu [Naburianus, Nabû-ri-man-nu]

Flourished **Probably 5th century BCE**

Naburianu was a Babylonian astronomer whose name is mentioned by **Pliny** in his first-century text, *The Natural History*. In 1923, he was identified with an astronomer by the name of Nabû-?-man-nu by the cuneiform scholar Paul Schnabel. The name occurs in the colophon of a lunar ephemeris of System A from Babylon for the year 263 of the Seleucid era, or 48/47 BCE. Schnabel reconstructed the name to Nabû-ri-man-nu and concluded that he was responsible for discovering the System A method of computation of the Moon's position, dating him to around 427 BCE. Schnabel's claim has been effectively challenged by **Otto Neugebauer**, who points out that the inclusion of Nabû-ri-man-nu's name on the ephemeris is hardly evidence that he invented the system of computation on which it is based.

Najm al-Dīn al-Miṣrī: Najm al-Dīn Abū ʿAbd Allāh Muḥammad ibn Muḥammad ibn Ibrāhīm al-Miṣrī

Flourished **Cairo, (Egypt), *circa* 1300–1350**

Little is known of the life of the Cairene applied astronomer Najm al-Dīn al-Miṣrī, who was a contemporary of **Mizzī**. Several works, though, help document his scientific activities. Following are some of them:

1. A concise treatise on spherical astronomy entitled *Treatise on the Universal Operations [of Timekeeping] by Calculation*.
2. A short treatise on approximate methods of timekeeping.
3. A huge set of tables covering 419 folios, extant in two codices, which form the first and second halves of a single copy that was later split. In the main table, the time since the rising of the Sun or a star is tabulated in terms of three arguments. With nearly 415,000 entries, this is the single largest mathematical table ever compiled before the late 19th century.
4. An anonymous treatise, which can be attributed to Najm al-Dīn al-Miṣrī, gives detailed instructions on how to use these as universal auxiliary tables for solving all problems of spherical trigonometry for any terrestrial latitude. (The tables and the commentary have been analyzed in Charette, 1998.)
5. The previous item forms the prologue of an illustrated treatise – also anonymous – on the construction of over 100 different astronomical instruments (astrolabes, quadrants, sundials, *etc.*). This work has been recently shown to be by Najm al-Dīn al-Miṣrī (Charette, 2003). The text and its accompanying illustrations represent one of the richest and most astounding medieval sources on the topic of astronomical instrumentation.

Although Najm al-Dīn's writings suggest that he was not a first-rate astronomer, especially on the theoretical level, his intuitive and practical, "hands-on" approach to timekeeping (*mīqāt*) and instrumentation did yield original results.

Napier, John

Born **Merchiston Castle near Edinburgh, Scotland, 1550**
Died **Edinburgh, Scotland, 4 April 1617**

John Napier spent much time in devising methods of facilitating and shortening astronomical calculations.

Napier was educated at Saint Andrews University and traveled on the Continent in his youth. Settling down at his family seat of Merchiston, he devoted his attention to many subjects, writing on theology and politics, and investigating various branches of science. His invention of logarithms with base e was announced in 1614. The invention was of great assistance to **Johannes Kepler**, and made possible the rapid development of astronomy in the 17th century. He also created the mathematical tool known as Napier's bones. (Local legend considered Napier to be a wizard.)

Napier was married, widowed, and remarried. His descendants still hold the title of Lord Napier.

Nasawī: Abū al-Ḥasan ʿAlī ibn Aḥmad al-Nasawī

Born **Rayy, (Iran), 1002/1003**

Nasawī was an astronomer and mathematician whose name indicates that his family was originally from Nasā, a town in ancient Khurāsān that is in present-day Turkmenistan. He spent most of his life in his birthplace. In the introduction to his book, *Bāz-nāma* (On caring for falcons), Nasawī states that he served in the army, had been in the service of the kings, and trained birds of prey for 60 years, since age eight. Bayhaqī remarks that Nasawī lived until the age of 100. However, the date of his death is unclear.

Nasawī's disciple Shahmardān Rāzī, as well as **Naṣīr al-Dīn al-Ṭūsī**, refer to Nasawī as *al-ustādh al-mukhtaṣṣ* (distinguished teacher), probably due to his expertise in mathematics and astronomy. The famous Iranian poet Nāṣir-i Khusraw (1003–1088) writes in his *Safar-nāma* that he met Nasawī in Simnān (Iran) in 1046, where the latter was teaching Euclid's *Elements*, medicine, and arithmetic. Nasawī also quoted from discussions he had had with **Ibn Sīnā**, which led Nāṣir-i Khusraw to conclude that Nasawī had been a disciple of Ibn Sīnā. It has been claimed that Nasawī was also a disciple of **Kūshyār ibn Labbān**, but Nasawī would have been too young when Kūshyār died.

Nasawī wrote several astronomical works, only one of which is extant. *Kitāb al-lāmiʿ fī amthilat al-Zīj al-jāmiʿ* (Illustrative examples of [the 85 chapters] of [Kūshyār's] *Zīj-i jāmiʿ*) is also called *Risāla fī maʿrifat al-taqwīm wa-'l-asṭurlāb* (A treatise on the almanac and the astrolabe).

Only a few of the tables from *al-Zīj al-Fākhir* (The glorious astronomical tables) have survived following the Leiden manuscript of Kūshyār's *Zīj-i jāmiʿ*. These tables indicate that the values used for the planetary mean motions are extracted from **Battānī**'s *zīj*, confirming remarks in *al-Zīj al-mumtaḥan al-ʿarabī*, a recension of **Muḥammad ibn Abī Bakr al-Farisī**'s *Zīj* preserved in Cambridge.

Ikhtiṣār ṣuwar al-kawākib (Summary of the constellations) is dedicated to al-Murtaḍā, the Shiʿite leader from Rayy. This nonextant work was a summary of **ʿAbd al-Raḥmān al-Ṣūfī**'s book on the constellations.

Nasawī was also a noted mathematician and wrote works on arithmetic, geometry, and spherics. Among his works are his *al-Muqniʿ fī al-ḥisāb al-Hindī*, a treatise on Indian arithmetic whose purpose was, among other things, to be useful for both businessmen and astronomers. Chapter 4 of *al-Muqniʿ* deals specifically with sexagesimal reckoning used in Islamic astronomy. *Al-Tajrīd fī uṣūl al-handasa* (An abstract of Euclid's *Elements*) was composed for those who wanted to learn geometry in order to be able to understand **Ptolemy**'s *Almagest*.

Nasawī also wrote works on philosophy, pharmacology, and medicine.

Nasmyth, James Hall

Born **Edinburgh, Scotland, 19 August 1808**
Died **South Kensington, (London), England, 7 May 1890**

James Nasmyth advocated volcanic origin of the craters and other lunar features and devised a novel arrangement for the optical path of a Cassegrain telescope, yielding what is now identified as the Nasmyth focus in reflecting telescopes. The marriage of the painter Alexander Nasmyth and Barbara (*née* Foulis) Nasmyth yielded four sons and seven daughters, of which James was the youngest. On 16 June 1840, Nasmyth married Anne Hartop, daughter of the manager of the ironworks in Barnsley near Manchester, England. There were apparently no children from this marriage.

James Nasmyth showed exceptional mechanical aptitude and took an early interest in foundries and chemical laboratories. In his late teens, he made model steam engines and constructed, under a commission from the Scottish Society of Arts, a primitive automobile that he called a "steam road-carriage." After working as an associate of the noted machine toolmaker and engineer Henry Maudslay, Nasmyth established his own factory at Patricroft near Manchester. There he manufactured machine tools, hydraulic punches, pile drivers, and steam hammers, the latter an invention for which he bitterly disputed priority. The enterprise proved so profitable that Nasmyth was able to retire to the town of Penshurst in Kent at the age of 48.

Encouraged by his close friend, the Liverpool brewer and accomplished amateur astronomer **William Lassell**, Nasmyth became a telescope maker. At Patricroft, he used a succession of Newtonian reflectors, culminating in a 13-in. instrument. Ever inventive and attempting to improve objects that attracted his attention, Nasmyth introduced both an improved mirror grinding and polishing machine, and an improved formulation of speculum metal used to cast mirrors. After moving to Kent, Nasmyth erected a 20-in. telescope of innovative design. By introducing a planar tertiary mirror inclined at an angle of 45° between the primary and secondary mirrors of a Cassegrain reflector, the necessity of perforating the primary mirror was obviated, and a more accessible eyepiece position was provided in a hollowed-out trunnion bearing for the tube mounting. Neglected for decades, this "bent Cassegrain" or "Nasmyth" configuration became widely adopted in the 20th century on many large professional instruments featuring heavy spectrographs and large modern alt-azimuth mountings.

Always keenly interested in the Moon, Nasmyth became one of the first to contribute to **William Birt**'s committee to map the Moon. Unlike Birt, who looked for evidence of ongoing changes in the lunar surface, Nasmyth focused on the origins of the features that he saw scattered over its crowded surface. A self-taught amateur, he enlisted a more learned collaborator for his work: **John Carpenter**, a computer and later assistant astronomer at the Royal Greenwich Observatory. In their book on the Moon, an influential work about the lunar surface, Nasmyth and Carpenter accepted that lunar craters had been formed by volcanic action. But they did not attempt to gloss over the fundamental difference of form between terrestrial craters and their lunar counterparts. Terrestrial volcanic craters consist of a caldera or hollow atop a mountain, but the interior bowls of lunar craters are almost invariably depressed below the level of the surrounding surface. And yet despite the apparent differences in form, Nasmyth and Carpenter nevertheless affirmed **John Herschel**'s view that lunar craters manifest "the true volcanic character in its highest perfection."

Nasmyth and Carpenter endorsed a version of **Pierre de Laplace**'s cosmogony, in which particles of diffused primordial matter condensed and aggregated into a spherical planetary body consisting of a solid shell encompassing a molten core. Consistent with his empirical approach, Nasmyth did not take the formation of such a solid shell on faith but confirmed at an iron-works that cold slag floated on molten slag. During an 1865 visit to Vesuvius, then undergoing an eruption, he and Carpenter observed a lake of molten lava on the plateau or bottom of the crater on which vast cakes of the same lava that had solidified were floating.

Nasmyth applied these principles to the evolution of the Moon. He theorized that cooling from the outside inward, the Moon's encasing outer shell would cause pressures to build up in the still-molten interior until a portion of the molten interior burst through the shell "with more or less violence according to the circumstances." As each successive shell cooled and contracted in the attempt to accommodate itself to the core beneath it, the skin would crease into alternating ridges and depressions, "like a long-kept shriveled apple." Nasmyth and Carpenter saw everywhere on the surface of the Moon evidence of this general process.

The main problem in understanding the origin of the lunar features remained their sheer size relative to those of the Earth. The Vesuvian crater was less than 2 miles across, tiny by lunar standards. Even the largest terrestrial volcanic craters measure only some 15 miles across, yet lunar craters such as Tycho and Copernicus, with diameters of 50 and 56 miles respectively, were not even the largest specimens of their kind.

Nasmyth and Carpenter, proposed a "fountain model" solution: The reduced surface gravity of the Moon, combined with the negligible resistance of its thin atmosphere, would cause lunar volcanoes to eject a pyramid of matter around an orifice. Their theory required the ejected material to fall symmetrically in order to build up the crater walls and produce a ring structure. Later, the vent hole would fill with lava to produce the crater floor or give rise to the central peaks found in many of the lunar formations. As the lunar crust grew thicker and more rigid, and the reserves of lava dwindled, these last gasps of the Moon's dying internal activity that created the central peaks found in so many craters were, according to Nasmyth and Carpenter, evidence that such internal activity had ceased long ago.

Nasmyth's and Carpenter's theory was widely accepted and overshadowed other theories of the origin of the craters until well into the 20th century. The impression made by their book was greatly enhanced by the inclusion of 24 photographs of exquisite plaster-of-Paris models of lunar formations. Taken under oblique lighting, these plates made the book almost as much a work of art as a piece of scientific literature. The models were very deceptive, however, as they consistently depicted the Moon's surface as far more jagged than it is in reality. These rugged landscapes and sharp, craggy peaks provided evocative illustrations in popular books on the Moon for decades.

Nasmyth also made many observations of the Sun. His depiction of the granulation of the solar photosphere as a series of luminous filaments that he called "willow-leaf structure" remained in vogue for several decades but was ultimately proven to be an illusion.

Nasṭūlus: Muḥammad ibn ˁAbd Allāh

Flourished **10th century**

Nasṭūlus is credited with constructing two astrolabes. The first, dated 927/928, is considered the oldest surviving astrolabe (though not the first ever constructed). This elegant instrument is preserved in the Kuwait Museum of Islamic Art. It has a single plate (for latitudes 33° and 36°) on the back of which are four quadrant scales and a shadow scale. The throne bears the inscription, "Made by Nasṭūlus (or Basṭūlus) in the year 315." The second astrolabe, of which only the *mater* is still extant, bears no date but was probably constructed around 312 hijra (925). It is preserved in the Museum of Islamic Art in Cairo; the inscription "Made by Nasṭūlus" appears on the throne. It contains the earliest and only geographical list to appear on an instrument before *circa* 1100. The purpose of the gazetteer on the *mater* is evidently to show which plates should be used in different cities. Most of the latitudes included are derived from **Khwārizmī**'s geographical table, although the remainder may have been taken from other early sources such as **Battānī** (*circa* 910). Although no original plate has survived, the instrument has various Mamluk additions, dated 1314.

We know almost nothing about this astronomer, and even his name remains in doubt. Some historians have interpreted the manuscripts to refer to someone with a Greek name, perhaps Βατύλος/βαθύλος or Απόστολος. However, it is unclear whether he is a Muslim or Christian. King claims that he was a Muslim based on the testimony of the 10th-century astronomer **Sijzī**, who states that a certain Muḥammad ibn ˁAbd Allāh (clearly a Muslim name), known as Nasṭūlus, was the first person to design the astrolabe with a crab-shaped rete. Sijzī adds that Nasṭūlus also invented the hours drawn on the face of the alidade and the operation with the azimuth on the back of the astrolabe. This statement was later repeated by **Bīrūnī** in his *Istīˁāb*, in which he adds that Nasṭūlus was one of the people who worked on instruments for determining eclipses. On the other hand, M. Hinds suggests Nasṭūlus might refer to the Christian sect of the Nestorians, and Kunitzsch points out that the form Nasṭūrus was attested in 10th-century Egypt, and was used by Christian men. Nasṭūlus would then be just another form of Nasṭūrus.

Mònica Rius

Alternate name

Basṭūlus

Nayrīzī: Abū al-ˁAbbās al-Faḍl ibn Ḥātim al-Nayrīzī

Flourished **Baghdad, (Iraq), last half of the 9th century**

Nayrīzī is reputed to have been among the best mathematicians and astronomers of his day, though not much biographical information is known. In astronomy, his best-known work, a commentary on the *Almagest* of **Ptolemy**, is no longer extant. This must have been one of the earliest commentaries to be written in Arabic, because the *Almagest* had been first translated into Arabic only a century earlier. He is also credited with the composition of two *zīj*es (astronomical tables used for predicting planetary motions). The longer was said, by the bio-bibliographer Ibn al-Qifṭī, to have been based on the *Sindhind*, an Indian classic in astronomy. The shorter was, presumably, based upon the *Almagest*. These works were cited by several astronomers from the ˁAbbāsid period, although they are no longer extant. Three shorter, more specialized treatises survive: (1) on the spherical astrolabe; (2) on finding the *qibla* direction (the direction toward Mecca, toward which pious Muslims pray five times a day); and (3) on constructing hour lines in a hemispherical sundial. **Ibn Yūnus**, in his own *zīj*, criticized some elements of Nayrīzī's astronomical work while praising him as a renowned mathematician.

Neison, Edmund

➜ **Nevill [Neville], Edmund Neison**

Nemicus, Tadeá

➜ **Hájek z Hájku, Tadeá**

Nernst, Walther Hermann

Born **Briesen, Wąbrźezno, Poland, 25 June 1864**
Died **Muskau, (Sachsen), Germany, 18 November 1941**

After elucidating the third law of thermodynamics, for which he won the 1920 Nobel Prize in Chemistry, physicist Walther Nernst worried about the consequences of the second law for the fate of the Universe. Entropy seemed to require an eventual "heat death" to everything. **Victor Hess**'s discovery of cosmic rays gave Nernst hope that perhaps there was a constant source of new matter and energy at large, so that the Universe could go on – much as it is – indefinitely. Nernst called this a steady-state cosmology.

Neugebauer, Otto E.

Born **Innsbruck, (Austria), 26 May 1899**
Died **Princeton, New Jersey, USA, 19 February 1990**

Austrian–German–American mathematician and historian of mathematical astronomy Otto Neugebauer meticulously demonstrated the technical content of ancient mathematical astronomy and the ingenuity in abstract thinking of ancient mathematicians and astronomers.

Otto Neugebauer's father, Rudolph Neugebauer, was a railroad engineer. The Protestant family moved to Graz, Austria, when Otto was still young. There Otto attended the Akademisches Gymnasium, studying mathematics, mechanics, and technical drawing, in addition to the Greek and Latin required by the curriculum. In 1917 he enlisted in the Austrian army, ostensibly to avoid taking the Greek examination to receive his graduation certificate. Neugebauer became a lieutenant of artillery, spending the remainder of the war as a forward observer on the Italian front.

In 1919 after his discharge, Neugebauer entered the University of Graz to follow a course in electrical engineering and physics, transferring to the University of Munich in 1921. There he attended lectures by Arnold Sommerfeld and Arthur Rosenthal. After the death of his parents and as the result of Austrian hyperinflation, Neugebauer lost his entire inheritance and suffered a difficult winter, but in 1922 he changed the focus of his education, moving to the Mathematisches Institut at the University of Göttingen, where he studied under Richard Courant, the new director of the institute, and with Edmund Landau and Emmy Noether. By 1923 Neugebauer became an assistant at the institute, and in 1924, special assistant to Courant, and was put in charge of the library. During 1924 he spent time at the University of Copenhagen with Harald Bohr, with whom he published his only paper in pure mathematics.

During this time Neugebauer studied Egyptian mathematics, publishing a seminal document on the *Rhind Papyrus*, a late Egyptian mathematical document.

In 1927 Neugebauer received his *venia legendi* for the history of mathematics, and became a *Privatdozent* (lecturer). He soon married Grete Bruck, a fellow student, also a mathematician: Their two children, Margo and Gerry (a distinguished infrared astronomer), were born in 1929 and 1932, respectively. The following year Neugebauer traveled to Leningrad, Russia, to work with Wilhelm Struve in preparing the *Moscow Papyrus*, an important text in Egyptian mathematics, for publication. In 1929 Neugebauer founded a Springer series devoted to the history of mathematical sciences, astronomy, and physics, the *Quellen und Studien zur Geschichte der Mathematik, Astronomie und Physik*. Under his editorship, its focus would be primarily on Egyptian mathematics.

Starting in 1927, Neugebauer had learned Akkadian in an investigation of Babylonian mathematics, which eventually enabled him to establish the origin of the sexagesimal system, and collect a substantial corpus of texts later published as *Mathematische Keilschrift-Texte*, in several volumes. This corpus demonstrates the richness of Babylonian mathematics.

Neugebauer was founding editor of the review journal *Zentralblatt für Mathematik und ihre Grenzgebiete* and a Springer series of short monographs on current mathematics. But when Adolph Hitler became chancellor of Germany, Neugebauer was removed from his job at the Courant Institut for presumed political unreliability. Obtaining a professorship at the University of Copenhagen starting in 1934, he prepared a series of lectures on Egyptian and Babylonian mathematics, and planned a volume on Greek mathematics.

In his 1928 review of *The Venus Tablets of Ammizaduga* by Stephen Langdon *et al*., Neugebauer demolished the earlier chronology of the Old Babylonian dynasty. In a paper a decade later, he similarly cast doubt on the use of the Sothic cycle for establishing the origin of the Egyptian calendar. Neugebauer became intensely interested in astronomical cuneiform texts, which were primarily ephemerides in the form of arithmetic functions for computing lunar and planetary phenomena. He developed a method using linear Diophantine equations to check these functions, with the result that many previously unrelated cuneiform fragments were joined and dated. This work showed that some functions ran continuously for hundreds of years, and provided the basis for much significant work to follow. After publishing some of his results in 1938, Neugebauer had his work interrupted by difficulties with Springer and his editorship on the *Zentralblatt*, from whose board he resigned in December. Neugebauer was immediately offered a position at Brown University in the United States, which he readily accepted, moving to Providence, Rhode Island, and founding *Mathematical Reviews* in 1939. He shortly afterward applied for American citizenship.

At Brown University, Neugebauer quickly published several papers on ancient astronomy and mathematics, later reprinted in his book *Astronomy and History* (1983). His most famous work is *The Exact Sciences in Antiquity*, a survey of Egyptian mathematics and astronomy, and their relation to Hellenistic science and its descendents. Neugebauer's treatment of the subject emphasizes the transmission of ideas as they were developed, with many cultures adding to the corpus of understanding and observations of astronomical phenomena.

With his collaborator Abraham Sachs, Neugebauer published all the known Assyrian astronomical texts as *Astronomical Cuneiform Texts* (1955), most dating from the last three centuries BCE. In his preface he commended the spirits of the ancient scribes of Enu ma-Anu-Enlil, who "by their untiring efforts … built the foundations for the understanding of the laws of nature … they also provided hours of peace for those who attempted to decode their lines of thought two thousand years later."

Neugebauer published several analyses of Egyptian astronomical documents, tomb ceilings, coffin lids, zodiacs, and papyri, collecting these works in the three-volume work *Egyptian Astronomical Texts* (1960–1969). His later *History of Ancient Mathematical Astronomy* (1975) indicated, however, that the Egyptian contribution to mathematical astronomy was minimal.

Along with the chief librarian at Brown University, a classicist and papyrologist, Neugebauer published *Greek Horoscopes* (1959), the standard work on the subject, containing an introduction to the methods of Greek astrology. He planned a history of mathematical astronomy from antiquity to **Johannes Kepler**, and published many ancient texts from several languages, including Greek, Latin, Indian, Arabic, and Ethiopic. Neugebauer's *History of Ancient Mathematical Astronomy* established the history of ancient astronomy on a new foundation and demonstrated the continuity of the science from ancient times to the present. The material included planetary and lunar theory, astrological sources, the works of **Ptolemy** and their derivatives, chronology, astronomy, and his own methods that had proved so useful. In later publications he dealt with astronomy in the Middle Ages, Byzantine sources, and analysis of **Nicolaus Copernicus**'s *De revolutionibus*, Ethiopic astronomy, chronology, and the calculations of the ecclesiastical calendar, with an analysis of the primitive astronomical section of the *Book of Enoch*.

Neugebauer became professor of the history of mathematics at Brown University, and was named the Florence Pirce Grant University Professor at Brown University in 1960. After his retirement, he moved to the Institute for Advanced Study at Princeton University, where he spent the remainder of his life. Some of the work Neugebauer completed during his last years was published posthumously.

Neugebauer received honorary doctorates from Saint Andrews University (Scotland), Princeton University, and Brown University; was elected to membership in academies of science and the arts of Denmark, Belgium, Austria, Britain, Ireland, France, and the United States; received the Balzan Prize (1986), the Franklin Medal (American Philosophical Society, 1987), and awards from the History of Science Society, the Mathematical Association of America, and the American Council of Learned Societies; and in 1967, became the only historian of science ever awarded the Russell Lectureship of the American Astronomical Society. His approach to the history of mathematical astronomy continues in the work of many influential scholars.

Neumann, Carl Gottfried

Born **Königsberg (Kaliningrad), Russia, 7 May 1832**
Died **Leipzig, Germany, 27 March 1925**

Carl Neumann developed new techniques in mathematical physics that have found diverse applications in dynamical astronomy and other research areas. Neumann was born into a noted academic family; his aunt was married to the astronomer and mathematician **Friedrich Bessel**. His father, Franz Ernst Neumann, a professor of physics at Königsberg University, contributed to advancements in the wave theory of light and the mechanical theory of heat. Neumann attended Königsberg University and completed his doctorate in 1855. After post-doctoral work at the University of Halle, Neumann became a *Privatdozent* (lecturer) there until his promotion to assistant professor in 1863, when he accepted a position at the University of Basle. After 2 years, he moved to the University of Tübingen, before settling at the University of Leipzig in 1869. One of Neumann's prominent students was **Hugo von Seeliger**. He remained there until his retirement (1911). In 1864, Neumann married Hermine Mathilde Elise Kloss.

Neumann's initial work on the Galilean–Newtonian theory of mechanics influenced mathematicians, physicists, and astronomers of the time, many of whom studied under him. His chief contributions were in mathematical physics: the application of mathematical techniques to the study of mechanics and electrodynamics, especially harmonic analysis ("potential functions") used in the solutions to partial differential equations (*e. g.*, Laplace's equation). These tools have since become standard for the mathematical modeling of physical processes involving electricity, electromagnetism, fluid dynamics, and gravitation.

Today, Neumann's methods and techniques are found in a surprising array of applications, including structural analysis, contact problems with friction (*e. g.*, the Dirichlet–Neumann algorithm), domain decomposition algorithms for the treatment of elastic body problems, spectral properties of the Neumann Laplacian involving stars and comets, and even the global potential functions used in programming the paths of robots.

Neumann was a cofounding editor (with Alfred Clebsch) of the prestigious and influential journal *Mathematische Annalen*, led subsequently by **Felix Klein** and David Hilbert.

Nevill [Neville], Edmund Neison

Born **Beverley, (Humberside), England, 27 August 1849**
Died **Eastbourne, (East Sussex), England, 14 January 1940**

Edmund Nevill, regarded for a short time as the preeminent selenographer in Britain, provided a firm basis for later lunar studies. Nevill was educated at Harrow and New College, Oxford. During the Franco–Prussian war of 1870/1871, he joined the French army, serving on the staff of marshal Ney. After the war, Nevill followed a journalistic career and for a time was parliamentary reporter for *The Standard* (London), as well as a theater critic. He worked alone and without financial sponsorship, and produced a contribution of outstanding importance in its day. He wrote under the pseudonym "Edmund Neison" in the conviction that the holder of an ancient name should not make a career in science. Nevill played an excellent game of tennis and was a golf enthusiast. His wife, Mabel (*née* Grant), whom he married in 1894 and who was South Africa's tennis champion for 11 years, survived him by several years.

Following an early interest in astronomy, Nevill became a fellow of the Royal Astronomical Society in 1873 at the age of 24. Using the classic work of **Wilhelm Beer** and **Johann von Mädler**, Nevill initiated a serious study of the Moon with a 6-in. refractor and a 9.5-in. With–Browning reflector from his residence in Hampstead, London. His voluminous book on the Moon was an important text; though based largely on the work of Beer and Mädler and in places merely a translation of *Der Mond*, it skillfully integrated all contemporary data to produce one of the most useful lunar reference works available in the English language and established Nevill's place in the history of astronomy.

In 1873 and 1874, Nevill argued for the existence of an appreciable lunar atmosphere and endorsed the idea that the Moon's craters represented the results of "vast volcanic convulsions," although he felt under obligation to discuss, at some length, Beer and Mädler's view that the surface of the Moon showed an "entire dissimilarity to that of the Earth." This was the general impression furnished by the small telescope that Beer and Mädler had employed, but with resemblances more compelling following the work of **Jean Chacornac**, Nevill found that closer examination with powerful instrument revealed far greater terrestrial analogy in the structures of the Moon than otherwise appears even possible. He reported that while a general analogy is often traceable between terrestrial volcanic regions and the more disturbed portions of the lunar surface, through powerful telescopes the larger craters appeared "less and less like volcanic orifices or craters." Indeed, their enclosing walls lost their regularity of outline and appeared instead as confused masses of mountains broken by valleys, ravines, and depressions, an irregularly broken surface.

Although Nevill accepted the probability of minor changes on the Moon and was convinced that the change reported by the German selenographer **Johann Schmidt** in 1867 within the small crater Linné on the plain of the Mare Serenitatis had been real, he departed from the conventional view that the alteration signified a volcanic upheaval, suggesting that it represented the comparative whimper of a landslide. However, Nevill expressed doubt when the German astronomer **Hermann Klein** reported in 1877 that Hyginus N was of recent origin.

Nevill had earlier written about the possibility of a lunar atmosphere (1873) and in greater detail on that subject in *Popular Science Review* in October 1874. Nevill was unafraid to voice his opinions. He was a founding member of the short-lived Selenographical Society (1878–1882), and served as its secretary until his career took an unexpected turn in 1882.

Though chiefly known for his work on lunar morphology, Nevill had a very strong interest in lunar theory and in 1877 confirmed the reality of an inequality in the longitude of the Moon, produced by the action of Jupiter, an effect that had been detected by Newcomb in 1876. The value obtained by Nevill for this term is close to that currently accepted. That same year he published a memoir containing the theoretical foundations of a complete analytical development of lunar theory, essentially a simplification of earlier treatments.

As part of the preparations to observe the transit of Venus in December 1882, a long-discussed plan to set up an observatory in Durban, South Africa was finally activated through the efforts of Harry Escombe and **David Gill**. Nevill was offered and accepted the post of government astronomer at Natal, and sailed for Durban arriving on 27 November 1882, a few days before the transit. He encountered many difficulties, but the weather at least was in his favor and the phenomenon was successfully observed. It was an auspicious start; Nevill conceived many plans, including observations to perfect the tables of lunar motion, and the establishment of the observatory as a meteorological center. He also became government chemist and official assayer for Natal, acting sometimes as pathologist in instances of suspected poisoning. However, promises of official funding were unfulfilled, and things became more difficult until, in 1911, the observatory was closed.

Nevill gave up his scientific career and returned to England. On retirement he settled at Eastbourne on the South Coast where he remained agile and unimpaired in mind and body unto the last, indulging his varied interests, especially chemistry. In the 1870s he had, with C. T. Kingzett, pressed for the setting up of a body to represent the profession of chemistry. At a meeting in the rooms of the Chemical Society (of which he was a fellow) on 26 April 1876, a committee was appointed as a first step toward the foundation of the Institute of Chemistry. Nevill was an original member of its council, serving from 1877 to 1880, and for some time was honorary corresponding secretary for the Institute of Natal Province. In 1935 he was awarded the Medal of the Royal Chemical Society.

Nevill was inactive, astronomically speaking, for almost three decades after returning to the United Kingdom from Africa, and he was assumed to have long since died. Twice, he refused the invitation to become a Fellow of the Royal Society, though in 1908 he was finally persuaded to accept. Nevill also declined the presidency of the Royal Chemical Society, and though a fellow, seldom, if ever, attended meetings of the Royal Astronomical Society. He researched Babylonian history, wrote several novels (but never submitted them for publication), and in 1886 published a popular outline of astronomy.

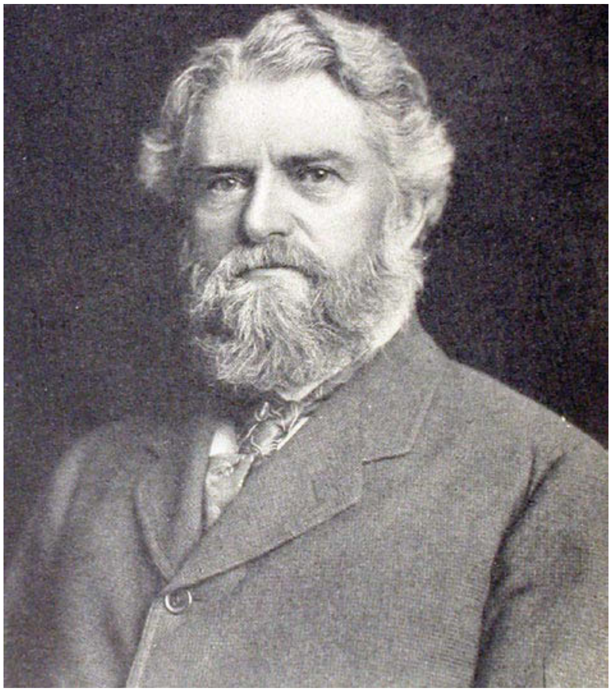
Newcomb, Simon

Born **Wallace, Nova Scotia, (Canada), 12 March 1835**
Died **Washington, District of Columbia, USA, 11 July 1909**

The commanding figure of United States astronomy in the 19th century, Simon Newcomb systematized and brought unparalleled precision to our knowledge of the Solar System.

The oldest of seven siblings born to parents of New England extraction, Newcomb grew up in the British colony of Nova Scotia, later part of Canada. His father, John Burton Newcomb, was an itinerant village schoolmaster; his mother, Emily Prince, was the daughter of a New Brunswick magistrate.

Largely home-schooled or self-taught, Newcomb spent his childhood in various parts of Nova Scotia and Prince Edward Island. Around age 15, he grew estranged from his mother's Calvinist beliefs and never really settled on an alternate faith. Apprenticed at 16 to a quack doctor, he ran away in 1853 and joined his father



in the United States, gaining a schoolteacher's position at Massey's Cross Roads, Maryland.

Through relentless study of authors ranging from Euclid to **Isaac Newton**, Newcomb acquired an increasingly profound understanding of mathematics. He submitted his first paper to **Joseph Henry**, secretary of the Smithsonian Institution, and was encouraged to persevere. Having moved closer to Washington, DC, Newcomb started to draw on the riches of the Smithsonian library. Henry soon recommended the United States Coast Survey as a suitable outlet for his talents. Referred in turn to the Nautical Almanac Office, then in Cambridge, Massachusetts, he arrived in December 1856 and became an astronomical computer. Newcomb simultaneously enrolled in Harvard's Lawrence Scientific School, studying mathematics under **Benjamin Peirce** and obtaining his B.Sc. in 1858. He never looked back.

When the Civil War began in 1861, Newcomb was appointed to the United States Naval Observatory in Washington, replacing staff that had departed to join the Confederacy. In 1863, he wedded Mary Caroline Hassler, granddaughter of the founder of the Coast Survey, Swiss-born Ferdinand Hassler. They would have three daughters, Anita, Emily, and Anna. In 1864, Newcomb was naturalized as a United States citizen.

In 1875, Newcomb was offered the directorship of Harvard College Observatory but turned it down, just as he declined the opportunities to replace Henry at the Smithsonian Institution or to head the Coast and Geodetic Survey. Instead, he accepted the superintendency of the Nautical Almanac Office in 1877. By then, he was accumulating honors: the Gold Medal of the Royal Astronomical Society, the Huygens Gold Medal of the Dutch Academy of Science, memberships in European scientific societies, and honorary degrees.

Newcomb served as president of the American Association for the Advancement of Science [AAAS] in 1877. He shared responsibility for the 1874 and 1882 American observations of the transits of Venus. In 1876, he lectured at the newly created Johns Hopkins University in Baltimore, Maryland, turning his course into a best-selling book, *Popular Astronomy* (1878). Newcomb was formally named a professor of mathematics and astronomy at Johns Hopkins University in 1884.

In 1890, the Royal Society of London awarded Newcomb the Copley Medal, and the Paris Académie des sciences chose him in 1895 to replace **Hermann von Helmholtz** as a foreign associate. In 1898, Newcomb received the Astronomical Society of the Pacific's first Catherine Wolfe Bruce Medal, and became, in 1899, the first president of the Astronomical and Astrophysical Society of America, later the American Astronomical Society. In 1907, France made him a Commander of the Légion d'honneur. Elevated by the United States to the rank of rear admiral, he was buried with full military honors in Arlington National Cemetery.

Newcomb's first important scientific result was his demonstration that the asteroids could not have originated, as **Heinrich Olbers** had suggested in 1803, from the fragmenting of a single planet. The work's 1862 publication in the German research journal *Astronomische Nachrichten* attracted notice abroad.

By then, Newcomb was already mastering the practical side of astronomy at the Naval Observatory, standardizing procedures, and tracking down systematic errors in stellar position catalogs. He took part in eclipse expeditions of 1860, 1869, 1870, and 1878, and played a key role in procuring for the observatory the nation's then largest telescope, a 26-in. refractor, inaugurated in 1873.

On the theoretical side, Newcomb analyzed the orbits of the Solar System's then-known outermost two planets, Uranus and Neptune, and published greatly improved tables for both by 1874. But he won fame by tackling a subject that was starting to exercise astronomers, namely, the gap between the observed motion of the Moon and theoretical attempts to represent it. By 1869, **Peter Hansen**'s 1857 lunar theory, based on data from 1750 to 1855, was clearly deviating from observations.

Newcomb realized that he could recover precise positional data from the Paris Observatory's records of lunar occultations, which yielded results stretching back to 1675. His reduction of the occultations was finished by 1888, although Newcomb was unable to complete the entire analysis before his retirement. With the inclusion of eclipses reported by **Ptolemy**, the observations spanned some 2,600 years. In a summary of his results, Newcomb identified a fluctuation that could not be attributed to gravity. It was later established as arising from the variable rotation (mostly slowing) of the Earth, as Newcomb had suspected.

Ensconced at the Nautical Almanac Office, Newcomb initiated a comprehensive redetermination of the constants of dynamical astronomy, from the best data obtained since 1750 by the world's observatories, in order to prepare new tables and formulas for the construction of ephemerides. One of the investigation's fruits was an improved value for the anomalous advance of Mercury's perihelion. (He favored some slight deviation from Newtonian gravity over the hypothetical intra–Mercurian planet Vulcan as the explanation.) With the help of several skilled mathematicians, Newcomb essentially completed this monumental endeavor by 1894.

Newcomb's retirement in 1897 did not end his career. In 1899, he published new tables of Uranus and Neptune, superseding his own earlier effort. A modest congressional stipend and later Carnegie grants from 1903 onward, enabled him to remain active in the international movement to standardize astronomical constants and basic data. Newcomb produced new catalogs of reference stars and rederived the principal constant of precession. Many of his numerical values endured until the advent of satellites and electronic computers led to superior determinations.

In other work, Newcomb refined the calculation of Jupiter's mass. In 1892, he deduced the approximate rigidity of the Earth. In the early 1900s he made the first quantative estimate of the background light of the night sky (equivalent approximately to one fifth magnitude star per square degree) and showed that the zodiacal light actually extends almost to the north ecliptic pole.

Newcomb also sought to better determine the distance to the Sun. Since the transits of Venus had proven disappointing, he measured anew the speed of light in order to find the distance directly from Earth's orbital velocity. His value for the speed of light was confirmed by the 1882 experiments of **Albert Michelson**. Though uncertainty persisted, Magnus Nyrén's 1883 constant of aberration yielded a result that turned out to be substantially correct.

Among the most distinguished scientists of his time, Newcomb was a celebrated figure who wrote astronomy textbooks and popularizations, works on economics, various opinion pieces (including a notorious refutation of the possibility of flying machines), and even some fiction.

First and foremost, Newcomb raised 19th-century positional astronomy to a pitch of perfection widely admired by his peers. Upon taking charge of the *Nautical Almanac*, he proposed changes in the ephemerides that were partially adopted by 1882. Results of his work were used by United States almanac makers from 1901 to 1960. Internationally, Newcomb's constants, theories, and tables for the Sun and the inner planets were not wholly superseded until 1984, so that his influence on astronomical ephemerides spans over a century. His contributions have been overshadowed by the more glamorous field of astrophysics, but Newcomb's precise determination of Mercury's perihelion advance lent inescapable significance to **Albert Einstein**'s derivation of the same within general relativity.

Most of Newcomb's works are found in the *Astronomical Papers Prepared for the Use of the American Ephemeris and Nautical Almanac*, 1879–1913, and in his 1895 volume, *The Elements of the Four Inner Planets and the Fundamental Constants of Astronomy*. Over 40 of his books and papers are available as microforms from the Canadian Institute for Historical Microreproductions. Newcomb's personal papers are held at the United States Library of Congress. He is widely held to have been the prototype of Walt Whitman's "Learned Astronomer."

Newton, Hubert Anson

Born **Sherborne, New York, USA, 19 March 1830**
Died **New Haven, Connecticut, USA, 12 August 1896**

Hubert Newton, who made some of the first rigorous studies of meteor orbits and their distribution in interplanetary space, was among the first to recognize meteors, fireballs, and meteorites as the same objects differing only in mass and velocity.

Newton was the fifth son of 11 children born to educators William and Lois (*née* Butler) Newton. At age three, he witnessed the spectacular Leonid meteor storm; his later prediction concerning its maximum activity in 1866 brought him fame. Newton was schooled locally until 1846 when he entered Yale College. He showed great aptitude for mathematics and the physical sciences, and won election to the Phi Beta Kappa Society. On 14 April 1850, Newton married Anna C. Stiles, with whom he parented two daughters.

Following his graduation in 1850, Newton studied mathematics privately for several years before accepting the position of mathematics tutor at Yale College in 1853. He was elected professor of mathematics in 1855, a position he held until his death. Newton also became director of the university's observatory. Under his charge, a research program on meteor photography was developed, principally carried out by **William Elkin**.

In the early 1860s, Newton conducted a survey to find accounts of outbursts similar to the 1833 Leonid storm, then regarded as an unpredictable phenomenon. He correctly deduced that the Perseids are distributed around the Sun in an elliptically shaped ring, though his calculated orbit differed significantly from today's accepted orbit, first determined by **Giovanni Schiaparelli** in 1866.

In an important 1864 paper, Newton coined the term "meteoroid" to describe interplanetary debris and suggested that the orbits of meteoroids closely resemble those of some comets. His review of 13 historical observations of the Leonids revealed cyclical outbursts with a period of about 33 years, and that the shower had been active since at least 902. Newton successfully predicted a Leonid meteor storm for 1866. He concluded that the Earth passes through the densest part of the meteor swarm during these times, strong evidence that the meteors are not uniformly distributed throughout their orbiting ring. Newton calculated that the Leonid meteors are spread out over 40 million miles along their orbit, with a stream thickness exceeding 100,000 miles.

Newton found five orbits consistent with the data, noting that analysis of the stream's nodal regression would single out one of them. In 1867, **John Couch Adams** showed that Leonid meteoroids move along highly elliptical orbits, with periods of 33.25 years and aphelia as distant as Uranus. Calculations by Carl A. Peters, Schiaparelli, **Urbain Le Verrier**, and **Theodor von Oppolzer** showed that Leonid meteoroids follow orbits nearly identical to that of a comet observed in 1866 (now identified as comet 55P/Tempel–Tuttle). This was the second occasion for evidence linking a comet with a meteoroid stream, following Schiaparelli's 1866 connection of the Perseids with comet 109P/Swift–Tuttle.

Further evidence that meteoroids are cometary decay products came from Newton's study of the Bielid (also known as Andromedid) meteors, which had produced impressive displays in 1798, 1830, 1838, 1841, and 1847; the irregular intervals defied simple explanation. Newton observed over 1,000 Bielids per hour on 24 November 1872, inspiring him to investigate the swarm named for their connection to comet 3D/1826 (Biela). After discovering the parent comet's close encounters with Jupiter in 1772 and 1841, Newton determined the planet's perturbing effect on the meteoroids' orbits and its contribution to the comet's breakup into meteoric fragments. Newton later demonstrated how Jupiter and Saturn could "capture" passing comets, perturbing the meteoroids coming from these comets from parabolic to elliptical orbits.

Newton's studies of the Bielids led to his investigation of how meteoroids burn up in the Earth's atmosphere and on how they might produce meteorites on the ground. He developed a sizeable collection of meteorites that he later donated to Yale's Peabody Museum of Natural History. Newton noticed that many specimens showed a smoothed side, which he interpreted as the "leading side" of the meteorite that bore the brunt of heating and melting by its passage through the atmosphere, and a rougher "trailing" side, which he believed escaped the worst of the ablative process. Studying meteor trails, Newton suggested that irregularly shaped meteoroids would experience differential air resistance, leading to a trail that would straighten after leading parts melted and smoothed and would diverge when asymmetric parts lead.

Newton confirmed this theory after studying a remarkable photograph, made by amateur astronomer John Lewis, of a fireball that appeared over Ansonia, Connecticut, on 13 January 1893. Newton measured Lewis's photographic plate to determine the distances from the fireball's trail to several bright stars that appeared on the plate. From the varying brightness of the fireball's trail, Newton concluded that it rotated more rapidly during the latter portions of its flight through the atmosphere – the first mention in the scientific literature of meteoroid rotation. From his study of the Ansonia fireball, Newton urged that photography of meteor trails would allow their orbits to be determined with considerably greater accuracy.

Newton's investigations turned to the origin and distribution of comets. In an 1878 paper, he argued that the distribution of cometary aphelia and inclinations were consistent with the interstellar-capture theory proposed by **Pierre de Laplace**. While this idea for the origin of comets is no longer held to be true, Newton importantly showed for the first time that long-period comets could be captured into short-period orbits through the gravitational perturbations of the planet Jupiter.

Newton's interests in meteoric phenomena were wide-ranging. He analyzed the nebular hypotheses of **Immanuel Kant** and Laplace, each of whom had attempted to explain the Solar System's origin through the contraction of a primordial cloud. Applying these theories to the origin of comets, Newton thought that Laplace's version of the nebular hypothesis accounted for most of the long-period comets, with orbital inclinations greater than 30°, while Kant's version, which argued that the comets were closely associated with the planets and should show orbits of smaller inclinations, better explained the short-period comets. Newton also wrote several papers and gave many lectures on the history of meteors and meteorites, including the worship of meteorites by ancient cultures and American Indians. He served as an expert witness in an Iowa dispute over meteorite ownership. Newton aggressively advocated adoption of the metric system of weights and measures, and lobbied for the 1866 enactment legalizing the metric system in North America.

Upon his retirement in 1886, Newton addressed the American Association for the Advancement of Science on the relationship between meteorites and shooting stars (meteors). He also speculated on the processes responsible for the origin and formation of meteorites; this talk included the first-ever discussion of cooling rates, a tool used by modern meteoriticists to analyze the origins and evolutionary histories of primordial Solar System material. Newton died on the date of the Perseid meteors' maximum activity, having witnessed a fine display of these meteors just the night before.

Newton served as president of the American Association for the Advancement of Science during 1885 and 1886. In 1872, he was elected foreign associate of the Royal Astronomical Society, and in 1892 was elected as a foreign member of the Royal Society of London. Newton was awarded the J. Lawrence Smith Gold Medal of the National Academy of Sciences for his work on meteors in 1888. He was a founding member of the National Academy of Sciences. The University of Michigan awarded Newton an honorary Doctor of Laws degree in 1868.

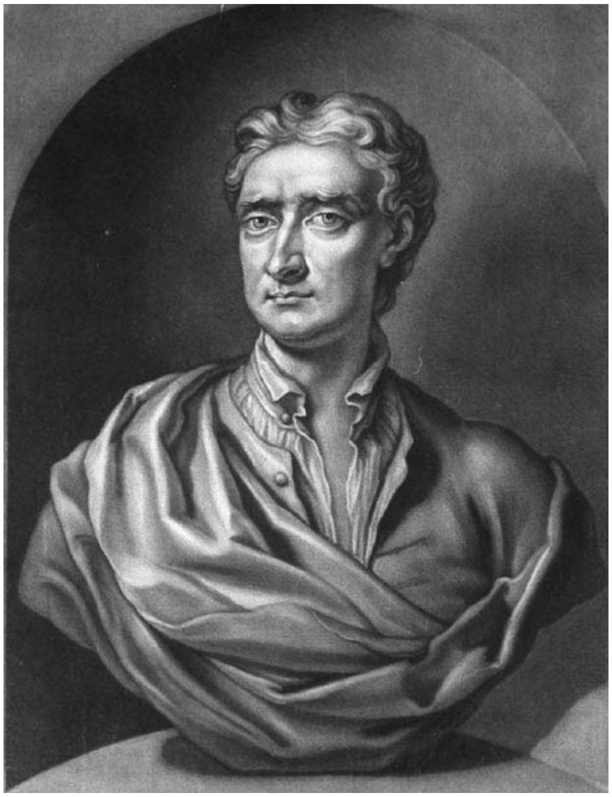
Newton, Isaac

Born **Grantham, Lincolnshire, England, 25 December 1642**
Died **London, England, 20 March 1727**



Sir Isaac Newton was born as a fatherless child on Christmas day. He was then given by his mother Hannah at 3 years to be reared by his grandmother. The young Isaac did not receive undue parental nurturing. There were stories of how his youthful inventions alarmed the inhabitants of Grantham village, such as a night-flying kite that carried a lit candle. The sundial he constructed as a youth is now owned by the Royal Society of London.

After a grammar school education in Grantham, Newton entered Trinity College, Cambridge, in June 1661 and was chosen as a scholar in 1664. In 1669, the college elected him a fellow and the university, through the influence of **Isaac Barrow**, the incumbent, appointed him Lucasian Professor of Geometry.

In December 1671 Newton presented a 2-in.-diameter reflecting telescope – the first ever constructed – to the Royal Society, which led to his election as a fellow. The telescope had a short lifetime because its mirror surface clouded over in a fortnight: It took over a century for nontarnishing reflectors to be made. This was swiftly followed by Newton's 1672 "New theory of light and colour," sometimes viewed as his first scientific paper. This had the effect of promoting his new reflecting telescope design by exaggerating the chromatic aberration from which refracting telescopes suffered. This exaggeration, which disturbed **Robert Hooke** and **John Flamsteed**, was reinforced in Newton's *Opticks* of 1704, and effectively blocked achromatic lens development until 1740.

Using a prism and a chink of sunlight, Newton claimed to demonstrate that white light was composed of various colored rays that had merely been separated by the prism. Hooke disagreed, commenting that he could not see the necessity for such an inference. Then, drawing from his alchemical studies, in a 1675 letter to the Royal Society, Newton formulated his immortal concept of the seven colors of the rainbow.

Newton was taught the new physics of **René Descartes**, and accepted the Cartesian vortex theory of planetary motions, adhering to it until the early 1680s, but he modified it with his own view of a downward-flowing gravity ether: This had a "sticky and unguent" nature as it pulled objects downward, as he explained in his 1675 letter. He was, at the time, immersed in the alchemical tradition, and this theory emerged from it. Modern Newtonian scholarship has shown that Newton's early computations in the plague years concerning the *conatus recedendi* (or tendency of the huge ethers rotating round the Sun to recede) cannot be seen as an early perception of the inverse-square law of gravitational attraction, contrary to several centuries of interpretation.

Around 1679/1680, in addition to his arduous alchemical labors on such matters as preparing the elixir and fixing antimony, Newton's major interest lay in decoding the Apocalypse (Revelation) in order to analyze a presumed theological heresy of the fourth century concerning the Holy Trinity. The Platonist philosopher Henry More at Trinity College recorded the enthusiasm with which Newton participated in discussion on such issues. We should therefore hesitate before accepting the received notion that Newton then linked **Johannes Kepler**'s first two laws of planetary motion to dynamical principles, as he later claimed and as many books have repeated. But no documents of this character exist (as science historian D. T. Whiteside demonstrated) dateable prior to the autumn of 1684, when, at **Edmond Halley**'s bidding, he struggled with the great problem, and solved it.

As a student, Newton had observed the comet of 1664 (C/1664 W1), but it was too distant for any orbital parameters to be inferred. The comets C/1680 W1 and 1P/1682 Q1 (Halley) were decisive for his thinking, with characteristics that seemed to be pointing to features of the to-be-born gravity theory. That of 1680 had its perihelion a mere fraction of the solar radius, yet was well outside the plane of the Solar System and so had little implication for the solar-vortex theory. Newton scrutinized it and received data from Flamsteed, after which he declined to believe what Flamsteed was telling him, that "ye two comets," one of which faded away in the evening sky and the other of which reappeared in the morning sky a week later, were one and the same. Years later, the comet merited 17 pages of his *Principia* for its parabolic orbit – but, in 1680, discussing its motion in the context of his vortex-theory with Flamsteed, he preferred **Giovanni Cassini**'s view that it was in orbit round Sirius. Hooke's seminal words to him, written on 6 January 1680, that throughout the Universe a force of gravity worked so that "the Attraction is always in a duplicate proportion to the distance from the Center Reciprocall …" had hitherto lain dormant in his mind. Then the only bright, periodic comet (later named after Halley) conveniently turned up in 1682, orbiting within the ecliptic plane but in the reverse direction to the planets, and this acted as a trigger.

Newton's alchemical laboratory fire then went out for a couple of years. In the summer of 1684, following a visit of Halley, a more austere, left–brain process began as he apprehended that the "two comets" of 1680 were in fact one. In November of 1684 Halley received a draft of *De Motu*, which employed the inverse-square law. Newton there demonstrated the link to Kepler's first and second laws, using a cumbersome logic based upon relative volumes. Dealing with small changes in an elliptical orbit, it was a rudimentary integration procedure. The proof thus laboriously constructed required the rest of *De Motu* as its context, because it used the concepts there developed of force, impulse, and momentum conservation.

In the spring of 1685, Newton accomplished his "moon-test" computation, justly his most famous. For his predecessors, the 27.3-day sidereal lunar orbit had carried an astral meaning, from the Moon's passage against the starry constellations, but Newton ignored that and viewed it only as resulting from a central force. He became able in the 1680s to compute acceleration by a centripetal force. "If stopped," he explained, the Moon would fall a distance in 1minute, equal to the distance an object on Earth would fall in 1 second; a 60-fold ratio was employed, related to the 60 Earth-radii lunar distance. There was no computation of acceleration, of "g," despite the many textbooks that have averred this. Newton was now able to treat uniform circular motion as accelerated, toward its center.

Then began the great synthesis of many physical ideas in the 2 1/2 years during which Newton wrote his *Principia*, from the autumn of 1684 to March of 1687. **Nicolaus Copernicus** had made the Sun stationary, which Newton transformed into the immobility of the Solar System's center of mass. Newton incorporated the work of **Galileo Galilei**, who had first discerned accelerated motion in free fall, where distance fallen in equal times goes as the sequence of odd numbers and is the same for all objects, replacing the old notion that heavy bodies fall faster. Descartes, and now Newton, affirmed that one physics should link the Earth and sky, demolishing the old duality between the "sublunary" world and the immutable heavens: Newton extended the work of **Jean Buridan**, who had developed the notion of impetus, whereby a body keeps moving, in place of **Aristotle**'s notion that a body moves so long as it is pushed. Robert Boyle had described a vacuum at the top of a mercury column, which Newton now envisaged throughout the immensity of space; Newton derived Kepler's three laws of planetary motion, which had ellipses replacing circular epicycles; Barrow, Newton's mathematics teacher at Trinity, had taught a rudimentary calculus concerning "just nascent quantities," which Newton employed to describe the motions of bodies; last but not least, from Hooke came Newton's inverse-square law of gravitational attraction. A new Universe gleamed, rational to the core.

In dealing with the three-body problem, Newton's calculations were given to five decimal places and eight-figure accuracy, generating a huge error (200%) for lunar mass. He found the Earth–Moon mass ratio to be 22:1 rather than the currently accepted 81:1. Newton thus left to posterity an ultra-dense Moon. As a result, his first computation of the Earth–Moon barycenter in 1713 (for the *Principia's* second edition) located it outside the Earth, from which derived the main error in his historic computation, linking the fall of an apple to the lunar orbit.

Newton also explained why the Earth has two tides a day, a question that had so baffled Salviati and Sagredo in Galileo's *Dialogue*, and indeed many previous natural philosophers. Newton formulated the inverse-cube law of tidal pull, whereby "the force of the moon to move the sea varies inversely as the cube of its distance from the earth." This accounted for the Moon having a larger tidal pull than the Sun, although having only a tiny fraction of its gravity. Thereby he could explain why there are two high tides a day aligned with the Moon. Newton intuited this law with little by way of explanation, so his contemporaries such as Halley and **David Gregory** attempting to explain this tidal argument could do so only in a qualitative sense.

The mighty synthesis thus accomplished had no practical use to astronomers. British ephemerides (for planetary and lunar positions) were not improved: Paris became the main center of their production over this period. After his 1693 nervous breakdown, Newton made one further scientific endeavor. He grappled with lunar theory in 1694/1695, using Flamsteed's new, high-precision data. This was the supreme scientific problem of the age, holding out the promise of finding longitude at sea. Could Newton explain the Moon's erratic path using his gravity theory, since the rest of the Universe obeyed it? He could not (in Whiteside's view). His hitherto respectful partnership with Flamsteed suffered from this, with a (successful) ploy of laying the blame for the failure upon the astronomer, as if he had demurred in sending the data. A fruit of this struggle appeared in 1702, with a lunar "theory" which was, paradoxically, not evidently based upon gravitational principles. This 1702 *opus* was the most frequently reprinted work of Newton's in the first half of the 18th century: In seven steps of "equation" it obtained a final lunar longitude, accurate to several arc minutes.

A modified version appeared in Book III of the *Principia's* 2nd edition of 1713. Thus began the idea of ancillary equations, as a means of solving the three-body problem. Newton reintroduced epicycles into astronomy, a century after Kepler had banished them: His neo-Horroxian 1702 lunar theory was laden with four of them, and as such they reappeared in his *Principia*. French sources could never believe that this model with its wheels moving upon wheels had been deduced from the gravity theory, while English histories soon managed to retell the story using the mid-18th-century theories of **Leonhard Euler** or **Johann Tobias Mayer** as being "Newtonian."

In his *Algebra* of 1685, **John Wallis** commented upon a mathematical tract of the 1660s by Newton, *De analysi*, which Newton would not allow to be published; while admiring certain conventions and nomenclature, Wallis perceived in it no germ of a new fluxions theory, nor did anyone else in the 17th century, despite wide circulation of the manuscript. Only retrospectively, during the great fluxions battle with **Gottfried Leibniz** at the beginning of the 18th century, were such claims first advanced. (The *Principia* contained integral but not differential calculus, the former having developed somewhat earlier than the latter.) Newton's *Arithmetica Universalis* published in 1707 and taken from his mathematical lecture notes of the 1680s, compiled by **William Whiston**, enjoyed a much greater popularity in its time than either the *Principia* or *Opticks*, but it contained no trace of fluxions, Newton's term for the differential calculus, and rather argued against the concept of introducing arithmetical terms into geometry.

Albert Einstein once declared that, "the solution of the differential law is one of Newton's greatest achievements," but the equations $F = ma$ and $F = m\,\mathrm{d}v/\mathrm{d}t$ were invented around 1750 by Euler in Berlin; no one in Newton's lifetime had heard about them. The Berlin Academy of Sciences showed no inclination to view Euler's great discoveries as having been anticipated. What the *Principia* stated was, merely, "change of motion is proportional to motive force impressed" with quantity of motion having been earlier defined as the product of mass and velocity. That was a statement about impulse as proportional to change in momentum and uses no rate-of-change concept. As I. Bernard Cohen has observed, Newton never wrote anything resembling F = kmv. The *Principia* with its geometrically structured proofs, achieved a depth of inscrutability unmatched by any other scientific text. Much of what is called "Newtonian" science is the reformulation of Newton's work using Leibnizian calculus, a task accomplished largely on the Continent in the 18th century.

The myths that surround the image of Newton tend to exaggerate the extent to which he used "fluxions," but not always. For example, it is often asserted that he developed the equation $F = GMm/r^2$, a formula which was not, in fact, published in his lifetime. In "a famous but delusive phrase" (Rupert Hall), Newton averred in 1712 that his masterwork had first been composed in fluxional terms and then, later on, recast into a geometrical format. Generations of historians have reaffirmed that Newton had first composed his *Principia* in fluxional form and then recast it into its inscrutable geometric format, but not until 1975 did. D. Whiteside disprove this notion and lay it to rest.

"Newton's method of approximation" was invented in 1845 by John Simpson, known today for his "Simpson's method" for finding the approximate area under a curve. It is an iterative technique where the same equation is reused, and employs the Leibnizian calculus. Newton's own method of approximation, described in his *De Analysi* and which he used to solve the Kepler equation for elliptical motion, was neither iterative nor fluxional. For each step of approximation it generated a new and different equation. Simpson was not eminent enough to hang onto the credit for his invention, which became attributed to Newton in the latter half of the 18th century.

Few paid Newton more golden compliments than did Leibniz: "taking mathematics from the beginning of the world to the time of Sir Isaac, what he had done was much the better half," he wrote to the Queen of Prussia in 1701. But after his mistreatment by the Royal Society in the fluxions dispute, he described Newton as "a mind neither fair nor honest." Leibniz first published papers on the differential calculus in 1684; these were seminal for the European development of the subject. Newton's first work on the subject appeared in 1704, *De Quadratura*, which gave what we would call implicit functions. It did not describe time-dependent functions or how to find the gradient of a curve, and was primarily about methods of integration.

Newton wrote over a million words on chemistry alchemy, and believed that transmutation could possibly make or unmake gold, as expressed in his one published chemical alchemical text, *De Natura Acidorum* (1710), which described that process. He read alchemical texts eagerly, but seems not to have written like an alchemist; he sought no path of redemption or perfection through such labors. Ultimately his relation to the western alchemical tradition was that of terminator. Once his *Opticks* had affirmed the atomic view ("God in the Beginning form'd Matter in solid, massy, hard, impenetrable moveable Particles … even so very hard, as never to wear or break in pieces"), the colorful language of alchemy had to transform into particulate affinity theory during the 18th century.

Hardly was the ink dry from his *Principia* in March 1687 when Newton was elected to represent Cambridge University in parliament in an attempt to defy the king's promotion of Roman Catholic professors. This morally courageous act put his career at risk and got him sternly rebuked from the feared judge Jeffreys. Two years later the king had fled the country, Jeffreys was in the Tower, and Newton was in parliament. When in 1695 he became warden of the Mint, the nation's recoinage was successful, and the Bank of England first floated paper money, a difficult exercise in credibility. When Newton was elected president of the Royal Society in 1704, its membership and prestige climbed steadily. From being the most reclusive of scholars, where most of the tales about him concern his absent-mindedness, he became a man of public affairs: Member of parliament, Justice of the Peace, knight, president of the Royal Society, and master of the Mint. In his religious views, Newton was probably a mortalist (disbelieving in human survival after death) and an anti-Trinitarian, either of which would have utterly debarred him from holding public office.

In the last year of his life, in a Kensington garden far from the bustle and fumes of London and while having tea with **William Stukeley**, Newton first told his story of the apple. Thus had the law of gravity dawned upon him. He located it in 1666, as London burnt and the plague raged. Earlier narrations beginning in the 1690s had involved his Mother's garden at Grantham but lacked mention of this fruit. The neo-Biblical simplicity of this story proved irresistible, and it has flourished ever since.

Nicholson, Seth Barnes

Born **Springfield, Illinois, USA, 12 November 1891**
Died **Los Angeles County, California, USA, 2 July 1963**

American observational astronomer Seth Nicholson is probably best known for the discoveries of four satellites of Jupiter, numbers 9–12, but his most significant contribution may have been the discovery, with **Charles St. John** that the atmosphere of Venus contains at most a vanishingly small amount of water and molecular oxygen. Nicholson was the son of a schoolteacher and principal with a master's degree in geology from Cornell University. He received a BS from Drake University in 1912 (and an honorary LLD in 1949). He and Drake University classmate Alma Stotts went on to the University of California (Berkeley) and Lick Observatory for graduate work in astronomy and married in 1913, having three children. Nicholson was very prompt in completing the traditional Lick Observatory requirement to determine the orbit of a comet accurately enough for publication with a paper on the orbit of comet C/1912 V1 coauthored by O. Lanzendorf that same year. He supported his graduate studies by serving as an instructor of astronomy, completed the Ph.D. in 1915, and accepted an appointment at Mount Wilson Observatory, where he remained formally until his retirement in 1957 and informally for the rest of his life. Nicholson served as a civilian with the Office of Scientific Research and Development in 1944 and later with the Atomic Energy Commission.

Nicholson discovered his first jovian satellite (Sinope) while still a graduate student and a volunteer assistant at Lick when most of the astronomers were on an eclipse expedition to Russia. Therefore he had extra time for observing with the 36-in. Crossley. He had been assigned the task of photographing the known, faint outer satellites in order to improve their orbits; and, on the plates taken to track the eighth moon (discovered in 1908 by **Philbert Melotte**) found Jupiter IX. In 1938, while other Mount Wilson astronomers were at the general assembly of the International Astronomical Union in Stockholm, Nicholson once again had extra telescope time, this time at the 100-in. Hooker, to survey the region around Jupiter. He set the telescope to track Jupiter, which left faint stars as elongated trails on the plates and satellites carried along by Jupiter as small circular images. This technique revealed Jupiter X and XI. Jupiter XII came in 1951.

Systematic observation of Neptune showed Nicholson that it should be possible to determine the mass of its satellite Triton from the motion of Neptune around their mutual center of mass. This was done by **Harold Alden** in 1942.

Nicholson spent many years on the solar program initiated by **George Hale**. He collected data on sunspot numbers and magnetic fields over several sunspot cycles and looked for correlations with terrestrial phenomena using a spectroheliograph sensitive to polarization. In 1922, he and St. John looked hard for features due to water vapor and molecular oxygen in the spectrum of Venus. They concluded that the amount of oxygen must be less than 0.1% of what would be found above the same ground area on Earth and that there was less water vapor than would make a 1-mm layer if it precipitated out as liquid.

The most important long-term contribution was Nicholson's development with **Edison Pettit** in the 1920s of a vacuum thermocouple as a detector for infrared radiation beyond the longest wavelengths to which photographic emissions are sensitive. This enabled them to measure the thermal infrared emission from, and therefore the surface temperatures of the Moon, and terrestrial planets, and temperatures of the visible layers in the atmospheres on the Jovian planets. They found, for instance, that the subsolar point on Mars was sometimes above freezing and that the difference between day and night temperatures on Venus was relatively small, indicating that, although its rotation is slow, it does not always keep the same face toward the Sun.

Nicholson was somewhat unfairly drawn into the controversy about the rotation and distance of the spiral nebulae. He remeasured some of the plates on which **Adriaan van Maanen** thought he had seen motion outward along the arms (corresponding to rotation with leading arms) and tentatively confirmed the motions, but later, under the guidance of **Edwin Hubble**, he measured some of the plates again and came to agree with Hubble that there was no detectable proper motion.

Nicholson was elected to the National Academy of Science in 1937 and received the Bruce Medal of the Astronomical Society of the Pacific [ASP] at their June 1963 meeting in San Diego. He was by then too ill to attend and participated in the ceremony *via* a telephone hookup. Nicholson had twice served as president of the ASP and edited its *Publications* for some years, remaining on its board of directors, publications committee, and lecture committee until his death. He was a scoutmaster from 1923 to 1938, served on a boy scout troop committee and as a commissioner, and received scouting's Silver Beaver Award.

Nightingale, Peter

Flourished **Denmark, 1290–1300**

The life of calendricist Peter Nightingale is only fragmentarily known. It is here assumed that Petrus de Sancto Audomaro (Peter from Saint Omer) is also identical to Peter Nightingale.

Possibly he is identical to the unknown astronomer at Roskilde, Denmark, who in 1274 measured day by day the declination of the Sun and computed the corresponding lengths of the day, data later used by Nightingale and **William of Saint Cloud** in their calendars.

Nightingale must have left Denmark in the 1280s to study at Bologna. There, he obtained a master's degree, and lectured on astronomy, or rather astrology, at the Faculty of Medicine. His popular Tabula Lunae, a diagram to determine the zodiacal sign of the Moon for every month, most likely is from this period. He also made a similar diagram to find the reigning planet for every day.

Around 1292, Nightingale left Bologna for Paris, at this time a flourishing center of astronomy comprising names like **Campanus of Novara**, **John of Sicily**, and William of Saint Cloud. In Paris, Nightingale worked out a new edition of **Robert Grosseteste**'s calendar, which had expired in 1283 at the end of its 76-year period based on four Metonic cycles of 19 years. Nightingale made the correction needed for another 76 years starting in 1292, improved the Moon tables, and added information about the Sun's declination and length of the day. This calendar and its subsequent prolongation became a standard in much of Europe in the 14th century.

Another achievement of Nightingale in practical astronomy was his improved equatorium, found in the "Tractatus de Semissis" from 1293. An equatorium is an analog computing device, based on the Ptolemaic model of the planetary system, designed to find the longitudes of the planets. Earlier equatoria had the drawback of requiring a separate unit for each planet. In Nightingale's equatorium they were merged into a single unit, thereby reducing considerably the number of graduated circles to be drawn. He seems to have worked together with William of Saint Cloud on this project.

Apart from the highlights described earlier, mathematical tables and commentaries to astronomical works of others are found among the extant manuscripts of Nightingale. Of the commentaries, the one on the combined quadrant and astrolabe by **Jacob ben Mahir** is of particular importance because it explained and spread knowledge of this ingenious instrument.

After his years in Paris, the only known information about Nightingale's life is that in 1303 he held a position as canon at the Roskilde Cathedral.

Nīlakaṇṭha Somayāji

Born **Tṛkkaṇṭiyūr, (Kerala, India), 14 June 1444**
Died **after 1501**

Nīlakaṇṭha Somayāji was one of the foremost names of the Kerala School, which produced several outstanding astronomers and mathematicians over the centuries. The end of the Kerala School (about 1600) seems to have coincided with the fall of the Hindu Vijayanagar empire. Nīlakaṇṭha was the son of Jātaveda and a performer of the Soma sacrifice. His student days were spent in the house of another Kerala astronomer, **Parameśvara**, although his own teacher was Parameśvara's son, Dāmodara.

Nīlakaṇṭha's most important text is the *Tantrasaṅgraha*, a comprehensive treatise on astronomy written in 1501. The *Tantrasaṅgraha* reveals Nīlakaṇṭha to be a follower of the *dṛggaṇita* system of astronomy founded by Parameśvara. He prepared several other important texts, including an extensive commentary on the *Āryabhaṭīya* of **Āryabhaṭa I**. He also wrote the *Golāsara*, which explains the parameters of his planetary models, the celestial sphere, and other computational principles.

Nīlakaṇṭha combined the earlier and incomplete heliocentric models of Āryabhaṭa I and Parameśvara within his *Tantrasaṅgraha* and developed a fully heliocentric system, wherein the five planets moved in eccentric orbits around the Sun. He also made significant contributions to geometrical theorems and infinite series.

Nininger, Harvey Harlow

Born **Conway Springs, Kansas, USA, 17 January 1887**
Died **Westminster, Colorado, USA, 1 March 1986**

Harvey Nininger has been called the father of modern meteoritics. As an exceptionally successful meteorite hunter, Nininger collected specimens of 226 meteorite falls not previously identified, of which only eight were actually seen to fall. He began collecting and studying meteorites in 1923, during a period when the leading scientists of the day thought there was nothing left to learn from them. By the time Nininger retired, the Space Age had dawned and meteorites had become a key component of research into the origin of the Earth and the Solar System.

Nininger was the son of farmers James Buchanan and Mary Ann (*née* Bower) Nininger. In their simple home there were only two books, the Bible and a mail order catalog. Science was considered the work of the devil. As a result, Nininger was 20 years old before he passed an eighth-grade equivalency test and entered Northwestern State Normal College at Alva, Oklahoma, eventually matriculating from McPherson College in Kansas. After receiving a B.S. in Natural History from McPherson College in 1914 and an A.M. from Pomona College in California in 1916, Nininger worked as a biologist, serving both as a professor of biology at several small colleges and as a field entomologist for the United States Department of Agriculture.

In 1923, while teaching at McPherson College, Nininger learned of the existence of meteorites through an article in *Scientific Monthly*. Three months later, a brilliant fireball passed over the town as he was walking home. Nininger set out to find the meteorite that produced the fireball. Although he did not find that meteorite, he did find another one, and his life changed forever. Meteorites became his passion: Nininger set out to learn everything he could about them. He also started a program to collect meteorites, although he was not able to generate much support for this endeavor. In 1928, George Merrill, head curator of the Smithsonian Institution, had told him, "Young man, if we gave you all the money your program required and you spent the rest of your life doing what you propose, you might find one meteorite." However, Nininger was not dissuaded and devised a successful program of collecting meteorites based on educating the people who work the land and offering to buy the meteorites that they found. In 1930, Nininger resigned his professorship at McPherson College and moved to Denver, Colorado, where he joined the staff of the Colorado Museum of Natural History (now the Denver Museum of Nature and Science). He spent the next 16 years searching for and collecting meteorites and investigating meteorite craters. In 1932, Nininger and Frederick Leonard (1896–1960), professor of astronomy at the University of California at Los Angeles, founded the Society for Research on Meteorites (later renamed the Meteoritical Society).

In 1946, Nininger left Colorado with his collection of eight tons of meteorites to establish the American Meteorite Museum, near Winslow, Arizona. His intent was to use the tourist income from the museum admission and sale of meteorite specimens to support his studies of the nearby Barringer Meteor Crater. In 1939, he had been granted a formal permit to continue his investigation of the crater. Although Nininger had originally accepted the idea that the meteorite lay in the bottom of the crater, he eventually was convinced by the calculations of **Forest Moulton** that the meteorite had exploded on impact. His discovery in 1948 of metallic spheroids in the area around the crater provided proof of the explosion theory. These spheroids were produced by condensation of the vaporized meteorite from the fireball that resulted from the impact. Thousands of tons of them, representing the majority of the mass of the impactor, are present in the soil surrounding the crater.

Rapid expansion of interest in meteorites inevitably led to differences of opinion and controversy. Nininger was a participant in several of these early disputes. In 1941, Lincoln LaPaz published a theory of meteorites composed of antimatter, a topic of high interest as popular knowledge of the emerging disciplines of atomic and nuclear physics began to reach the broader scientific community. LaPaz speculated that craters otherwise devoid of evidence of a meteoric origin might have been formed by antimatter or "contraterrene" meteorites that exploded as they annihilated normal terrestrial matter. Nininger properly invoked Occam's razor in pointing out that much more plausible explanations could be put forward to justify the existence of such craters. The dispute escalated in a series of rebuttals on both sides of the argument before gradually dying out during World War II as the society ceased all professional publishing activities. The debate over the contraterrene meteorites was only the first of several acrimonious disputes between Nininger and LaPaz. Their feud came to a head at the 1949 meeting of the Meteoritical Society, when Nininger and his wife Addie resigned from the society after a priority dispute erupted at the meeting. By that time, the society was polarized by the contentious debates which appear to have involved, in addition to technical issues, LaPaz's view that Nininger's effort to earn a living by selling meteorites was unprofessional and not in the best interest of science. Their fights nearly destroyed the society in the view of a number of members who witnessed the years of wrangling.

In late 1948, Nininger's permit to collect meteorites on Barringer Crater Company property was withdrawn, limiting his research on the crater to government land. Shortly thereafter, highway traffic was rerouted so that it no longer passed in front of the museum. In 1953, the American Meteorite Museum was moved to Sedona, Arizona, where it operated until Nininger retired in 1960.

The meteorites that Nininger collected are a permanent legacy to his work. About 20% of his collection was purchased by the British Museum of Natural History in 1958. The remainder of his collection was acquired by the Arizona State University [ASU] in 1960. The Nininger Meteorite Collection became the centerpiece of ASU's Center for Meteorite Studies, which currently houses the largest university-based meteorite collection in the world.

Nininger received an honorary Sc.D. degree from McPherson College in 1967 and an honorary Sc.D. from Pomona College in 1976. The Meteoritical Society honored him with its highest award, the Frederick C. Leonard Medal, in 1967. During his lifetime he wrote four books, three booklets, and more than 150 scientific papers.

On 5 June 1914, Nininger married Addie Delp, and their union resulted in three children, Robert, Doris, and Margaret. Addie was an integral part of Nininger's meteorite program, running the household (both at home and during extended field trips), acting as field assistant, helping to run the Meteorite Museum, serving as chair of the Committee on Catalog of the Society for Research on Meteorites, and coauthoring "The Nininger Collection of Meteorites." Although Addie died in 1978, Nininger continued to live a full life, attending the Meteoritical Society's 50th anniversary meeting in Mainz, Germany in 1983. Nininger's field program was carried on by his son-in-law Glenn I. Huss (husband of Margaret), who operated the American Meteorite Laboratory in Denver until his death in 1991 and who collected an additional 239 meteorites previously unknown to science.

Nīsābūrī: al-Ḥasan ibn Muḥammad ibn al-Ḥusayn Niẓām al-Dīn al-Aʿraj al-Nīsābūrī

Born **Nīshāpūr, (Iran)**
Died **(Iran), 1329/1330**

Niẓām al-Dīn al-Aʿraj al-Nīsābūrī composed several widely studied astronomy texts in the 14th century, which indicate the integration of astronomy within a tradition of religious scholarship in Islamic civilization. He was born into a Shīʿa family with roots in Qum.

The sources say little about Nīsābūrī's early life and education. By mid-1303, Nīsābūrī had begun to write *Sharḥ Taḥrīr al-Majisṭī* (Commentary on the recension of the *Almagest*), a commentary on **Naṣīr al-Dīn al-Ṭūsī**'s *Taḥrīr al-Majisṭī* (Recension of the *Almagest*) of **Ptolemy**. As was true for many commentaries in Islamic science, Nīsābūrī did not simply explain the meanings of the original text but included the results of his own work as well. In the *Sharḥ*, Nīsābūrī devoted much space to observations of the obliquity of the ecliptic and to **ʿUrḍī**'s work on instrument construction. Nīsābūrī also investigated whether Venus and Mercury had been observed to transit the Sun, an observation that would determine the position of the Sun with respect to Mercury and Venus. In 1304, Nīsābūrī arrived in Azerbaijan; by 1306 he was in Tabrīz, the largest city in Azerbaijan, where he completed the *Sharḥ*. In Tabrīz, Nīsābūrī also began to study with the astronomer **Quṭb al-Dīn al-Shīrāzī**.

Nīsābūrī completed his second major text, *Kashf-i ḥaqā'iq-i Zīj-i Īlkhānī* (Uncovering of the truths of the Īlkhānid astronomical handbook), in 1308/1309. The *Kashf*, a commentary on Ṭūsī's astronomical handbook entitled *Zīj-i Īlkhānī*, refers to the *Sharḥ*. Nīsābūrī wrote the *Kashf* right after the *Sharḥ* inasmuch as the *Kashf* focused on topics that were closely connected to the *Sharḥ*, such as the observation and prediction of planetary positions.

The *Tawḍīḥ al-Tadhkira* (Elucidation of the *Tadhkira*), a commentary on Ṭūsī's *al-Tadhkira fī ʿilm al-hayʾa* (Memento on astronomy), was Nīsābūrī's third and final text on astronomy. A cross-reference to a *Tadhkira* commentary in the *Sharḥ* shows that Nīsābūrī had begun to compose the *Tawḍīḥ* before he finished the *Sharḥ*.

In the *Tawḍīḥ*, Nīsābūrī investigated theoretical topics, such as non-Ptolemaic models for planetary motions, and topics that combined theory and observations, such as physical hypotheses that accounted for the observed variations in the obliquity of the ecliptic. Although the *Sharḥ* and the *Tawḍīḥ* evinced a mastery of the technical innovations of Islamic astronomy, Nīsābūrī did not make significant advances with the most difficult questions. Shīrāzī, however, did, and the weight of Shīrāzī's reputation may explain the coincidence of the date of the appearance of the *Tawḍīḥ* with the date of Shīrāzī's death in 1311.

Īlkhānid ministers patronized Nīsābūrī's scientific work. The Īlkhānids were the descendents of Hülegü Khān (died: 1265), who had patronized the construction of the famous observatory at Marāgha, Azerbaijan, where both Ṭūsī and Shīrāzī worked. Nīsābūrī dedicated the *Sharḥ* to Khwāja Saʿd al-Dīn Muḥammad ibn ʿAlī al-Sāwajī. Sāwajī was chief minister (along with Rashīd al-Dīn) under Īlkhānid Sultan Ghāzān (reigned: 1295–1304) and continued in that post until 1312 when Rashīd al-Dīn had him executed. Shīrāzī's acquaintance with Sāwajī would have provided a way for Nīsābūrī to gain Sāwajī's patronage. There is a 1309 copy of the *Kashf* dedicated to al-Sāwajī. Nīsābūrī dedicated the *Tawḍīḥ* to a certain ʿAli ibn Maḥmūd al-Yazdī.

Because the *Sharḥ* and the *Tawḍīḥ* were clearly written and intended for nonexpert astronomers, they became important components of a tradition of religious scholarship that included astronomy. Many manuscripts of the *Sharḥ* and *Tawḍīḥ* have ownership statements from the libraries of *madrasa*s (colleges of religious studies). Two reports attest to how the *Tawḍīḥ* was the most important text at **Ulugh Beg**'s *madrasa* in Samarqand for the study of the *Tadhkira*. Later works on Islamic astronomy, also with *madrasa* library ownership statements, refer to Nīsābūrī as *al-shāriḥ* (the commentator).

Nīsābūrī's best-known text, his Quran commentary entitled *Gharāʾib al-Qurʾān wa-raghāʾib al-furqān* (The curiosities of the Quran and the *desiderata* of the demonstration), demonstrates the importance of science for religious scholars. Nīsābūrī in general relied heavily on Fakhr al-Dīn al-Rāzī's (died: 1209) al-*Tafsīr al-kabīr* (The great commentary), but frequently disagreed with Rāzī about the use of science and philosophy *(falsafa)* to portray nature. The *Gharāʾib* reflected Nīsābūrī's scientific education and privileged the views of the natural philosophers *(falāsifa)*, while Rāzī had favored the positions of the theologians *(mutakallimūn)*. Through subtle rewordings and emendations of scientific detail, Nīsābūrī rebutted Rāzī's critique of science and *falsafa* in his portrayal of nature. Nīsābūrī completed *Gharāʾib* in 1329/1330, a date which the bio-bibliographers consider to be the date of his death.

Nishikawa, Joken

Born **Hizen, (Nagasaki and Saga Prefectures), Japan, 1648**
Died **Nagasaki, Japan, 1724**

Joken Nishikawa strove to identify the practical and theoretical merits and defects of both Chinese and European astronomy. He was the son of a provincial official from Nagasaki. Joken was his penname, but he also used Tadahide, among others, as a first name throughout his life. Nishikawa learned astronomy from Kentei Kobayashi and developed Confucian scholarship under the tutelage of Soju Nanbu. At the age of 50, he retired and devoted himself to astronomy and calendar studies. As his writings on astronomy, geography, and pragmatic matters received recognition, Nishikawa was invited to Edo (present–day Tokyo) by the eighth *Shogun* Yoshimune Tokugawa in 1719 to discuss his ideas about Eastern and Western knowledge.

Nishikawa's productivity was evident in a number of fields spanning the intellectual and purely philosophical as well as the pragmatic and empirical. He passed on a sense of scholarship to his children and others. Nishikawa's third son, Masayoshi (1693–1756), learned astronomy from his father and was assigned to the Tenmongata (Bureau of Astronomy) as an official astronomer in 1740.

It is easy to oversimplify the changes that occurred in scientific thinking in 17th-century Edo Japan. This period started with a strong reliance on Chinese classics and the theory of five elements as exemplified in **Gensho Mukai**'s commentaries on western astronomical concepts. As the century closed, these traditions were giving way to an amalgamation of study that might be termed "pure" astronomy in the modern sense.

Nishikawa was somewhat of a pioneer in this intellectual movement; his greatest contribution was to delineate matters of speculative philosophy relative to matters best studied by empirical means. In his 1712 work, *Tenmon Giron* (Discussions of the principles of astronomy), Nishikawa discussed the moral and physical dualism of "two heavens." One was the heaven of *Meiri,* which Nishikawa considered a realm of philosophical speculation and most similar to the more classic idea of Li. The second was that of *Keiki*, which he considered the realm of empirical investigation and most like that of the classic Qi.

While some have considered Nishikawa to be closed to western concepts and rigid in his Confucian upbringing, his work must be viewed within its context. His intellectual work helped to free his own empirical investigations as well as those of many who followed. In *Ryougi Shusetsu* (An explanation of collected materials on celestial and terrestrial globes, 1714), he concerned himself with geographical as well as astronomical phenomena from the standpoint of both empiricism and pragmatism. While not rejecting Chinese Classics, he felt that western-based methods in areas such as navigation were clearly superior to those that had been coupled with the more mystic sides of classical Chinese works. He maintained skepticism toward the traditions of ancient Chinese classics as well as European ideas that he felt did not conform to empirical verification. Nishikawa abandoned traditional portent astrology but just as strongly rejected the zodiacal astrology of the west. To those who followed, he advocated relying on empirical verification of postulates rather than blind acceptance of any dogma, whether from China or Europe.

(In this extensive article, Nakayama clarifies differences between epistemological views in Europe and Japan at the time Nishikawa lived. Whereas his explanation of Chinese classics require the reader to find supplemental material in order to grasp their full impact, this article provides a necessary base to understand the development of empiricism in the early Edo era as a mode of inquiry based on aspects of Aristotelian cosmology and pragmatic social need.)

Sugimoto, Masayoshi and David L. Swain (1989). *Science and Culture in Traditional Japan*. Rutland, Vermont: Charles E. Tuttle and Co. (This volume presents a comprehensive and scholarly view of scientific development in Edo Japan. Unlike many of his predecessors in Nagasaki, Nishikawa lived and worked in a time when the study of western concepts was somewhat freed from its previous relation to Christianity and the possible negative consequences of such a link. Sugimoto and Swain provide an excellent social backdrop for placing Nishikawa's work within a historical context.)

Nordmann, Charles

Born **Saint-Imier, now Bern Canton, Switzerland, 18 May 1881**
Died **Paris, France, 28 August 1940**

Charles Nordmann was an early pioneer of radio astronomy, the creator of multicolor photometry techniques, and a noted popularizer of astronomy. After receiving his *Licencié ès sciences* in 1899, he spent the following year at the Meudon Observatory, near Paris, under the directorship of **Pierre Janssen**. There, Nordmann began a study of the Sun, its activity, and effects on the Earth's magnetic field. From 1902 to 1903, he worked in the magnetic service at the Nice Observatory.

For his doctoral research at the University of Paris, Nordmann attempted to test the prediction of **Henri Deslandres** that the Sun ought to emit Hertzian (*i. e.*, radio) waves. He constructed a horizontal antenna, 175 m long, and installed it on the glacier of the Bossons (on Mont Blanc). Despite Nordmann's best efforts, no definite signals were ever received. Radio waves were not to be detected from the Sun until 1942. Nonetheless, Nordmann was awarded his degree (1903) under the guidance of **Jules Poincaré**.

That same year, Nordmann became an *auxiliaire* at the Paris Observatory and in 1905, was given the position of *aide-astronome*. **Maurice Löwy**, the director, encouraged him to pursue astronomical photometry. In 1906, as *astronome adjoint*, Nordmann devised a three-filter visual photometer that employed colored solutions to isolate the red, green, and blue regions of the spectrum. These experiments were performed on the observatory's 23-cm coudé telescope. His preliminary research investigated the apparent time differential (as a function of wavelength) on the observed minimas of eclipsing binary stars, a phenomenon independently described by **Gavril Tikhov**. Nordmann's observations were designed to test the potential dispersive powers of the interstellar medium on the speed of light, an idea ultimately rejected. However, recognition that the color index of a star (obtained by multicolor photometry) provided an effective measure of its surface temperature (given by the Planck curve) was first accorded to other observers.

During World War I, Nordmann worked in the field of sound-ranging techniques to locate the positions of German artillery. For these efforts, he was awarded the *Croix de guerre* in 1915 and made an *Officier de la Légion d'honneur* in 1918 (a *Chevalier* after 1912).

In 1920, Nordmann was appointed *astronome titulaire* at the Paris Observatory and began teaching at the École Supérieure des Postes et Télégraphes. He continued research in multicolor photometry and was succeeded in that effort by **Daniel Chalonge**. A significant part of Nordmann's work, however, was devoted to writing popular accounts of scientific discoveries, *e. g.*, *Einstein and the Universe: A Popular Exposition of the Famous Theory* (Paris, 1921).

Norton, William Augustus

Born **East Bloomfield, New York, USA, 25 October 1810**
Died **New Haven, Connecticut, USA, 21 September 1883**

William Norton wrote what was likely the earliest astronomical textbook produced in the United States; he was also a significant contributor to 19th-century ideas on the structure and behavior of cometary tails, terrestrial magnetism, and solar activity. By 1870, Norton went so far as to suggest, though without describing an exact mechanism, a link not only between solar coronal activity and Earth's auroral displays, but also with the observed activity in cometary tails.

Born the son of Herman and Julia (*née* Strong) Norton, William graduated in 1831 from the United States Military Academy at West Point, at that time arguably the premier technical, scientific, and engineering school in America. From 1831 to 1833, Norton served as both an artillery officer in the field during the Black Hawk War, and as an assistant professor of Natural and Experimental Philosophy at West Point. Norton left the army to become professor of natural philosophy and astronomy at the University of the City of New York (later renamed New York University) from 1833 to 1839. He then took a post as chairman (1839–1850) of mathematics and philosophy at the then struggling Delaware College (later renamed the University of Delaware), becoming interim president for a year (1850). A brief stint followed at Brown University, Providence, Rhode Island, as professor of natural philosophy and civil engineering. Norton finally settled down as professor of civil engineering at Yale's Sheffield Scientific School from 1852 until his death. He married Elizabeth Emery Stevens in 1839.

Seemingly inspired by the Great March Comet of 1843 (C/1843 D1), Norton acquired an early and lasting fascination with the behavior of comets, terrestrial magnetism, and the Sun. In 1844, Norton published an article, "On the Mode of Formation of the Tails of Comets," in the *American Journal of Science and Arts*. There, he explained the formation of cometary tails as originating from the evaporation of matter in the nucleus that was then swept away by the "repulsive force" of the Sun, which he suggested was magnetic rather than electrical in nature. Norton further explained the complexity of structures observed in cometary tails through a combination of the Sun's "repulsive force" *and* the centrifugal forces arising from a postulated rotating cometary nucleus. In 1859 and 1861, Norton presented evidence supporting his ideas from the widespread observations made upon Donati's comet (C/1858 L1). His studies of comets, terrestrial magnetism, and the Sun reached their fullest development in an 1870 paper, "The Corona Seen in Total Eclipses of the Sun." Here, Norton attempted to link phenomena of the corona and terrestrial magnetism by suggesting that the solar atmosphere itself was in fact an intense auroral display.

Norton was a natural and very successful teacher of astronomy; his textbooks reflected his experience in making the subject more understandable to students. *An Elementary Treatise on Astronomy in Four Parts* was one of the first astronomy textbooks published in America by an American astronomer. Norton's text, concentrating on both mathematical and practical aspects of the subject, was typical of those of the period, but differed in the greater degree to which it utilized illustrations and diagrams and in its more concise language as compared to others. This volume went through four editions, the last being published in 1881 as *Treatise on Astronomy, Spherical and Physical*. While at Yale, Norton authored a second textbook, *First Book of Natural Philosophy and Astronomy* (1858).

Norton's scientific interests extended to thermodynamics and molecular physics. He was elected a member of the American Philosophical Society, the National Academy of Sciences, and a corresponding member of the National Institute for the Promotion of Science.

Norwood, Richard

Born **Stevenage, Hertfordshire, England, 1590**
Died **Bermuda, 1675**

Richard Norwood was notable for his works on navigation and surveying. He wrote an autobiographical journal in 1639 in which he described his father (Edward?) as a gentleman who had suffered financial adversity. After Richard's formal schooling ended, he was apprenticed to a fishmonger at age 15. Contact with seafaring men started him on a series of voyages and adventures and initiated his devotion to the study of navigation, which he pursued by studying every book on the subject that came his way. Norwood married Rachel Boughton in 1622; of their four children, their second son, Matthew, followed his father's interests.

In the 17th century, much effort in astronomy and mathematics was motivated by the practical needs of navigation and surveying, areas to which Norwood made notable contributions. He carried out the first survey of Bermuda in 1614/1615, taught mathematics in London from 1627 to 1637, and, in a futile attempt to escape religious strife, returned to Bermuda where he continued teaching. In 1663, Norwood completed a second survey, which still stands as the basis of boundaries on the island.

Besides his journal and surveys, Norwood wrote at least seven books, covering aspects of fortification, mathematics, and navigation. He was arguably the first person to provide, in his *Trigonometrie* of 1631, clear explanations of great circle sailing and how to use logarithms in solving plane and spherical triangles. While this book also contained tables of the declination of the Sun based on tables by Edward Wright and of a few stars precessed from **Tycho Brahe**'s catalog, Norwood's only book dealing specifically with an astronomical topic was *A table of the suns true place ... made according to many exact observations of the Sunne, taken in severall Years last past in the Somer Islands* [Bermuda] (1656).

His very influential *Sea-mans Practice* (1637) contained Norwood's measurement of the length of a degree, or after multiplying by 360, the circumference of the Earth: 25,036 English miles, very close to the modern mean value of 24,873 miles. It stood as the best available value for a long time; **Isaac Newton** used it in the 1713 and 1726 editions of his *Principia*. To arrive at this remarkable result, Norwood measured the latitude of York and London, England, and found the distance between those cities by chaining and pacing, correcting for winding roads, ascents, and descents. The vital implication for navigators was that a nautical mile (1 min of latitude) was not the 5,000 ft. that they had traditionally used but rather 6,120 ft. as Norwood stated, very close to our present-day value of 6,080 ft. For astronomers, knowing the size of the Earth accurately is the first step in measuring extraterrestrial distances.

The fact that three of Norwood's books were reprinted as recently as the 1970s is an indication of the lasting interest he holds for scholars. These and his *Journal* (published in 1945) are accessible primary sources.

Novara, Domenico Maria da

Born **Ferrara, (Italy), 29 July or 1 August 1454**
Died **Bologna, (Italy), 15 or 18 August 1504**

Domenico da Novara was a teacher of **Nicolaus Copernicus**.

Domenico's family name was Ploti; they originated in Novara, a city in northwestern Italy, and later moved to Ferrara in northeastern Italy, where Domenico was born. He obtained both the title of Doctor of Arts and Doctor of Medicine, but we do not know at which university he studied. A possible record of his education is contained in an astrological text ascribed to Dominicus. The author testifies he was a pupil of **Johann Müller** (Regiomontanus), who traveled in Italy between 1460 and 1467 and later between 1472 and 1475, and lived in various Italian cities for long periods, including Ferrara. In any case, da Novara taught astronomy at Bologna University from 1483 till his death.

During this period da Novara was requested to publish prognostications for every year; many of them (in Italian and Latin) have survived and represent the only works we know by him. Apart from the astrological judgments they contain, the interesting parts of these publications are the preambles, where he discusses his scientific and philosophical theories.

The most famous was the prologue for the prognostication of 1489, in which da Novara presented his theory on the shift of the terrestrial polar axis. This was based on the comparison of the latitudes of Cádiz in Spain and several places in Italy, determined in his own time, with those reported in **Ptolemy**'s *Geography*. His conclusions were wrong, because they were based on unreliable data, but they are important because they represent one of the first attempts to suppose an Earth not at rest.

From later sources we know da Novara computed the obliquity of the ecliptic in 1492, obtaining a value very close to the actual one for this year.

Between the end of 1496 and the beginning of 1497, Copernicus registered in the Public Register of the German College in Bologna University. No record of his life in Bologna can be found in Copernicus's works, but **Rheticus** later reported that Copernicus lived in da Novara's house and helped him in his astronomical observations. Three of these observations are indeed reported by Copernicus: the observation of Aldebaran eclipsed by the Moon on 9 March 1497, and the observations of the conjunction of Saturn with the Moon on 9 January 1500 and 4 March 1500.

Numerov [Noumeroff], Boris Vasil'evich

Born **Novgorod, Russia, 17/29 January 1891**
Died **Orel, (Russia), 13 September 1941**

Boris Numerov was one of the principal organizers of Soviet astronomy after the 1917 Bolshevik Revolution. Both a theoretician and a practitioner, Numerov specialized in celestial mechanics, astrometry (positional astronomy), and gravimetry. He was the key Soviet figure in applied celestial mechanics before World War II. His principal legacy was the Institute of Theoretical Astronomy of the Russian Academy of Sciences, which has unfortunately closed very recently. Numerov was elected a corresponding member of the Soviet Academy of Sciences in 1929.

Numerov was a graduate (1913) of Saint Petersburg University and for a short time (1913–1915) a supernumerary astronomer at the Pulkovo Observatory. Like the renowned astronomer Sir **Arthur Eddington**, Numerov debuted as an observer with a zenith-telescope. From 1917 until his arrest in 1936, Numerov taught at Leningrad University where he was named a professor in 1924. In 1919, he founded and operated the Computing Institute, which, in 1923, was merged with the Astronomical–Geodetical Institute, also initiated by Numerov, to become the Leningrad Astronomical Institute. In 1943, the latter was transformed into the Institute of Theoretical Astronomy – the principal center for celestial mechanics research in Russia. Apart from his other duties, in 1926/1927, Numerov was the director of the Voeikov Main Geophysical Observatory and, in 1931–1933, chief of the Department of Applied Mathematics within the State Optical Institute. He fostered the development of the Abastumani Astrophysical Observatory in Georgia.

Numerov arranged computations for the *Astronomicheskii Ezhegodnik SSSR* (USSR Astronomical Almanac; first issued in 1921), which provided annual information on astronomical events of all kinds. He produced a number of astronomical tables and handbooks. He paid full attention to the data obtained by astrometrical and gravimetrical instruments and strove to improve them. Numerov performed significant applied research, including gravimetrical measurements to identify potential ore and oil deposits. He initiated the creation of an annual ephemeris of minor planet elements and positions, published to this day. Numerov also developed a method for using minor planet data to determine the Equator and equinox for star catalogs. His disciples worked in many institutions of the then USSR.

Internationally known for his scientific and organizational activities, Numerov was arrested (along with many other Leningrad astronomers, including Pulkovo's director, **Boris Gerasimovich**), at the beginning of Stalin's Great Terror. Imprisoned and tortured as a supposed saboteur and fascist spy, Numerov was executed by a firing squad in prison, before the Nazis captured the city. Many aspects of Numerov's heritage are visible even today. Minor planet (1206) Numerowia was named for him, as is a crater on the farside of the Moon.

Nunes, Pedro

Born **Alcácer do Sal, Portugal, 1502**
Died **Coimbra, Portugal, 11 August 1578**

Pedro Nunes is chiefly known for his theoretical work on celestial navigation, and his translations into Portuguese of works by **John of Holywood** (Sacrobosco) and **Ptolemy**. Nunes was the son of Jewish parents converted to Christianity. During his youth, Portugal was a leader in voyages of exploration and discovery; in the year of Nunes's birth, Vasco da Gama undertook his second voyage to India, and Brazil had already been discovered 2 years earlier. In 1517, Nunes started his university studies in humanities, philosophy, and medicine at the University of Lisbon, and, by 1521/1522, he had gone to Salamanca to study at the university there. In Salamanca Nunes married Dona Guiomar Aires in 1523, and they had six children (two boys and four girls).

Nunes returned to Portugal in 1524/1525, and on 16 November he was named cosmographer of the kingdom. At that time he was Doctor of Medicine. Nunes's nomination was due to his wide knowledge of astronomy – the course of medicine included studies of mathematics and astronomy, required for the practice of astrological medicine.

At the University of Lisbon, Nunes was in charge of lecturing on the subjects of moral philosophy, logic, and metaphysics. In 1532, he went to Évora as tutor of the Infants D. Luís and D. Henrique, future cardinal and king of Portugal. Another pupil was D. João de Castro, who would become one of the greatest Portuguese navigator pilots and was the future Viceroy of India. On 16 October 1544 Nunes was named lecturer of mathematics at the University of Coimbra, where he had been transferred from Lisbon in 1537. He lectured on that subject until his 25th year jubilee in 1562.

On 22 December 1547, Nunes was named First Cosmographer of the kingdom. He became so famous that in the year before his death, he was consulted by Pope Gregory XIII about his project of calendar reform. Some studies about Pedro Nunes state that he had been **Christoph Clavius**'s professor when the latter attended classes at the College of Arts at Coimbra in 1556/1557, but such information is erroneous.

Nunes's work is vast, not just limited to mathematics and the nautical sciences; he also wrote poetry. Nunes was considered the greatest Portuguese navigator of the Renaissance, and yet he did not set foot overseas. His fame was due to his scientific work, mainly nautical. His worries about the practical workability of knowledge showed a preponderance of the utilitarian mind over the speculative one. To him, "science" had its sphere of action limited to the "certain and true" things. This practical aspect is seen in the style Nunes used to write out his texts and notes, endowed with great clarity and rigor concerning the presentation of rules and the demonstration of theorems.

Nunes's work can be divided into two major groups: The first is translations and annotations, the second, original works.

Nunes's *Tratado da Sphera com a Theorica do Sol e da Lua* and the *1° Livro da Geografia de Ptolomeu Alexandrino* include the annotated translations of three works. The *Tratado da Sphera* is the translation of the book of Sacrobosco with his own notes attached; the *Theorica do Sol e da Lua* comprises the translation of the first three subjects of **Georg Peurbach**'s *Theoricas dos Planetas*, with 17 added notes of his own. The third translated work is the first book of geography by Ptolemy, also with notes by Nunes.

After some questions posed by the Portuguese navigator Martim Afonso about the direction and course line of a ship at sea, Nunes was the first to develop the theory of loxodromics, demonstrating that the line drawn by a ship at the sea's surface, when it cuts all the meridians on the same oblique angle, is not a great circle, as they used to think, but a spheric spiral that rounds the Earth's poles an infinite number of times. He also demonstrated that the only circular course lines are the meridians and the parallels that equal the angles of the course of 0 and 90°. Consequently, he wrote *Tratado sobre certas duvidas da navegação que Martim Afonso propoz ao Author*, as well as *Tratado em defensão da Carta de marear com o regimento da altura*, where Nunes also demonstrated a new way to calculate the distance to the pole.

One of Nunes's masterpieces is *De Crepusculis Liber unus; Allacen Arabis vetustissimi Liber de Crepusculis*. In this work he solved the problem of how to find the day with the smallest twilight, and also presented a method for measuring angles with more accuracy. At that time, in order to measure the altitudes of the stars and planets, astronomers used the cross-staff, the quadrant, and the plane astrolabe, all of which devices lacked precision. In his work *De Regulis et Instrumentus*, Nunes described his invention thus:

> … due to the smallness of the device, it is not possible to subdivide its parts, therefore it is not possible to estimate the part of the height that should be needed to add to the whole number of degrees. It would be convenient to describe, inside the device's surface area, 44 concentric circles, dividing the external quadrant in 90 equal parts, the closest in 89, the following in 88, and so on, always in the same sequence.

Later, Nunes's idea would be improved by Jacob Curtio and Clavius, but it was Pierre Vernier who made possible the practical workability of this solution to the problem of reading fractions of angles, and whose name is associated with it today.

Nušl, František

Born **Jindřichův Hradec, (Czech Republic), 3 December 1867**
Died **Prague, (Czech Republic), 17 September 1951**

František Nušl was one of the founders of modern Czech astronomy. He was the son of Ignác Nušl and Františka Nušlová (*née* Novotna) and was educated at the Czech Charles-Ferdinand University in

Prague (bachelor of philosophy 1905). He and his wife Aloisie (*née* Doležalová) had two sons and a daughter. Nušl taught mathematics and physics at a high school before receiving his Ph.D. and was appointed an associate professor of mathematics at the Czech Technical University, Prague (full professor: 1911). He was director of the National Astronomical Observatory in Prague from 1918 and professor of astronomy at Charles University until his retirement in 1937. Nušl served as president of the Czechoslovak Astronomical Society (1922–1948) and vice president of the International Astronomical Union (1928–1935).

Nušl's work was largely in practical astronomy and construction of astrometric instruments. In 1899, he constructed the first model of a mirror astrolabe with an artificial mercury horizon to measure the time of star transit over the almucantar (parallel of altitude) using the method of equal altitudes. A professional instrument, later called a circumzenithal, was constructed in 1901 in cooperation with Josef Jan Frič, an amateur astronomer, engineer, and owner of a fine mechanics and optics factory in Prague. Nušl used the instrument in a photographic mode in 1907 to measure short-term variations of refraction of light in the atmosphere. He and Frič presented a portable model at the International Union of Geophysics at its 1924 general assembly in Madrid, Spain, and it was later used in international longitude measurements and to determine astronomical coordinates of the Czechoslovak fundamental triangulation network. During the same period, he designed two other less successful instruments with mirrors and mercury horizons: A diazenithal (to measure the time a star crosses a particular azimuth) and a radiozenithal (to measure the time a star crosses a great circle, inclined to the horizon). Nušl also improved the state of micrometers and regulators in use at his observatories, made use of the then new radio telegraphic signals for the time service, and applied the instruments to problems of geodesy.

Beginning in 1898, Nušl assisted Frič in building a private observatory at Ondrejov, near Prague. It was donated to the state in 1928, merged with the National Astronomical Observatory (with Nušl as the first director), and is now the home of the Astronomical Institute of the Academy of Sciences of the Czech Republic. Nušl was also active in visual observations of meteors and in popularization of astronomy and physics. His publications appeared in Czech, German, and French.

O

O'Connell, Daniel Joseph Kelly

Born **Rugby, Warwickshire, England, 25 July 1896**
Died **Rome, Italy, 14 October 1982**

The O'Connell effect was discovered by Daniel O'Connell, British–Irish director of the Vatican Observatory. It is a variation in the period of eclipsing binary stars. Tidal effects, star spots, circumstellar disks, and other models have been proposed to explain it.

Odierna [Hodierna], Giovanbatista [Giovan Battista, Giovanni Battista]

Born **Ragusa, (Sicily, Italy), 13 April 1597**
Died **Palma di Montechiaro, (Sicily, Italy), 6 April 1660**

Giovanbatista Odierna was an early observer of Jupiter and Saturn and one of the first to discover and describe nebulae. He was the son of Art Vita Dierna, who was either a mason or a shoemaker according to different sources, and Serafina Rizo. Very probably, his family lived under inferior, more probably poor conditions. While mostly referred to as Odierna, it seems that the man himself always used"Hodierna" as his name; it is not completely clear why and how he changed the name.

Odierna was self-educated, at least in science. As a young man, he observed the three comets of 1618/1619 (C/1618 Q1, C/1618 V1, and C/1618 W1) from Ragusa, with a Galilean type telescope and fixed magnification 20. He became a Roman Catholic priest and was ordained at Syracuse, Sicily, in 1622. From 1625 to 1636, Odierna served as a priest in Ragusa, and taught mathematics and astronomy at his hometown.

Odierna was an enthusiastic follower of **Galileo Galilei**. In 1628 he wrote the *Nunzio del secolo cristallino*, an appraisal of Galilei's *Siderius Nuncius*. Odierna was particularly impressed by Galilei's resolution into stars of the Milky Way and the "nebulae" like Praesepe; this generated a lifelong interest in nebulae, although most of his astronomical work concentrated on the bodies of the Solar System.

In 1637, Odierna followed Carlo and Gulio Tomasi, the Dukes of Montechiaro, to the newly founded Palma di Montechiaro. They gave him a house and a piece of land on which to live and funded his publications; he served them first as a chaplain and then as a parish priest. In 1644, Odierna earned a doctorate in theology. In 1645, he was named archpriest, in 1655 court mathematician.

Besides his duties as priest, Odierna practiced astronomy, as well as natural philosophy, physics, botany, and other sciences. He studied light passing through a prism and formulated a vague explanation of the rainbow. He developed an early microscope and studied, for example, the eyes of insects and the fangs of vipers. He also studied meteorological phenomena.

Odierna's contributions to astronomy, though interesting and remarkable in particular if one takes his isolated life into account, have had at best little impact, because his publications had only limited circulation and were hardly known outside Sicily. Therefore, standard tracts on the history of astronomy rarely spend more than a few lines on this early priest astronomer. Also, his astronomy always tended to be mixed up with astrology. In 1646 and 1653, Odierna observed Saturn and created drawings showing the planet with its ring quite correctly; he had a short correspondence with **Christiaan Huygens** on this subject around 1656. His *Protei caelestis vertigines sev. Saturni systema*, published in 1657, is among his best-known publications.

In 1652, Odierna observed eclipses of Jupiter's satellites, as well as the passages of their shadows over the disk of the planet. In 1656, he published in the *Medicaeorum Ephemerides*, probably his best-known work, the first published ephemerides of the Galilean satellites, based on an improved theory of the motion of Jupiter's moons by the contribution of three types of periodic disturbances – analogous to contemporary planetary theory. In his 1656 *De Admirandis Phasibus in Sole et Luna visis*, Odierna gives a treatise on the appearance of the Sun and the Moon, including sunspots and eclipses.

Perhaps Odierna's most interesting work is his 1654 *De systemate orbis cometici; deque admirandis coeli characteribus*, which unfortunately was forgotten and ignored until it was recovered by G. Serio *et al.* (1985). Odierna thought there were profound differences between comets and nebulae: Because of the motion and changing appearance of comets, he thought them to be made up of a more terrestrial matter, while nebulae should be made up of stars, and thus *Lux Primogenita*. In the first part he follows Galilei's ideas on comets. In the second, more interesting part, he describes and lists 40 nebulae he had observed, with finder charts and some sketches, which Odierna classifies according to their resolvability into stars as Luminosae (star clusters to the naked eye), Nebulae (appearing nebulous to the unaided eye, but resolved in his telescope), and Occultae (not resolved in his telescope). About 25 of them can be identified with real deep-sky objects (mostly open clusters); the others are either asterisms or insufficiently described for identification.

Today, the original discovery of between ten and 14 deep-sky objects, and two independent rediscoveries (of the Andromeda and the Orion Nebula), are attributed to Odierna. The formal list includes: the Alpha Persei cluster (Melotte 20), NGC 6231, M6, NGC 6530, M36, M37, M38, M47, M41, and NGC 2362, as well as probably M33, NGC 752, M34, and NGC 2451 and perhaps NGC 2169 and NGC 2175. Odierna ‘s deep-sky discoveries occurred within a larger project he endeavored, compiling a sky atlas, *Il Cielo Stellato Diviso in 100 Mappe*, a work he never completed.

Oenopides of Chios

Born **Chios, (Khíos, Greece), *circa* 490 BCE**
Died ***circa* 420 BCE**

Little is known about the life of mathematician and astronomer Oenopides; his place of birth in Chios is reasonably well documented, and there is circumstantial evidence indicating that he spent time in Athens as a young man.

Oenopides made a number of contributions to mathematics and astronomy. He is thought to have settled on the value of 24° as an estimate for the angle that the ecliptic makes with the celestial equator. (**Eudemus** attributed the concept of the ecliptic to Oenopides, although the Babylonians were aware that the apparent path of the Sun through the zodiacal constellations was inclined to the plane of the Equator.) This is uncertain, because there is no explicit reference to this estimate in the Greek sources; however, **Proclus**, discussing Euclid IV, 16, says that the construction of a 15-sided regular polygon within a circle was included because it is useful in astronomy. (The 360° division of the circle was not yet developed as a common usage, and this figure would generate central angles of 24°.) It is possible that Oenopides originated both the estimate (24°) and the construction of the 15-sided figure. **Plato** appears to allude to Oenopides's research on the ecliptic when he includes him in the *Erastae*.

Oenopides seems to be best known for his research on the Great Year. As knowledge of astronomy progressed in classical times, this concept came to refer to the period after which the motions of the Sun, the Moon, and all of the planets would repeat themselves. Aelian and **Aëtius** give Oenopides credit for an estimate of 59 years for the period of the Great Year; it is not clear which, if any of the planets were intended to be accounted for within this period. It seems likely that Oenopides made his estimate based on a lunar month of roughly 29 and one-half days, and a 365-day solar year. This could quickly lead to the ratio of 730 lunar months for every 59 years; since 59 is a prime number, it would then provide a possible figure for the Great Year period. It appears that Oenopides attempted to confirm this estimate based on observations throughout his life.

Oenopides's contributions to mathematics may have a wider significance as well. In his commentary on Euclid's *Elements*, Proclus cites Oenopides as the originator of two theorems (I.12 and I.23), both having to do with elementary constructions. Ivor Bulmer-Thomas in the *Dictionary of Scientific Biography* makes the interesting conjecture that "it may have been [Oenopides] who introduced into Greek geometry the limitation of the use of instruments in all plane constructions … to the ruler and compass." This may be significant for astronomy because it suggests that Oenopides developed a serious interest in the methodology of mathematics, with a particular focus on the distinctions between theoretical and applied mathematics.

Offusius, Jofrancus

Born **Geldern, (Nordrhein-Westfalen, Germany), before 1530**
Died **possibly Paris, France, after 1557**

Astrologer Jofrancus Offusius is an almost unique example of a scholar in the French cultural area who studied the technical details of **Nicolaus Copernicus**'s *De revolutionibus* in the first two decades after its publication in 1543. Offusius's examination of Copernicus's ideas is well documented by the annotations and by appended manuscript pages in his copy of *De revolutionibus* (now preserved in the National Library of Scotland), and his influence is attested by eight further copies of his annotations made by his students or by their students. The longest annotation occurs in the most complex part of the book, where Copernicus deals with the lunar parallax. While his major criticism there is marred by an erroneous start, Offusius's series of short corrections to the later part of the paragraph demonstrate that he could handle the detailed calculations with more accuracy than Copernicus did.

Very few details are known regarding Offusius's life. **Girolamo Cardano** refers to Franciscus Offusius Geldrensis when discussing cipher codes in his *De rerum varietate* (Basel, 1557), from which we deduce his place of birth. Offusius records in his *De revolutionibus* that he had been in Seville, Spain in 1550; later he was in England for a year under the patronage of the Elizabethan *magus* **John Dee**. In 1557, Offusius published in Paris *Ephemerides* for that year based on calculations derivative from Copernicus's work. It was during his time in Paris that he must have operated an atelier for astronomy students including Jean Pierre de Mesmes, who worked with Offusius for some time between 1552 and 1557. In one of his own annotations, de Mesmes referred to his teacher as "not one of the common astronomers." Circumstantial evidence suggests that the 16th-century central European astronomers **Paul Wittich** and/or **Tadeá Hájek z Hájku** saw Offusius' own annotated copy, for Wittich's own annotations show influence from that specific copy and include the name "Jofrantius" in the margin.

Pontus de Tyard, a 16th-century astronomer and philosopher, mentions meeting Offusius in Dieppe, presumably in 1556, and remarked that his tables (ephemerides) were "different from all the rest." In the preface to his *Ephemerides*, Offusius indicated that he had worked on planetary influences for 14 years, and had become increasingly dissatisfied with the *Alfonsine Tables,* which he rejected as worthless. Apparently for January 1557, Offusius used the Copernican *Prutenic Tables*, but for the remainder of the year he employed some not very successful modification of them. In the book's preface, he announced that Mercury would twice pass in front of the Sun that year, predictions that proved quite wrong.

After 1557 Offusius disappeared from the scene, but in 1570, his widow published *De divina astrorum facultate*, a book that deals with planetary distances, a topic rarely addressed between Copernicus's *De revolutionibus* and **Johannes Kepler**'s *Mysterium cosmographicum* of 1596. The preface to the book is dated 1556. Using a geocentric framework, Offusius attempted to find an esthetically pleasing principle to establish the planetary distances to be used for his theory of astrological aspects. He worked within the traditional notions that the Sun was 19 times further than the Moon, and that Saturn was about 19 times farther than the Sun. He then had to insert two other planets within each of these two intervals, which he achieved with proportional spacing so that the ratio of the distances of each pair was the same, 8/3 (nearly the cube root of 19). His starting point must have been the solar distance of 576 terrestrial diameters, the square of 24, whose beauty pleased him greatly. In an obscure way Offusius argued that his proportions were related to numbers associated with the Platonic polyhedra, a feature that **Tycho Brahe** commented on favorably and that no doubt helped persuade him to take seriously Kepler's later use of these polyhedra to explain the spacing of the planets in the Copernican system.

Öhman, K. Yngve

Born **Stockholm, Sweden, 27 March 1903**
Died **Lund, Sweden, 17 June 1988**

Yngve Öhman, the founder of Swedish solar astronomy, designed, built, and used the first narrow-band interference filter (the birefringent quartz polarizing monochromator) useful for monitoring solar activity. The son of Karl E. and Ida (*née*) Cassel Öhman, he saw comet 1P/Halley at age seven and built a small telescope by 17. Öhman began studies at Uppsala University in 1922, receiving a Ph.D. in 1930 for work with **Bertil Lindblad** on luminosities and distances of stars. Other important early influences at Uppsala were **Östen Bergstrand**, **Hugo von Zeipel**, and **Knut Lundmark**. The thesis work was done partly with spectrograms taken at the Mount Wilson Observatory, California, by **Milton Humason** and **Paul Merrill** and brought back to Sweden by Lindblad. Öhman recognized that the spectral absorption features due to CaH at 6365 Å and to neutral calcium at 4227 Å were much stronger in dwarf stars than in giants of the same (relatively low) temperature, and so could be used to estimate stellar intrinsic luminosities (and so stellar distances) even in quite low-dispersion spectra.

Öhman held positions at Stockholm Observatory most of his life (1930–1938 as assistant or observer, with a year away at Mount Wilson in 1933/1934; as observer at the Saltsjöbaden Observatory of Stockholm 1939–1953; and as occupant of a personal chair of astrophysics 1953 to 1968, when he retired). He also spent brief periods at Uppsala, Boulder, Colorado, USA and Mount Wilson again. As early as 1929, Öhman had predicted that the light from solar prominences and from comets should be polarized because of fluorescence, and was eventually able to verify this in both cases (comet C/1940 R2, and the solar case within days of commissioning his new filter).

Robert Wood first showed that one could separate out a single spectral feature using a sandwich with a quartz slab between two polarizing filters. It is a property of quartz that two perpendicular polarizations of light travel at different speeds, and so arrive at the other side of the slab out of phase, producing an interference pattern, in which some wavelengths come through at almost full strength and others are not transmitted at all. Öhman extended this idea to a "layer cake" with four quartz slabs (relative thickness 1:2:4:8, all of order millimeters) and five films of Polaroid around and between them. The slab thicknesses were chosen so that the 6563 Å wavelength of hydrogen came through, and the next transmission peaks were nearly 1000 Å away and so could be blocked by ordinary colored glass filters. Such a device picks out a bandwidth of about 50 Å. Thus it is not as good a monochrometer as the spectroheliograph of **George Hale** and **Henri Deslandres**, but has the enormous advantage that you can image the whole Sun at once, instead of one thin slice at a time. The filter can be tuned to somewhat different wavelengths by tilting it, and it automatically acts as a polarimeter as well. Such devices are widely used in solar observatories today. The idea had occurred somewhat earlier to **Bernard Lyot**, but he had not yet constructed a device at the time Öhman started using his.

Öhman's main field was observational solar astronomy. He developed solar patrols. At first, these observations were performed at the Satlsjöbaden Observatory. However, because of the weather conditions at Stockholm, setting up a solar observatory elsewhere was the goal. Together with **Donald Menzel**, Öhman first studied the conditions for solar research in northern Sweden. The region around Abisko research station was a better site than Stockholm, and for a while the alternative of Abisko seemed viable, but more favorable conditions were found on the island of Capri, where a station for solar research was established by Öhman and the Royal Swedish Academy of Sciences. Öhman's interest in Capri as a site for solar observations had been aroused when Axel Munthe's villa *San Michele* had been willed to the Swedish state and opened for use by scientists and artists. Öhman also developed good contacts with the foundation Centro Caprense di Vita e di Studi, from which initial support was given.

Regular observations at Capri began in the summer of 1952. Soon the station ran a continuous solar flare patrol. Flares, prominences, and other solar phenomena were studied with photometric and spectroscopic methods. Several Swedish astronomers worked at the Capri station as assistants, gaining important training in solar observation techniques. The best known of Öhman's students in solar and stellar astronomy are Jan Stenflo, Kirsten Fredga, and Dainis Dravins.

Öhman's involvement in international astronomy began as early as 1938, when he chaired the local organizing committee for the 1938 general assembly of the International Astronomical Union [IAU] in Stockholm, and he was president of an IAU solar commission in 1952–1955. Both Öhman and the Capri observatory were active in the International Geophysical Year (1956–1958), and he served on committees for the European Space Research Organization and the journal *Solar Physics*. The Royal Swedish Academy of Sciences elected him to membership and awarded one of the several medals Öhman received for his contributions to international solar astronomy.

Öhman's interests were not confined to solar astronomy: The construction of scientific payloads for use on sounding rockets, the influence of geomagnetic storms on power distribution systems, solar energy, and other alternatives to fossil fuels were only some of the fields in which he worked. He held several patents. Öhman's archive shows that he was active with scientific and technological questions up until his death.

Öhman's papers are at the Center for the History of Science, Royal Academy of Sciences, Stockholm.

Olbers, Heinrich Wilhelm Matthias

Born **Arbergen near Bremen, (Germany), 11 October 1758**
Died **Bremen, (Germany), 2 March 1840**

Credited with the independent discovery of four comets and two of the first four asteroids discovered, physician Heinrich Olbers was one of the leading astronomers of the early 19th century. Functioning as an amateur in his private observatory, Olbers was widely respected by his astronomical colleagues. Though he neither discovered nor resolved Olbers' paradox, it is invariably given his name.

Young Olbers lived with his father, Johann Jürgen Olbers, a Protestant minister, and 15 brothers and sisters. His interest in astronomy originated at the age of about 14, but due to a limited curriculum in the exact sciences at the humanistic Gymnasium in Bremen, he was forced to study mathematics on his own. Olbers's first attempts in astronomy were the calculation of the solar eclipse of 1774, the calculation of the orbit of comet C/1779 A1 (Bode) from his own observations (in 1779), and a discovery of a comet (C/1780 U1, independently discovered by Jacques Leibax Montaigne (1716–1785?) of Limoges, France. While studying medicine at Göttingen University, Olbers also attended lectures in mathematics and physics. In medicine he specialized on ophthalmology; after graduation in 1781 he moved to Vienna, where he spent one year practicing in hospitals. During that year Olbers also visited the Vienna Observatory and enjoyed life in the aristocratic society.

Toward the end of 1781 Olbers opened a private ophthalmologic practice in Bremen and soon attracted many patients. He slept only 4 hours a day, reserving his nights for astronomical observations. During the next 30 years he was able to practice medicine while working in astronomy at a level comparable to the best professional astronomers. In 1820 Olbers decided to devote all his time to astronomy, so he closed his medical practice.

Olbers converted one part of the second floor of his Bremen house into an observatory, the equipment included movable telescopes and comet seekers made by such renowned instrument producers as Dollond and Fraunhofer. By fortunate chance, one of the best-equipped private observatories in the region was in nearby Lilienthal. After 1786, Olbers collaborated with its owner, **Johann Schröter**. **János von Zach** visited Olbers in Bremen as well as the Lilienthal observatory in September 1800 and published a description of both observatories in his journal *Monatliche Correspondenz* in 1801. During that visit, on 20 September, Schröter, Zach, Olbers, **Carl Harding,** and about 20 other outstanding astronomers from Germany and the rest of Europe founded *Vereinigte Astronomische Gesellschaft*, the first astronomical society in the world.

When Olbers discovered the comet of 1796 (C/1796 F1), he elaborated a new method for calculating its parabolic orbit using only a few observed positions. The methods developed by **Joseph-Jérôme de Lalande** and **Pierre de Laplace**, common at that time, were based on subsequent approximations, and lead often to erroneous results. However, Olbers's method was much simpler, satisfactorily precise, and reliable. Zach published it in Weimar (1797) under the title "Üeber die leichteste und bequemste Methode, die Bahn eines Kometen aus einigen Beobachtungen zu berechnen." The Olbers method was widely adopted and used throughout the 19th century. Olbers computed about 20 orbits of comets, including an orbit for comet C/1798 X1 (an independent discovery by Olbers, but credited to **Alexis Bouvard**), as well as for the periodic comet 13P/1815 E1 that he discovered.

When the first-known minor planet (1) Ceres disappeared behind the Sun, astronomers were not successful in finding it when it emerged from the Sun's glare a few months later. **Carl Gauss** developed a new method of determination of an elliptic orbit, and computed the expected positions. On 1 January 1802, Olbers found Ceres near the place given by Gauss, exactly one year after the original discovery of Ceres by **Giuseppe Piazzi** in Palermo. As a result, a close friendship developed between Olbers and the younger Gauss. Olbers discovered two other minor planets – (2) Pallas in 1802 and (4) Vesta in 1807 – the third, (3) Juno, was found at Lilienthal by Harding.

In 1812, Olbers suggested that a comet's tail was composed of particles driven away from the nucleus of the comet in the anti-solar direction by repulsive forces from the Sun. Olbers supposed that the forces were electrical in nature. He also offered the insight that the direction and orbital speed of the comet as well as the gravitational influence of the Sun all had a marked influence on the morphology of the comet's tail.

The question "Why the sky is dark at night?" had earlier been raised by **Johannes Kepler**. He pointed out that in the infinite space, uniformly filled by stars, every line of sight had to end on a surface of a star, so that the sky had to appear as bright as the stellar surface, *e. g.*, as the Sun. Like **Edmund Halley** and **Jean Loys de Chéseaux**, Olbers came independently to the same conclusion. He published it in 1823 under the title "Über die Durchsichtigkeit des Weltraums" in *Berliner astronomisches Jahrbuch fuer das Jahr 1826*. Since that time the problem has been referred to as Olbers' paradox. The contemporary (not correct) solution assumed slightly absorbing matter dispersed between the stars, but the correct solution (the finite age and energy density of the Universe) was later given as a part of relativistic cosmology.

In 1837, Olbers pointed out, based on his study of the Leonid meteor showers of 1799 and 1833, that maxima in the strength of that shower might occur on intervals of 3, 6, or 34 years and predicted another great storm in 1867. However, though he studied other celestial phenomena, Olbers's main interest continued to be comets. His preoccupation with the subject caused him to assemble one of the finest libraries on the history of astronomy of its time. With a particular emphasis on cometography, the Olbers library was thought to be "essentially complete" and formed a valuable addition to the library of the Pulkovo Observatory when purchased by **Friedrich Struve** from the Olbers estate.

Olbers himself saw his major contribution to astronomy in the fact that he influenced the young **Friedrich Bessel** (later director of the observatory in Königsberg) to enter a career as a professional astronomer. Bessel's interest in astronomy was aroused after listening to Olbers's lectures. Later, after meeting Olbers on the street in 1804, Bessel showed him his calculations for the orbit of Halley's comet (IP/Halley) based on **Thomas Harriot**'s observations in 1607. Impressed by the young man's self-taught mathematical ability, Olber's suggested some additions and arranged to have the computations published.

In two marriages, Olbers was the father of a daughter and a son. His first wife, Dorthea Köhne, died while giving birth to their daughter in 1786, only a year after their marriage. Olbers remarried in 1789, and Anna Adelheid Lurssen gave birth to a son. Anna died in 1820.

Olcott, William Tyler

Born **Chicago, Illinois, USA, 11 January 1873**
Died **George's Mills, New Hampshire, USA, 6 July 1936**

Tyler Olcott founded and nurtured the American Association of Variable Star Observers [AAVSO], served as its secretary for nearly 25 years, and wrote a number of popular books on astronomy.

Olcott, the son of William Marvin and E. Olivia (*née* Tyler) Olcott was raised in Norwich, Connecticut, in the ancestral Tyler home in which he lived for his entire life. Educated at Trinity College, Hartford, Connecticut, Olcott studied at the New York Law School. Though admitted to the state bars in New York and Connecticut, he never practiced law as a career. Olcott married Clara Hyde of Yantic, Connecticut, in 1902; they had no children.

Olcott's introduction to astronomy occurred during a 1905 summer vacation, and he was instantly captivated by the night sky. As he taught himself the stars and constellations he wrote a book on the subject of the naked-eye sky, *A Field Book of the Stars* published in 1907. This was followed by the acquisition of a small telescope with similar results: *In Starland with a 3-inch Telescope*, reflecting his deepening appreciation of the night sky, was published in 1909. After acquiring skills with the telescope, Olcott sought out an application of those skills in the service of astronomy. He found an ideal application in variable star astronomy as he chanced upon a presentation on the subject at a meeting of the American Association for the Advancement of Science. There, he heard **Edward Pickering** describe a scientific need for amateur observers. When Olcott wrote to Pickering asking for more information, the Harvard College Observatory [HCO] director dispatched one of his staff, **Leon Campbell,** to Connecticut to train Olcott and deliver the necessary charts and reporting forms to him. Olcott was so delighted with the experience that he wrote an article describing both the techniques and the need for observers for *Popular Astronomy* and volunteered to facilitate the work of other interested amateur observers. That invitation led Frederick Leonard (1896–1960) to recruit Olcott as the variable star section leader for the Society for Practical Astronomy [SPA]. In addition, with encouragement from Pickering, Olcott undertook the formation of the AAVSO in 1911 and within a year had resigned from the SPA.

From 1911 until his death, Olcott voluntarily served as the recording secretary of the AAVSO and in various other capacities, corresponding with amateur and professional astronomers and prospective new members. He traced and distributed hundreds of variable star charts, instructed observers, acted as liaison between the variable star observers and HCO, compiled AAVSO variable-star observations and notes for use by Pickering and for publication each month in *Popular Astronomy*, and gave numerous public talks on astronomy and variable star observing. In the process Olcott established contacts with noted astronomers at home and abroad.

Olcott published the AAVSO's initial report of 208 observations in the December 1911 issue of *Popular Astronomy*. By the end of its first year the AAVSO had published over 6,000 observations of variable stars in *Popular Astronomy*. From that point on, the number of observations being sent to the AAVSO each year rose dramatically: to 11,600 in 1912; 17,400 in 1917; 19,300 in 1921; and 26,900 in 1924. Under Olcott's guidance, the AAVSO grew very rapidly from a handful of amateur and professional observers in 1911 to about 480 observers in 1936. By the time Olcott died, the AAVSO was receiving nearly 55,000 observations per year.

With rapid growth from 1911 through the 1920s and 1930s, and under the guidance and encouragement of Olcott, the AAVSO membership gained a strong sense of identity and personality. Olcott organized the AAVSO's first regular annual meeting at HCO in November 1915. In October 1918, the AAVSO was incorporated under the laws of the Commonwealth of Massachusetts. HCO then provided a room for the AAVSO's headquarters, and the organization continued to grow. United by their love of astronomy, telescope making, and variable star observing, the AAVSO members' common interest was strengthened by their sharing the common purpose and scientifically important goal of providing researchers with long-term variable star measurements in a reliable and efficient way. The AAVSO is now the largest variable star organization in the world, receiving, processing, and disseminating some 400,000 variable star observations each year, and maintaining an international database that now contains over 11 million observations of variable stars.

Olcott was a life member of the American Astronomical Society, the British Astronomical Association, and the Société Astronomique de France. He was made a fellow of the Royal Astronomical Society of Great Britain, and a fellow of the American Association for the Advancement of Science. He was also appointed to two terms as a member of the Visiting Committee of the Department of Astronomy of Harvard University.

The Field Book of the Skies (first published in 1929) became widely known as the definitive handbook for amateur astronomers, and was published in revised editions after Olcott's death.

The AAVSO council presented, posthumously, the Merit Award of The American Association of Variable Star Observers – the association's highest honor – to William Olcott as "the Founder and Life Secretary of our Association whose words and writing and patient guidance have led many to know and love the stars."

Olivier, Charles Pollard

Born **Charlottesville, Virginia, USA, 10 April 1884**
Died **Bryn Mawr, Pennsylvania, USA, 14 August 1975**

Charles Olivier contributed to several fields of astronomy: In meteors, he corrected an erroneous belief about meteor shower radiants, and established and guided the American Meteor Society [AMS] for over six decades. He also discovered and studied double stars and made invaluable contributions to the standardization of variable – star visual photometry.

The Olivier family lived in Charlottesville, the site of the University of Virginia. Olivier's parents, George Wythe and Katharine (*née* Pollard) Olivier, owned the University Book Store, purchased with the proceeds of her family estate, and operated a boarding house in their home. Katharine had been raised in the surrounding Albemarle County, and the couple knew most of the university faculty well.

A year before Charles' birth, the university dedicated the Leander McCormick Observatory and its 26-in. Alvan Clark refractor. **Ormond Stone**, director of the observatory and a frequent guest at the Olivier home, encouraged young Olivier to become an astronomer. While still a boy, he eagerly learned how to use the Clark refractor and smaller observatory instruments.

Olivier accompanied the Leander McCormick Observatory's staff to Scottsville, Virginia, in an attempt to photograph the 1899 Leonid meteor shower, his first scientific expedition, and later to Winnsboro, South Carolina, for the 28 May 1900 solar eclipse. During the summer of 1901, Stone employed Olivier to measure stellar magnitudes in variable star fields using a wedge photometer.

While an undergraduate at the University of Virginia (1901–1905), Olivier published variable star observations and meteor shower reports in *Popular Astronomy*. In August 1905, two months after he earned his BA degree, Olivier volunteered as a member of a United States Naval Observatory [USNO] solar eclipse expedition to Daroca, Spain. While there, he met Samuel Mitchell, who would later play an important role in his career. Back in the United States, Olivier began graduate work at the University of Virginia, supported by a Vanderbilt Fellowship, earning a master's degree in astronomy in 1908.

Conducting graduate research at the Lick Observatory from July 1909 to December 1910, Olivier studied stellar spectra and acted as **Heber Curtis**'s assistant in an apparition-long study of comet 1P/Halley. He published double star measurements, a report about the 1909 Perseid meteor shower, and a photographic report about the great January comet C/1910 A1 (with **Paul Merrill**); he also demonstrated that the η Aquarid meteors are likely debris from Halley's comet based upon their orbital similarities.

Olivier earned his Ph.D. in astronomy from the University of Virginia in June 1911. His dissertation, "175 Parabolic Orbits and other Results Deduced from Observations of 6200 Meteors," was drawn mainly from his personal observational data. One of Olivier's important conclusions in the dissertation attacked a notion prevalent in the early 20th century, advanced by **William Denning**, that meteor radiants were stationary in the sky and were intermittently active for periods of days to months. Olivier argued that due to orbital motions of the Earth and the meteor streams this was impossible. He used his own meteor plot data to demonstrate that radiants actually move against the background sky, and only exist for a few days. Over a period of 20 years beginning with his 1911 dissertation, Olivier's theoretical and observational arguments demolished the credibility of Denning's stationary radiants.

In 1911, Olivier accepted a position as an assistant professor of physics and astronomy at Agnes Scott College. While there, he volunteered to direct the meteor section of Frederick Leonard's (1896 – 1960) Society for Practical Astronomy, and simultaneously founded the American Meteor Society [AMS], an organization that continues to promote and collect meteor observations to the present day.

During the summer of 1913, Olivier volunteered at the Yerkes Observatory, and then in June 1914 accepted an adjunct professorship at the University of Virginia, where Mitchell had just been appointed director of the Leander McCormick Observatory. During his early career at McCormick Observatory, Olivier contributed to Mitchell's photographic parallax program. When the United States entered World War I, Olivier volunteered but was disqualified from service on physical grounds, and instead was appointed to the Scientific Staff of the Aberdeen Proving Grounds in Maryland. His supervisor from October 1918 to January 1919 was **Forest Moulton** who assigned Olivier the problem of adapting astronomical photographic techniques to the task of finding cannon shell burst ranges at night. After World War I, Olivier collaborated with Mitchell and Harold Lee Alden (1890–1963) on the visual photometry of variable star fields, and continued his earlier work measuring parallax plates, from which he also discovered a number of new double stars. By the end of his life, Olivier claimed discovery of 198 new double stars.

Olivier married Mary Frances Pender on 18 October 1919. They had two daughters, Alice Dorsey and Elise Pender Olivier during their 15-year marriage.

Olivier obtained leave from his faculty and observational duties from October 1923 to July 1924 to do library research at the USNO in Washington. The product of this work was his first book, *Meteors*, published in 1925. Mary Frances helped him prepare the text for publication. The book, dedicated to Olivier's father who died in 1923, included a comprehensive review of meteor observation history, techniques of meteor observation and height determination, the connection between comets' orbits and meteor streams, and meteorites. *Meteors* also continued Olivier's attack on the belief that meteor showers could have long-lasting, stationary radiants. Olivier explained how inappropriate observational and data reduction practices of the past had contributed to that erroneous belief.

Olivier was appointed secretary of the American Astronomical Society's [AAS] Committee on Meteors in 1916. As *Meteors* was going to press 8 years later, Olivier was elected president of the Meteor Commission of the International Astronomical Union [IAU], a position he held for 10 years. In 1927, Olivier was appointed to the IAU's Commission on Double Stars.

In 1928, Olivier became professor of astronomy and director of the Flower Observatory at the University of Pennsylvania. There, Olivier concentrated upon double star measurements and the photometry of variable star fields using the 18-in. Brashear refractor. Olivier supervised the consolidation of the Flower Observatory with the private observatory of Gustavus Wynne Cook (1867–1940), bequeathed to the university. The Cook Observatory included a 28.5-in. Cassegrain reflector and a 15-in. siderostat refractor.

In 1930, Olivier published his second book, dedicated to Mary Frances. Intended as a sequel to *Meteors*, *Comets* was a nonmathematical treatment of what was then known about the origin, physical composition, and visual presentations of various comets, and associated meteor showers. It was based on Olivier's observations since about 1900. He included a chapter about comet collisions with the Earth that anticipated the 1990s popularization of comet catastrophes.

Until its cessation in 1951, Olivier published monthly articles about AMS results in *Popular Astronomy*. Thereafter, he published periodic reports about the society's findings in *Meteoritics* and *Flower and Cook Observatory Publications*. These reports and Olivier's frequent correspondence with AMS observers to suggest observational goals and to praise or cajole the members' participation, were crucial to the vitality of the organization and its longtime productivity. Olivier directed the American Meteor Society from 1911 until 1973, when he selected David Dering Meisel (born: 1940), an AMS member who had become a professional astronomer, as the new executive director.

After Mary Frances Olivier died in 1934, Olivier raised his daughters by himself, although his sister, Katharine Olivier Maddux, helped him on many occasions. Olivier got married a second time, to Ninuzza Seymour, on 23 October 1936. This marriage ended in a divorce. Olivier did not marry again until 24 July 1950, when he wed Margaret Ferguson Austin who survived him.

Appointed emeritus professor of the University of Pennsylvania in 1954, Olivier continued reducing data produced by members of the American Meteor Society for another 20 years in retirement. In 1974, at age 90, he published his sixth, and final, catalog of hourly sporadic meteor rates.

Olivier was a tireless observational astronomer for 73 years. He also popularized astronomy in newspaper articles, on the radio, and by giving personal presentations to astronomy clubs and community groups. In 1979, the IAU named a lunar crater in his honor.

Olmsted, Denison

Born **East Hartford, Connecticut, USA, 18 June 1791**
Died **New Haven, Connecticut, USA, 13 May 1859**

Denison Olmsted was a prominent member of the scientific community in antebellum America. Remembered for pioneering contributions in astronomy, geology, and meteorology, he authored a number of widely used textbooks, including *An Introduction to Astronomy* (1839) and *A Compendium of Astronomy* (1841).

Son of farmers Nathaniel Olmsted and Eunice Kingsbury, Olmsted entered Yale College in 1809 and received his bachelor's degree in 1813. After teaching in New London, Connecticut for two years, he earned a master's degree (1816) from Yale. In 1817, he was appointed to a professorship of chemistry at the University of North Carolina, which he accepted after spending another year of preparation in that subject. A member of the short-lived American Geological Society (founded at Yale in 1819), Olmsted was also instrumental in creating the first state-sponsored geological survey (of North Carolina, 1823–1824), whose reports helped to stimulate other states to conduct geological surveys, starting in the 1830s. In 1825, he returned to Yale as a professor of mathematics, natural philosophy, and astronomy, where he spent the rest of his life. One of Olmsted's most notable students was **Jonathan Lane**.

Olmsted's most notable contributions to astronomy arose from his observations of the 13 November 1833 Leonid meteor storm. He noted that the radiant point, in the sickle of Leo, followed the diurnal movement of the sky. In papers published in the *American Journal of Science and Arts*, Olmsted correctly argued for the shower's origin in interplanetary space, whose meteoric particles traveled along parallel paths and were consumed by fire in the Earth's atmosphere. Along with American astronomers **Edward Herrick** and **John Locke**, he helped to establish the annual nature of these (and other) meteor showers. Olmsted likewise investigated the aurora borealis and the zodiacal light, publishing theories of their purported origins in a related "nebulous body."

Using a small telescope at Yale in 1835, Olmsted and tutor **Elias Loomis** were the first American astronomers to recover comet 1P/Halley at its predicted return.

Olympiodorus the Younger [the Platonist, the Neo-Platonist, the Great]

Born **Alexandria, (Egypt), 495–505**
Died **after 565**

Olympiodorus the Younger is remembered for having continued the Platonic tradition at Alexandria following the closing of the Greek Academy at Athens by Emperor Justinian of Byzantium in 529. His most influential writings include commentaries on **Plato**'s *Phaedo*, Alcibiades I, Gorgias, and Philebus. Olympiodorus's commentary on Plato's life is most widely cited. Although his authorship of other works is disputed, it is agreed that the extant remains of Olympiodorus are student notes (or copies of notes) taken from his public lectures delivered at Alexandria.

Olympiodorus's works are also valued for information they provide on the life and work of earlier thinkers, notably Damascius, Iamblichus, Syrianus, and significantly, **Ptolemy**. In his *Phaedo*, Olympiodorus offers several valuable sentences, suggesting that Ptolemy lived near Alexandria at Canobus, where he devoted himself to astronomy for 40 years. Further, it was there that he had stone tablets carved to preserve his astronomical discoveries. Details about these inscriptions made at the temple of Serapis have been disputed since the 17th century. Prompted by their interest in Ptolemy, Isaac Vossius and **Ismaël Boulliau** were the first to study Greek manuscript copies of Olympiodorus found in Florence and Paris.

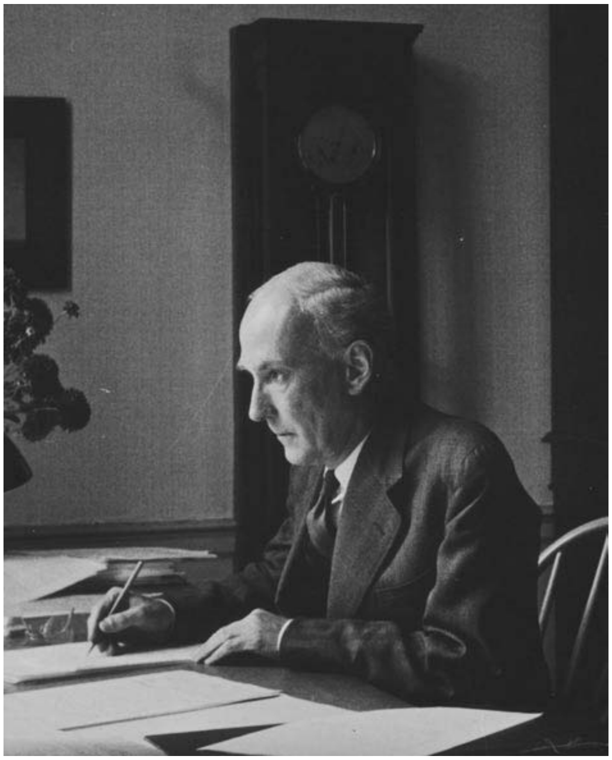
Oort, Jan Hendrik

Born **Franeker, The Netherlands, 28 April 1900**
Died **Wassenaar, The Netherlands, 5 November 1992**



Dutch astronomer Jan Oort is eponymized in the Oort cloud (of potential future comets on the outskirts of the Solar System), in the Oort constants (of galactic rotation), and in the Oort limit to the density of mass in the disk of the Milky Way Galaxy.

Oort was the son of physician Abraham H. Oort and Hannah Faber. He and his wife, Johanna Maria Graadt van Roggen had two sons and a daughter.

Oort began studies at the University of Groningen in 1917 and was quickly inspired by **Jacobus Kapteyn** to take up astronomy. He completed his doctoral dissertation, on "The Stars of High Velocity," under **Pieter van Rhijn**, following Kapteyn's death and after 2 years at Yale Observatory (1922–1924), where he learned astrometry from **Frank Schlesinger**. Oort's thesis already contained the idea that stars moving faster than about 65 km/sec (an Oort limit) in a particular direction would probably escape from the Galaxy.

Oort spent the rest of his career at the Leiden Observatory and Leiden University as staff member (1924–1930), lecturer (1930–1935), professor extraordinary (1935–1945), full professor and director of the observatory (1945–1970), and in retirement until shortly before his death. The only exception was the period of World War II, 1940–1945, when the university was closed by the occupying forces, and Oort withdrew to a small village in the center of Holland. During his early years at Leiden, Oort was most influenced by **Ejnar Hertzsprung** and **Willem de Sitter**. He, in turn, was formal advisor or mentor to a large fraction of the next two generations of Dutch astronomers.

Jan Oort's approach to science, strongly determined by Kapteyn, was one of close confrontation between observation and interpretation, with a minimum of speculation and, if possible, avoidance of intricate mathematical treatment. He was a man of extraordinary perception, gifted with remarkable intuition for choosing promising courses of research.

Oort received numerous awards, among which were the Kyoto Prize, the Balzan Prize, and the Vetlesen Prize. He was a member of 16 foreign science academies including all the major ones and the recipient of ten honorary degrees.

Oort's scientific activities spanned more than 70 years; his first paper dates from 1922, his last one from 1992. The leading motive in nearly all of his research was the problem of the structure of the Universe at large. In the early 1920s this was still synonymous with the problem of the structure of the Milky Way; only later in the 1920s did it become apparent that the Galaxy is just one among numerous, more-or-less similar, stellar systems. By the time of Oort's last papers, research on the Universe concentrated on the large-scale features in the spatial distribution of stellar systems and on their relation to the initial stages of the Universe.

Rotation of the Galaxy. In a paper of 1927, which brought him international fame, Oort confirmed **Bertil Lindblad**'s hypothesis that the (flattened) Galaxy is a rotating stellar system. He demonstrated by means of available observational data on stellar distances, radial velocities, and proper motions that the bulk of the stars move in nearly circular orbits around a center, the direction of which coincided with the center of the system of globular clusters as proposed by **Harlow Shapley**. The proof lay in the differential motions exhibited by stars located at different distances from this center for which the distance could then be estimated at about 20,000 light years. In a subsequent paper of 1928 on the dynamics of this rotating system, Oort showed that it offered a natural explanation for a variety of phenomena observed earlier, among which were the ellipsoidal velocity distribution of stellar velocities and the peculiar distribution of the directions of the largest stellar velocities – the socalled asymmetry in high velocities. The Oort constants describe this differential rotation in the form of derivatives.

Hidden and observable matter in the Galaxy. In a paper of 1932 Oort derived the strength of the field of force in the stellar system, in particular the force perpendicular to the plane of symmetry (the galactic plane), from a comparison of the velocity distribution of the stars with their density distribution. In the region near the Sun, this force could not be satisfactorily explained by adding the contributions from matter present in the form of stars and interstellar matter [ISM], and Oort suggested the possible existence of an additional component, called "hidden matter" or "dark matter." In his George Darwin Lecture in 1946 he discussed the physics of the ISM: the formation of dust particles from the gaseous medium, the interaction with hot stars, and possible mechanisms of star formation. The upper limit to the local mass density in the galactic disk, implied by the velocities of stars perpendicular to it, is the "Oort limit."

Radio-astronomy, spiral structure, and the galactic center. Following up on the discovery of cosmic emission at radio wavelengths by **Karl Jansky** and **Grote Reber**, Oort was the first to realize its far-reaching implications for astronomy. Of two fields of application, the measurement of the continuum spectrum and that of emission lines, he pursued in particular the latter after van de Hulst's prediction, in 1943, of the 21-cm emission line due to neutral interstellar hydrogen, HI. Its measurement became the primary objective, first of the Dwingeloo Radio Observatory (operational in 1956) and, next, of the Westerbork Synthesis Radio Telescope (in 1970) in the Netherlands, both largely the result of Oort's efforts. The measurement resulted in the mapping of the spiral-like distribution of HI in the Galaxy and of the HI structural patterns in other nearby galaxies. Oort's discovery, with C. A. Muller and Ernst Raimond, of clouds of neutral hydrogen gas apparently falling at high speed into the Milky Way from its halo or from inter-galactic space, was an important product of this program. Another topic of particular interest in Oort's research was the central region of the Galaxy with its explosive nature and small-scale spiral structure. He spoke in favor of a central black hole at least from the 1980s.

The Oort and Walraven map of polarization of the light of the Crab Nebula was probably the last serious optical astronomy done from the Netherlands, as the community turned to radio astronomy and to optical observatories in more favorable locations. It laid the ground for later studies by **Jan Woltjer** and others demonstrating the need for an ongoing energy source in the supernova remnant, later found in the form of a pulsar.

Large-scale structure in the distribution of galaxies. Whereas already early in his career Oort on several occasions had expressed his deep interest in the large-scale structures on a cosmological scale, he addressed these thoroughly only in the later stages of his career. His substantial review article on superclusters published in 1983 became the standard reference for many subsequent investigations.

Comets. Oort's interest in the origins of comets arose because a student, A. J. J. van Woerkum, had begun a thesis on the topic with Woltjer and became Oort's student after his first advisor's death. Oort postulated the existence of a spherical reservoir of comets beyond the domain of the major planets, now called the Oort cloud. Some comets will occasionally be perturbed in their orbit by passing stars; as a result comets may now be classified as either "new" ones that for the first time pass through the region of the Earth's orbit or "old" (periodic) ones that as a consequence of Jupiter's gravitation remain captured in the inner regions.

European Southern Observatory. Following up on a suggestion by **Walter Baade** of Mount Wilson Observatory, Oort in 1954 called a meeting of leading European astronomers and proposed that they join financial and personnel resources for the establishment of a joint southern observatory, a proposal he pursued with utmost perseverance. After a long struggle, requiring much diplomacy and insistence on the part of Oort, **André–Louis Danjon**, **Otto Heckmann**, and **Bertil Lindblad**, the international convention was signed in 1962.

International Astronomical Union [IAU]. A strong advocate of international collaboration, Oort contributed considerably to the activities of the IAU. From 1935 until 1948 he was its general secretary, except during the years 1940–1945 (World War II) during which the secretariat was filled temporarily by **Walter Adams** of Mount Wilson Observatory. Oort's efforts contributed considerably to the resumption of cooperation within the IAU among astronomers from the formerly hostile countries. During the years 1958–1961 Oort was president of the IAU. At the time of the General Assembly [GA] of the International Union in 1976 at Grenoble, France, Oort was the only remaining member to have attended all of the GAs since the first in Rome in 1922.

Öpik, Ernst Julius

Born **Port Kundu, (Estonia), 23 October 1893**
Died **Bangor, Co. Down, Northern Ireland, 10 September 1985**

Ernst Öpik was among the first to put forward a number of ideas now regarded as part of mainstream astronomy, including a way of measuring distances to other galaxies (before it was generally agreed that there were other galaxies), a composition discontinuity as the cause of red-giant structure, and the need for a three-body process to carry nuclear reactions beyond the formation of helium to carbon and heavier elements.

Öpik was educated at Tallinn High School in Estonia and graduated with honors and a gold medal in 1911. At school, and later at university, he supported himself and helped his parents by teaching mathematics, science, and languages. He had to choose between music and science and decided on a career in astronomy.

Öpik graduated with first class honors from Moscow Imperial University in 1916 and held teaching posts there for 3 years. During the Bolshevik Revolution he volunteered for the White Russian Army. From 1919 to 1921 he headed a new astronomy department at the Turkestan University in Tashkent and then returned to his native Estonia as associate professor at Tartu University, where he obtained his doctorate in 1932 with a thesis on meteor observations.

Between 1930 and 1934 Öpik held the post of research associate and visiting lecturer at Harvard University and Harvard College Observatory. During this time he founded the meteor research group at Harvard. He then returned to Estonia and established his family home there.

After the German occupation of Estonia in 1941, and with the Soviet armies about to reoccupy the country in 1944, Öpik and his family fled to the west by horse and cart. They eventually reached Hamburg Observatory where they were given succor. Öpik became professor of astronomy in the Baltic University in Hamburg, which was set up to accommodate displaced scholars and students from the east. When his plight became known, **Eric Lindsay**, a Harvard graduate and director of Armagh Observatory from 1937, invited Öpik to Armagh, Northern Ireland, in 1947 as a research associate. He remained at Armagh until his retirement in 1981.

While he was still an undergraduate at Moscow University in 1916, Öpik wrote a paper on the densities of 40 visual binaries, which he derived from their corrected surface brightness. He excluded from his survey one binary with known orbital elements, o_2 Eridani (40 Eri B). Taking its spectrum as A0, its parallax as 0.17 arc seconds, and the mass ratio as unity, he found a density 25,000 times that of the Sun. Assuming that this was an impossible result, Öpik sought another explanation. He was not the first to think the density of a white dwarf was incredible; in 1905, **John Gore** of Dublin estimated the density of Sirius B at nearly 32,000 times the Sun's and thought it "entirely out of the question."

In 1921 Öpik published an article in the Russian astronomy magazine *Mirovedenie* that included an estimate of the distance to the Andromeda Nebula from dynamical considerations. By connecting the observed velocity of rotation of the Nebula to the centripetal acceleration, and hence its gravitational attraction and mass, he obtained a distance of 785 kpc. The following year a similar paper appeared in the *Astrophysical Journal* and, assuming a new value for the mass–luminosity ratio, his estimate was now 450 kpc. These values compare well with a modern estimate of 690 kpc considering that they predate the extragalactic scale based on Cepheid luminosities.

In 1932 Öpik set out to investigate the stability of a large cloud of meteors and comets attached gravitationally to the Solar System. He calculated the perturbation effects of stars passing through the cloud, making the reasonable assumption that objects in very large orbits about the Sun would spend most of their time at aphelion. He decided that a system of comets could persist without great losses for over 3 billion years, in orbits about the Sun, at distances up to 5 parsecs. Subsequent studies have reduced this distance by a large factor, but the basic conclusion is still valid. **Jan Oort** introduced his concept of a cloud of comets surrounding the Sun in 1950.

In 1938 Öpik tackled the problem of the origin of red giant stars, which must have sizes up to hundreds of times that of the Sun, because they are very bright, although very cool. He realized that in stars like the Sun, nuclear burning takes place only in the central 10% by mass. As the available hydrogen fuel is depleted, there is no longer enough pressure to support the central regions; the core collapses; and, as a result, the outer envelope expands to an enormous size. Öpik's hand calculations were confirmed about 10 years later by **Fred Hoyle** and **Martin Schwarzschild** using electronic calculators.

In 1950 Öpik put forward a theory to explain the occurrence of ice ages on the Earth with periods of several hundreds of millions of years. He suggested that transport of fresh hydrogen into the solar core could increase the rate of energy generation, affecting temperatures on the Earth. Other factors are now thought to be more important.

Öpik made many contributions to knowledge of the planets and the minor bodies of the Solar System. He anticipated the desert-like nature of the surface of Venus, and his prediction of craters on Mars was confirmed 15 years later by planetary probes. His statistical studies of Earth-crossing comets and asteroids led to a better understanding of the dynamics of these bodies and their influence on the Earth. In recognition of this work, Minor planet (2099) was named for Öpik.

In 1950, on the initiative of Lindsay and with the active support of **Hermann Brück**, the *Irish Astronomical Journal* began publication with Öpik as editor. Over the following three decades the journal became a channel for his views on astronomical and other matters. During this time he was also a visiting professor in the Department of Physics and Astronomy at the University of Maryland.

Öpik was an accomplished amateur musician, both as a performer and composer. He wrote some 3,000 pieces for piano as well as some choral works. An appraisal of his musical attainments is given by Mary de Vermond of the University of Maryland in a special issue (1972) of the *Irish Astronomical Journal*.

For his contributions to astronomy, Öpik received many honors. He was fellow of the Estonian Academy of Sciences from 1938, member of the Royal Irish Academy from 1954, foreign associate of the United States National Academy of Sciences [NAS] from 1975, and foreign honorary member of the American Academy of Arts and Sciences from 1977. He received honorary degrees of Doctor of Science from Queen's University, Belfast, in 1968 and from the University of Sheffield in 1977. He received the J. Lawrence Smith Medal of the NAS in 1960, the F. C. Leonard Medal of the International Meteoritical Society in 1968, one of six Gold Medals of the American Association for the Advancement of Science in 1974 awarded in connection with the fourth centenary of **Johannes Kepler**'s birth, the Gold Medal of the Royal Astronomical Society in 1975, the Catherine Wolfe Bruce Gold Medal of the Astronomical Society of the Pacific in 1976, and the *Grand Prix* of the Louis Jacot Foundation "La Pensee Universelle" in 1978. He was elected a fellow of the Royal Astronomical Society in 1949.

On his retirement at the age of 88, Öpik went to live in the seaside town of Bangor. He continued as an associate editor of the journal until his death. He was survived by his second wife Alide, and by one son and five daughters. Öpik's grandson, Lembit Öpik, has served as a Member of Parliament at Westminster in London.

Oppenheimer, J. Robert

Born **New York City, New York, USA, 22 April 1904**

Died **Princeton, New Jersey, USA, 18 February 1967**

American physicist J. Robert Oppenheimer features in world history as the leader of the Manhattan Project, which developed the first American atomic (fission) bombs, but his contributions to astronomy concern the structure of neutron stars (using the eponymous Tolman–Oppenheimer–Volkoff equation of state) and the unstoppable collapse of objects larger than some critical mass.

Oppenheimer was the elder of two sons. (The younger, Frank Oppenheimer, was also a physicist.) Robert graduated from the Ethical Culture High School in New York at age 16. He received his A.B. in physics from Harvard University in 1925 (which also awarded him an honorary D.Sc. in 1947, one of many honorary degrees) and his Ph.D. in physics in 1927 from Göttingen University in Germany for work with Max Born on what is now called the Born–Oppenheimer approximation (for quantum mechanical calculations of systems of particles with very different masses; they worked on molecules). After brief fellowships in Leiden and Zürich (1928/1929), he took up joint appointments at the California Institute of Technology and the University of California, Berkeley, progressing from assistant professor (1929–1931) to associate (1931–1936) to full professor (1936–1947).

Oppenheimer apparently had a gift for languages, and after his brief stays in Göttingen and Leiden was able to write scientific papers and converse in German and Dutch. His adult nickname, Oppie, was an Americanization of the Dutch. Oppenheimer married Katharine Harrison in 1940. Neither of their children, Peter and Katharine, evinced any interest in science.

Oppenheimer was director of the Los Alamos National Laboratory from 1943 to 1945 and professor of physics and director of the Institute for Advanced Study in Princeton from 1947 to 1966. He served as chair of the General Advisory Committee of the Atomic Energy Commission from 1946 to 1952, was president of the American Physical Society (1948), and was elected to a number of national academies of science (United States, Danish, Brazilian, and most remarkably, the Japanese).

It can be argued that his most important long-term influence on physics was in building up the large theory groups at Caltech and Berkeley, so that an American no longer had to go to Europe, as Oppenheimer had, for advanced training. Among his students who have become important astrophysicists are **Philip Morrison** and Robert Christy (professor emeritus, Caltech). The best known of his post-doctoral fellows in the area of astrophysics and gravitation was probably Leonard Schiff, who developed the theory of one of the classic astronomical tests of general relativity.

Oppenheimer's work on topics relevant to astrophysics was confined to a narrow time window, beginning with a 1937 attempt, with Robert Serber, to identify a particle newly discovered in the cosmic rays (now called the μ meson or muon) with a particle predicted by Hideki Yukawa to carry the strong or nuclear force. The Yukawa particle, now called the pion, was later discovered in the cosmic rays and, although its mass is similar to that of the muon, it is otherwise fundamentally different.

Two papers, with Serber and with **George Volkoff**, in 1937–1938 contained the first careful calculations of the structure of neutron stars, which had been predicted in 1933/1934 by **Walter Baade** and **Fritz Zwicky**. They showed in particular that there was an upper limit to the mass of a stable neutron star, similar to the Chandrasekhar limit for white dwarfs. The number they found, 70% of the mass of the Sun, was too small because they had not been able to include the effect of the nuclear force, but only those of quantum mechanics and general relativity. A 1939 paper with **Hartland Snyder** was entitled "On Continued Gravitational Contraction," and dealt with the behavior of a mass above the critical limit. It is generally considered to be a prediction of black holes. Oppenheimer did not live to see observational confirmation of either neutron stars (the 1967/1968 discovery of pulsars) or black holes (the 1972 measurement of the mass of the compact object in the X-ray binary Cygnus X-1).

In the postwar period, Oppenheimer did very little original scientific research, but did make some contributions on the role of mesons in generating cosmic-ray showers. He mentored a number of younger physicists in this period, including Tsung-Dao Lee and Chen Ning Yang, who shared the 1957 Nobel Prize in Physics for the prediction of parity nonconservation.

The last 25 years of Oppenheimer's life were inevitably dominated by the development of the atomic bomb (regrets for which he expressed the form of saying that "physicists had known sin") and its aftermath. His period of influence in the United States government and postwar development of atomic weaponry and energy ended abruptly when his security clearance was withdrawn in 1953. The subsequent trial divided the American physics community, including especially those who had worked with him closely at Los Alamos. He was given the Fermi Award in 1963 by the Atomic Energy Commission in a not uncontroversial partial apology.

President Kennedy had been scheduled to present the Fermi award on 2 December 1963. As it turned out, the presentation was made by President Lyndon B. Johnson, with the words:

> Dr. Oppenheimer, I am pleased that you are here today to receive formal recognition for your many contributions to theoretical physics and to the advancement of science in our nation. Your leadership in the development of an outstanding school of theoretical physics in the United States and your contributions to our basic knowledge make your achievements unique in the scientific world.

Oppenheimer's response typified the courtly grace, or pomposity, that had made him either loved or hated by so many:

> I think it is just possible, Mr. President, that it has taken some charity and some courage for you to make this award today. That would seem to me a good augury for all our futures . . . These words I wrote down almost a fortnight ago [that is, before Kennedy's death]. In a somber time, I gratefully and gladly speak them to you.

He developed throat cancer soon after, perhaps as a result of inveterate pipe-smoking and perhaps also from the effects of radiation exposure during the Los Alamos years, and died very shortly after being filmed in a tribute to Enrico Fermi.

Oppolzer, Egon Ritter von

Born **Vienna, (Austria), 1869**
Died **Vienna, (Austria), 15 June 1907**

Egon Oppolzer was the son of **Theodor von Oppolzer**. He was educated at the University of Vienna and the University of Munich; in 1897 he became an assistant at the Prague Observatory, where he discovered the variability of the minor planet (433) Eros. Oppolzer was appointed a professor of astronomy at the University of Innsbruck in 1901.

Oppolzer, Theodor Ritter von

Born **Prague, (Czech Republic), 26 October 1841**
Died **Vienna, (Austria), 26 December 1886**

Though trained as a physician, Theodor von Oppolzer excelled at celestial mechanics and published a monumental volume on the elements of all solar and lunar eclipses, visible from 1207 BCE to 2163. Oppolzer's father, Johann von Oppolzer, was a well-known physician, specialist on internal diseases, and professor of medicine at the Universities of Prague, Leipzig, and Vienna. Oppolzer received a private education (1851–1859) before he entered the Piaristen-Gymnasium in Vienna, from which he graduated *summa cum laude*. While his teachers encouraged his abilities in mathematics and science, Oppolzer fulfilled his father's wish that he study medicine at the University of Vienna, where he received his medical degree in 1865. Yet, it seems that he never wanted to work as a physician. In 1865, Oppolzer married Coelestine Mauthner von Markhof; the couple had six children. One of his sons, **Egon von Oppolzer**, became professor of astronomy at the University of Innsbruck.

Oppolzer's intellectual talents enabled him to pursue mathematical astronomy even through the course of his medical studies. His parents supported his interests by financing a private observatory located on the outskirts of Vienna, which was christened "Sternwarte Wien-Josefstadt." This observatory was equipped with a 7-in. refracting telescope, a meridian circle, and a wide-field cometseeker. Before the new Vienna Observatory was erected in the late 1870s, Oppolzer's principal telescope was likely unsurpassed in the Austro–Hungarian monarchy.

Two of the principal influences on Oppolzer's astronomical interests were **Maurice Löwy** and **Edmund Weiss**, both of whom then worked at the original Vienna Observatory. Loewy and Weiss observed minor planets and comets and computed their orbital elements and ephemerides. Oppolzer's first publication concerned the orbit of comet C/1861 G1. By the time his medical studies were completed, he had published some 56 papers in astronomical journals, dealing chiefly with orbit determinations. The following year, Oppolzer became a *Privatdozent* (lecturer) at the University of Vienna, without having acquired a Ph.D.

Oppolzer's preliminary research dealt with the orbital determinations and ephemeris calculations of asteroids and comets. Yet, he soon found ways to improve upon the cumbersome methods and auxiliary tables used at that time. These techniques enabled Oppolzer to recover the lost minor planets (62) Erato, (73) Klytia, and (91) Aegina. In 1870, he published the first volume of a textbook on orbit determination, whose methods for computing an elliptical orbit from three or four positions converged toward a solution much more rapidly than the method of **Carl Gauss**. In that same year, Oppolzer was appointed an extraordinary professor of astronomy and advanced geodesy at the University of Vienna.

Oppolzer undertook a major scientific and administrative task in the supervision of his nation's geodetic studies, which included a series of longitude measurements between Austrian cities and other European capitals. Reflecting certain patriotic motivations, this large-scale undertaking also evinced international cooperation in science on an unprecedented scale. Its ambitious goals were to conduct a topographic survey and establish the precise shape of the Earth. In 1873, Oppolzer became director of the Austrian Gradmessungs-Bureau (Geodetic Survey); in the following year, he was appointed Austrian representative to the International European Geodetic Congress (and later became its vice president). Between 1873 and 1876, Oppolzer personally supervised some 40 longitude determinations. Apart from his role as manager, he contributed ideas for new instruments that were applied in other countries.

In connection with the problem of the Earth's figure, Oppolzer was interested in gravity determinations. He improved existing methods of measurement by the use of reversible pendulums and eliminated sources of error. In 1883, the first determination of the absolute intensity of gravity was made in the basement of the new Vienna Observatory. Some years before its adoption in 1875, Oppolzer had promoted establishment of the metric system in the Austro–Hungarian monarchy. For these scientific and administrative activities, he was decorated with a series of medals from various countries and elected a member of numerous scientific institutions and academies. Oppolzer was awarded an honorary doctorate from the University of Leiden in 1871.

In spite of these responsibilities, Oppolzer never gave up astronomy. He was engaged with preparations for an expedition to Jassy in Romania to observe the 1874 transit of Venus. In 1875, Oppolzer had been offered the directorship of the Gotha Observatory but declined the invitation. In that same year, he was made an ordinary professor; by 1879, he had been elevated to the rank of full professor at the University of Vienna. Those years also witnessed construction of the new Vienna Observatory. After its director, **Karl von Littrow**, was released from teaching, the bulk of that activity fell to Oppolzer and Weiss. The former also prepared the second volume of his textbook on orbit determination, involving perturbation theory, which appeared in 1880.

Oppolzer's studies in celestial mechanics culminated with his refinements to the theory of the Moon's motion and the Sun–Earth–Moon system in connection with solar and lunar eclipses. Oppolzer possibly became interested in this subject on the occasion of the total solar eclipse of 18 August 1868. As a participant in the Austrian expedition to Aden, he was responsible for determining the position of the observing station and the times of contacts during the eclipse.

To arrive at a more accurate determination of the Moon's orbit, it was necessary for Oppolzer to compare historical and contemporary eclipse observations by means of a uniform theory. He began his investigations with the best available lunar theory of **Peter Hansen**. Yet, even here he found irregularities that could not be explained by the theory. Oppolzer then modified Hansen's theory and developed appropriate tables that allowed more efficient calculations to be made. In 1881, he published his "Syzygien-Tafeln für den Mond" (Syzygy tables for the Moon), which enabled the times of new and full Moons to be calculated in the distant past or future.

Oppolzer's study of eclipses reached its climax with the 1885 publication of his monumental *Canon der Finsternisse* (Canon of Eclipses). This massive undertaking required the assistance of ten human computers, half of whom worked as volunteers, half of whom were paid privately by Oppolzer. The calculations were performed by two independent groups and their results compared for accuracy. Described in 1887 as "one of the greatest works of calculation which has ever been accomplished by man," the *Canon* contains the elements for approximately 8,000 solar and 5,200 lunar eclipses, including visibility tracks of the solar eclipses. When completed, the *Canon* was of special use for chronological research, offering precise dates of historical events that otherwise might be known only to the nearest century.

Appearing well before the advent of mechanical or digital calculations, Oppolzer's *Canon* was reprinted (and translated into English) as late as 1962. In turn, his work has stimulated the computation of other eclipse catalogs, some more extended and specialized than the original. A newer compilation (1983), based on the more refined lunar theory of **Ernest Brown**, and generated by a digital computer, provides a significant test of the accuracy of Oppolzer's *Canon*.

Oppolzer did not live long enough to finish his modified lunar theory; his widow financed the partial completion of his manuscript by enlisting those computers who had worked on the *Canon der Finsternisse*.

A crater on the Moon and several minor planets are named for the subject or his relatives: (1492) Oppolzer, (237) Coelestina (his wife), (228) Agathe (his youngest daughter), and (153) Hilda (a daughter who died as a child).

Oresme, Nicole

Born **diocese of Bayeux, (Calvados), France, *circa* 1320**
Died **Lisieux, (Calvados), France, 11 July 1382**

French bishop, scholastic philosopher, economist, and mathematician Nicole Oresme is considered today as one of the principal forerunners of modern science. Oresme's contributions in mathematics and physics are considered decisive ideas for the development of modern science in the 16th and 17th centuries. Editions of Oresme's work were published well into the Renaissance.

Probably Oresme took his philosophical training at the University of Paris under **John Buridan**, whose influence in Oresme's works is evident. By 1348 he had a scholarship in theology at the college of Navarre at Paris, of which he became grand master (head) in 1356. Oresme left Navarre after his appointment as a canon at Rouen (1362). Later he was appointed Canon at the Sainte-Chapelle in Paris (1363) and Dean of the Cathedral of Rouen (1364). At the behest of King Charles V of France, from about 1370 Oresme translated and annotated many works of **Aristotle**, including *On the Heavens*, from Latin into French. In his commentaries he expressed his critique of several Aristotelian tenets by developing many original astronomical, physical, and economic ideas. As a reward for this extended and difficult work, Charles V had him appointed Bishop of Lisieux in 1377. Little is known of Oresme's last years.

Oresme is the author of more than 30 works, the majority of which are still unpublished and remain in manuscript form. As a scholastic philosopher he is famous for his critique of several Aristotelian positions. Oresme rejected two of Aristotle's main definitions, replacing them with his own – he rejected the definition of the place of a body as the inner boundary of the surrounding medium in favor of a definition of place as the space occupied by the body, and he replaced the definition of time as the measure of motion with a definition of time as the successive duration of things, independent of motion.

Oresme's main contributions to astronomy, mathematics, and kinematics are contained in several works produced throughout his life. His two major scientific works are the *Tractatus de configurationibus qualitatum et motum* (Treatise on configurations of qualities and motions), and the *De proportionibus proportionum* (On ratios of ratios). Oresme's main astronomical views are exposed in his early works *Questiones de Celo* and *Questiones de Spera*, in a work opposing astrology, *Questio contra divinatores*, and in his later work written in French, *Le livre du ciel et du monde* (Book on the heavens and the world), a translation of and commentary on Aristotle's *On the Heavens*.

A very interesting characteristic of his argumentation is that it often permitted Oresme to suggest unorthodox and radical philosophical ideas while disclaiming any commitment to them. For example, in treating the question of the plurality of worlds, he stressed the possibility that God by His omnipotence could create such a plurality, though he finally rejected this in favor of a single Aristotelian cosmos. Another famous example of Oresme's argumentation is his study of the rotation of the Earth. He brilliantly argued against the "proofs" of Aristotle for a stationary Earth, mainly in his *Le livre du ciel et du monde*. With a series of arguments based mainly on the idea of the complete relativity in the detection of motion and the demonstration that all observed phenomena can be saved equally well by the diurnal rotation of the Earth as by the rotation of the heavens, Oresme explained why we cannot exclude the possibility of a rotating Earth. Though he finally concluded, "The truth is, that the earth is not so moved but rather the heavens," he added, "However I say the conclusion [about the nonexistence of a such rotation] cannot be demonstrated but only argued by persuasion."

Another original astronomical idea of Oresme is the metaphor of the heavens as a mechanical clock, which is considered the first attempt to understand mechanically the celestial motions. He suggested the possibility that God implanted in the heavens at the time of their creation special forces and resistances – differing from those on Earth – by which the heavens move continually like a mechanical clock. Through his opposition to astrology Oresme was also able to expose other aspects of his views about the relation of celestial and terrestrial phenomena. For Oresme terrestrial phenomena arise from natural and immediate causes rather than from celestial influences, with the exception of the influences of the light of the Sun. Only ignorance, he claimed, causes men to attribute terrestrial phenomena to the heavens, to God, or to demons. Oresme composed his anti-astrology dissertation in Latin, but so strong was his desire to divert people from the false science that he produced a short tract against the practice in French.

Finally we must mention Oresme's idea to develop mathematical arguments in order to prove the probable incommensurability of the ratio of any two celestial motions. He started from a suggestion of the theologian–mathematician **Thomas Bradwardine** that an arithmetic increase in velocity corresponds to a geometric increase in the original ratio of force to resistance. Oresme went on to give an extraordinary elaboration of the problem of relating ratios exponentially by a treatment of fractional exponents conceived as ratios of ratios. His idea was the distinction between irrational ratios of which the fractional exponents are rational and those of which the exponents are themselves irrational. Based on this treatment he claimed (without any real proof) that the ratio of any two celestial motions is probably incommensurable. This excluded precise predictions of successively repeating conjunctions, oppositions, and other astronomical aspects with the methodology of astrologers. Oresme presented his original method for manipulating ratios in an independent work, the *Algorism of Ratios*.

Oriani, Barnaba

Born **Garegnano near Milan, (Italy), 17 July 1752**
Died **Milan, (Italy), 12 November 1832**

Barnaba Oriani was an accomplished observer and observatory director who contributed to planetary astronomy. He was of humble origins. His father Giorgio worked as a mason; his mother was Margherita Galli. Oriani began his studies in the Certosa of Garegnano, then at the College of San Alessandro, Milan, where he was educated and supported by the Barnabites (a religious order of the Catholic Church). He later joined the Barnabites, and, after studying the humanities, physical and mathematical sciences, philosophy, and theology, was ordained as a priest at the age of 23 in 1776. Despite his youth, he was admitted to the competition for teaching mathematics at the Como Gymnasium. His rejection diverted him to pursue his love of astronomy; shortly after his ordination Oriani was appointed to the staff of the Observatory of Brera in Milan. He became assistant astronomer in 1778.

For 5 months in 1786 Oriani traveled to Brussels, Amsterdam, and London, where he met a host of scientific luminaries. In 1787 Oriani was offered the full professorship of astronomy and directorship of the observatory to be founded in Palermo. He excused himself as he was not willing to leave his observatory in Brera. In any event, it was **Giuseppe Piazzi** who became the director of Palermo. These two met only once, in Brera in 1789, when Piazzi was returning from England and France. Piazzi had in Oriani a sincere and loyal friend; their correspondence spanning several decades became ever more frank as the years went on.

When observing the comet of 1779 (C/1799 A1), which had been discovered by **Johann Bode** on 6 January and independently by **Charles Messier** on 18 January, Oriani observed three "nebulous stars," namely M49, M60, and M61. M49 had been discovered in 1771 by Messier. Oriani found M49 on 22 April. (Messier had discovered it in 1771.) M60 had been discovered first by **Johann Köhler** on 11 April, then by Oriani the next day and by Messier on 15 April. M61, however, was the original discovery of Oriani on 5 May 1779, and was seen by Messier 6 days later.

Oriani's greatest work involved the orbit calculation of Uranus after its discovery by **William Herschel** in March 1781. After **Jean Bochart de Saron**, **Anders Lexell**, and others had shown that Uranus was not on a parabolic orbit and had obtained an approximate circular orbit, Oriani calculated the planet's elliptical orbit in 1783. He improved this calculation in 1789 by taking into account the perturbations of Jupiter and Saturn.

In 1786 Oriani conducted trigonometrical operations for measuring an arc of the meridian over Lombardy. He continued the ephemeris begun by **Joseph Lagrange**, and inserted in it many able and valuable discussions on the lunar theory, on refraction, and various practical and theoretical matters. His skill in spherical trigonometry enabled him to be the first in computing the path and perturbations of the first minor planet, (1) Ceres (discovered by his friend Piazzi in 1801). Oriani became one of the leading observers of the first four asteroids.

In 1802 Oriani was made director of the Observatory of Brera, and he became one of the founding members of the National Institute of the Italian Republic. That year he was sent to Bologna by order of the Italian Republic and found "astronomy almost abandoned." Oriani tried to revive the observatory there by offering its directorship to Piazzi, but he refused.

Oriani was long known in scientific circles as abbot and professor. When Napoleon established the republic in Lombardy, Oriani refused absolutely to swear hatred toward monarchy; the new government modified the oath of allegiance in his regard, retained him in his position at the observatory, and made him president of the commission appointed to regulate the new system of weights and measures. When the republic was transformed into the Napoleonic kingdom, Oriani received the decorations of the Iron Crown and of the Legion of Honor, was made count and senator of the kingdom, and was appointed (in company with Angelo de Cesaris) to measure the arc of the meridian between the zeniths of Rimini and Rome.

In private life Oriani was of a pleasing and amiable disposition, and a great encourager of study amongst the youths of his acquaintance. A longtime acquaintance, **Giovanni Plana** of Turin, wrote of him in tribute: "His splendid talents, by which he has rendered illustrious not only the Observatory of Milan, but the whole of Italy, made him highly respected, and caused his loss to be seriously deplored."

Orontius Finaeus

➔ **Finé, Oronce**

Osiander, Andreas

Born **Gunzenhausen, (Bavaria, Germany), 19 December 1498**
Died **Königsberg (Kaliningrad, Russia), 17 October 1552**

German theologian, reformer, astronomer, and mathematician Andreas Osiander's most notorious role in astronomy was the writing of an anonymous preface to the first edition of **Nicolaus Copernicus**'s *De Revolutionibus Orbium Coelestium*, suggesting that the heliocentric idea was merely a mathematical hypothesis and not the actual way the Solar System was laid out.

Osiander was admitted to the University of Ingolstadt on 9 July 1515, but left without a degree. He was ordained a priest in Nuremberg in 1520. In 1522 Osiander joined the cause of the Reformation, and became one of the leading spokesmen of Lutheranism. He frequently participated as a representative of Nuremberg's clergy at gatherings of Lutherans, among others the Marburg Conference (1529), the Diet of Augsburg (1530), and the signing of the Schmalkaldic Articles (1537). In 1548 Osiander refused to agree to the pro-Catholic Augsburg Interim, the compromise temporary settlement of the religious wars. His refusal made it necessary for him to leave Nuremberg, and he went to Königsberg. In 1549 Duke Albrecht of Prussia, who regarded Osiander as his spiritual father, appointed him as pastor of one of Königsberg's churches and professor of theology at the newly founded university of the city. Osiander retained the support of the duke until his sudden death.

Osiander was a rigid man, given to strong opinions that he did not express with moderation. His style fomented theological divisions in Königsberg that subsequently involved the whole German Evangelical Church. As a theologian Osiander developed a mystical interpretation of the Lutheran doctrine of justification by faith. His views found supporters among the strict Lutherans, who refused any compromise with Rome or Calvinism, and were opposed by the moderate wing, headed by Philip Melanchthon and the group of Wittenberg University, who strove for reconciliation.

Though Osiander was primarily engaged in theological matters, he also entertained a deep interest in mathematics and astronomy. It is known that Osiander corresponded with the mathematician **Girolamo Cardano** about horoscopes for some 5 years. But his place in the history of astronomy is mainly due to his involvement in the first edition of Copernicus's *De revolutionibus orbium coelestium*, and the famous preface that he inserted, in which he warned readers that the book was not intended to propose more than a mathematical hypothesis. Osiander was approached for the publication of the book by **Rheticus** professor at the University of Wittenberg and an admirer of Copernicus. Osiander is said to have been shocked by the implications of Rheticus's *Narratio prima*, the first published account of the Copernican system. He never accepted the possibility that the proposed system could be anything more than another attempt to "save the phenomena."

On 20 April 1541, in letters to Rheticus and Copernicus, Osiander stated his opinion, while Rheticus was waiting in Frombork (Frauenburg) for Copernicus to put the final touches on the manuscript of *De revolutionibus*. Osiander urged the inclusion in the introduction of the statement that even if the Copernican system provided a basis for better and easier astronomical computations, it might still be false. Historians agree that Copernicus firmly rejected Osiander's recommendation. At the time of the printing of the book, Copernicus was taken seriously ill in Frombork, and Rheticus supervised the printing of the manuscript in the printing shop of Johannes Petreius in Nuremberg. In the final phase of the printing Rheticus was appointed professor of mathematics in the University of Leipzig and was obliged to go there; he left Osiander to see through the final stages of the publication. Osiander surreptitiously slipped in an unsigned preface, denying that the book intended to propose more than a mathematical hypothesis, and represented as impossible a task of discovering how the Universe is laid out.

Osiander's statement was a reassertion of the traditional position regarding the astronomical method known as "save the phenomena." Copernicus appears to have believed in the reality of his system, but because Osiander's preface was unsigned, it was widely believed to represent the views of Copernicus. For this reason it was thought by most in succeeding years that Copernicus himself had not really believed that the Earth could move.

When copies of *De revolutionibus* reached Rheticus in Leipzig, he became enraged and sent to the City Council of Nuremberg a sharp protest written by Tiedemann Giese, one of the closest friends of the deceased Copernicus. Petreius replied that he had received the preface in a form undifferentiated from the rest of the material. Whereas Osiander never publicly acknowledged his authorship of the interpolated preface, he did so privately, and finally in 1609 in *Astronomia nova* **Johannes Kepler** stressed that Osiander, not Copernicus, had penned this preface.

Outhier, Réginald [Réginaud]

Born **La Marre, (Jura), France, 16 August 1694**
Died **Bayeux, (Calvados), France, 12 April 1774**

Réginald Outhier was an observational astronomer who also undertook geodetic work in Lapland and France. He studied in Poligny, Dole, and Besançon, the new capital of Franche-Comté. Outhier became a priest of the diocese of Besançon, acting as vicar at Montain near Lons-le-Saunier. It is there that he first became interested in astronomy.

In 1726 Outhier invented a moving globe that showed the apparent movement of the Sun and the Moon, and the movement of the nodes of Moon's orbit. This globe, 5 in. of diameter, was executed by J. B. Catin; it is represented in the *Machines de l'Académie* and was praised by A. Thiout in his treatise on watches and clocks (1741). As a consequence of his work, Outhier was named on 1 December 1731 a correspondent of **Jacques Cassini** (then in 1756 of **César Cassini de Thury**) at the Academy of Sciences in Paris, where he was invited to present his globe.

Paul d'Albert de Luynes, Bishop of Bayeux since 1729, who occupied his leisure in astronomy, gnomonics, and meteorology, invited Outhier to come to Bayeux to act as his secretary. Upon his arrival, Outhier sketched in the bishop's library a large meridian with lines marking the time from 5 min before and after real noon.

In 1733, Outhier joined the team of Cassini II, which measured the perpendicular to the Paris meridian; he participated in the work from Caen to Saint-Malo and (the last measures) in Bayeux. Then Outhier drew a map of the diocese of Bayeux (published in 1736). On the basis of these works, the Academy of Sciences designated him, in 1735, a member of the Lapland expedition commanded by **Pierre de Maupertuis**. It also provided him with a pension of 1,200 livres.

Outhier left Bayeux in December 1735 and, after 5 months of preparation, the Lapland expedition members proceeded to Dunkerque, where the Swedish physicist, **Anders Celsius** (coming from London with some instruments) met them. They took a ship on 2 May 1736, arriving in Tornea, near the Arctic Circle, on 22 June. Outhier wrote the "Journal du Voyage" in which he described the measures of the arc of the meridian done from 1736 till 1737 and the measure of a baseline on the ice in winter. He also drew several maps of the areas covered. This work, published in 1744, described the charming simplicity of life in Sweden and the habits of the Laplanders. It was translated into English in 1777.

Back in Bayeux, Outhier continued his geodetic work for the *Carte de France* at the request of Cassini III. In 1735 and 1736, the Paris Observatory triangulated the coasts of Picardy and Brittany and, in 1737, César Cassini de Thury and **Giovani Maraldi** followed the coast southward, leaving Abbé Outhier in charge of finishing the remaining Norman coasts near Cherbourg.

From 1749 until 1755, Outhier drew up the diocese almanacs. In 1750, he reported a light earthquake felt from Avranche to Cherbourg. He published in 1755 a map of stars of the Pleiades, the 35 main stars of which had been observed by **Pierre–Charles Le Monnier** and the others by himself. At Bayeux, Outhier made meteorological and astronomical observations: for example, the transit of Venus of 6 June 1761 with a 36-in. focal length refractor with a micrometer, and the lunar eclipse of 8 May 1762. He also traveled to Sens and drew topographical maps of the Meaux and Sens dioceses, probably called there by Monsignore de Luynes.

Outhier was named in 1748 Canon of the Bayeux cathedral, a benefice he left in 1767 to concentrate upon his scientific work. He had participated in two of the most important scientific operations of 18th-century France, the *Carte de France* and the Lapland expedition. Outhier was a correspondent of the Paris Academy of Sciences; he was also member of the Berlin Academy, and in France of the Caen and Besançon academies.

Ovid

Born **Sulmona (Sulmona, Abruzzo, Italy), 20 March 43 BCE**
Died **Tomis (Constanza, Romania), 17**

In a number of his poems the Roman poet Publius Ovidius Naso describes celestial mythology, constellations, and calendrical lore related to the sky. The chief source for his life is one of his own poems, *Tristia* 4.10. Descended from an equestrian family, he was born in

Sulmo, a mountain town some 90 miles northeast of Rome. Ovid and his brother were sent to Rome at an early age for training in rhetoric and to prepare for careers in public life. After an extended tour of the Greek East, Ovid returned to Rome to hold a few minor public offices but chose rather to devote himself to poetry under the patronage of Marcus Valerius Messalla Corvinus (64 BCE –8). The poet soon became the darling of the brilliant social life of the capital.

In 8, Emperor Augustus, for reasons not fully known, exiled Ovid to Tomis, the modern Constanza, a barely Romanized outpost on the western coast of the Black Sea. Life there was a sad and harsh change from his former life at Rome. After years of unsuccessful appeals to Augustus and to his successor Tiberius, the poet died there. Ovid was married three times and had at least two children; his last wife remained behind in Rome during his exile. Ovid has greatly influenced subsequent western literature and art, particularly with his love poetry.

Although clearly informed by literary rather than scientific considerations, much astronomical material is found in three of Ovid's works. His *Aratea*, a Latin version of **Aratus**'s *Phaenomena*, is now lost except for two brief fragments. Two other major works incorporating celestial references do survive, however, and both seem to have been composed at about the same time, before and during the poet's exile: the *Fasti* and the *Metamorphoses.* Taken together, these two works complement one another in Ovid's incorporation of celestial storytelling.

The 15 books of the *Metamorphoses* retell in dactylic hexameters almost the whole range of classical mythology based on the idea of change. The tales are mostly Greek in origin, but the last three books are concerned with Roman myth and history right up to Ovid's own day. An Ovidian cosmogony begins the *Metamorphoses* (1.5–88). Reminiscent of the beginning of **Hesiod**'s *Theogony*, the account details the evolution of the Universe out of disorder (*chaos*) and the role of the four elements in the process. Ovid also ascribes to divine intervention the eventual creation of the world and the appearance of humans. In Book Two, the story of Phaethon, with his attempt to drive the chariot of the Sun, features engaging passages with astronomical themes, including a description of the palace of the Sun and the constellations that the reckless young man encounters in his uncontrolled ride through the heavens (2.1–327). Elsewhere, astral myth in the form of catasterism appears. The most prominent of such episodes is that of Callisto and Arcas (2.410–530), which is also retold at *Fasti* 2.153–192. The tale is exemplary for Ovid's literary methodology: As in a number of other tales of terrestrial beings transported to the heavens, the poet reworks Aratus's version. The *Metamorphoses* concludes with the poet's description of the celestial portents and the comet, the *Sidus Iulium*, which appeared upon the death of Julius Caesar (15. 745–870).

The six books of the *Fasti*, Ovid's unfinished religious calendar in elegiac couplets, cover the year from January to June and relate stories associated with Roman holidays. The reader of the work is presumed to be conversant with the heavens, and the poet intersperses among the work's longer narratives calendrical references to astronomical occurrences. The *Fasti* likewise incorporates astral myths of many constellations, often presenting differing versions for a given star group and offering variants on the accounts in Aratus. This borrowing and adaptation is primarily a literary process (*variatio*), and at least some of the technical errors may also be attributed to the literary rather than the scientific bases of the work. Nevertheless, Ovid's so called "Eulogy of the Astronomers" (1.295–310) introduces the concepts of Stoicism, linking his work with a similar philosophical approach taken by Aratus.

The number of familiar constellations and stars in the *Fasti* is substantial, with 27 of the former traceable to those described by Aratus. The accounts vary in length and complexity, ranging from the involved to the simple, and some star groups (Hyades, Pleiades, Orion) are mentioned several times. As in the *Metamorphoses* Ovid also incorporates political and cultural themes into some of the tales. The concept of ruler catasterism, as promoted by Hellenistic monarchs and eventually supportive of the Augustan imperial program, is clearly evident in places. Most particularly this is true of the star Capella (5.111–28), to be linked ultimately to the constellation Capricorn, Augustus's own birth sign and a public symbol for the return of the Golden Age.

P

Page, Thornton L.

Born **New Haven, Connecticut, USA, 13 August 1913**
Died **Houston, Texas, USA, 2 January 1996**

Spectroscopist Thornton Page, son of prominent American physicist Leigh Page, was almost a martyr to astronomy; his near-fatal fall from the 82-in. telescope platform is recounted in **David Evans** and Derral Mulholland's history of the McDonald Observatory. Page's post-world-war work on binary galaxies foreshadowed what was to become the missing mass problem. Page is known in popular circles for having participated on the "Robertson panel," convened in January 1953 by the United States of America's Central Intelligence Agency as a "Scientific Advisory Panel on Unidentified Flying Objects."

Palisa, Johann

Born **Troppau, (Opava, Cech Republic), 6 December 1848**
Died **Vienna, Austria, 2 May 1925**

Johann Palisa was an excellent astronomical observer, discovering many minor planets whose orbits he helped to determine. He came from a poor family; his father dealt in salt. Palisa married twice. Two of his daughters married astronomers, Erna to Friedrich Bidschof, astronomer in Vienna and Trieste, and Hedwig to Joseph Rheden, a keen observer and collaborator of Palisa's. Palisa's mathematical abilities appeared quite early; after finishing school in Troppau, he began to study mathematics and astronomy at the University of Vienna in 1866. The astronomers of the old Vienna Observatory (**Karl von Littrow**, **Edmund Weiss**, and **Theodor Ritter von Oppolzer**) enabled him to earn some money doing observational and computational work. In 1870, after completing his military service, Palisa received a position at the observatory, located in the center of town, measuring positions of stars and planets with a meridian circle and making drawings of sunspots.

In 1871, Palisa worked for several months at the Geneva Observatory. He applied for and, with the recommendation of Weiss, received the position of the director of the Austrian Naval Observatory at Pola (now Pula, Croatia, on the Adriatic Sea). Palisa was responsible for time service observations and the Austrian Navy ship chronometers.

Taking advantage of the better observing conditions at Pola, Palisa took up Oppolzer's suggestion to observe minor planets with the 6-in. refractor there. The discovery of new ones by visual means required precise star charts including faint objects. Palisa used the *Bonner Durchmusterung* charts, as well as those of **Christian A. Peters** and **Jean Chacornac**, but he soon started to draw his own charts of small areas along the ecliptic. Furthermore, orbital determinations required precise positions of reference stars. For determining positions, Palisa used the Pola's 6-in. meridian circle by Troughton & Simms. In March 1874, Palisa discovered minor planet (136) Austria and by 1880, a total of 28 minor planets. He emphasized the importance of reobserving asteroids in order to secure good orbit determinations. In 1876, Palisa received the Lalande Prize of the Paris Academy of Sciences for the rediscovery of (66) Maja, lost since its discovery in 1861.

Meanwhile, a new observatory in Vienna featured a 27-in. Grubb refractor, then the world's largest. Weiss offered Palisa a position, which he accepted, giving up his rank of navy captain to become simply a member of an institute. By the end of 1880, Palisa moved to Vienna, where he received a Ph.D. in 1884. In May 1881, he discovered minor planet (220) Stephania; while in Vienna, he found a total of 93 asteroids using visual techniques. Palisa focused on determining their orbital elements and preparing star charts, using Vienna's 12-in. Clarke refractor. For over 40 years, he worked every clear moonless night. Palisa made careful notes about stellar positions in his copy of the *Bonner Durchmusterung*. In 1902, he published these notes under the title "Stern-Lexikon."

Palisa put forth his efforts into determining positions of objects recently discovered by **Maximilian Wolf** in Heidelberg and by

August Charlois in Nice. The Paris Academy of Sciences honored his work again in 1906, awarding him the Valz Prize, with **Maurice Loewy** declaring that Palisa had accomplished more in this field than other astronomers put together. Nearly every object he discovered was numbered and named, and could be reobserved during its next opposition. Only one, (719) Albert, was lost, finally rediscovered by the Spacewatch Project at Kitt Peak in spring 2000.

Palisa's style of work changed after 1892. Along with Wolf, he began to work on the production of a new photographic atlas along the northern region of the ecliptic: the Wolf–Palisa charts. Survey plates taken in Heidelberg were superimposed with precise coordinate grids prepared in Vienna. Their handy size made these prints especially valuable for direct work at the telescope. From 1908 to 1914, 180 sheets covering 50 square degree areas along the ecliptic were printed in Vienna; about 125 copies were sold. The price of each was set to earn enough money for the production of the next. World War I stopped the work; after 1918, it was impossible to sell enough copies, ending the production of these charts.

Palisa received an invitation to participate in a solar-eclipse expedition in 1883 at the Caroline Islands in the Pacific Ocean. Others in the expedition included **Pierre Jules Janssen** and **Étienne Trouvelot** from Paris and **Pietro Tacchini** from Rome. Astronomers thought they might find a new planet located between the Sun and Mercury, though the search was unsuccessful. Palisa was a government guest on board a French navy ship but had to find funding to return to Vienna *via* the United States, where he visited various observatories.

With the assistance of the Austrian emperor and the Academy of Sciences, as well as government and some private funds, he started naming minor planets he discovered in commemoration of those who supported his research.

In Vienna, Palisa was well known as an astronomy popularizer. He fascinated audiences with clear explanations of difficult problems. In 1910, he even rented the Vienna Musikvereinssaal, the concert hall of the best Viennese orchestras, to explain Halley's comet (IP/Halley) to the public. Vienna's immense growth around the turn of the century placed the observatory near the center of town, with deteriorating observing conditions. Palisa campaigned for a good telescope outside of the city, a wish left unfulfilled because of economic conditions.

After Weiss's retirement in 1909, Palisa hoped to be the Vienna Observatory's new director, but Josef von Hepperger (1855–1928), professor of theoretical astronomy, was appointed instead. For a short time, Palisa protested by giving up observing, but he could not stand to live without a telescope. He was forced to retire at the age of 71, but received special permission to continue his work and to use the observatory's equipment.

Palisa received many honors: the *Ritterkreuz* des Franz Josephs-Ordens (Austrian distinction: 1874); Lalande Prize of the Academy of Sciences, Paris (1876); Valz Prize of the Academy of Sciences, Paris (1906); Member of the Astronomische Gesellschaft (1875); *Bürger von Wien* (honorary citizen of Vienna, 1921); and Minor Planet (914) Palisana. A lunar crater (Palisa) is named in his honor.

Palitzsch, Johann

Born **Prohlis near Dresden, (Germany), 11 June 1723**
Died **Leubnitz near Dresden, (Germany), 21 February 1788**

Johann Palitzsch was the first to view Halley's comet (IP/Halley) on its 1758 return. Coming from a farm family, he studied astronomy at home and attended the Mathematischer Salon in Dresden. Thanks to his recovery of Halley's comet, Palitzsch became, in 1759, instructor in astronomy to the young Elector Friedrich August III. He is reputed to have recognized Algol's variability.

Palitzsch was instrumental in introducing both the potato and the lightning rod to Saxony. A small museum honoring him is being planned on the outskirts of Dresden.

Palmer, Margaretta

Born **Branford, Connecticut, USA, 1862**
Died **New Haven, Connecticut, USA, 30 January 1924**

Margaretta Palmer obtained the first doctorate in astronomy awarded to an American woman by an American institution. (Winifred Edgerton's 1886 doctorate had been awarded by the department of mathematics at Columbia University, whereas **Dorothea Klumpke Roberts** earned the equivalent degree, a *Docteur ès Science*, from the University of Paris in 1893.) Palmer was descended from a Branford, Connecticut, family that settled there in colonial days. She attended Vassar College, New York, where she was a student of America's first woman astronomer, **Maria Mitchell**. Palmer graduated in 1887 and for the next 2 years served as Mitchell's assistant. When Mitchell retired in 1888, she pleaded with the college president to find a place for Palmer, whom she described as "remarkably faithful and conscientious." Because the college did not have funding for Palmer's salary, it has been assumed that her employment under Mitchell was sustained through private funding provided by Mitchell herself.

In 1889, Palmer began work at Yale University. She was to carry out the reductions of observations of the minor planet (7) Iris that had been acquired the preceding year. In 1892, Yale opened its graduate school to women students. Palmer took advantage of this opportunity and acquired her Ph.D. in 1894. Her dissertation dealt with an improved orbit for comet C/1847 T1, which had been discovered by Mitchell and had catapulted her to lasting fame.

In 1894, Palmer undertook an enormous computational task, unfortunately left unfinished, related to the reduction of observations of the satellites of Jupiter. She set up 1,128 observational equations of condition with 13 unknowns. Illness interrupted completion of this project. If only she could have had the benefit of modern computing facilities! She also worked on the compilation of atmospheric refraction tables for correcting the apparent positions of celestial objects to their true coordinates.

The "Yale Index to Star Catalogues" was begun under **William Elkin**'s directorship of the Yale Observatory in 1897, with the assistance of J. S. Newton, daughter of the previous director. Soon, Palmer was put in charge of this monumental task. Such an undertaking had been suggested as early as 1878 by **Arthur von Auwers** of Germany, but was not begun, as the *Geschichte des Fixsternhimmels* [GFH], until 1897. The first of 24 volumes for Northern Hemisphere stars were not published until 1922, the last in 1936, and the 24 volumes for Southern Hemisphere stars appeared between 1937 and 1952. The "Yale Index" was never published, but Palmer made it known that anyone needing astrometric data for any particular stars would be furnished references to, or the actual observations from, such sources – a service indispensable for astronomers determining the proper motions of stars.

Elkin retired in 1910, and only acting directors supervised the work started under his regime. In 1918, **Ernest Brown**, a mathematics professor renowned for his analyses of the motions of the Moon, was instructed to close the Observatory until the end of World War I. Palmer was the only employee left, and her services were considered so valuable that she was given an appointment in the college's library, working half time classifying scientific and mathematical books, and allowed to continue her astronomical research the rest of the time.

When **Frank Schlesinger** was appointed Observatory director in 1920, he found Palmer to be an ideal assistant, familiar with previous projects and especially qualified to work with him on the first general catalog of trigonometric stellar parallaxes. This too was a tremendous undertaking, but one for which her previous work on the "Yale Index to Star Catalogues" proved invaluable. Sadly, Palmer did not live to see the completion of the catalog of parallaxes. She died as a result of an automobile accident.

Palmer had been a member of the American Astronomical Society from 1915 until her death. During that interval, she gave two oral reports at meetings of the society, one in 1918 on the "Yale Index" and another in 1921 on the orbit of comet 35P/1788 Y1 (Herschel–Rigollet).

Pannekoek, Antonie

Born **Vaasen, the Netherlands, 2 January 1873**
Died **Wageningen, the Netherlands, 28 April 1960**

Antonie Pannekoek made valuable contributions to our early understanding of the spectra of stellar atmospheres, but is best remembered for his majesterial history of astronomy. The son of Johannes and Wilhelmina Dorothea (*née* Beins) Pannekoek, he developed his interest in astronomy at an early age. As a young amateur Pannekoek was a careful and skilled observer. In 1891 he detected independently the brightness variations of Polaris (α Ursa Minoris), and was the first to determine its approximate periodicity. Concerned about the value of his data – the amplitude of variation is only 0.11 m – Pannekoek waited until 1913, when photographic and photometric data had become available, to propose the Cepheid nature of the star. Prior to his entrance into the university, Pannekoek also developed a light curve for β Lyrae and began a lifetime series of visual and photographic observations of the Milky Way. Pannekoek studied at Leiden University, where he earned a Ph.D. defending a thesis on the eclipsing system Algol (β Persei) in 1902 and acted as a staff member between 1899 and 1906. He married Johanna Maria Nassau Noordewier in 1903.

Pannekoek was launched on a successful career in astronomy when, in 1906, he had observed, independently from **Ejnar Hertzsprung**, that apparently bright red stars included some that must be substantially more luminous than others. His discovery of what later came to be known as red giants and red dwarfs was based on the significant differences between the parallaxes and proper motions of the groups of stars. Paradoxically, however, Pannekoek left astronomy to pursue his second passion, that of social justice and reform. As a political activist, one properly described as an antiauthoritarian Marxist, he spent the years from 1906 to 1914 as a teacher in Berlin, where he became one of the main leaders of the antirevisionist movement. Pannekoek contributed extensively to leftist publications in Europe and the United States. In 1914 he was deported from Germany. He returned to the Netherlands as a high school teacher while continuing his political writing and activism.

Pannekoek resumed his astronomical work in 1915, and was one of the first (in 1920) to recognize the relevance of **Meghnad Saha**'s law for deriving stellar diagnostics from spectroscopic observations. With that flash of insight, Pannekoek dropped the work he had to take up the theoretical study of stellar atmospheres and made important contributions to the field. **Marcel Minnaert** credited him with initiating the study of astrophysics in the Netherlands after Pannekoek founded, in 1921, what is now known as the Pannekoek Institute of Astronomy at the University of Amsterdam. He understood at an early date that certain line ratios in stellar spectra, which are correlated with stellar luminosity, actually probe the gravity in the stellar atmosphere. One of the striking results of his work on stellar atmospheres was his 1946 suggestion that in some pulsating stars the sound wave that moves outward converts gradually to a shock wave and ejects some material at the time of maxium radius on each pulsation cycle, a remarkably prescient suggestion that was later confirmed.

Throughout his career Pannekoek excelled in the careful measurement of astronomical information from photographic plates. The galactic studies he carried out during his early years in Amsterdam are characterized by a thorough understanding of what the eye can see on such plates. Pannekoek's knowledge of astronomical photography enabled him to pioneer, with **John Plaskett**, the quantitative analysis of photographic stellar spectra, on which the research during his later career strongly relied. Using spectra of Deneb (α Cygni) he had taken at the Dominion Astrophysical Observatory (near Victoria, British Columbia, Canada) in 1929, and a technique he invented (using log tables and mechanical calculators) for numerically integrating the equation of radiative transfer that arises from **Arthur Eddington**'s approximation, Pannekoek was the first astrophysicist to develop an empirical stellar (nonsolar) curve of growth similar to those developed for solar spectra by Harald von Klüber (1901–1978) and Minnaert. His 1930 chapter on ionization in stellar atmospheres in the *Handbuch der Astrophysik* was an important early fundamental contribution to the field. By 1935, Pannekoek had done extensive theoretical modeling of the line widths that could be expected in stellar spectra taking into account every known factor. The line widths were systematically in error, especially in cooler stars, but he predicted positions of maximum line intensity correctly. The missing factor in Pannekoek's equations was soon recognized when **Rupert Wildt** demonstrated the previously unappreciated role of negative hydrogen ions in the production of continuous absorption in cool stars.

In 1938, Pannekock made the first theoretical calculation of the widths of the Balmer series of hydrogen spectral lines applying the Stark effect to demonstrate the broadening of the wings of those lines as a function of stellar gravity. In other work, Pannekoek contributed to the understanding of metal concentrations on stellar opacity, showing that at high effective temperatures, hydrogen concentration was the dominant influence on stellar opacity and color, while at lower temperatures the effect of metallicity dominated. His analysis showed where the two effects were nearly balanced, proposing an effective temperature of about 10,500 K for stellar class A0, very nearly the value that has since been accepted.

Pannekoek's studies of the Milky Way galaxy continued for 60 years, and involved visual drawings and photographic surveys of both the Northern and Southern Hemisphere skies. He added isophote lines to show contours of brightness that have formed the basis for many popular star atlases. Pannekoek also studied the distribution of giant stars in the Milky Way using statistical approaches to the spectral parallaxes of A and K stars and spectral parallaxes of individual B stars. In this work he identified the clusters of the early stars later called associations. Pannekoek's work on the distribution of stars in the Milky Way Galaxy had a profound effect on thinking about galactic structure; his approach was later successfully applied by **Viktor Ambartsumian**, **William Morgan**, **Albert Whitford**, and Arthur Dodd Code (born: 1923).

In 1942 Pannekoek's career as professor in Amsterdam ended when he was dismissed by the German occupation forces. Until his death he remained active as a leading socialist theoretician and pursued individual astronomical studies. During and after World War II, Pannekoek's personality as both a leading scientist and a warm humanist found a remarkable expression in the historical work. His *A History of Astronomy* appeared first in 1951 in Dutch under the title *De groei van ons wereldbeeld*, which may be better translated as “The emergence of our view of the world.” His historiography reflects both of his lifetime preoccupations as he examined the history of astronomy from Babylonian to modern times in relation to the social and political systems extant in each relevant period. This remarkable book then not only offers an accurate and well-documented introduction to the history of the discipline, but also helps the modern reader to see the cosmos with the eyes of ancient people who shared with Antonie Pannekoek the delight of the beauty of the heavens. He gave full credit to Hertzsprung for distinguishing giant and dwarf stars despite his own contribution to the topic. The accuracy and insight Pannekoek offers on matters astronomical outweighs his occasional forays into political polemicism, and the book remains one of the standards in the field.

Harvard University conferred an honorary Ph.D. upon Pannekoek in 1936, while in 1951 the Royal Astronomical Society honored him for his astrophysical contributions by awarding him its Gold Medal.

Papadopoulos, Christos

Born **Prussa, (Turkey), 20 February 1910**
Died **Westcliff near Johannesburg, South Africa, 8 May 1992**

Christos Papadopoulos created what is likely to be the last great photographic atlas of the whole sky taken with one camera in one consistent sequence of well-controlled photographic charts corrected to visual magnitudes. Educated as a civil engineer in Greece, Papadopoulos fought with Greek resistance forces during World War II and then immigrated to South Africa after the war. Successful as a manager of engineering construction, he retired at the peak of his capacities to devote his time to two avocational interests: cinematography and astronomy.

Papadopoulos's greatest contribution to astronomy came in his combination of these two avocational interests in the creation of a photographic all-sky star atlas. The goal of this project was to completely photograph the sky with film and filter combinations that produced, as nearly as possible, a star atlas in which the photographic representation of the sky matched, to the greatest extent possible, the telescopic visual appearance of the sky at visual magnitudes as faint as 13.5. Similar undertakings by private individuals had previously been attempted only by **John Franklin-Adams** early in the 20th century, and again by Hans Verhenberg (1910–1991) in the middle of the same century. Neither effort was intended, however, to match the photographic representation to the visual appearance of the sky in a photometric sense.

Papadopoulos completed his Herculean task with the publication, in 1979/1980, of *The True Visual Magnitude Photographic Star Atlas*. One thousand photographic exposures of the southern, equatorial, and northern regions were taken from Papadopoulos's private observatory at his home in Westcliff, Johannesburg, and at the Stamford Observatory, Stamford, Connecticut, USA (by Charles E. Scovil). The plates were carefully matched on depth of exposure and sky brightness to produce the final atlas.

Papadopoulos was honored for this achievement by the presentation of the Astronomical Society of South Africa's Gill Medal in 1981.

Pappus of Alexandria

Flourished **probably 4th century**

Primarily a mathematician, Pappus also wrote commentaries on **Ptolemy**, **Aristarchus**, and **Theodosius**, and summaries of other astronomers such as **Apollonius** and **Eratosthenes**.

Pappus's dates from the literary sources are uncertain, though he was apparently computing an eclipse in 320. His most recent cited source is Ptolemy; a scholiast puts Pappus in the reign of Diocletian (284–305); and the *Suda* has him a contemporary of **Theon of Alexandria**, and flourishing in the reign of Theodosius (379–395).

His surviving work provided and continues to provide points of departure for developments in the history of mathematics. He, with Diophantus, provided François Vieta with his point of departure in the development of algebra; one problem in Collection 7 provided **René Descartes** with his point of departure for his *Geometrie*; and Pappus's work continues to appear as starting points for articles in mathematical journals.

Credited with being halfway between compiler–commentator and originator, Pappus was fully capable of extending the work of his predecessors. His greatest – or at least most famous – individual achievement is the universalizing of Euclid 1.47, the Pythagorean theorem. Pappus further extended work of **Archimedes** and (apparently) originated the theorems that were rediscovered and named after Paul Guldin.

As reporter of the *status quo* of the mathematics of his time, it is owing to Pappus that we have the Greeks' threefold division of problems: (1) solvable with straightedge and compass, called plane; (2) solvable with one or more conics, called solid; and (3) solvable with a more complicated curve, called linear. Modern mathematicians still find this classification appropriate, though they would rename (3) and further split it into algebraic problems and transcendental problems.

Pappus's principal surviving work is the *Collection*, a treasury of all the mathematics of his time, including some of his own, in eight books. We have fragments from his other works: a commentary on Ptolemy's *Almagest*, a commentary on Euclid 10, and a geography.

The *Collection* contains such mathematical topics as arithmetic, geometric, and harmonic means, the universalizing of Euclid, the globularizing of the spiral of Archimedes, and epitomes of Euclid, Apollonius, Aristaeus, and Eratosthenes; there is also a summary of mechanics. The astronomy is in book 6, which gives commentary on Theodosius's *Spherics*, **Autolycus**'s *On the Moving Sphere*, Aristarchus's *On the Size and Distance of the Sun and the Moon*, plus Euclid's *Optics and Phenomena*.

Parameśvara of Vāṭaśśeri [Parmeśvara I]

Born **Ālattūr, (Kerala, India), *circa* 1360**
Died ***circa* 1455**

Parameśvara, one of the foremost astronomers of Kerala, hailed from the village of Ālattūr (Aśvatthagrāma in Sanskrit), and his house, Vāṭaśśeri, was situated on the confluence of the river Nīla with the Arabian Sea. He was a *Ṛgvedin*, of the *Aśvalāyana Sūtra*, and belonged to the *Bhṛgugotra*. He was a pupil of Rudra I. He carried out astronomical observations near his house for some 45 years. He also observed a large number of eclipses between 1393 and 1432, which are recorded in his work *Siddhāntadīpikā*. Nothing else is known about the life of Parameśvara.

Parameśvara was a prolific writer and authored some 30 works. These include original treatises and commentaries on other works of astronomy and astrology. Among his original works on astronomy might be mentioned the following: *Dṛggaṇita* (1430); a work on spherics, *Goladīpikā* (1443); and three works on the computation and rationale of eclipses, *Grahaṇāṣṭaka*, *Grahaṇamaṇḍana*, and *Grahaṇanyāyadīpikā*. He also commented on a large number of astronomical works including the *Āryabhaṭīya*, *Sūryasiddhānta*, *Laghumānasa*, and *Līlāvatī*. Many of his works are yet to be published.

Parenago, Pavel Petrovich

Born **Ekaterinodar (Krasnodar), Russia, 20 March 1906**
Died **Moscow, (Russia), 5 January 1960**

Parenago was a doyen of Russian scholars of the Galaxy and the founding father (1938) and head (until his death) of the department of stellar astronomy at Moscow State University [MSU]. Among his many accomplishments, he played a significant role in fostering astronomical observations by amateurs. His name appears in the Kukarkin–Parenago relation between the periods and amplitudes of many different kinds of variable stars.

Parenago graduated from the faculty of physics and mathematics at MSU in 1929, concurrently working at the Astronomical–Geodetic Institute, which was soon incorporated into the present-day Sternberg State Astronomical Institute of MSU (1931). In 1935, he was awarded a doctorate in the physical and mathematical sciences (without the defense of a dissertation).

Parenago's main research field was stellar astronomy, especially studies of the structure, kinematics, and dynamics of our Galaxy. He investigated the spatial distributions and kinematics of many different classes of stars, especially variable stars. These results added important parameters to the concept of stellar populations and stellar subsystems. Parenago also made an important contribution to stellar dynamics, by creating a theory of the gravitational potential of the Galaxy. His works on the stellar luminosity function, the color–luminosity diagrams for different classes of stars, and interstellar extinction in the Galaxy were widely recognized for many years. Parenago's investigations were based on statistical treatments of the large databases that he had assembled from every accessible source.

Under the auspices of the International Astronomical Union [IAU], Parenago and Boris V. Kukarkin compiled the *Obshchii* *katalog peremennykh zvezd* (General catalog of variable stars, 1948), whose later editions are still being edited at Moscow. This catalog remains the most extensive of its kind to this day. Another of Parenago's catalogs, of the stars in the Orion Nebula (1954), achieved lasting usage, being an important collection of data on this region of star formation. Parenago authored one of the early textbooks on stellar astronomy (1938), which was repeatedly revised.

In 1948, Parenago was awarded the first Bredikhin Prize, the top astronomical award presented by the Soviet Academy of Sciences. The Order of Lenin was bestowed on Parenago in 1951, and he was elected a corresponding member of the USSR Academy of Sciences in 1953.

Parkhurst, Henry M.

Born **New Hampshire, USA, 6 March 1825**
Died **New York, New York, USA, 21 January 1908**

American amateur Henry Parkhurst observed variable stars and developed an accurate theoretical–observational relationship between orbital parameters and brightnesses for asteroids. He communicated with **Edward Pickering** on matters photometric, having initiated such measurements of long-period variable stars in 1883 and publishing a volume on a decade's worth of observations in 1893. Afterward, he published in the *Astronomical Journal*.

Parmenides of Elea

Born ***circa* 515 BCE**
Died **after 450 BCE**

Few details of cosmologist Parmenides's life are known. His dates are deduced from a story related by **Plato** that Parmenides and Zeno visited Socrates in Athens around 450 BCE, at which time Parmenides was reputedly aged about 65. An alternative chronology, ultimately deriving from **Apollodorus**, places Parmenides's birth around 540 BCE. However, this tradition is wrong and probably results from confusing Parmenides's birth with the founding of Elea.

Parmenides was the son of Pyres and appears to have originally come from Eastern Greece. He settled in Elea on the west coast of Lucania in Italy, where, according to ancient tradition, he was active in politics and renowned as a wise law-maker.

Parmenides was influenced by both **Xenophanes** and the Pythagorean Ameinias Diochaites, in whose name he erected a shrine. Indeed, in Antiquity Parmenides was considered to have been closely associated with the Pythagoreans, and in particular the Pythagorean school at Croton, southeast of Elea. Both his philosophical and astronomical ideas were similar to those of the Pythagoreans, so this connection is probably real. Parmenides founded the "Eleatic" school of philosophy, where his successors were Zeno and Melissus.

Parmenides made a greater contribution to philosophy than to astronomy. He denied that change was possible by maintaining that "what is" could not disappear, and similarly that that which does not exist could not come into existence. He denied the possibility of movement on similar grounds. He explained the apparent ubiquity of change and movement by suggesting that the senses are unreliable and do not reveal the true nature of the world. These speculations, and in particular their refutation, had profound implications on the development of Greek thought.

Parmenides's astronomical ideas are not easy to reconstruct. His surviving writings are few and fragmentary, and later sources are confused and contradictory in the views that they attribute to him. He appears to have considered the Universe to consist of a system of concentric rings or bands of fire, alternating with bands of darkness. These details come mostly from a later source, which is so heavily abridged as to be nearly incomprehensible. However, the bands are mentioned in surviving fragments of Parmenides's own writing. In the middle of the bands, guiding everything, was a divinity, personified as Justice or Necessity.

Parmenides's extant writings include the assertion that the Universe is both finite and spherical. He was not necessarily the first to hold this view, which seems to have been common among early Pythagoreans. However, his work is the first espousal of it for which the attribution is completely certain. Parmenides was speaking of the Universe as a whole, rather than just the Earth or the heavens. However, later sources misconstrue him to have said that the Earth is spherical, which his extant writings, at least, do not.

Parmenides described the Moon as an "alien light," wandering around the Earth and "always looking towards the rays of the Sun." This statement is usually taken to imply that he realized that the Moon shines by reflected sunlight. This interpretation seems reasonable, but is not undisputed. If it is correct then Parmenides is the first Greek known to hold this view. (Plato recorded that **Anaxagoras** held this opinion, but did not say that he was the first to do so.)

The extant fragments of Parmenides also mention the aether, the constellations (the signs in the aether), the Sun, the furthermost heaven, and the Milky Way, one of the first extant mentions of it in Greek.

The confused later sources attribute various ideas to Parmenides, in addition to the sphericity of the Earth, including among others, dividing the spherical Earth into five climatic zones, recognizing the Morning and Evening star as the same object, and considering the Sun, Moon, and stars as being made of compressed fire. However, these are all ideas that later sources often indiscriminately attributed to various pre-Socratics.

Unlike other early Greek philosophers, Parmenides wrote in hexameter verse rather than prose. About 150 lines of his poem *On Nature* survive, mostly through **Simplicius**, who quotes it in his commentaries on **Aristotle**. A further six lines are extant only in a Latin translation. Parmenides's ideas are described, with greater or lesser fidelity, by Plato, Aristotle, **Theophrastus,** and numerous later (and less reliable) sources.

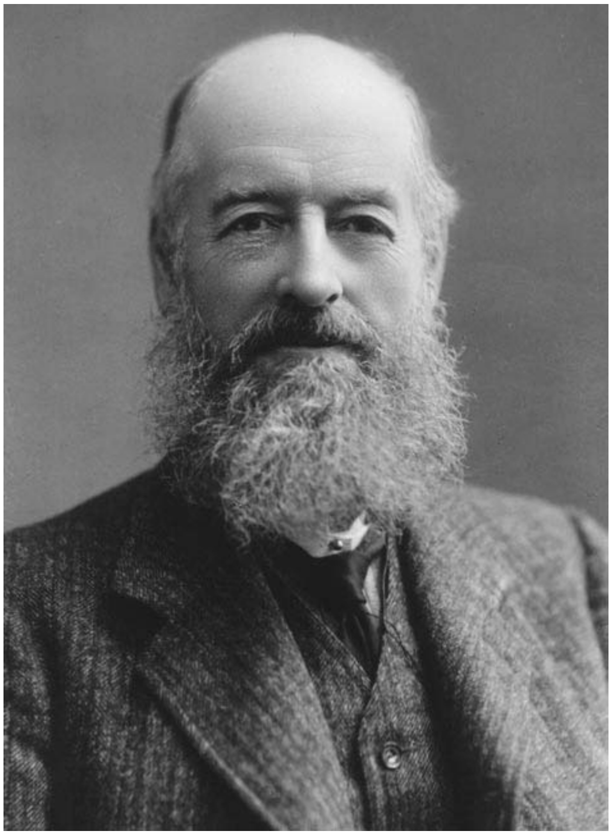
Parsons, Laurence

Born **Birr Castle, King's county (Co. Offaly), Ireland, 17 November 1840**
Died **Birr Castle, King's county (Co. Offaly), Ireland, 29 August, 1908**

Laurence Parsons, the eldest son of **William Parsons**, the Third Earl of Rosse, shared his father's enthusiasm for astronomy, continuing the study of nebulae and star clusters at Birr Castle, undertaking pioneering work on the infrared emission of the Moon and becoming the first to obtain what is now recognized as an excellent estimate of its surface temperature.



Parsons was educated at home by tutors, including the Reverend T. T. Gray and John Purser, later professor of mathematics in Belfast. The Third Earl and the Countess of Rosse took a keen interest in their children's education. The educational regimen included open-air activities on the estate and practical work in their father's well-equipped workshops. Known in his youth by his courtesy title of Lord Oxmantown, Parsons entered Trinity College, Dublin, as a nonresident student and excelled in mathematics and physics. He graduated in 1864 and immediately started to observe and sketch nebulae with the 3-ft. and 6-ft. reflectors. As a young man, Parsons had many opportunities, both in Birr and in London, to meet distinguished scientists who were friends of his father; this undoubtedly strengthened his ambition to be an astronomer.

In 1865, **Robert Ball** was appointed assistant astronomer and tutor to Laurence's younger brothers. Ball and Parsons differed by only a few months in age; they spent many nights together observing with the Birr telescopes. Parsons's first scientific paper in the *Monthly Notices of the Royal Astronomical Society* in 1866 described a water clock that he invented to drive an 18-in. equatorial telescope. His next paper, published by the Royal Society, collated all the observations of the Orion Nebula that had been made at Birr since 1849; it included an engraving of the nebula that **John Dreyer** judged as being "always of value as a faithful representation of the appearance of the Orion nebula in the largest telescope of the nineteenth century."

The Third Earl died in October 1867, and Parsons succeeded to the title and the estates. The same year, he was elected a fellow of the Royal Society and of the Royal Astronomical Society; he was also appointed High Sheriff of the county. In 1868, Parsons became a representative peer for Ireland in the House of Lords in Westminster. In 1870, he married Frances Cassandra Harvey-Hawke, only child of the fourth Lord Hawke and his second wife Frances (*née* Fetherstonhaugh).

In 1868, the Fourth Earl commenced the work for which he is best remembered, the study of radiant heat from the Moon. He was the first to make infrared measurements of any astronomical body other than the Sun. Parsons started by using a single thermocouple connected to a galvanometer but discovered immediately that the signals were affected by changes in the temperature of the 3-ft. telescope and by the ambient air temperature. He had the idea of using two identical thermocouples, connected in opposition and placed side by side in the focal plane of the telescope. One thermocouple was exposed to the Moon and the other to the sky.

At that time, no filters were available to transmit infrared radiation so Parsons used a plate of glass to block the infrared and differenced the measurements with and without the plate. He calibrated his observations by comparing his lunar measurements with those from blackened cans containing water at various temperatures. Parsons studied how the lunar radiant heat varied with the phase of the Moon and how the atmospheric attenuation varied with the distance of the Moon from the zenith. The results were summed up in his Bakerian Lecture, which he delivered to the Royal Society in March 1873. His final estimate of the lunar surface temperature was 197° F. A reanalysis of the Earl's data by William Merz Sinton (1925) in 1958 gave a value of 158° F, in good agreement with modern estimates. It was always a source of regret to Parsons that his contemporaries did not fully appreciate this achievement.

Parsons was a prolific inventor and never happier than when busy in his own workshops. As commercial thermocouples were not sensitive enough for his lunar measurements, he made his own and continued to perfect the design until a few years before his death.

Parsons was also continually trying to improve the drives of the Birr telescopes. In 1869, he fitted a clock drive to the great 6-ft. telescope that improved its ease of use but was never entirely satisfactory as the mount was not an equatorial type. In 1874, he replaced the old wooden altazimuth mounting of the 3-ft. speculum with an equatorial mounting of metal designed by B. B. Stoney and built in Dublin. While the new mount was a considerable improvement on the wooden one, it was not good enough for celestial photography.

Parsons was assisted in his investigations by a succession of talented assistants. These included Charles E. Burton, **Ralph Copeland**, Dreyer, and **Otto Boeddicker**.

The Fourth Earl took a keen interest in the development of the steam turbine, which had been invented by his youngest brother, Charles Algernon Parsons, and which revolutionized electric power generation and marine propulsion. Laurence served as chairman and director of the companies formed to exploit the invention. Charles frequently sought his advice on technical and business matters. In 1899, Laurence was made an associate of the Institute of Naval Architects in recognition of his contributions to marine technology.

Lord Rosse was elected chancellor of the University of Dublin in 1885 and remained in office until his death. He was made a Knight of the Order of Saint Patrick in 1890 and was Lord Lieutenant of King's County from 1892. Parsons served as president of the Royal Dublin Society (1887–1892) and the Royal Irish Academy (1896–1901). He received honorary degrees of DCL from Oxford (1870) and LLDs from Dublin (1879) and Cambridge (1900). The Institution of Mechanical Engineers made him an honorary member in 1888.

Following a gradual decline in health over 2 years, the Fourth Earl died and was buried in the old churchyard of Birr. He was survived by his wife and three children.

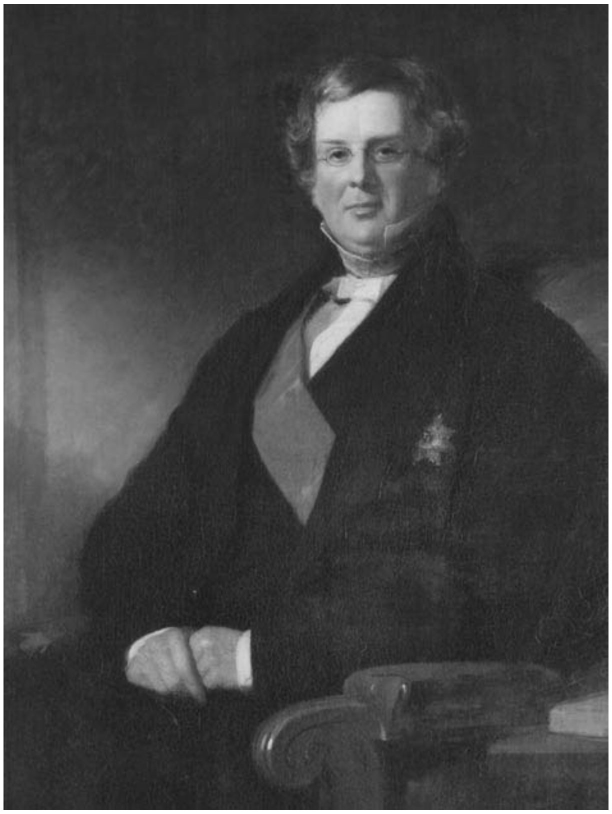
Parsons, William

Born **York, England, 17 June 1800**
Died **Monkstown, Co. Dublin, Ireland, 31 October 1867**

William Parsons, Third Earl of Rosse, a skilled engineer, ingenious scientist, and dedicated astronomer, constructed a reflecting telescope larger than any previously made, the largest in the world for seven decades. With it he discovered the spiral nature of many nebulae.



William was the eldest son of Sir Lawrence Parsons, Second Earl of Rosse and Alice (*née* Lloyd). The Parsons family came to Ireland from England at the end of the 16th century and settled in Birr, King's County (county offaly) (Parsonstown, King's County), in 1620. The Second Earl had been a prominent member of the Irish parliament since 1782, representing the University of Dublin and then his own county. With the passing of the Act of Union in 1800, his interest in politics waned and he devoted his time to the development of the town of Birr and the education of his family. William, with his brothers and his sisters, was educated at home by a series of tutors and governesses and with the active involvement of his parents.

When the title of Earl of Rosse passed to his father in 1807, William as eldest son assumed the courtesy title of Lord Oxmantown. He entered Trinity College, Dublin, in 1818 and then, with his brother John, transferred to Magdalen College, Oxford, in 1821. The following year he graduated with first class honors in mathematics. In 1823, Parsons was elected to represent King's County in the Westminster parliament; he held his seat until 1834, when he resigned in order to concentrate on his scientific interests.

Parsons became a member of the Astronomical Society of London (soon to become the Royal Astronomical Society) in 1824, just 4 years after its establishment. Through such a connection, he could have met **John Herschel**, whose father **William Herschel** had pioneered the building of large reflecting telescopes and their use in scanning the skies; in any event, Parsons and John Herschel exchanged numerous letters on astronomical matters. Parsons resolved to make a reflecting telescope as large as existing resources would allow. He could not benefit from the entire scope of knowledge of previous telescope makers, including the Herschels, for they took pains to keep some of their methods secret.

Parsons established a workshop and foundry at Birr Castle and trained his estate workers in all the practical skills that were required. After a long series of experiments to determine the optimum mixture of copper and tin for a speculum mirror, he settled on an alloy of four atoms of copper to one of tin, which he took to be in the ratio of 2.15:1 by weight. Parsons first tried making large mirrors from small segments of speculum soldered to brass plates. He invented a special machine (since widely adopted) for grinding, polishing, and parabolizing mirrors in a systematic way. The machine was driven by a small rotary steam engine of his design and made under his direction at Birr in 1827. On the strength of these achievements Parsons was elected to membership in the Royal Society in 1831. The same year he was appointed Lord Lieutenant for King's County.

In 1834, Parsons married Mary Wilmer-Field (1813–1885), the eldest daughter of a wealthy landowner who lived near Bradford, England. Mary inherited estates that were valued at £88,000 as well as a cash settlement of £8,700. Among her many interests, she became a pioneer photographer and one of the founders of the Photographic Society of Ireland.

After building a new forge, foundry, and workshop, Parsons resumed his experiments by constructing a 36-in.-diameter segmented mirror. After many trials and tribulations, in 1839 he succeeded in casting a perfect 36-in. speculum disk in one piece; it weighed 1¼ tons. A key factor in his success was the design of the casting mold, which had a base of closely packed steel strips through which gases could escape. The performance of this mirror encouraged him to attempt the casting of a 6-ft. monolithic mirror. When his father died in February 1841, William assumed the title of Third Earl of Rosse.

After many failures, two 6-ft. mirrors were successfully cast in 1842 and 1843, each weighing more than 3 tons. To avoid distortion when it was pointed in different directions, the mirror was supported by a system of 81 "equilibrated levers" suggested by **Thomas Grubb**.

The telescope tube resembled a giant barrel, 54 ft. long and 7 ft. in diameter, bulging to 8 ft. in the middle. The tube was pivoted about a huge universal joint at its base and slung with chains from two massive masonry walls, 23 ft. apart and parallel to the meridian. Horizontal movement was limited to 10° on either side of the meridian; a vertical range of nearly 110° was possible. The cost of the entire telescope was estimated between £20,000 and £30,000.

In February 1845, **Thomas Romney Robinson** of the Armagh Observatory and **James South** of London were present for the initial observations. Despite unfavorable weather, they caught a glimpse of a magnificent double star and numerous faint stars shining in M67. In April 1845, Parsons made a pencil drawing of the M51 nebula that caused a sensation when it was displayed at a meeting of the British Association for the Advancement of Science in Cambridge in June 1845. As the spiral arms suggested some sort of motion, the nebula was called "The Whirlpool." Parsons went on to discover 15 other spiral nebulae.

In autumn 1845 observational work was brought to a halt by the failure of the Irish potato crop and the resulting Great Famine. The Earl and Countess of Rosse devoted all their time and most of their income to alleviating the terrible effects of the famine. By 1848, when observations were resumed, there were many other demands on Parsons's time, so he employed a succession of able assistants, most notably **George Stoney** and **Robert Ball**. As the fame of the Great Telescope spread, visitors came from all over the world to see it and, if the weather allowed, to view the heavens.

Parsons received many honors. He was president of the Royal Society from 1848 to 1854 and was awarded its Gold Medal in 1851. He was made a knight of Saint Patrick in 1845; Napoleon III created him a knight of the Legion of Honor in 1855. Parsons was a member of the Royal Irish Academy (1822) and a member of the Imperial Academy of Science of Saint Petersburg (1852). He received honorary degrees from Cambridge (1842) and Dublin (1863). Parsons was chancellor of the University of Dublin from 1862 until his death. From 1845, he was a representative peer for Ireland in the Westminster parliament. The International Astronomical Union named the lunar crater at 17°. 9 S and 35°. 0 E in his honor.

In 1867, the Third Earl's health declined, and he took a house by the sea, just south of Dublin. He died after an operation to remove a tumor on his knee, and was buried in the old church of Saint Brendan in Birr; some 4,000 of his tenants attended his funeral.

Of the 11 children born to the Earl and Countess of Rosse, only 4 survived to adulthood. The eldest, **Laurence Parsons**, followed his father's interest in astronomy; Randal became a canon in the Church of England; Richard Clere became a successful railway engineer; and the youngest, Charles Algernon, became world famous as the inventor of the steam turbine.

After the death of the Fourth Earl in 1908, the Leviathan was partially dismantled, and one 6-ft. speculum was sent to the Science Museum in London. The great tube lay recumbent for many years until, as a result of the efforts of the sixth and seventh Earls, funding for restoration was secured in 1994. The telescope was completely reconstructed in 1996 to form the centerpiece of a historic science museum at Birr Castle.

Pawsey, Joseph Lade

Born **Ararat, Victoria, Australia, 14 May 1908**
Died **Sydney, New South Wales, Australia, 30 November 1962**

Australian radar and radio astronomer Joseph Pawsey led the group that, coming out of radar work in Australia during World War II, developed into one of the world's outstanding radio astronomy groups, whose early contributions included the demonstration of the very high equivalent temperature of emission from the solar corona, the precise location of the radio source Taurus A (leading to its identification with the Crab Nebula supernova remnant), and the development of interferometric and image processing techniques adopted by radio and optical astronomers and in ionospheric research and other areas. Pawsey was born to poor farming parents, Joseph Andrew Pawsey and Margaret Pawsey, in Ararat, Victoria, Australia. He did not start school until age eight, when he attended a small local school. At age 14, he received a government scholarship to attend boarding school at Wesley College in Melbourne, and then another to attend the University of Melbourne in 1926. Pawsey earned a B.Sc. (Honors) degree in 1929 and an M.Sc. (First Class Honors in Natural Philosophy) in 1931, and was granted an 1851 Exhibition Research Scholarship to Cambridge University, where he worked in the Cavendish Laboratory with J. A. Ratcliffe.

At the Cavendish Laboratory, while working toward his Ph.D., Pawsey studied the effects of the ionosphere on radio propagation. His observations of the reflection of radio waves from the E region of the ionosphere led to the discovery of irregularities, which move rapidly due to strong winds. This proved to be of pivotal importance in later ionospheric physics research.

After receiving his Ph.D. in 1934, Pawsey worked for 5 years at EMI Electronics Ltd., near London, on the design of aerials, especially the television transmitter being designed at Alexandra Palace. It was during this period that he met and married Greta Lenore Nicoll from Battleford, Saskatchewan, Canada, a marriage that resulted in two children, Margaret and Stuart, born in England, and another, Hastings, later in Australia. The time spent at EMI established him as an expert in antenna design, a skill that was used and developed later in his radio astronomy research. During this period, Pawsey was directly associated with 29 patents for devices that remained in wide use for several decades. However, only one external publication was written, due to EMI's policies to restrict access to research results.

After World War II broke out, Pawsey returned to Australia and took a position in Sydney with the Radiophysics Division of the Council for Scientific and Industrial Research [CSIR], later to become the Commonwealth Scientific and Industrial Research Organization [CSIRO]. During the war, he built up and led a team of engineers and physicists in studying radar transmission and reception and developing radar systems for the military. Because his work was classified, few publications were made public.

Pawsey had been interested in the prewar observations that **Karl Jansky** and **Grote Reber** had made, showing the existence of radio emission from the plane of the Galaxy. Although the science of radio astronomy had not yet been christened, Pawsey saw that the group he had assembled during the war could be kept intact if they could continue to study these phenomena and, encouraged by E. G. ("Taffy") Bowen, the chief of the Radiophysics Laboratory of CSIR, he led his group of researchers into this area. In 1945, using equipment that was originally part of the military defense of Sydney, located on a high cliff overlooking the ocean, Pawsey set up a radio receiving antenna operating at a frequency of 200 MHz. He used the interference between the direct rays and those reflected off the ocean to study the radio emission from the Sun, an approach known in optics as the Lloyd's mirror technique.

Two important results were published in *Nature* in 1946. The first was that intense radiation was emitted from a sunspot group, and this was so intense as to be nonthermal in origin. In that paper, Pawsey discussed the possibility of getting one-dimensional information about the source using two-beam interferometry with Fourier synthesis. This became one of the most powerful methods for studying the radio sky. The second discovery was that, at a wavelength of 200 MHz, the Sun has a lower limit of emission corresponding to a temperature of 1 million degrees. Soon afterward, from these observations, Pawsey and Tabsley established the intensity of thermal emission from the "quiet" Sun.

Pawsey's group studied the size, position, movement, spectrum, and growth and decay of various sources of radio emissions on the Sun. The group invented the swept-lobe interferometer (for location of rapidly moving sources on the Sun), the swept-frequency receiver (providing a spectrum of disturbances), and the grating interferometer, which had a resolving power of as little as one-twentieth of a degree, a much finer resolution than had been possible before. These techniques are now in general use in radio astronomy. Pawsey and S. F. Smerd reviewed much of this work in a chapter of a book on the Solar System edited by Gerard Kuiper. This, and an article written with E. R. Hill on cosmic radio waves, remained for many years essential reading for any student in the subject.

Members of the group discovered discrete radio sources in the Milky Way and external galaxies, and by accurately locating them were able to identify them optically. To achieve this, first the Lloyd's mirror technique, then two-aerial and radio-link interferometers were developed for the first time, followed by a series of linked antennas in the shape of a cross. The first survey of neutral hydrogen in the sky by the Pawsey group gave the first clear evidence of the spiral structure of our Galaxy. Again, these methods later became normal procedures in radio astronomy observatories around the world. Among the best-known members of the group were John Bolton (who located the Crab Nebula source and later built up the radio astronomy group at the California Institute of Technology) and Bernard Y. Mills, whose association with the T-shaped interferometer led to its frequently being called the Mills cross.

In 1955, with Ronald N. Bracewell, Pawsey wrote a book on radio astronomy that became the standard text in the field for many years. This was translated into Russian in 1958 with **Iosef Shklovsky** as editor. In 1962 Pawsey accepted the position of director of the American National Radio Astronomy Observatory in Green Bank, West Virginia, USA. During a visit to Green Bank in 1962 before taking up the post, he was diagnosed with brain cancer and, returning to his home, died. During his last illness, assisted by his devoted colleagues to get to his office each morning, Pawsey wrote the introduction to and edited a special radio astronomy issue of the *Proceedings of the Institution of Radio Engineers in Australia*, published in February 1963, which became a minor landmark in the instrumental aspects of radio astronomy.

Pawsey was a Foundation Fellow of the Australian Academy of Sciences (which now awards a Pawsey Medal in his honor), a foreign fellow of the Royal Society of London (which awarded him its Hughes Medal in 1960), and president of Commission 40 (radio astronomy) of the International Astronomical Union [IAU] from 1952 to 1958, in which role he played a key part in the definition of the IAU system of galactic coordinates, enabling the location of astronomical objects to be described in relation to the plane and center of the Milky Way, rather than in relation to the rotation axis and orbit of the Earth. The IAU named a lunar crater for him in 1970.

Payne-Gaposchkin [Payne], Cecilia Helena

Born **Wendover, Buckinghamshire, England, 10 May 1900**
Died **Cambridge, Massachusetts, USA, 5 Dec 1979**

Cecilia Payne (later Payne-Gaposchkin) demonstrated in her 1925 Ph.D. dissertation that nearly all stars have the same chemical composition, with the apparent enormous differences due largely to the wide range of stellar temperatures. She also showed that this composition was dominated largely by hydrogen and helium (which was not immediately accepted) and later became a noted expert on novae and other kinds of variable stars.

Her father was Edward John Payne, a historian, barrister, and scholar at University College, Oxford; her mother, Emma Pertz, a painter and copyist in oils, was a granddaughter of Chevalier G. H. Pertz, Hanoverian scholar and member of Parliament. Cecilia

was their oldest child, soon followed by Humfry and Leonora. When her father died, Cecilia was only four, and her mother was left with three small children whom she raised "by a miracle of courage and self-sacrifice" in the environment of Edwardian England. Cecilia Payne married **Sergei Gaposchkin** in 1934, with whom she had three children: Edward Michael, Katherine Leonora, and Peter John Arthur. All three have had some involvement in astronomy.

After attending elementary school in Wendover, Payne had the opportunity to further her education when the family moved to London. Even at an early age she had learned much science independently, fascinated, for example, by the chemical elements. With a keen interest in science or possibly classics, she attended Saint Mary's College, Paddington, London, England, from 1913 to 1917 and Saint Paul's Girls School, Brook Green, Hammersmith, from 1918 to 1919.

Payne was awarded the Mary Eward Scholarship for Natural Sciences and was thus enabled to attend Newnham College, Cambridge University, Cambridge, England (1919–1923). There she first pursued the study of natural sciences with a concentration on botany, but, inspired by a lecture by **Arthur Eddington**, she changed her course of study to include more astronomy, graduating in 1923. She wrote her first paper in astronomy on the proper motions of stars in the cluster M36 in 1923.

Impressed by a lecture given by **Harlow Shapley**, then director of the Harvard College Observatory in 1922, Payne traveled to the United States for further study and in pursuit of a research career in astronomy. Payne was the first recipient of the Ph.D. in astronomy from Harvard College Observatory, which she received in 1925, as the first of Shapley's many students.

Her thesis, published as *Stellar Atmospheres*, applied **Meghnad Saha**'s is theory of ionization to establish the temperatures of the cool giants and the relative abundances of the chemical elements in their atmospheres. The first result, that nearly all stars had essentially the same abundance ratios, much like the terrestrial ratios for elements heavier than carbon, was incorporated into mainstream astronomical thinking immediately. The second result, that hydrogen and helium were by far the most common elements, was not. Shapley and **Henry N. Russell**, who had also read the work in advance of publication, recommended that Payne modify this conclusion and speak of "anomaous excitation" and a concentration of light elements on the surfaces of the stars. Nevertheless, the initial conclusion was essentially right, and has led to the thesis being described as "the best Ph.D. thesis in astronomy ever written" and Payne being described as the greatest woman astronomer of all time. Additional observations and analysis by Russell, **William McCrea**, **Carl von Weizäcker**, and others led to the accepted fraction of hydrogen and helium in the stars and Sun gradually increasing from a percent or two in 1925, to 10% in 1930, to more than 90% by 1960.

The 1920s were probably the happiest period of Payne's life. During this time she wrote several papers discussing spectral analysis and application of the Saha equation. Payne's second monograph, *The Stars of High Luminosity* (1930), established the temperature scale and uniform composition for the hotter stars of types 0, B, and A. Her collaborators included Shapley, **Leon Campbell**, **Donald Menzel**, Frederick Wright, **Fred Whipple**, and, from 1934 onward, very often Sergei Gaposchkin. On instruction from Shapley, Payne turned her attention from spectroscopy (which was to be Menzel's bailiwick) to variable stars.

Payne-Gaposchkin wrote a textbook, *Introduction to Astronomy* (1954), a monograph on *Variable Stars* (1938) with Gaposchkin, a definitive monograph, *The Galactic Novae* (1964), and an acclaimed popular account of stellar evolution, *Stars in the Making* (1953). The latter was credited by some young astronomers as their inspiration for entering the field. Her last book was *Stars and Clusters*, summarizing much that was known on this topic. She had a deep familiarity with individual stars, and even with specific spectral lines, and discussed them and recalled their characteristics as though they were friends.

In addition to her work in astrophysics and spectroscopy, Payne-Gaposchkin spent many years working with variable stars, including those enigmatic objects – the novae – and made significant contributions to the understanding of their nature. She frequently worked with photometric observations made by her husband, and they often published together. In their study of the galaxies, the Large Magellanic Cloud and the Small Magellanic Cloud, the two made roughly a million observations of variables, from which they were able to estimate the distance to these objects.

Payne-Gaposchkin was indefatigable in her research endeavors and was highly valued by her colleagues. She received her MA and D.Sc. from Cambridge University, England, in 1952. Payne-Gaposchkin also made occasional forays into history, contributing papers to the *Journal of the History of Science* and writing obituaries of several astronomers. She wrote "The Nashoba Plan for Removing the Evils of Slavery: Letters of Frances and Camilla Wright, 1820–1829" published in the *Harvard Library Bulletin*, 1975, based on a collection of letters passed down in her family.

In addition to her scientific work, Payne-Gaposchkin was an editor of the observatory publications for over a decade, and had teaching duties. Unfortunately, she suffered from overt discrimination both at Harvard and in the astronomical community because she was a woman; she was not even considered for certain positions, in spite of the extraordinary caliber of her scientific work. For example, it was not thought possible for her to make her own observations at remote observatories, as the accommodations would not permit a single woman even to visit the site. This excluded her from positions for which less talented men could readily apply.

For many years Payne-Gaposchkin had no official position at Harvard University and received a very low salary. Eventually, after the retirement of Harvard's president Lowell, she was named Phillips Professor of Astronomy. After Shapley retired as the observatory director, Payne-Gaposchkin received a professorship at Harvard, the first woman to hold this title. She then became chairman of the Department of Astronomy, the first woman to become chair of any department at Harvard University. After her retirement from this institution, she worked for some years at the Smithsonian Astrophysical Observatory, doing research exclusively.

Payne-Gaposchkin was remembered with affection and admiration by her colleagues; she was called "an astronomer's astronomer," and considered a genius. She was an inspiration to her many students and members of the general public as a role model and articulate scientist. Her sense of humor was subtle, and she was addicted to puns.

Among the honors received in Payne-Gaposchkin's lifetime were the first Annie Jump Cannon Prize of the American Astronomical Society, in 1934; honorary degrees from Smith College and elsewhere; and prizes and lectureships of the American Philosophical Society, the Franklin Institute, and the American Astronomical Society. At the latter, she was the first woman to deliver the Henry Norris Russell Prize (being introduced by the first woman to be president of the Society, E. Margaret Burbidge) in 1976. Minor planet (2039) Payne-Gaposchkin and a feature on Venus were named for her. A number of her own Ph.D. students have made important contributions to astronomy, including **Helen Sawyer Hogg**, **Joseph Ashbrook**, Elske Smith van Panhuijs, Frank Drake, Paul Hodge, and Andrew Young.

Payne, William Wallace

Born **Somerset, Michigan, USA, 10 May 1837**
Died **Elgin, Illinois, USA, 29 January 1928**

William Payne is remembered as the 19th-century founder of Goodsell Observatory at Carleton College and as the independent publisher of three popular astronomical journals. The son of Jesse and Rebecca (*née* Palmer) Payne, William earned bachelor's (1863) and master's (1864) degrees from Hillsdale (Michigan) College with proficiencies in mathematics and languages. While a teacher in the Cambria Township (Hillsdale County) schools, Payne studied law and received his LL.B. degree in 1866 from the Chicago Law School. He relocated to Mantorville, Minnesota, and formed a partnership with Robert Taylor but grew discontented in the practice. Payne returned to teaching and was chosen superintendent of Dodge County schools. He cut his editorial teeth by launching *The Minnesota Teacher and Journal of Education* (*circa* 1867–1871), which was later united with *The Chicago Teacher* to become *The Western Journal of Education*. In 1870, Payne married Josephine Vinecore; the couple had one daughter, Jessie.

In 1871, Carleton College president James W. Strong hired Payne as a professor of mathematics and natural philosophy at the college's Northfield campus. Remarkably, Payne undertook construction of an astronomical observatory, though the college, founded in 1866, consisted of but three buildings. By 1878, a small wooden observatory, housing a clock, a transit instrument, and an 8-in. Clark refracting telescope, was completed. Time signals derived from astronomical observations were first relayed by telegraph from the unfinished structure in 1877. This service, eventually the largest in the northwest, provided time for more than 12,000 miles of railroad lines. Payne influenced railroad officials to adopt standard time upon its inauguration in 1883. From 1887 to 1897, Charlotte R. Willard operated Carleton's time service. While it was under Payne's guidance, the United States Signal Corps (1881) and later the National Weather Service (1883) designated the observatory as an official meteorological station.

By the 1880s, astronomy was the most vital and important of the college's programs; Payne successfully advocated the need for more precise astronomical equipment and a larger observatory. A 5-in. meridian circle was installed, and in 1890, funds were secured for installation of a 16-in. refractor – then the sixth largest telescope in the nation. The new brick observatory was named after the college's founder, deacon Charles M. Goodsell. Its plan of work was to be threefold: "[u]ndergraduate instruction ...; a school for practical astronomy ...; and original research."

In 1882, Payne launched the first of three journals that were to spread Carleton's name throughout the astronomical community. *The Sidereal Messenger* aimed to bring an understanding of developments in astronomy to wider audiences, chiefly instructors, amateur astronomers, and the public. Sprinkled with Protestant natural theology, *The Messenger* reflected Payne's deep religious sentiments. Payne privately managed its expenses, and his subscriptions grew. When astronomer **George Hale** sought to create a research journal devoted to astrophysics, he found it necessary to compromise on a joint publication coedited with Payne. For three years (1892–1894), *Astronomy and Astro-Physics* was published at Northfield. In 1895, the University of Chicago acquired Hale's interest and the *Astrophysical Journal* was born (1895).

Many of *The Messenger*'s former subscribers found its transformation from a popular to a technical journal undesirable. Circulation of *Astronomy and Astro-Physics* actually declined even as new subscribers were added from a handful of astrophysics practitioners. To reclaim his general readers, in 1893 Payne launched another privately owned journal, *Popular Astronomy*. Subtitled "A Review of Astronomy and Allied Sciences," *Popular Astronomy* reiterated *The Messenger*'s forum on celestial events, news of the profession, essays, and a distinctive focus on pedagogy. For more than five decades, *Popular Astronomy* served as the principal channel of communication, or "trade" journal, within the American astronomical community.

In 1892, Payne represented astronomy on a subcommittee chaired by Johns Hopkins University chemist Ira Remsen. The subcommittee reported jointly to Harvard University president Charles W. Eliot and the National Educational Association's Committee on Secondary School Studies, which was popularly known as the Committee of Ten. One of the committee's recommendations was that astronomy courses should be reduced from college prerequisites to elective subjects. While seemingly an innocuous decision, its cumulative effect was to bring about a decline in astronomy education after 1900; that was an outcome strongly antithetical to Payne's own views.

Payne's teaching was conducted by the lecture-recitation method. He advocated the "mental discipline" model of pedagogy and favored adoption of textbooks that students might "read and reread thoroughly and exhaustively." One Carleton student, who punned, "He never knew pleasure, who never knew Payne," immortalized Payne's reputation as an instructor.

Additional faculty were hired to support the growth of Carleton's astronomy program, including alumni **Herbert Wilson** (1879), who succeeded Payne as editor of *Popular Astronomy* (1909–1926), and **Edward Fath** (1902). The college trained some of the era's leading women astronomers, including **Anne Young** (1892), director of Mount Holyoke College Observatory, and **Mary Byrd**, who earned a Carleton Ph.D. in 1904 and directed the Smith College Observatory. Payne received an honorary degree from Hillsdale College (Ph.D., 1894) and Carleton conferred a similar honor (Sc.D., 1916) at the college's golden anniversary.

In response to a controversy surrounding Carleton's second president, William H. Sallmon, who was himself forced to resign, Payne (along with several other faculty members) resigned in 1908. Although Payne had resigned, he was still awarded a Carnegie Endowment pension in recognition of his outstanding service to the college. The college purchased *Popular Astronomy* from Payne. After Wilson's retirement, **Curvin Gingrich** continued its publication as editor from 1926 to 1951. When Gingrich died in 1951, Carleton College elected to abandon the publication of *Popular Astronomy*.

A new demand for Payne's services arose from President Theodore Roosevelt's directive that the National Bureau of Standards conduct tests of accuracy on portable watches. In a replay of his Carleton appointment, the Elgin National Watch Company hired Payne in 1909 to establish an astronomical observatory and time service in Illinois. He retired as director emeritus of the Elgin Observatory in 1926.

Apart from his role in creating the Goodsell Observatory and Carleton's astronomy department, Payne's contributions lay chiefly in the realm of practical service and popularization. His formal training was completed before photographic plates or methods of spectral analysis were widely adopted, which may in part explain why he never conducted research. Payne recognized the prejudices that researchers associated with popularization, yet was never deterred by those prejudices. The astronomical journals that he founded and edited brought acclaim to the college that far outlasted his own services. Goodsell Observatory is listed on the National Register of Historic Places, as a site where important contributions were made to Minnesota astronomy education and the "scientific literary field" embraced by Payne's journals.

Carleton College Archives, Northfield, Minnesota, retains selected papers of Payne, chiefly in its President's Annual Reports (1873–1895), Series 42, Box 1, together with a biographical file. Payne's extensive correspondence was discarded after his departure from the college, a significant loss for the history of American astronomy.

Pearce, Joseph Algernon

Born **Brantford, Ontario, Canada, 7 February 1893**
Died **Victoria, British Columbia, Canada, 8 September 1988**

Joseph Pearce was a stellar astrophysicist who, with **John Plaskett**, confirmed the rotation and scale of the Milky Way Galaxy. Pearce was the son of Joseph William Pearce and Clarissa Augusta Rounds. He entered the University of Toronto in 1913, but interrupted his studies in 1915 to join the Canadian army as a signals officer. After suffering wounds in France in 1916, he returned to Canada, rising to the rank of major by 1919. Pearce completed his BA at Toronto in 1920, acting as a class assistant to **Clarence Chant** during term, while working as a magnetic observer for the Dominion Astrophysical Observatory [DAO] in Victoria, British Columbia, during the summers. At Chant's insistence, Pearce obtained a research fellowship at the Lick Observatory in 1922 and began his Ph.D. studies with **Robert Aitken**. In 1924, Plaskett required a replacement at the DAO and, on Aitken's recommendation, Pearce was hired, despite not having finished his degree. It was not until 1930, after much prodding by Plaskett, that he obtained the Ph.D. Pearce married Esther Mott in 1917, and they had two children, Josephine and Richard. Esther Pearce died in 1945, and he married Elizabeth Allan in 1947.

Plaskett had completed his survey of O stars when Pearce arrived and recruited him to work on the B-star program, a survey of all B stars brighter than magnitude 7.5 and north of declination −11°, altogether some 1,056 stars. The work was undertaken with the DAO's 72-in. reflector. Plaskett had keenly followed the work of **Bertil Lindblad** and **Jan Oort** on the possible rotation of the Galaxy and had conferred with Oort in Leiden in 1927. Although the B-star survey was incomplete – it would be finished in early 1929 and published in 1930 – Plaskett and Pearce had sufficient data to test the theory. With useful data for about 500 O and B stars, they were able to locate the galactic center near to where Oort found it and near the point **Harlow Shapley** indicated from his globular cluster measurements. Plaskett and Pearce published their preliminary results in the *Monthly Notices of the Royal Astronomical Society* in 1928 and their final results in the *Publications of the Dominion Astrophysical Observatory* in 1930. They calculated a galactic rotation speed of 275 km/s at the distance of 10 kpc from the galactic center.

The O- and B-star data also provided Plaskett and Pearce with the possibility of solving the problem of the location and motion of the interstellar gas. **Arthur Eddington**, in 1926, argued that interstellar calcium was spread throughout the Galaxy in clouds that were relatively stationary as stars moved through them. Ca II lines would show up only in very hot stars. By 1929, possibly with preliminary data from Plaskett and Pearce, **Otto Struve** and **Boris Gerasimovic** posited that interstellar calcium did move, but at half the rate of the stars. In 1930, Plaskett and Pearce, with their extensive data, showed that this seemed to be the case. Plaskett retired in 1935, and Pearce embarked upon an expanded B-star program with Robert M. Petrie, adding stars brighter than magnitude 9 and north of declination +20°. The final results did not appear until 1962. Pearce, like other DAO staff, computed a number of spectroscopic binary orbits, and observed stars in the Pleiades and Hyades. Few of these results were published.

Pearce became assistant director of the DAO in 1936 and director in 1940 on **William Harper**'s death. He held the position until 1951, when he turned over the reins to Petrie. Pearce remained on staff until 1958, when he retired.

Pearce was a long-time supporter of the Royal Astronomical Society of Canada, being a key figure in the Victoria Centre and a member of the national council for a decade, culminating in his tenure as president in 1940. He was also a vice president of the American Astronomical Society in 1943/1944, and a member of the American Association for the Advancement of Science, the Astronomical Society of the Pacific, and the Société Astronomique de France. He was a fellow of the Royal Society of Canada (president 1949/1950). Like other DAO staff members, Pearce was a contributor to International Astronomical Union commissions, as a member of Commissions 27, 42, and 30 (Radial Velocities, of which he was president from 1948 to 1952).

Pearson, William

Born **Whitbeck, (Cumbria), England, 23 April 1767**
Died **South Kilworth, Leicestershire, England, 6 September 1847**

Reverend Dr. William Pearson cofounded the Astronomical Society of London (now the Royal Astronomical Society [RAS]), made a number of elaborate astronomical clocks and demonstration instruments, and published a valuable treatise on practical astronomy. The son of yeoman farmer William and Hannah Pearson, the younger William pursued his education and career vigorously in spite of his modest origins, spending the first half of his working career as a highly successful schoolmaster, and then evolving as a beneficed clergyman in his later years.

As an amateur astronomer who was active in the astronomical community at the beginning of the 19th century, Pearson's earliest astronomical interests appear to have been focused strongly on the design and construction of clocks, orreries, and planetary machines. Well acquainted with instrument maker Edward Troughton (1753–1836), Pearson utilized gears with substantially more teeth than the standard horological practice of the day and produced smoothly functioning and effective clocks, watches, and demonstration machines. Pearson's interest in observational astronomy flourished in later years, leading to the publication of his *Practical Astronomy*, which was more appreciated in the decades after his death than after its publication in 1829.

Peary, Robert Edwin

Born **Cresson, Pennsylvania, USA, 6 May 1856**
Died **Washington, District of Columbia, USA, 20 February 1920**

Robert Peary, Arctic explorer and naval officer, was the son of Charles Nutter Peary and Mary (*née* Wiley) Peary. Peary's father died when he was 2 years old, leaving him to be raised by his mother, who had a strong influence on his life. Peary attended Portland (Maine) High School and then Bowdoin College, from which he received a degree in civil engineering in 1877. For 2 years, he worked as a surveyor at Fryeburg, Maine, before joining the United States Coast and Geodetic Survey as a draughtsman. In 1888, Peary married Josephine Diebitsch of Portland, and the couple had two children.

Peary was commissioned as a civil engineer in the United States Navy from 1881 to 1891. His interest in Arctic exploration developed from a private trip he made to Greenland in 1886. On several of his later expeditions, he was accompanied by his wife. Peary decided to use northern Greenland (and its coast) as points of departure for trying to reach the North Pole. He made observations of the Sun to determine his positions and set several new records for northern latitude, including Greenland's northernmost point, Cape Morris Jesup.

Peary's final push toward the North Pole began in 1908, with support from the National Geographic Society and other private patrons. Peary's claims to have reached the North Pole in April 1909, ahead of competitor Frederick Cook, were widely accepted in his day. For his reputed accomplishment, Peary received worldwide recognition and a number of awards, including a Gold Medal from the Congress. However, these claims have not stood up to later scrutiny, and substantial discrepancies exist in Peary's account. Most polar authorities no longer accept Peary's assertion to have reached the North Pole, or many other alleged discoveries.

During an earlier Greenland expedition, Peary recovered three massive fragments of an iron meteorite from the Cape York shower. These are known from Eskimo folklore as "The Tent," "The Woman," and "The Dog." Peary's wife later sold these meteorites to the American Museum of Natural History, where they remain on display.

Peary's popular writings, which described the numerous hardships, trials, and disappointments he experienced, nonetheless served to inspire later generations. He was buried at the Arlington National Cemetery. Peary's collections are housed in the National Archives, but they were not publicly opened until the 1980s.

Pease, Francis Gladhelm

Born **Cambridge, Massachusetts, USA, 14 June 1881**
Died **Pasadena, California, USA, 7 February 1938**

American optician and spectroscopist Francis Pease is most widely remembered for his contributions to the design and construction of the 60-, 100-, and 200-in. telescopes at Mount Wilson and Palomar observatories, but he also obtained the first accurate rotation curves of spiral galaxies and with **Albert Michelson** made the first direct measurements of the diameters of stars other than the Sun. Pease graduated from the Armour Institute of Technology in Chicago (now part of the Illinois Institute of Technology) in 1901 with a BS in mechanical engineering, and received honorary MA and Sc.D. degrees from the institute in 1924 and 1927. While a student, he worked evenings at the Petitdidier optical shop, and his employers recommended him to **George Ritchey**, the chief optician at Yerkes Observatory. Ritchey's father had also been one of Pease's teachers at Armour. Thus, with Ritchey, **Walter Adams**, and **Ferdinand Ellerman**, Pease moved west with **George Hale** in 1904 as one of the founding staff members of Mount Wilson Observatory. He remained there the rest of his life, apart from a year of war work in 1918 as chief draftsman in the engineering section of the National Research Council.

The history of astronomy has focused more closely on discoveries and theories than on the instruments used to make them and verify them; Pease's reputation as an astronomer consequently is less than it might otherwise have been. On the other hand, his role at Mount Wilson Observatory has been somewhat exaggerated, at the expense of Ritchey's reputation. Even before Ritchey was fired in 1919, Hale, the Mount Wilson director, had worked to make Ritchey an "unperson," preventing him from receiving outside recognition. Pease customarily is credited in whole or in large part for many of the instruments at Mount Wilson and Mount Palomar observatories, including the 60-inch 100-inch and 200-inch reflecting telescopes, the 60-foot and 150-foot tower telescopes, and the 20-foot and 50-foot interferometers. Actually, Ritchey led the work on the 60-inch reflecting telescope, and also on the 100-inch until November 1912, when Pease was placed in charge of the design for its mounting. Even then, Ritchey continued to figure the mirror.

Pease also made observations with the instruments at Mount Wilson Observatory. Not only did his observing experience contribute to his design skills, but some of Pease's observations were significant in themselves. During August, September, and October of 1917, he managed to take a 79-hour exposure of the Andromeda Nebula (M31). From the spectrograms taken with this exposure, and from an even longer one of 84 hour made a year earlier by Adams, Pease confirmed the spectroscopic rotation of the nebula.

From 1917 through 1919, working with the 60-inch reflector at Mount Wilson Observatory, Pease took some 66 plates of the spiral nebula M33. A nova appeared on four of the plates, and its observed magnitude was consistent with the distance to the nebula determined by **Edwin Hubble** from Cepheid stars also found in the nebula.

In 1928 Pease was the first to identify a planetary nebula in a globular cluster (M15). Previously cataloged as a star, the planetary nebula is now named Pease 1. It was, for many years, the only known planetary in a globular cluster, and they are still very rare.

Pease's most famous astronomical discovery was the first measurement of the diameter of a star other than our own Sun. Physicist **Albert Michelson** redesigned his stellar interferometer, and in the summer of 1920 had it mounted on the 100-inch reflecting telescope at Mount Wilson Observatory. He had to return to the University of Chicago at the end of the summer, and left Pease in charge of the measurements. In December Pease reported success, having determined an astounding diameter of 240 million miles for the star Betelgeuse.

A decade later Pease built a 50-foot interferometer, potentially capable of measuring stellar diameters half the size of what the 20-foot interferometer had measured. However, the instrument was not a complete success; thermal gradients allowed deflections in the support beam, which in turn allowed unacceptable fluctuations in the optical path lengths from the outer mirrors to the eyepiece.

Pease also worked with Michelson on a more accurate determination of the velocity of light. The measurements were begun in the summer of 1922 and continued over subsequent summers, to and beyond Michelson's death in May 1931, first between Mount Wilson and Mount San Antonio (1924–1938) and later on the Irvine Ranch in Orange County, California (1930–1934).

Although Pease was a member of most of the renowned astronomical societies, he received no major awards and held no major offices in them. In 1905, he married Carline T. Furness, who must not be confused with **Caroline Furness**, director of Vassar College Observatory for many years. Pease's most ambitious telescope design was surely the 300-inch one made in 1926.

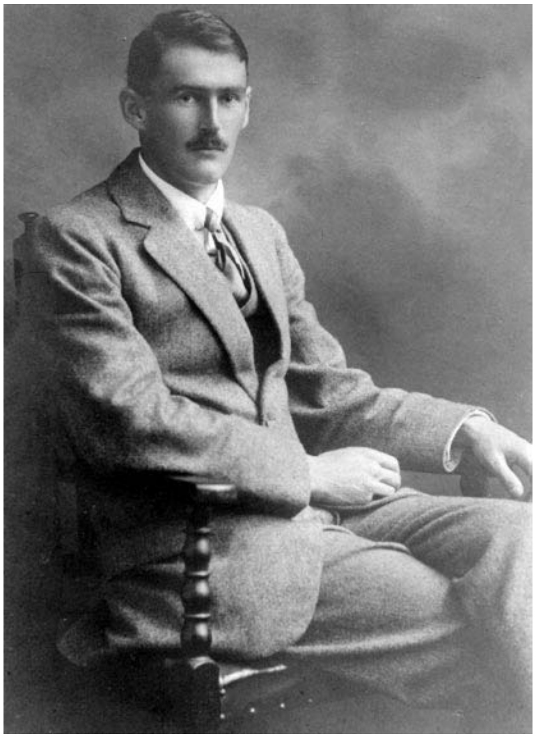
Peek, Bertrand Meigh

Born **Boscombe, Dorset, England, 27 December 1891**
Died **Melbourne, Victoria, Australia, May 1965**



Bertrand Meigh Peek is best remembered as the author of many of the Jupiter *Memoirs* of the British Astronomical Association [BAA] and especially of the classic book *The Planet Jupiter*.

Peek had a traditional English upbringing through private schools and the University of Cambridge, where he was a three-time winner of the mathematics prize and a tennis champion. His highest degree at Cambridge was an MA. Peek rose to the rank of major in the British army, serving with The Hampshires Regiment in India during World War I. After the war, Peek took up a career as a teacher, and became headmaster of a school in Solihull, Birmingham, England. Peek's other avocational activities included a continued involvement in sports, chess (a member of the Anglo–Soviet match teams), and music – he composed at least one symphony. He was an early amateur radio operator.

Although Peek was interested in many fields of amateur astronomy, and contributed results to the Double Star and other BAA sections, it was his lifelong interest in planetary astronomy that produced his greatest contributions. Peek was briefly director of the BAA's Mars Section and then Saturn Section. In 1933, while director of the Saturn Section, Peek carried out an exhaustive mathematical analysis of the motions of **William Hay**'s white spot on Saturn. Then, in 1934, he swapped posts with the then director of the Jupiter Section, Reverend **Theodore Phillips**, who had done so much to direct amateur observations to form a scientifically reliable body of work. Like Phillips, Peek maintained an active correspondence with many amateur astronomers, including Hugh M. Johnson (born: 1923) and **Walter Haas**, active observers in the United States who, as Peek noted, helped sustain the work of the section during World War II.

Often Peek would visit Phillips's observatory to observe with him. Peek continued Phillips's high standards both of observation and of analysis. He insisted on a careful scientific approach to his own and others' observations, taking care to exclude subjective effects and emphasizing numerical results – particularly the Jovian wind speeds that could be deduced from visual transit measurements. Although color changes on Jupiter are perhaps an equally important phenomenon, of which Peek made careful observations, he became skeptical of the possibility of reaching reliable conclusions from these subjective impressions and therefore devoted little attention to Jovian colors in his writings.

Peek retired from the directorship of the BAA Jupiter Section in 1949, when his health declined, then embarked on writing *The Planet Jupiter*. In this book, only the second book published on Jupiter, he summarized the observed phenomena of the atmosphere, with notably lucid narrative and occasional dry wit. *The Planet Jupiter* was the definitive text for a generation until spacecraft visited the planet. Peek's health recovered somewhat, and he resumed observing to codiscover the 1955 South Tropical Disturbance.

An active participant in BAA affairs, Peek served as the BAA president from 1938 to 1940, and the association owed much to his leadership and stabilizing influence during World War II.

Peirce, Benjamin

Born **Salem, Massachusetts, USA, 4 April 1809**
Died **Cambridge, Massachusetts, USA, 6 October 1880**

Benjamin Peirce established an American presence in celestial mechanics, trained a number of leading astronomers, and played an important role in the development of the institutional structure of American science.

Peirce was the son of Benjamin and Lydia Ropes (*née* Nichols) Peirce. The Peirces were among the oldest families in the United States; Peirce's ancestor, John Pers of Norwich, England, came to the New World in 1637. Peirce attended the Salem Private Grammar School where he became acquainted with **Nathaniel Bowditch**, father of his classmate Henry Ingersoll Bowditch. Peirce entered Harvard University in 1825, at a time when the university was in a dire financial crisis. When Nathaniel Bowditch became one of Harvard's trustees the next year, he forced a thorough reorganization of the university, including the dismissal of a mathematics professor whose grasp of mathematics, according to Bowditch, was less than that of "Peirce of the Sophomore class." Recognizing the capability of the young Peirce, Bowditch employed him to help read proofs of his translation of **Pierre de Laplace**'s *Traité de méchanique céleste*.

After graduating in 1829, Peirce taught for 2 years at a private school before becoming a tutor in mathematics at Harvard University in 1831. Appointed temporary head of the Department of Mathematics in 1832, Peirce became permanent head of the department when his predecessor retired for medical reasons. Peirce received his MA in 1833, and was appointed a professor of mathematics and natural philosophy. In the same year, he married Sarah Hunt Mills. They would have a daughter and four sons, including two, James Mills Peirce and Charles Sanders Peirce, who would themselves become mathematicians.

Peirce was active in computing the orbits of comets and developing the mathematics of perturbation functions in celestial mechanics. In 1842, he was appointed Perkins Professor of Mathematics and Astronomy. His public lectures on the great March sungrazing comet C/1843 D1 helped stimulate public support for expansion of the Harvard College Observatory and acquisition of the 15-in. Merz and Mahler refractor, at that time one of the world's three largest refractors. Peirce was the first in the United States (1848) to give lectures in celestial and analytical mechanics.

Peirce's interest in celestial mechanics would lead him into several controversies. After **Urbain Le Verrier** and **John Adams** discovered that the irregularities in the motion of Uranus could be accounted for by assuming the existence of a hitherto undiscovered planet, and made detailed predictions of where such a planet might be found, on 23 September 1846 the German astronomer **Johann Galle** discovered Neptune in very nearly the position predicted by Le Verrier. However, Le Verrier's predicted distance was far in excess of the actual distance, which led Peirce and United States Naval Observatory astronomer **Sears Walker** to conclude that the discovery of Neptune, far from being a triumph of celestial mechanics, was in fact little more than a coincidence. This contention was bitterly disputed on both sides of the Atlantic and added to an already intense debate over Le Verrier's priority in comparison to Adams.

At about the same time, Peirce's activities expanded to include administrative affairs of the university as well as the institutional structure of science in the United States. In 1846, he was asked to draw up a plan for what became Harvard University's Lawrence Scientific School. Peirce was a member of a committee that drafted and distributed the constitution of the American Association for the Advancement of Science [AAAS] as that organization emerged from the American Association of Geologists and Naturalists in 1848. In these activities, Peirce joined with other influential figures in mid-19th-century American science such as **Joseph Henry**, first director of the Smithsonian institute; **Alexander Bache**, director of the United States Coast Survey; and others who corresponded and met frequently. In their correspondence they described themselves as the "scientific Lazzaroni." In residence primarily in Cambridge and Washington, and well connected politically and socially to elites in both centers of American culture, the Lazzaroni tended to act in concert on matters involving the institutional structure of science in America.

Peirce's connections with the Lazzaroni would lead him to another controversy. In 1856, as part of the Dudley Observatory's scientific council, Peirce found himself in the midst of a power struggle. The scientific council, consisting of Peirce, Bache, Henry, and **Benjamin Gould**, first director of the Dudley Observatory, had coordinated a plan of detailed astronomical observations with the Coast Survey. However, Gould's delays in implementing the plan and demands for further improvements in the observatory created a major feud between the scientific council and the observatory's trustees over governance of the institution. The trustees prevailed; in 1859, the scientific council was effectively dissolved.

Peirce did not abandon his teaching and scientific pursuits during these years of external involvement. In a paper presented orally at a meeting of the AAAS in 1851, Peirce showed that Saturn's rings could not be solid, but must instead be fluid. Peirce's paper credited **George Bond** of Harvard College Observatory with reaching the same conclusion observationally the previous year, but failed to mention that Bond offered a mathematical argument to support his observations, leading to yet another acrimonious dispute. It would be several years before **James Maxwell** demonstrated theoretically that the rings must be solid particles rather than a fluid. Peirce's students at Harvard University included the astronomers **George Hill**, **Percival Lowell**, and **Simon Newcomb**. Peirce was responsible for Newcomb's postgraduate commissioning as professor of mathematics at the United States Naval Observatory.

Peirce considered himself a candidate to replace **William Bond** as director of the Harvard College Observatory when the latter died in 1859. That placed him in direct competition with the younger Gould, who had been forced to resign at Dudley Observatory, as well as with Bond's son George, who was selected to fill the post. Peirce's candidacy disrupted his previously friendly relationship with Gould irreparably.

Peirce shared with other Lazzaroni members a desire for a more exclusive national venue in which leading scientists might share their research and influence national science policy. In 1863, he joined with Bache, Louis Agassiz, and Gould to work with US Senator Henry Wilson in writing the congressional act that established the National Academy of Sciences. Peirce was, of course, one of the 50 elite scientists selected for initial membership in the academy. The fact that Bond, his rival at Harvard, was not among the 50 scientists contributed to their continuing animosity.

In 1867, Henry prevailed upon Peirce to accept appointment as the director of the United States Coast Survey after Bache's death. Gould had been working part-time for the Survey as director of longitude determination since 1852. In that year, he published a statistical method for discarding discrepant observations that was widely adopted as Peirce's criterion but was later discredited. Peirce's 1870 work on linear associative algebra is considered the first major original contribution to mathematics produced in the United States and marks the beginning of the acceptance of American mathematics as a field separate from astronomy by European mathematicians. Peirce was highly effective as an administrator of the Coast Survey until he returned to full-time teaching at Harvard University in 1874.

Peirce was honored on both sides of the Atlantic with membership in scientific societies: He became a member of the American Philosophical Society and one of 50 foreign members of the Royal Society of London in 1852, a fellow of the American Academy of Arts and Sciences in 1858, and an honorary fellow of the University of Saint Vladimir in Kyiv in 1860. When Peirce died, his pallbearers included James Joseph Sylvester, J. Ingersoll Bowditch, Newcomb, and Oliver Wendell Holmes, a Harvard classmate who later wrote a tribute to Peirce.

Peiresc, Nicolas-Claude Fabri de

Born **Belgentier, (Var), France, 1 December 1580**
Died **Aix-en-Provence, (Bouches-du-Rhône), France, 24 June 1637**

In addition to fostering scientific correspondence, Nicolas Peiresc discovered the Orion nebula and tracked the satellites of Jupiter in order to solve the longitude problem. He was the son of Réginald Fabri, descendant of a Pisan family, and Margareta Bomparia, both of whom represented notable Provencal lineages and connections. After Peiresc attended Jesuit schools in Aix and Avignon, his father and uncle sent him on an extended trip to Italy (1599–1602) to prepare him further for the family post in the parliament of Provence. During his first year in Italy, Peiresc studied in Padua, where he met **Galileo Galilei** before settling in Montpellier to study law. After finishing his legal studies there, Peiresc attained a doctorate degree in civil law in Aix (1604). When his uncle died on 24 June 1607, leaving open the family *parlement* position, Peiresc immediately filled the seat and held it for 30 years until his own death. For much of his adult life, Peiresc was at the center of an important correspondence network as a mediator to whom others looked for diplomatic solutions. For example, when Galilei was put under house arrest, Peiresc warned Cardinal Barberini that the failure to change Galilei's verdict might yield a comparison with Socrates' trial and similar condemnation.

Among his many interests and activities, Peiresc dedicated time to astronomical observations. In November 1610, while repeating some of Galilei's observations published in *Sidereus Nuncius*, Peiresc and cleric Joseph Gaultier de la Valette (1564–1647) were apparently the first to observe a nebula in the constellation of Orion. Peiresc also observed the moons of Jupiter with the help of Gaultier and mathematician **Jean Morin**, and subsequently wrote a commentary he never published.

Peiresc's most important and practical astronomical contribution stems from his work on longitude calculations. The main problem of determining longitude involves finding an accurate timekeeper. In the early 17th century, the regular motions in the heavens provided the most accurate clock. Peiresc originally planned to use the satellites of Jupiter as that celestial clock. Between November 1610 and May 1612, Peiresc made regular observations of the Jovian moons. Near the end of this period of observation, Peiresc felt his calculations were adequate enough for testing. He sent his assistant Jean Lombard to make observations of the moons of Jupiter in locations as far away as North Africa, Malta, and the Levant. The local time difference between the appearance of a configuration of Jupiter's satellites as they appeared in Aix (according to Peiresc's tables) and the appearance of that same configuration observed in Malta (by Lombard) could be used to calculate the difference in longitude between the two locations. After Lombard's mission failed due to the difficulty of this technique, Peiresc largely abandoned work in astronomical observations for 16 years.

Between 1616 and 1623, Peiresc lived in Paris, where he met and associated closely with the circle of thinkers surrounding the librarians Pierre and Jacques Dupuy. It was through the Dupuy brothers that Peiresc met **Marin Mersenne** and others. Peiresc never married; his relationships did not extend beyond the intellectual friendships he had with such men as the Dupuy brothers and Mersenne. In 1618, Louis XIII granted Peiresc the abbacy of a monastery in Guîtres, north of Bordeaux, making Peiresc's ties to the church stronger and his distance from marriage further. Peiresc returned to Aix in the summer of 1623; in the next year, he took the tonsure in order to regularize his position as abbé of the Guîtres monastery.

By 1628, Peiresc again took up the task of establishing longitude positions from his home in Aix, but with a different plan. He determined to use observations of lunar and solar eclipses made in different cities to establish the separation of longitude between them. To begin this new project, he requested others (among them the Dupuys) to send him observations of eclipses that occurred in January and February of 1628. He later distributed the observed times of the eclipses, which could then be compared to astronomical tables. According to the observations made in Paris and Aix in 1628, Peiresc calculated that the separation in longitude between the two cities was 3° 30′ 2″ greater than the previous standard.

Because of plague and public unrest between 1629 and 1631, Peiresc temporarily abandoned Aix for his country home in Belgentier, where he was unable to continue his astronomical observations. In 1632, Peiresc returned to Aix, where he resumed his telescopic observations and his larger project of gathering observations of eclipses from diverse locations in order to make longitudinal calculations. To aid him in this project, he recruited priests and Jesuits stationed in various locations from Rome to Mount Sinai. Despite the condemnation of Galilei in 1633, Peiresc explained to his recruits that making observations would not bring harm to souls and could even encourage others to follow in their footsteps.

For making eclipse observations, Peiresc stressed the need to use a telescope, but the network of observers he assembled did not always perform as he wished. Complications included letters and instruments lost in the mail, bad weather, sick observers, and faulty clocks – a crucial problem given the importance in determining the precise time of any given observation. These and other difficulties made Peiresc's task of compiling observations all the more difficult. He was, however, able to find some success with a lunar eclipse on 28 August 1635; it resulted in correcting, and reducing by about 1,000 km, the length of the Mediterranean found on contemporary maps. To further increase the accuracy of such observations, Peiresc, along with the help of **Pierre Gassendi** and others, established the Provençal school of astronomy, where he could instruct future observers and achieve more uniformity in his project. However, after his death, the school folded, with most of the remaining students and teachers moving to Paris.

Pèlerin de Prusse

Born **Chelm (Chelmno), Poland, mid-to-late 1330s**
Died **after 1362**

Pèlerin de Prusse is known less for his original work than for disseminating knowledge of astronomy and astrology. He studied at the University of Paris under the direction of the well-known scientist and mathematician **Albert of Saxony**, and graduated as master of arts by 1359. In that year Pèlerin requested and received permission from the University of Paris to deliver "extraordinary lectures" (public lectures given outside ordinary lecture hours) on a book that may have been about either astronomy or astrology: The document referring to the lectures uses the equivocal Latin word *astrologia*, and the book to be lectured on is not specified. It is perhaps worth noting that Pèlerin's associate Robert le Normand had in the previous year been given similar permission for extraordinary lectures on **Ptolemy**'s astrological *Tetrabiblos* and on the pseudo-Ptolemaic *Centiloquium*, also astrological.

No doubt on the basis of his academic work, Pèlerin was soon appointed court scholar to Charles, Duke of Normandy (later King Charles V of France). He was but one of a number of astrologers–astronomers associated at one time or another with Charles' court, but he seems to have been especially favored. Court records call him Charles' "beloved clerk," and Pèlerin was in the early 1360s installed in his own rooms, with his manservant, in Charles' new palace, the Hôtel Saint-Pol.

Two surviving works by Pèlerin testify to the nature of his contributions to astronomy. One is the *Livret de elecions* (1361), an astrological treatise with some astronomical side benefits, such as the promotion of a relatively new and sophisticated instrument, the planetary equatorium. The other work, the *Practique de astrolabe* (1362), is on a more familiar instrument, the planispheric astrolabe. The *Practique* is a strictly astronomical work, based largely on a Latin treatise said to have been translated from the Arabic of **Māshā 'allāh ibn Atharī**. Pèlerin expressly, and accurately, disclaims any originality for his work. His role is to put knowledge of the stars into French at the command of Charles, who was at the time sponsoring similar efforts by other scholars, including the above-mentioned Le Normand as well as the famous scholar-bishop **Nicole Oresme**. The same kind of vernacularizing role was played later by the English writer **Geoffrey Chaucer**, whose *Treatise on the Astrolabe* (*circa* 1391) was also based on Māshā 'allāh. What George Sarton says about Chaucer can be said with equal justice about Pèlerin: "the study of [his] scientific knowledge is important not so much from the point of view of the history of science *stricto sensu*, but rather for the understanding of popular diffusion of scientific ideas of his time."

Pèlerin's date of death is inferred from the date of his last known written work.

Peltier, Leslie Copus

Born **near Delphos, Ohio, USA, 2 January 1900**
Died **Delphos, Ohio, USA, 10 May 1980**

As a prolific variable star observer as well as the independent discoverer of 12 comets and six novae in over six decades of observing, Leslie Peltier established himself as the leading amateur astronomer of his time. His autobiography, *Starlight Nights*, lead countless readers into astronomy. **Harlow Shapley** called him "the world's greatest non-professional astronomer."

Peltier was born to Stanley W. Peltier, a strawberry farmer and distributor, and Resa (*née* Copus) Peltier, a schoolteacher. Both parents were avid readers; their home was filled with books on many subjects. Peltier's love of books, reading, and his woodworking, designing, and architectural skills were absorbed from his parents.

Peltier's elementary education in a one-room schoolhouse was typical of the time. Living on a farm gave him the independence to study and observe whatever interested him as he went about his farm chores. He taught himself the geology, flora, and fauna of the Delphos area. At 5 years of age, through the kitchen window Peltier had noticed bright stars in the night sky, which his mother identified as the Seven Sisters, or Pleiades. But it was not until a dark night 10 years later that Peltier suddenly realized that he knew much about many aspects of nature but not about the stars. That night marked the beginning of his avid interest in astronomy. The librarian at the Delphos Public Library suggested that he read Martha Evans Martin's *The Friendly Stars*. Using this simple but well-written book, Peltier learned about the bright stars starting with Vega.

Peltier purchased his first telescope, a 2-in. French spyglass, with 18 dollars that he earned by picking 900 quarts of strawberries on the family farm for 2 cents per quart. The telescope had a focal length of 36 in. with eyepieces for 35× and 60× magnification. Thus began the long and successful observing career that would span more than six decades.

The next book Peltier consulted was **William Tyler Olcott**'s *A Field Book of the Stars*. Olcott invited those with small telescopes who were interested in assisting professional astronomical research to write to him. Peltier wrote immediately; Olcott's response described the systematic observations of variable stars by the American Association of Variable Star Observers [AAVSO], and included an AAVSO application. When Peltier returned the application, he received charts and instructions for observing. On 1 March 1918 Peltier made his first variable star observation of R Leonis. On 1 March every year thereafter, Peltier observed R Leonis in commemoration of that first observation. Beginning with his first report, for March 1918, Peltier sent consecutive monthly reports to the AAVSO until his death, never missing a single month. Peltier's monumental total of 132,123 observations will insure that he remains among the leading variable star observers of all time.

In November 1918, the AAVSO offered to loan Peltier a 4-in. Mogey refractor. News of the young observer was spreading among professional astronomers, and shortly thereafter Princeton's **Henry N. Russell** loaned Peltier a 6-in. refractor, a comet seeker of short focus, through the AAVSO. In 1921, Peltier's father helped him build his first full observatory; it was ready for observing in January 1922.

Around 1937, the idea for the transportable, rotating observatory came to Peltier, perhaps due to his experience and expertise in furniture design. His idea was to be seated in a comfortable chair while observing variable stars or hunting for comets, and have the whole observatory revolve with the chair and telescope. Using both new and junkyard parts, Peltier built such an observatory. The chair included an adjustable headrest for comfort during long observing sessions, and a hot plate to warm his feet. Peltier's unique design later became famous as the "Merry-Go-Round observatory."

In 1959, the Miami University of Ohio donated a 12-in. Clark refractor, and a dome to contain the telescope. With the larger telescope, Peltier was equipped to observe much fainter stars and so he modified his observing program, concentrating on stars fainter than 11th magnitude. One important aspect of the new program was Peltier's observation of cataclysmic variable stars during their quiescent phase.

Peltier made independent discoveries of 12 comets, between 13 November 1925, and 26 June 1954; 10 of these comets bear his name. He carved the year of each comet discovery into the wooden tube of his 6-in. comet seeker. Peltier also made independent discoveries of six novae or recurring novae (Nova Aurigae 1918; Nova Cygni 1920; RS Ophiuchi 1933; DQ Herculis and CT Lacertae [both 1934]; and Nova Herculis 1963).

Except with his close friends, Peltier was a shy man and was uncomfortable with strangers. However, through the years Peltier met many prominent astronomers who came to visit him in Delphos, including **George van Biesbroeck**, **William Morgan**, **Bart** and Priscilla **Bok**, **Donald Menzel**, **Polydore Swings**, **John Hall**, **William Hiltner,** Clyde Fisher, and Walter Scott Houston. In 1932, Houston persuaded Peltier to travel with him to an AAVSO meeting in Cambridge, Massachusetts – a rare occurrence for Peltier who seldom left Delphos.

Peltier met Dottie Nihiser, daughter of a local beekeeper, in 1925. They shared many interests including geology and a love of nature. She attended Ohio Wesleyan University and had a great interest in archaeology. On the other hand, Peltier never finished high school. When his brother left for World War I, Leslie dropped out of high school and took over more farm chores, but his acquisition of knowledge never stopped. He married Dottie on 25 November 1933; she bore two sons, Stanley H. and Gordon J. Peltier. In 1934, Peltier left the farm to work at the Delphos Bending Company, designing children's toys and juvenile furniture. He was still employed by the company at the time of his death.

During the 1930s and 1940s, Peltier wrote articles on comet hunting, nature, and equipment design that appeared in magazines such as *The American Photographer*, *Popular Science*, *Nature Magazine*, and *Sky & Telescope*. He was the subject of articles in many popular newspapers and magazines. In 1965 Peltier's first book, *Starlight Nights, the Adventures of a Star-Gazer* was published. *Starlight Nights* is an autobiographical ode to the joys of observing both the night sky and nature. The language of the book is poetic, humorous, and beautifully descriptive in the style of a 19th-century naturalist. In 1972, Peltier published *Guideposts to the Stars: Exploring the Skies throughout the Year*. Departing from astronomy, in 1977 he published *The Place on Jennings Creek*, a natural history of their home, Brookhaven, and its surrounding areas.

Peltier was awarded a honorary D.Sc. degree by Bowling Green State University (Ohio) in July 1947. In August 1965, at the dedication of **Clinton Ford**'s observatory near Wrightwood, California, the mountain on which the observatory stood was christened Mount Peltier. Minor Planet (3850) was named Peltier in his honor in 1989. From 1925 to 1954 Peltier received the Astronomical Society of the Pacific's Donohoe medal for most of his comet discoveries. AAVSO honored Peltier with its First Merit Award in 1934, and with the Nova Award in 1963. Peltier also received the G. Bruce Blair Award from the Western Amateur Astronomers. After his death, the Astronomical League established the Leslie C. Peltier Award "for significant contributions to observational astronomy" and made the first award posthumously to Peltier himself.

Peregrinus de Maricourt, Petrus

Flourished **France, *circa* 1269**

Petrus Peregrinus is best known for his *Epistula de magnete*.

Of Peregrinus' life, almost nothing is known except what is revealed by his works and suggested by his name. Maricourt is almost certainly a reference to the village of Méharicourt in Picardy, and the appellation Peregrinus indicates that he was a crusader. But since his *Epistula de magnete* was written on 8 August 1269 from the siege of Lucera in Italy, the assault on which had been declared a crusade, it need not be assumed that he had visited the Holy Land.

Epistula de magnete is addressed to Peregrinus's dear friend Sigerus de Foucaucourt. Although not primarily an astronomical work, the text does describe two instruments with astronomical significance: an instrument incorporating a magnetic compass that could be used to determine the azimuth of celestial bodies and a magnetic clock, in the form of a lodestone terella (spherical magnet), which Petrus claimed would mimic the diurnal rotation of the heavens. This text was read by, and influenced, **William Gilbert**, and in the plagiarized form of the *De Natura Magnetis* (1562) of Jean Taisnier, it was studied by **Johannes Kepler** some years before Gilbert's own *De magnete* (1600) was published. It may, therefore, have contributed to Kepler's conceptualization of celestial forces.

Peregrinus also wrote, sometime after 1263, a *Nova Compositio Astrolabii Particularis*, a treatise on the construction of the astrolabe notable for its clarity, its comprehensiveness, and its unusual choice of projection. Petrus described both the standard stereographic projection from one pole and the universal projection of **Zarqālī** in which the West Hemisphere and East Hemisphere of the celestial sphere are projected onto a single plane, but opted for a projection in which the North Celestial Hemisphere and South Celestial Hemisphere were both projected onto the equatorial plane. However, this treatise does not seem to have been very popular; it survives in only four manuscripts, and does not appear to have been printed in the early modern period.

Péridier, Julien Marie

Born **Sète, Hérault, France, 3 February 1882**
Died **Le Houga, Gers, France, 19 April 1967**

An electrical engineer by profession, Julien Péridier was an accomplished amateur astronomer who devoted the later years of his life to the development and operation of a substantial private observatory and scientific library. Péridier's early interest in astronomy can be traced to 1900 when he first observed variable stars. In 1933, Péridier established an observatory near the village of Le Houga in southwest France. It was equipped with a double 8-in. refractor with optics by André Joseph Alexandre Couder, a 12-in. Newtonian reflector that was made by George Calver, and a small transit telescope from Troughton & Simms. For nearly 30 years, Péridier observed actively from this station, while hosting young French astronomers who used his facilities for their own research as well as the observatory's programs. The main subjects of the research carried out at Le Houga were planetary physics, photometry, and stellar photometry, especially studies of variable stars and flare stars. There was also some work on double stars and galaxies. Péridier not only directed and sponsored this research but also published the results in the *Annales Astrophyśique* and also a score of *Publications de l'observatoire du Houga*, copies of which were exchanged with major observatories around the world. The Le Houga Observatory was selected by **Donald Menzel** as one of the sites from which Harvard College Observatory successfully observed the occultation of Regulus by Venus in July 1959. The last major project at the Le Houga Observatory was a 5-year National Aeronautics and Space Administration-sponsored program, conducted jointly with Harvard University from 1961 to 1965, involving multicolor photoelectric photometry of the Moon and planets with the 12-in. reflector.

Gérard de Vaucouleurs, who was both a collaborator at Le Houga from 1939 to 1949 and Péridier's longtime friend, likened him to the great private sponsors of American astronomical research including **Percival Lowell** and **Robert McMath,** as well as the great French amateur **René Jarry-Desloges**. This brief biography was extracted from an obituary prepared by de Vaucouleurs.

Perrin, Jean-Baptiste

Born **Lille, Nord, France, 30 September 1870**
Died **New York, New York, USA, 17 April 1942**

French physico-chemist Jean Perrin was one of the early enthusiasts for nuclear (subatomic) energy sources for the Sun and stars, along the lines pursued more thoroughly by **Arthur Eddington**. He was the son of an army officer, who died soon after Jean's birth. He entered the Paris École Normale Supérieure in 1891, receiving his doctoral degree in 1897 for work on cathode rays and X-rays. Perrin showed that cathode rays are deflected in magnetic fields and so must carry negative charges, part of the evidence that led J. J. Thompson to the discovery of the electron.

Perrin began teaching at the University of Paris (Sorbonne) in 1897, and he was given a chair in physical chemistry there in 1910. Perrin remained at the Sorbonne until 1940, when he emigrated to the United States. Perrin was married in 1897 to Henriette Duportal; they had two children. Although he did not die in France, Perrin was eventually (1948) reburied in the Panthéon in Paris.

Perrin's work mainly focused on the nature of molecules. The atomic theory, which claimed that elements are made up of discrete particles called atoms and that chemical compounds are made up of molecules, was not fully appreciated at the end of the 19th century, and it had important opponents like Ernst Mach (1838–1916) and Wilhelm Ostwald. Robert Brown in 1827 had described the motion of very small particles, suspended in a fluid; in 1905 **Albert Einstein** gave some quantitative explanations for Brownian motion. Perrin studied colloidally suspended particles undergoing Brownian motion, and in 1908 started a series of experiments on this subject. Only then did he learn of Einstein's work, and finally – by using the "ultramicroscope" – he was able to confirm Einstein's predictions experimentally. Perrin was able to work out the size of the water molecule and a precise value for Avogadro's number. These results made clear that atomism was more than just a useful hypothesis. Already in 1913 Perrin had summed up the then known facts on molecules in his influential book *Les Atomes*. He was awarded the 1926 Nobel Prize in Physics.

During World War I, Perrin served in the Engineering Corps of the French army, working on remote acoustical detection of submarines and artillery fire, and inventing for the purpose a device called the telesite meter. In later years Perrin also became involved with institutional and organizational development of science in France. Thus in the late 1930s he was responsible for establishing both the Centre National de la Recherche Scientifique and the Palais de la Découverte in Paris at the 1937 International Exposition. He also was influential in the establishment of the Institut d'Astrophysique in Paris, and in the construction of the large Observatoire de Haute Provence. Perrin held honorary doctorates from several universities and in 1923 was elected a member of the French Academy of Sciences and served as its president in 1938.

Perrine, Charles Dillon

Born **Steubenville, Ohio, USA, 28 July 1867**
Died **Villa General Mitre, Argentina, 21 June 1951**

Charles Perrine, discoverer of Himalia (the sixth) and Elara (the seventh) satellites of Jupiter and nine new comets, began his astronomical career in the United States, but spent a large portion of it studying the Southern Hemisphere skies as director of the Argentine National Observatory at Córdoba, Argentina.

The son of Peter and Elizabeth Dillon (*née* McCauley) Perrine, Charles graduated from high school in Steubenville, Ohio, in 1884, and by 1886 had moved to San Francisco, California, where he worked as a business secretary until 1893. Interested in astronomy since high school, Perrine volunteered to observe the 1 January 1889 solar eclipse as part of an expedition organized by the Lick Observatory and became acquainted with **Edward Holden**. By 1893, Perrine had convinced Holden that he should be employed at Lick Observatory as the observatory secretary.

Perrine began his career in astronomy assisting Holden with nighttime celestial photography. By 1895, he had demonstrated sufficient aptitude that he was appointed assistant astronomer while continuing to serve as the observatory secretary. That same year, using the observatory's 12-in. Clark refractor, Perrine discovered the first of many comets credited to him. He was given full-time responsibility as an assistant astronomer 2 years later. As **James Keeler**'s assistant, Perrine continued to expand his observing repertoire, gaining skill on the Crossley 36-in. reflector as Keeler struggled to subdue the mechanical problems that plagued that instrument. After Keeler died and **William Campbell** was appointed to replace him, Campbell promoted Perrine to a full status as an astronomer. Mechanical upgrading of the Crossley reflector was incomplete at that time, so Campbell gave Perrine full responsibility for the instrument and its program. One of the many modifications Perrine made to the instrument was to place the photographic plate holder inside the tube at the primary focus, thus eliminating light loss from one reflection. Perrine's celestial photographs taken with the Crossley were excellent and in fact in some cases were substituted for photographs taken by Keeler before the instrument was fully functional in the *Keeler Memorial Volume* of the *Publications of the Lick Observatory*.

Perrine already had received five Astronomical Society of the Pacific's Donohoe Medals, each one for the discovery of "an unexpected" comet, when he was awarded the Paris Academy of Sciences' Lalande Prize and Gold Medal in 1897 for his comet discoveries. In total, between 1895 and 1902 Perrine discovered nine new comets and recovered four returning periodic comets. He made good use of the Crossley reflector for several other discoveries. Using the 36-in. telescope, he discovered the apparent superluminal motion of the expanding light bubble around Nova Persei (1901). Thought to be a nebula, the visual appearance was actually caused by the light from the nova event reflected from the surrounding interstellar medium as the light moved outward from the star. Perrine studied this phenomenon using photographic, spectroscopic, and polarization techniques. In 1904, he discovered Himalia, and found Elara in 1905.

Perrine had a deep interest in solar eclipses. Between 1900 and 1908, he led one Lick Observatory eclipse expedition to Sumatra (1901) and participated in several others. Campbell placed Perrine in charge of the Lick Observatory's observations of the 1901 opposition of the minor planet (433) Eros to measure the Earth–Sun distance. Perrine used Lick Observatory observations of Eros to publish an estimate of the solar parallax based on the Eros data in 1904.

Perrine left the Lick Observatory when he was appointed director of the Argentine National Observatory in Córdoba, Argentina, in 1909. He continued a program of modernization of Córdoba's facilities for conventional astrometry, the traditional program at Córdoba Observatory since it had been founded by **Benjamin Gould**. Equipment for the modernization had been ordered by Gould's successor, **John Thome**, who died before the Repsold meridian circle was completed in Hamburg, Germany. Perrine eventually completed the publication of all of the observatory's astrometric observations in 16 volumes of the *Resultados del Observatorio Nacional Argentino* along with an additional volume containing photographs from the 1910 return of Halley's comet (IP/Halley).

However, astrometry did not interest Perrine. His lasting contribution was the creation of the Astrophysical Station at Bosque Alegre (50 km southwest of Córdoba), which houses a 60-in. reflecting telescope. Almost from the day he arrived at Córdoba, Perrine was committed to establishing a leading position for Argentina in the emerging field of astrophysics. He persuaded the national government to fund the 60-in. telescope for which the mirror and mounting were to be produced in the shops at Córdoba. After upgrading the mechanical shops in anticipation of work on the 60-in. telescope, Perrine was successful in building a 30-in. reflecting telescope in the Córdoba shops and achieved noteworthy results with this instrument, the largest in the Southern Hemisphere. Unfortunately, he underestimated the difficulty of working the larger glass, and the project dragged on for many years. The delays in finishing the 60-in. mirror created a severe political problem for Perrine in the xenophobic atmosphere that dominated Argentina in the late 1920s and 1930s. He retired from the director's position of the Córdoba Observatory in 1936, but continued to live in South America until his death. Perrine was replaced by the Argentine astrophysicist Enrique Gaviola, who wisely arranged to have the large mirror finished by J. W. Fecker in the United States.

As a consequence of Perrine's farsightedness as the third director of the observatory, Córdoba became, for a time, the main astrophysical station in the Southern Hemisphere. Perrine wrote more than 200 papers between 1896 and 1947 on a variety of astronomical topics, including radial velocities of stars, comets, solar eclipses, the nature of globular clusters, nebulae, nova, and astronomical instrumentation.

In 1905, Perrine married Bell Smith of Philadelphia, Pennsylvania, USA. He was honored by Santa Clara College, California, in 1905 when that institution conferred an honorary D.Sc. upon him. Perrine was elected president of the Astronomical Society of the Pacific in 1902 and a foreign associate of the Royal Astronomical Society in 1904.

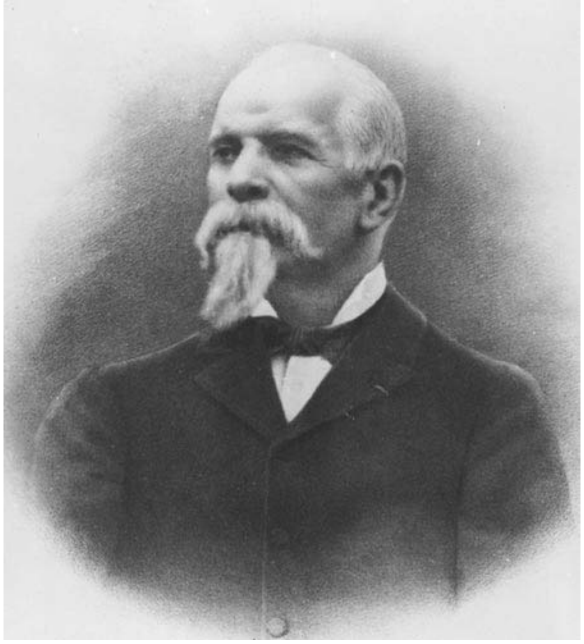
Perrotin, Henri-Joseph-Anastase

Born **Saint-Loup, Tarn-et-Garonne, France, 19 December 1845**
Died **Nice, Alpes–Maritimes, France, 29 February 1904**

Henri Perrotin achieved much of his recognition for his observations of planets and asteroids, as well as for his work in celestial mechanics on the determinations of their orbits. His astronomical observations were published in 50 notes in *Comptes rendus de l'Académie des sciences* from 1875 to 1903 and in *Astronomische Nachrichten* from 1875 to 1889.

Perrotin was born into a family of modest means in the southwest of France, and received scholarships for his education at the lycée in Pau. He began his astronomical career with **Félix Tisserand**, a professor of celestial mechanics at the Faculté des Sciences of Toulouse. When Tisserand became director of the Toulouse Observatory in 1873, he appointed Perrotin as astronomer. The year after, the novice astronomer discovered his first asteroid, which he called (138) Tolosa. Perrotin discovered five more, the last one in 1885.



Following the method used by **Urbain Le Verrier** for the big planets, particularly Jupiter and Saturn, Perrotin started to develop the first precise orbital theory of the minor planet (4) Vesta, the topic of his thesis in 1879. In this work, he used a perturbation function of the eighth order in the eccentricities and inclinations, an achievement that has been applied by astronomers to verify recent theories of Vesta.

In 1880, Perrotin was directed by the Bureau des longitudes to banker Raphaël Bishoffsheim to install the private observatory that Bischoffsheim was founding in Nice on Mont Gros. After visiting the most important observatories in Europe to study their organization and development, Perrotin supervised the installation on Mont Gros the next year. As its first director, a position he held for more than 20 years until his death, he devoted himself to setting up a well-equipped observatory, and to supervise its growth. His work and research there related to astrometry (of asteroids, comets, double stars, and satellites), astrophysics (pertaining to the study of planetary surfaces and the velocity of light), and celestial mechanics (orbits of asteroids and planets).

In 1882, the Académie des sciences designated Perrotin as the leader of the expedition to observe the transit of Venus in Patagonia, at Carmen de Patagonès (Argentina) on the banks of the Rio Négro. His return to Nice marked the beginning of the most active part of Perrotin's career. He provided the impetus for a variety of work concerning the construction of instruments and scientific research. Perrotin greatly contributed to the renown of the observatory, supervising the installation of many instruments, including the 30-in. refractor (1886), one of the world's largest at the time. He used it to carry out observations of double stars, and of large and small planets.

Perrotin tried to verify two findings of **Giovanni Schiaparelli**: his discovery of the so called canals of Mars and his determination of Venus's rotational period as 225 days. On both counts, Perrotin confirmed the Milan astronomer's results, though later findings disproved the former and showed the inaccuracy of the latter. Yet his own detailed observations of the Martian surface proved of great interest, and his drawings of Venus's surface (1890) show that 70 years before their widespread recognition, he had visually noticed the now famous Y- and Ψ-shaped markings recognized today in the Venusian clouds.

Perrotin also organized meteorological and magnetic observations, and contributed to physics by determining the velocity of light. He made a series of accurate observations using the slotted-wheel technique developed by **Armand-Louis Fizeau**, and applied it to beams sent between Mont Gros and Mont Vinaigre, the highest point of the massif of Estérel 46 km away. The 299,880 km/s value obtained in 1902 was regarded as the best until the measurements taken by **Albert Michelson** in 1926.

Perrotin founded the *Annales de l'Observatoire de Nice* in 1887. He managed the publication of the first ten volumes, and wrote several of them. He was twice awarded the Lalande Prize by the Académie des sciences (1875 and 1884), and was a corresponding member of the Académie des sciences (1892) and of the Bureau des longitudes (1894).

Peters, Christian August Friedrich

Born **Hamburg, (Germany), 7 September 1806**
Died **Kiel, Germany, 8 May 1880**

During the second third of the 19th century, a time of widespread emphasis on astrometrical precision, Christian Peters studied from and worked with the first two observers of stellar parallax and deduced the orbit of an unseen companion of the star Sirius. Born in a family of merchants, Peters displayed a precocious ability in the mathematical sciences. He received encouragement from **Christian Schumacher**, the genial founder and first editor of the leading astronomical scholarly journal, *Astronomische Nachrichten*. Peters's first astronomical publications, completed before he was 20, appeared in that journal in 1826.

On matriculating at the University of Königsberg in East Prussia (presently Russia) and studying under **Friedrich Bessel**, Peters joined the leading exponent of the scientific value of precision measurement. Peters's scientific career developed in the direction suggested by Bessel, who advocated the application of advanced mathematical techniques to improve precision by paying close attention to the analysis of both stochastic and systematic errors. Bessel's first extended application of careful error analysis involved the seconds pendulum; Peters's 1834 Ph.D. dissertation discussed the effect of air resistance on the pendulum. Bessel successfully applied his techniques to the centuries-old search for stellar parallax in 1838, inspired by the preliminary announcement by **Friedrich Struve** in 1836 of a parallax for the star Vega. Peters, who worked from 1839 untill 1849 under Struve's direction at the Pulkovo Observatory, some 400 miles up the Baltic Sea coast from Königsberg, made the critical comparison of the emerging measures of stellar parallax his specialty.

Peters worked productively as one of Struve's four assistants, publishing in 1842 his determination of the motion of the pole star and the constant of nutation. He became an adjunct (1842) and then an extraordinary (1847) member of the Saint Petersburg Academy of Sciences. In 1852, Peters won the Royal Astronomical Society of London Gold Medal for his work at Pulkovo Observatory. He also engaged in a polemical exchange with **Johann von Mädler**, Struve's successor at the University of Dorpat observatory.

In 1844, Bessel announced that irregularities he detected in the proper motions of Sirius and Procyon implied that these stars were orbited by unseen companions. After Bessel's death in 1846, August Ludwig Busch, Bessel's successor at Königsberg, made it possible for Peters to return as full professor of astronomy. In 1851, Peters produced a 60-page paper calculating the orbit of the companion of Sirius, despite Struve's doubts about its existence. While testing what was then the world's largest objective lens, United States telescope-maker **Alvan Clark** observed the predicted companion for the first time in 1862.

In 1854, Peters accepted the prestigious directorship of the Altona Observatory, in a suburb of Hamburg, and with this position also the editorship of the *Astronomische Nachrichten*. While at the professional summit of the German-speaking astronomical community for the next quarter of a century, Peters published a more technical journal (that appeared more frequently) than before, but he was opposed by astronomers working within the Russian empire. The practice of separate publication of the most important results from Pulkovo in the *Astronomische Nachrichten* came to an abrupt end as soon as Peters became editor. German astronomers complained of a greater degree of partisanship in the journal, and its circulation suffered.

After Germany was unified in 1870, the imperial authorities agreed to Peters's 1864 suggestion to move the instruments of the Altona Observatory 50 miles to Kiel and build a larger observatory for the university there. Peters served as professor of astronomy at Kiel from 1874 until his death.

Peters, Christian Heinrich Friedrich

Born **Coldenbüttel, (Schleswig-Holstein, Germany), 19 September 1813**
Died **Clinton, New York, USA, 18 July 1890**

Christian Peters, who played a subsidiary role in the rise of the American astronomical community to international prominence, was one of several senior scientists who emigrated from Europe to the United States prior to the American Civil War.

Peters received a classical education at the Gymnasium in Flensburg, Germany, obtained a Ph.D. from the University of Berlin in 1836 in theoretical physics, and continued his studies under **Carl Gauss** at the Göttingen Observatory, after which he devoted himself to positional astronomy. Under Gauss's influence, German astronomers of the 1830s engaged in a substantial program of geodetic mapping. Peters worked on a survey of Mount Etna in Sicily from 1838 until 1843, and was then promoted to director of the government trigonometric survey of Sicily. When in 1848 that island was swept by an antimonarchial revolution, one of a dozen or so that year throughout Europe, Peters supported the revolutionaries. He left for neutral Turkey when the monarchial troops invaded and reestablished the royal government.

During 5 years in Constantinople with few prospects for scholarly work, Peters managed to learn Arabic and Turkish. He then joined the group of skilled scientists going to the United States. In 1854, at the urging of the American ambassador to Turkey, he emigrated to Massachusetts, where **Benjamin Gould**, who had known him in Göttingen, helped him get a position in the United States Coast and Geodetic Survey, working under Gould's supervision. Peters arrived in his new country the same year as **Franz Brünnow** came from the University of Berlin Observatory to head the new observatory at the University of Michigan.

Mercantile philanthropists in Albany, New York, had subscribed generously to the establishment of a research-grade astronomical observatory, the first American observatory devoted solely to research, and invited Gould to be director; he agreed to act as a scientific consultant during construction. Although there is little doubt that the head of the Coast Survey, **Alexander Bache**, would have allowed Gould to be present during construction, he preferred to remain in Cambridge, Massachusetts, and to send Peters to Albany. The contrast between the diffident and competent Peters and the nervous and abrasive Gould so struck the businesslike trustees that they invited Peters, who resigned from the Coast Survey, to step in as director of what was to be called the Dudley Observatory. Gould, Bache, and the head of the Smithsonian Institution, **Joseph Henry**, interpreted Peters's acceptance of the position as betrayal, and by personal intervention and material inducements persuaded the trustees to release Peters, who was then shunted to the directorship of the Hamilton College Observatory in Clinton, New York.

As director there from 1858 to 1890 under difficult circumstances, Peters conducted a program of precision positional astronomy to the standards of accuracy demanded by contemporary research. The 13.5-in. refractor on an equatorial mount at Hamilton was the largest American-made refractor in the United States when Peters arrived. Its quality had convinced Gould to engage its maker, Charles A. Spencer of Canastota, New York, to build the main research instrument of the Dudley. Noting the acclaim afforded Brünnow's discovery of several new asteroids, Peters undertook the colossal project of mapping all stars, down to 14th magnitude, within a zone of 30° on either side of the ecliptic, during which effort he discovered at least 42 new asteroids of his own. Most of his results appeared in the *Astronomische Nachrichten*, the leading scholarly astronomical journal of the day, although he made use of the *Astronomical Notices* as well, founded and edited by Brünnow while he was in the United States (1858–1862).

Two problems frustrated Peters's ambitious research program. The first was inadequacy of means. He wrote several times to his close friend **George Bond**, director at the Harvard Observatory, lamenting his arrears in pay; on 1 February 1863, he mentioned consulting a lawyer about obtaining the previous year's salary. Fortuitously, in 1867, the owner of a railroad living in nearby Delphi Falls donated enough money to Hamilton to endow its astronomer with a modest salary; the Litchfield professor of astronomy from then on directed the now-renamed Litchfield Observatory. Peters's plan of work envisioned 182 charts of carefully determined star positions, but only 20 were ever published.

A second development doomed Peters's plan: instrumental change. The 1870s and 1880s saw the increasing use of photography in positional astronomy – Peters himself was one of three American representatives participating in the International Astrophotographic Congress held in Paris in 1887 – but all work at Hamilton College was visual. Even so, the quality of his work elevated Peters to the elite National Academy of Sciences in 1876, the Royal Astronomical Society of London in 1879, and the French Legion of Honor in

1889. He was selected as chief of the 1874 American transit of Venus expedition sent to New Zealand.

The Coast and Geodetic Survey, the United States Naval Observatory, the Nautical Almanac, and the Harvard College Observatory were the leaders in the emerging American participation in contemporary astronomical research in the second half of the 19th century. The careful, numerous, and hard-won contributions of Christian Peters to positional astronomy were a minor but helpful part of that process.

(Contains the most balanced account of Peters' career; her count of 48 discoveries of asteroids, however, differs from the usually reliable *Poggendorff's Biographisch-literarisches Handwörterbuch*, which counts 42. Vol. 3, p. 1027. Leipzig, 1898.)

Peter of Ailli

➔ **D'Ailly, Pierre**

Petit, Pierre

Born	**Montluçon, (Allier), France, 8 December 1594 (?) or 31 December 1598**
Died	**Lagny-sur-Marne, (Seine-et-Marne), France, 20 August 1677**

Physicist, mathematician, astronomer, and instrument maker Pierre Petit was christened on 31 December 1598. He was one of seven children born to Pierre Petit, then *contrôleur en l'élection* in Montluçon, a town situated in the Bourbonnais region of France, and Marie (*née* Bonnelat) Petit. As a young man, Petit assumed the duties of his father's office in 1626. But being more interested in scientific matters, he gave up this position and went to Paris in 1633. During his lifetime, Petit served in many official capacities, as a *commissaire provincial d'artillerie*, as an engineer and geographer to King Louis XIV, and as *intendant général des fortifications* in France.

While at Paris, Petit became a friend of **Marin Mersenne**, and was included in meetings of Mersenne's circle. Petit also became acquainted with Etienne Pascal and his mathematician son, Blaise Pascal. It was from Mersenne that Petit learned about **Evangelista Torricelli**'s experiments with the barometric vacuum and, helped by the Pascals, he successfully repeated them. Following Mersenne's death, this group met at the residence of Henri-Louis Habert de Montmor, and became known as the Académie de Montmor. There, Petit was introduced to **Adrien Auzout**, **Jean Picard**, and **Christiaan Huygens**. In conjunction with Auzout and Picard, Petit helped to perfect an instrument known as a filar micrometer, used to measure the very small angles of celestial objects viewed through a telescope. Petit also produced the earliest surviving sketch (1662) of the "magic lantern," or lantern projector, in his correspondence with Huygens.

By 1664, however, the Académie de Montmor had exhausted its funds. An appeal for assistance was directed to Jean-Baptiste Colbert, French statesman and financier. Two years later, King Louis XIV established the Académie royale des sciences, following many of the suggestions proposed by the academicians. Petit, however, was not among the founding members of the Académie des sciences, perhaps because he held a full-time government position. In 1667, however, Petit was named a corresponding member of the Royal Society of London.

Petit's most important astronomical work was his *Dissertation sur la nature des comètes* (1665). Therein, he speculated that a bright comet seen in December 1664 was the same as another viewed in 1618. Petit surmised that the comet had an elliptical orbit with a period of 46 years. He even went so far as to predict the return of this comet in 1710. Petit, however, was wrong about the particulars of this assertion. (Comets C/1664 W1 and C/1618 W1 were neither identical nor periodic). Yet his suggestion that comets might be periodic phenomena helped to diminish lingering fears and superstitions about their mysterious nature.

Petit also published a study on magnetic declination. His astronomical equipment included graphometers, quadrants, and objective lenses fashioned by the optician **Giuseppe Campani**. Petit married and had, among his children, one daughter, "Marianne", who became a *bénédictine* at Lagny-sur-Marne. A street and place, situated in the old part of Montluçon, bear Petit's name.

Pettit, Edison

Born **Peru, Nebraska, USA, 22 Sept 1889**
Died **Tucson, Arizona, USA, 6 May 1962**

Edison Pettit, American astronomer best known for accurate measurements of the color temperatures of planets and stars, was the son of George Knox Pettit and Martha Ann Knox. He married Elizabeth Schmauser and, later Hannah Bard Steele. Their children were Helen Bard Pettit Knaflich and Marjorie Steele Pettit Meinel.

Edison Pettit was given no middle name because his parents thought "Edison" was a unique first name. (He was born at the time of Thomas Edison's inventions relating to electrical power.) George Pettit owned a sawmill and converted its machinery from steam-belt drive to steam-generated electricity drive. Young Edison Pettit, in fact, earned money for his education by helping to his father's growing electrical power plant wire up the village.

Pettit received his B.Ed. from Nebraska Normal College, Peru, Nebraska, in 1911. Following this he taught, first, science at Minden (Nebraska) High School, and then physics and astronomy at Washburn College, Topeka, Kansas, before going on to Yerkes Observatory to work on a Ph.D.

Pettit was a Ph.D. student at Yerkes when the army drafted him into World War I. At the Induction Center, when the soldiers manning the induction desk saw he gave "astronomer" as his job on his papers, they commented, "Of what use is an astronomer ? " Fortunately, the officer in charge recognized Pettit's worth and assigned him to the United States Army Signal Corps. There Pettit worked with the optical scientist, **Robert Wood** at Johns Hopkins University. He was given the task of measuring the optical properties of materials and of assisting Wood in experiments with gas-filled balloons used as reconnaissance platforms. On the first flight, they nearly brought down the municipal gas supply of Baltimore.

Following the war, Pettit finished his Ph.D. at Yerkes Observatory where he had met his second wife, Hannah, the first woman to earn a Yerkes/University of Chicago Ph.D. in astronomy (guided by **Edwin Frost,** then director). They both extensively used the Yerkes 40-in. telescope. One night, while he was rewinding the drive weights, Edison's necktie got caught in the telescope drive mechanism and threatened to slowly strangle him. From the library, Hannah heard him cry out. She got scissors, ran to the dome, and severed his necktie. After that Edison never wore a necktie, only a black bow tie. Edison Pettit received his Ph.D. in 1920 for studies in solar physics, especially the spectra of prominences. Hannah's was for astrometric work. In 1920, shortly after establishing a solar observatory on Mount Wilson in California, **George Hale** asked Edison to join him on the staff of Mount Wilson Observatory [MWO]. Pettit accepted, and asked if there also was a position available on the staff for Dr. Hannah Pettit. Hale replied that it was not possible for women to be on the staff: only men. This remained true for five decades. Much of Edison Pettit's MWO work was done with the 60-ft. solar tower, to be followed in a few years by the 150-ft. tower.

In the winter of 1925–1926, the Pettit family went to the University of Arizona, Tucson, where Edison did research at the Tucson Tuberculosis Sanitarium (now the Tucson Medical Center) on ultraviolet transmission of glasses and the possible beneficial effect of solar ultraviolet radiation on tuberculosis patients. (His first wife, Elizabeth, had died of tuberculosis.) In 1930, he again took his family to Tucson where he assisted **Andrew Douglass** in upgrading the 36-in. telescope of the university's Steward Observatory, at that time located on the campus.

In addition to his solar work, Pettit had a laboratory at the MWO Pasadena offices to support his developments in radiation measurements of astronomical sources. In the 1920s, he built an ultrasensitive thermocouple and, with **Seth Nicholson**, made the first measurements of the temperature of the Moon, both the solar-illuminated and night surfaces, which showed the fine granular nature of the lunar surface.

Pettit and Nicholson extended temperature measurement to Venus, Mars, Jupiter, and Saturn, using the MWO 100-in. telescope. The values they obtained were confirmed in the 1970s when spacecraft first visited these planets. In 1944, Pettit was asked to use his expertise to build three thermocouples and to hand-deliver them to Alamogordo, New Mexico, where they were used to monitor the output of the first nuclear explosion.

During the summers of 1930–1936, Pettit took his family to Yerkes Observatory and made solar prominence observations using Hale's spectroheliograph on the 40-in. refractor. Pettit's attention was focused on why eruptive prominences show several sudden jumps in their upward motion before blasting into space. To follow this up he went to Michigan in the summers of 1936–1938 to test and then to use the new spectroheliokinematograph at the McMath–Hulbert Observatory.

In 1939, Pettit built a home observatory equipped with an Alvan Clark 6-in. refractor. For years this old telescope had lain in a barn, covered with trash, on a farm in Michigan. It now had been offered for sale. The owner would not let a buyer inspect it, but Pettit could see that although the telescope had been neglected, it was at least intact. After the owner accepted his fair price offer, another astronomer slyly told her that Pettit had offered too little, so she raised the price.

Nonetheless, Pettit took the 6-in. home to Pasadena and refurbished it so that it looked and worked like new. Now he could do much more of his observing from his home rather than on Mount Wilson, an advantage since his wife Hannah was a semi-invalid.

Shortly after **Yngve Ohman** invented the quartz-polarizing monochromator, Pettit designed and built one in his small home machine shop, adding a time-lapse movie camera. Attaching this at the eyepiece of his telescope made possible photographing solar prominences from the convenience of home. Assisted by Marjorie, he obtained enough movies of eruptions to enable him to refine a set of "laws" describing the motion of eruptive prominences. Understanding why they erupt in this manner required the discovery of magnetohydrodynamics and model of solar flares; subtleties in their behavior still puzzle solar theorists.

The Clark refractor saw additional duty as Pettit frequently had groups of amateur astronomers and the public come to look through the 6-in. at the planets, especially during the excellent 1940 opposition of Mars. That telescope and monochromator are still in use, but now in a small observatory in Prescott, Arizona.

A backyard telescope has other advantages. One winter morning in 1941, Pettit went out before dawn to pick up the morning newspaper. He was startled to see a new bright star shining low in the south. He immediately ran to the backyard, opened the sliding roof, and turned the telescope on the new star – Nova Puppis. Reading off its coordinates and measuring its magnitude, he sent a telegram to Harvard College Observatory with the news. However, Pettit was about 2 hours too late to be the discoverer of a nova, since a telegram had just been received from South America where it had been discovered first.

As photoelectric observations took center stage for precision brightness measurements, Pettit's interests moved from solar and planetary observations to measuring the radial brightness distributions of over 500 galaxies. During his retirement years, he used his home machine shop to build spectrographs and small instruments for a number of observatories and universities. Following the death of Hannah, and a subsequent stroke, Edison moved to Tucson to live with Marjorie Meinel and her family.

Pettit received a honorary degree from Carthage College (LL.D.) in 1935, and craters both on the farside of the Moon and on Mars are named for him.

Peucer, Caspar

Born **Bautzen, (Sachsen, Germany), 1 June 1525**
Died **Dessau, (Sachsen-Anhalt, Germany), 25 September 1602**

In his textbooks Caspar Peucer argued for the importance of studying astronomy; he also wrote on the new star of 1572, and defended certain aspects of astrology.

Peucer was the child of Gregor Beucker, a *Bürger* of Bautzen, and Ottilie Simon. He was educated at the University of Wittenberg, matriculating there in March 1543, and graduating MA in September 1545. He went on to distinguish himself as a professor at Wittenberg, first in lower mathematics (1550), then higher mathematics (1554), and finally, after graduating as a doctor of medicine in 1560, in the medical faculty. His first wife, Magdalena, was the daughter of Philipp Melanchthon; she bore him three sons and seven daughters, but died in 1575. Between 1576 and 1586, Peucer was imprisoned as a crypto-Calvinist by August von Saxony, whom he had previously served as counselor and physician. His release was effected through the petition of Joachim Ernst von Anhalt, whom he then likewise served in both of these capacities. In 1587 Peucer married Christine Schild, a widow of Bautzen; this second marriage was without any issue.

Peucer's significance to astronomy lies partly in his authorship of astronomical texts, and also in the position he held within the astronomical community of the later 16th century. Peucer's professors at Wittenberg had included Melanchthon, **Rheticus**, and **Erasmus Reinhold**, and as a professor of higher mathematics (astronomy) in his own right, and an author of textbooks that had their origin in his lectures, Peucer played a large part in propagating both the Philippist view of the importance of astronomy within the arts curriculum and the so called Wittenberg interpretation of the Copernican world system. Peucer's pupils included Johannes Praetorius, Victorin Schönfeld (who became professor of mathematics at Marburg), and Jørgen Dybvad (later professor of theology, natural philosophy, and mathematics at Copenhagen). In addition, he was consulted by princes, including Landgrave **Wilhelm IV** of Hessen-Kassel, about such phenomena as the supernova of 1572 (SN B Cas), and he included among his correspondents the Danish astronomer **Tycho Brahe**. Peucer's standing within the astronomical community is suggested by the fact that Brahe attempted to use Peucer as the arbiter of his disputes with **Christoph Rothmann**, and addressed to him an important epistolary defense of his claim to priority in the development of the geoheliocentric world system.

The most astronomically significant of Peucer's own works are the *Elementa doctrinae de circulis coelestibus*, first published in 1551, and the *Hypotheses astronomicae*, first published under his name in 1571, after a previous version had been published in 1568 without his consent. His treatise on the new star of 1572 was published at Wittenberg, and later reproduced by Brahe. Peucer's *De dimensione Terrae* of 1550 was essentially a geography textbook, but one heavily indebted to the techniques of spherical astronomy. His *Commentarius de praecipuis divinationum generibus* of 1553 is worthy of mention since it included a section on astrology, the practice of which provided one of the chief motivations for astronomical study in the early modern period; in defending the legitimacy of certain forms of astrological divination Peucer was again following the lead of his father-in-law Melanchthon.

Peurbach [Peuerbach, Purbach], Georg von

Born **Peurbach near Linz, (Austria), possibly 30 May 1423**
Died **Vienna, (Austria), 8 April 1461**

Georg von Peurbach continued a strong tradition in which the University of Vienna was considered to have the best astronomy scholars in Europe during the 15th and early 16th centuries.

Peurbach was born sometime after 1421, the date of 30 May 1423 coming from a horoscope published as late as 1550. Peurbach received a bachelor's degree in 1448 and his master's degree 5 years later, both at the University of Vienna. As a lecturer at the university there, he was one of the leaders in reviving classical Greek and Roman literature in the arts and sciences. After observing an occultation of Jupiter by the Moon in 1451, Peurbach spent the last decade of his life making observing instruments, lecturing on astronomy and the classics, collaborating with men such as **Johann Müller** (Regiomontanus) on astronomical observing and theory, and serving as imperial astrologer to the king of Hungary. Peurbach died of unknown causes.

Peurbach evidently made many astronomical observations during the last 10 years of his life with his famous student Regiomontanus, including taking measurements of lunar eclipses during 1457–1460 whereby the two astronomers carefully noted observing location and times, altitudes of the Moon and various stars, and degree to which the Moon was seen inside the Earth's umbral shadow. Such observational detail was not only highly unusual for medieval observations, but it also helped to set a precedent for 16th-century observers who tried to emulate the work of the Vienna astronomers. Peurbach observed Halley's comet (IP/Halley) in 1456, using instruments to record the ecliptic positions of the comet's head and tail on two nights and to make some assessment of the comet's distance from parallax measures. That a comet's position would be measured as seriously as a planet's indicated the beginning of moving away from **Aristotle**'s claim that comets were merely atmospheric phenomena; this was also apparently the first attempt to seriously determine a comet's distance from parallax, a procedure elaborated upon by Regiomontanus and widely discussed and refined in the 16th and 17th century by others.

Led by Peurbach and Regiomontanus, the Vienna group sought actively to reform astronomy by improving on theory through the beginning of systematic observation of the planets, Sun, Moon, and stars. Peurbach's *Nouae theoricae planetarum* (New theories of the planets), which involved revised theories of the Ptolemaic system (evidently augmented by the ideas of Arabic astronomers), was published posthumously in numerous editions from 1472 to 1596, edited by such notable scholars as Regiomontanus, **Peter Apian**, **Erasmus Reinhold**, and Philip Melanchthon. No less than 56 printings of this Latin text appear to have been made up to 1653, with additional printings in other languages. (While still working toward his master's degree, Regiomontanus apparently heard Peurbach's lectures on this text in 1454 at Vienna.)

Peurbach also prepared and issued tables predicting eclipses of the Sun and Moon (a practice continued by Regiomontanus), and

Peurbach seems also to have supervised the collecting and copying of astronomical manuscripts, leading evidently to the establishment of the scientific printing press by Regiomontanus to publish astronomical tracts (including Peurbach's *Nouae theoricae planetarum* and the ancient poet **Manilius**'s *Astronomicon*).

At the request of Cardinal Bessarion, Peurbach began in 1460 a translation, with commentary, of **Ptolemy**'s *Almagest*; this was cut short by Peurbach's death, but was continued to completion by Regiomontanus and eventually published under the title *Epitome of the Almagest* in 1496. The *Epitome* was an important reference in the following decades for **Nicolaus Copernicus** during his preparation of *De Revolutionibus*. Peurbach also influenced Regiomontanus for the development of advanced trigonometric relationships that would be used by astronomers in the century to come.

Peurbach's *Theoricae novae planetarum* was published by Regiomontanus from his printing press in Nuremberg. Though many Peurbach manuscripts seem to have circulated (particularly on astronomical theory and practice, including instrumentation), other work by Peurbach was even more delayed in terms of printing, his observations not being fully published until nearly a century after his death by **Johann Schöner**.

Pfund, August Hermann

Born **Madison, Wisconsin, USA, 28 December 1875**
Died **Baltimore, Maryland, USA, 4 January 1949**

American spectroscopist and colorimetrist August Pfund received a BS from the University of Wisconsin in 1901 and a Ph.D. from Johns Hopkins University, Baltimore in 1906. He held research positions from 1906 to 1910, an associate professorship (1910–1927), and a professorship at John Hopkins University from 1927 until his retirement. Pfund appears occasionally in astronomy books because of his discovery of the fifth series of hydrogen lines, that is, those arising from the $n = 5$ electron shell, the third in the infrared after the Paschen and Brackett series. Pfund lines have wavelengths longer than 2.28 μm. There is no limit to such series, and transitions from $n = 108$ and 109 can be studied at radio wavelengths.

Pfund received medals from the Franklin Institute and the Optical Society of America.

Phillips, Theodore Evelyn Reece

Born **Kibworth, Leicestershire, England, 28 March 1868**
Died **Walton-on-the-Hill near Headley, Surrey, England, 13 May 1942**

Reverend Theodore Phillips led the British Astronomical Association [BAA]'s Jupiter Section for 31 years. In the process, from both his own outstanding observations and those of other observers, Phillips compiled an unprecedented continuous record of the visual surface features of Jupiter, a record that for the most part cannot be duplicated from any other source. His analysis of the currents in various zones and belts of Jupiter is a model for all such efforts.

The son of an Anglican minister, Reverend Abel Phillips, Theodore matriculated at Oxford, where he graduated with a BA degree from Saint Edmund's Hall, Oxford, England, in 1891 and earned a MA at Oxford University in 1894. Ordained as a minister in the Church of England in 1891, Phillips served as the curate of the parish of the Holy Trinity at Taunton, and then was appointed to a similar role at Hendford, Yeoville, in 1895.

It was around 1895 that a parishioner, aware of Phillips's interest in science, made a gift of a 3-in. Grubb refractor to Phillips. When Phillips chanced upon Saturn during his first observing with this telescope, the beauty of the object created an enthusiasm for astronomy that would influence him for the rest of his life. In 1896 Phillips joined the BAA and began systematically observing Jupiter and Mars with a 9¼–in. reflector on an alt-azimuth mount. With respect to Jupiter, Phillips soon recognized the importance of the pioneering work of **Arthur Williams**, which had in the main been largely ignored by the directors of the Jupiter Section. Soon after Phillips joined the section in 1896, the apparition memoirs began to reflect this new awareness. In 1901 Phillips was appointed director of the BAA Jupiter Section. He changed little at first, but by 1914 had completely revised the reporting process for Jupiter. Instead of preparing drift charts for each individual observer, the practice that emerged from his initial emphasis on the work of Williams, Phillips consolidated the results of all observers for each zone or belt, in the process not only simplifying the reporting but also making the analysis much more rigorous and likely more accurate. Takeshi Sato, a planetary observer, called Phillips the "Father of the Jupiter Observation." William Edwin Fox (1898–1988), a later BAA Jupiter Section director, characterized Phillips by stating "as a planetary draughtsman, he was unsurpassed."

Phillips sustained his energetic role in astronomy in spite of increasingly demanding professional assignments. In 1901, the same year he successfully assumed responsibility for the Jupiter Section, he was reassigned to a curacy in the parish of Saint Saviour, Croyden, followed by another assignment as curate in Ashstead, Surrey. While assigned at Croyden, Phillips met and married Millicent Kynaston; they had one son.

Phillips's involvement in astronomy continued to grow during this period. Having been elected a fellow of the Royal Astronomical Society [RAS] in 1899, Phillips was elected to the RAS Council in 1911. He served nearly continuously in that body until his death, including terms as secretary (1919–1925) and president (1927–1929). Phillips is one of only two amateur astronomers to serve as the RAS president after 1907, the other being **William Steavenson**.

Reverend Phillips assumed even greater church responsibility when, in 1916, he became the rector of Headley. This was, however, seen as a longer-term assignment, so he built an observatory near the rectory that eventually housed two telescopes, an 8-in. Cook refractor, and a 12-in. Calver equatorial reflector that was later replaced by an 18-in. With reflector. Phillips observed double stars with the refractor but employed the reflectors for his planetary studies. Phillips was fond of using the filar micrometer, which had reached its engineering peak in the 19th century, and contributed a long series of double star measures in annual reports to the *Monthly Notices of the Royal Astronomical Soceity*.

Phillips's planetary observing was not limited to Jupiter. For a time Phillips was known as one of the world's more prolific Mars' canalists along with BAA observers **Percy Molesworth** and **Eugéne Antoniadi**. When he observed Mars for the first time (with the 9¼-in. reflector), Phillips is reported to have declared "My experience of Martian observation this winter has led me to believe that Mars is not nearly so difficult an object as is commonly supposed, and that many of the canals are easy." Phillips observed at every opportunity during 43 oppositions of Mars. His drawings, which eventually displayed no canals, reflect the care and skill he evidenced in his Jupiter observations.

Phillips was known as an inspiring person and a gifted speaker. It would have been interesting to listen to a sermon on the heavens delivered by the amateur astronomer–minister. Headley Observatory was known as the "Mecca" of British amateur astronomy at that time. Every year in June, Phillips and Millicent would entertain guests at Headley Observatory, including young noteworthies like Steavenson, Frederick James Hargreaves (1891–1970), and Reginald Lawson Waterfield (1900–1986). In the warm summer afternoons, Theodore, Millicent, and guests would stroll along the wildflower covered countryside area of Nottingham.

It is characteristic of Phillips's broad interests in astronomy that in his second presidential address to the BAA, he attacked a theoretical problem rather than an observational topic. At the time, professional astronomer **Herbert Turner** was actively promoting amateur involvement in what is now known as data mining. (See also **Mary Blagg**.) At Turner's suggestion, Phillips undertook the harmonic analysis of the light curves of about 80 long-period variable stars. He demonstrated that those long-period variables could be classified into two groups based on the constancy of the third harmonic in one case but a simple linear relationship between the second and third harmonics in the other. Phillips's study became a classic in the literature of variable-star analysis.

In 1923 Phillips and Steavenson edited a book entitled *Splendour of the Heavens* published by Hutchinson & Company. It first appeared as two volumes containing 979 pages and was very readable, discussing solar and stellar spectroscopy in great detail. It featured almost 1,000 illustrations and numerous fine colored plates that contributed to the book's popularity. Top British astronomers and BAA section directors collaborated as authors of *Splendour*, which was widely used as a text for teaching nonastronomers at the time. Chapters were included on ancient constellations and Chinese astronomy in addition to more conventional astronomical topics. Astronomer Freeman J. Dyson claimed that he learned science more from books than from teachers: "My favorite book was *The Splendour of the Heavens*, a huge and lavishly illustrated compendium of popular astronomy …"

Phillips was honored by the RAS with their presentation of the Jackson-Gwilt Medal and Prize in 1918, and was the first recipient of the BAA's Walter Goodacre Medal in 1930. Just weeks before his death, Oxford University conferred the degree D. Sc. *honoris causa* on Phillips, which fortunately he was able to receive in person.

Philolaus of Croton

Born **Croton, (Crotone, Calabria, Italy), *circa* 460 BCE**

Philolaus held that the Universe and everything in it are constituted by the harmonious combination of unlimited and limiting principles.

Philolaus was born in southern Italy, but immigrated to Greece proper, presumably for political reasons. He was active in Thebes until shortly before Socrates' death in 399, and perhaps also in Phlio, a small city near Corinth. The ancient story that **Plato**'s *Timaeus* was plagiarized from Philolaus' only book is surely false, but may be indicative of the latter's interests and outlook. He stated the main Pythagorean tenet as follows: "Everything that is known has number, for without this nothing can be thought of or known" (fr. 5).

Most scholars agree today that the system of the world with a moving Earth, attributed by **Nicolaus Copernicus** and **Galileo Galilei** to the Pythagoreans, was due in fact to Philolaus. In this system the Earth, however, circumambulates not the Sun, as in the systems of **Aristarchus** and Copernicus, but a distinct cosmic source of heat and light, which Philolaus called "hearth of the universe," "house of Zeus," "mother of the gods," and "altar, bond and measure of nature." We earthians cannot see it because it is permanently eclipsed by the "counter-earth," which in turn we cannot see because it constantly shows us its unilluminated face. Ten divine bodies "dance" around the hearth, *viz.*, the firmament of the fixed stars, the five planets, after these the Sun, under it the Moon, then the Earth, and then the counter-earth. The number 10 = 4 + 3 + 2 + 1 was accorded a privileged status by the Pythagoreans. Thus, the counter-earth is not simply postulated *ad hoc* to ensure the occultation of the hearth, but derived so to speak from formal requirements of a well-built world. According to Philolaus, the Sun is like glass, receiving the reflection of the cosmic fire and filtering its light and warmth to us, so that in a sense there are two suns, the primary fire and its mirror image.

Aristotle reports that in this Pythagorean system, the quick motion of all the said bodies was supposed to produce an incredibly strong sound. By assuming that their speeds are in the same ratio as musical concords, it was concluded that the sound caused by the circular movement of the heavenly bodies is a harmony. Because this beautiful "music of the spheres" continually strikes our ears since our birth, we do not hear it.

Philoponus, John

Born **(Egypt), *circa* 490**
Died **(Egypt), *circa* 570**

John Philoponus (literally "Lover of work"), a Christian philosopher, scientist, and theologian, is one of the most important and certainly most original natural philosophers in Late Antiquity. His life and work are closely connected to the city of Alexandria and the Alexandrian Neoplatonic school. Although the geocentric Aristotelian–Neoplatonic tradition formed his intellectual roots and concerns, he was also an original thinker who eventually broke with that tradition in many respects, helping to lead eventually to the demise of the predominance of Aristotelianism in the natural sciences.

Philoponus' *œuvre* falls into three different parts. First, there are the commentaries on **Aristotle**, which belong to the early period (until about the mid-530s); some of these depend heavily on the lectures of Philoponus' teacher **Ammonius**. Then, in a string of polemical treatises, Philoponus turns to attacking squarely fundamental doctrines of Neoplatonic–Aristotelian natural science. One aim of these treatises may have been to integrate fully the still largely pagan school at Alexandria into a Christian social and intellectual context. In this he failed; leadership of the school remained in pagan hands well into the 6th century. Philoponus seems to have dissociated himself from the school, because from the 540s onward he was writing theological–exegetical works, most importantly a commentary on the biblical creation myth (*De opificio mundi*).

From the point of view of astronomy, Philoponus' two most important contributions to the development of science are his theory of matter and the theory of the impetus, which he seems to have embedded into a whole new view of explaining natural and forced motion of bodies. According to this new theory, the continuation of motion (*e. g.*, of an arrow) is no longer explained by the surrounding medium (air) acting as moved mover (as Aristotle thought), but by invoking the notion of a "force" that is imparted to the moved object by the original mover and that resides in it for the duration of the movement. Philoponus suggests (*De opificio mundi,* I 12) that one might well understand celestial motion in this way, *viz.*, that the celestial bodies have received a powerful impetus at the time of their creation, by which they continue to move in accordance with the will of God.

Philoponus' theory of matter is significant as a landmark in the history of cosmology. He vehemently opposed the Aristotelian dichotomy of the cosmos into a divine, eternal superlunary region and a sublunary region that is subject to generation and corruption. According to him, matter is uniform throughout, and the material basis of the heavens is in fact no different from the material basis of the terrestrial elements and the more complex structures they give rise to. Philoponus' ideas were viciously opposed by the contemporary Neoplatonist **Simplicius**, whose influential writings assured that Philoponus never received the kind of acknowledgment and attention he deserved.

Although this does not play a central role in his writings on natural philosophy, there is enough evidence to suggest that Philoponus was also an expert astronomer. Our oldest description of the construction and use of an astrolabe, written in the first half of the 6th century, is attributed to him; **Theon**'s earlier work on it is now lost. Moreover, we have fairly accurate knowledge of the date of one of his treatises (*De aeternitate mundi contra Proclum*) because he mentions that in the 245th year after Diocletian (529) there occurred a conjunction of all planets in Taurus; since the Sun counted as one of the planets, this conjunction was unobservable and could be inferred only on the basis of long-time observation and theory.

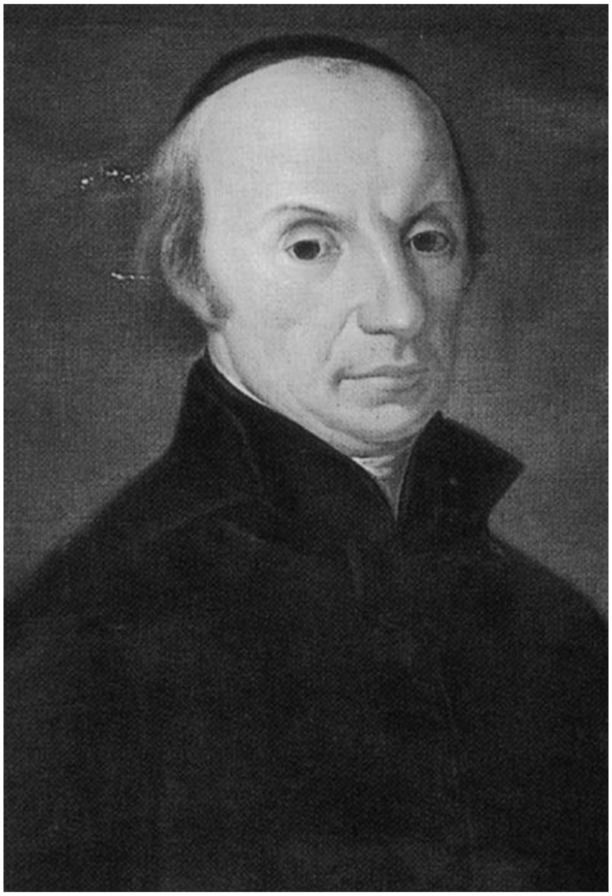
Piazzi, Giuseppe

Born **Ponte in Valtellina, (Graubunden, Switzerland), 16 July 1746**
Died **Naples, (Italy), 22 July 1826**



Giuseppe Piazzi was the discoverer of the first minor planet, (1) Ceres, and published two important star catalogs. Piazzi was the ninth of ten children born to Bernardo Piazzi and his wife, Antonia Francesca Artaria. He came from a family of nobles; his father worked in a land registry office in the Villa di Tirano.

In an age of limited career choices, Piazzi became a Theatine monk in Milan, which gave him the opportunity of broadening his knowledge in the classics and mathematics. He finished his novitiate at the abbey of San Antonio. Studying at Theatine colleges in Milan, Turin, Rome, and Genoa, Piazzi acquired a taste for mathematics and astronomy, earning a doctorate in these subjects. He then taught philosophy at Genoa, mathematics at the new University of Malta (1770–1773), and mathematics at Ravenna (1773–1779). In 1779, Piazzi was appointed professor of dogmatic theology in Rome.

It was not until 1780 that Piazzi found a permanent home when he accepted the chair of mathematics at the Academy of Palermo in Sicily. In 1787, Piazzi became a professor of astronomy and resolved to build one of Europe's finest observatories. He soon obtained a grant from Prince Tomaso d'Aquino Caramanico, Viceroy of Sicily. To equip his new institution, and to facilitate communication with other European astronomers, Piazzi traveled to France and Great Britain. There, he accompanied a group of scientists who were determining the longitude difference between the Paris and Greenwich observatories. While in England, Piazzi became acquainted with Sir **William Herschel** and observed the solar eclipse of 3 June 1788 with Astronomer Royal **Nevil Maskelyne**. But the most substantive result of Piazzi's visit was the 5-ft. vertical circle, a masterpiece of 18th-century technology, which was completed for him by instrument-maker Jesse Ramsden.

In 1789, Piazzi set up his observatory in the Santa Ninfa tower of the royal palace, for the purpose of creating a new catalog of fixed stars, which he considered as the basis of fundamental astronomy. The observatory at Palermo was the southernmost observatory located in Europe and offered unequaled access to the southern skies. Piazzi estimated the possible systematic errors of the Ramsden circle to be between 1 and 3 arc seconds. After a decade of laborious observations, he published his first catalog of 6,748 stars in 1803. With it, Piazzi was able to show that the proper motions of stars are not the exception but the rule. He also made famous the star 61 Cygni, whose abnormally large proper motion led him to call it the "flying star." The Institut de France awarded Piazzi's catalog the Lalande Prize in 1803. Baron **János von Zach**, editor of the *Monatliche Correspondenz* (the world's first astronomical journal), pronounced Piazzi's catalog as "epochal."

Piazzi once described his own personality in a letter to a friend, **Barnaba Oriani**: "My temper is fiery, and even though I am older I cannot suppress it. I have formed many wrong judgments because of it, but even if I am wrong my heart is not bad." Piazzi remained youth-oriented, flamboyant, and inclined to quick judgment. His health was delicate and illness interrupted his observations many times.

Even before publication of his star catalog, Piazzi had become famous. On 1 January 1801, he discovered the "missing planet" between Mars and Jupiter, which he named Ceres Ferdinandea, after the patron goddess of Sicily and its King Ferdinand. While looking for a seventh-magnitude star in Taurus with Ramsden's circle, Piazzi spotted a somewhat fainter object not previously cataloged. He continued to observe the moving point of light until 12 February, after which it became lost in twilight. He was criticized by astronomers all over Europe for not sharing news of his discovery sooner. Thereafter, the Göttingen mathematician **Carl Gauss** calculated the object's orbital elements by a new method that enabled it to be recovered at the end of the same year. Piazzi was subsequently offered the directorship of the Bologna Observatory but declined the invitation.

Piazzi was anxious to create another star catalog, but for all his enthusiasm, his eyesight had begun to fail. By 1807, he had to entrust work on the new catalog to his assistant, **Niccolò Cacciatore**. In 1813, Piazzi published the second catalog of 7,646 stars; it too received a prize from the Institut de France.

During this period, Piazzi was charged by the government of Naples with renovating the system of weights and measures used in Sicily. In 1808, he published an essay on the subject and was given another annual pension by King Ferdinand for establishment of the metric system. In turn, the Great Comet C/1811 F1 prompted him to publish his views on its nature. Piazzi supposed that comets were not formed along with the planets, but were produced from time to time in deep space, where they eventually dissipated.

In 1817, Piazzi was invited to Naples to examine the Capodimonte Observatory being constructed there. Though he at first declined the invitation to become its director, Piazzi finally agreed to become director-general of both the Naples Observatory and the Palermo Observatory. King Ferdinand gave him 93,500 lire in value of land, which he could sell or administer as he wished. Piazzi was also appointed president of the Royal Academy of Sciences in Naples; Cacciatore succeeded him as director of the Palermo Observatory. While at Naples, Piazzi introduced many innovations but sorely missed Palermo.

Piazzi received an unusual honor from admiral **William Smyth**, the son of an American-born loyalist who came to England after the Revolution. Smyth was also an astronomer and became acquainted with Piazzi. When the admiral's son was born in 1819, he was named **Charles Piazzi Smyth** and later became the Astronomer Royal for Scotland.

In 1825, Piazzi wrote, "It is a month since I have been in Naples, having left Palermo with regrets. Perhaps I will never see it again." The following year, he succumbed to cholera. In 1871, his native village remembered him by erecting a statue in Piazza Luini. Minor planet (1000) is named Piazzia in his honor.

Picard, Jean

Born **La Flèche, (Sarthe), France, 21 July 1620**
Died **Paris, France, 12 October 1682**

Jean Picard made notable contributions to early precision astronomy, geodesy, cartography, and hydraulics. Picard, the son of a bookseller, attended lectures at the Jesuit College of La Flèche, where **René Descartes** had been a student. He studied Greek and Latin literature and theology, and was initiated to astronomy during a course on Aristotelian philosophy. Picard's earliest known astronomical work occurred on 21 August 1645, when he assisted **Pierre Gassendi** in the observation of a solar eclipse. He also attended Gassendi's lectures on astronomy at the Collège de France in Paris. Like his mentor, Picard became an ordained priest (1650) and then traveled throughout Europe, learning the Italian and German languages. He held several ecclesiastical positions, as *abbé* and *prieur* at Rillé and Brion, and was also a schoolmaster. By and large, his astronomical studies were conducted privately, although Picard became an informal member of the Académie de Montmor.

Together with **Adrien Auzout** and **Pierre Petit**, Picard devised a movable-wire (filar) micrometer and used it to measure the angular diameters of the Sun, Moon, and planets. In 1666, he was named a member of the Académie royale des sciences, an appointment that brought Picard's astronomical and geodetic skills to the fore. Thereafter, he applied both telescopic sights and cross hairs to other scientific instruments used for angular measurements, chiefly quadrants and sectors, and proposed that meridian observations be conducted by the method of corresponding heights. His assistant, **Philippe de la Hire**, was the first to implement Picard's suggestion of establishing a mural quadrant in the meridian plane (1683).

Armed with these newer techniques, Picard undertook his principal investigation, namely the measurement of an arc of the meridian. Supported by the Académie des sciences, this operation sought to determine a more precise value for the radius of the Earth. Picard employed the method of skeleton triangulation along the meridian between Paris and Amiens. His results, published as *La Mesure de la Terre* (1671), attained a precision some 30 to 40 times greater than previously achieved. Picard's meridian line eventually led to the first accurate trigonometric survey of France. He subsequently applied these methods to the creation of a precision map of the Paris area (*Carte des Environs de Paris*, 1678), which superseded all former cartographic ventures.

In 1671, Picard traveled to **Tycho Brahe**'s former observatory on the island of Hven to accurately determine its location, so that Brahe's observations could be compared directly with those at Paris. Picard (at Hven) and **Jean Cassini** (at Paris) used observations of the eclipses of Jupiter's satellites to determine the longitude difference of the two observatories. It was the first attempt to employ this method simultaneously, which was made possible by the ephemerides of Jupiter's satellites prepared by Cassini. During this project, Picard observed an annual displacement of the pole star (Polaris), which was not explained until 1728 by **James Bradley** as due to the combined effects of nutation and the aberration of starlight.

Picard brought back to Paris his Danish assistant, **Olaus Römer**, and a copy of Brahe's registers of observations. In 1673, he moved into the newly constructed Observatoire de Paris, where Cassini was installed. Picard participated on several expeditions to determine precise coordinates of various cities and harbors, for the purpose of creating a new map of France. This map, drawn and published by de la Hire (1693), afforded corrections as great as 150 km in longitude and 50 km in latitude over previous cartographic methods.

Picard also played a role in hydraulics, helping to solve the problem of supplying water to the fountains at Versailles. He oversaw the survey when the Grand Canal was dug in order to create artificial ponds or tanks needed to supply the fountains. Out of this survey arose Picard's correction of the apparent level, due to the curvature of the Earth. His posthumous treatise on the subject, *Traité du Nivellement* (1684), became a standard reference for more than a century.

In 1982, an international conference was held at Paris to commemorate the tercentenary of Picard's death and to highlight his role in the institutionalization of science in France during the 17th century.

Piccolomini, Alessandro

Born **Siena, (Italy), 13 June 1508**
Died **probably Siena, (Italy), 12 March 1579**

Alessandro Piccolomini is best known for producing the first star atlas, in 1540, with 47 star maps designed for the general reader.

Piccolomini was born into an illustrious family whose members included Pope Pius II and Pope Pius III. As a young man in his hometown of Siena, he joined the Accademia degli Intronati, an organization that fostered the development of the use of Italian as a literary language on par with Latin. Around 1538 Piccolomini moved to Padua, where he eventually became a professor of philosophy at the university and joined the Accademia degli Infiammati, a group that promoted Italian works as well as had an interest in the fields of astronomy and mathematics. Piccolomini rose in the ranks of the church and in 1574 became the Archbishop of Patras, in Greece. He never went to Greece, however, and remained in Italy as coadjutor to the Archbishop of Siena until his death. During his lifetime Piccolomini was an important literary and philosophical figure, writing numerous comedies, sonnets, and philosophical treatises, and translating several classical works into Italian.

Although not an astronomer, Piccolomini did produce a few treatises on mathematical astronomy. These works were written in Italian because of his strong interest in promoting the literary use of the language. Piccolomini's first astronomical work was *De la sfera del mondo* (On the sphere of the Universe, Venice, 1540), a cosmographical work in which he defends the Ptolemaic universe. Though there are a few inferences in later editions that hint at a sympathy with the Copernican system, Piccolomini constantly supported the Ptolemaic viewpoint throughout his life. In his *Della filosofia naturale* (On natural philosophy, Rome, 1551) he mounted a staunch defense of a central and immovable Earth. His most original astronomical work was his *La prima parte dele theorique ovvero speculationi dei pianeti* (Part one of the theories or speculations of the planets, Venice, 1558), in which he endeavored to save the appearances of the motions of the planets in terms of the Ptolemaic theory. Piccolomini particularly noted that the Ptolemaic theory does not represent reality but is merely a useful tool for the astronomer.

Piccolomini's best-known astronomical work is undoubtedly *De le stele fisse* (On the fixed stars, Venice, 1540), his companion volume to *De la sfera del mondo*. *De le stele fisse* is famous as being the very first star atlas and contains a series of woodcut star maps that seem particularly suited to the casual stargazer. The two books were dedicated to Laudomia Forteguerri, and designed so that she, and any other reader, would be able to recognize the different constellations and find them in the sky. The atlas proved to be quite popular with readers and went through at least 12 editions from 1540 to 1595. Piccolomini produced 47 star maps for the book, one for each of the Ptolemaic constellations except for Equuleus, which he considered too insignificant for inclusion. Unlike previous depictions of the constellations, he did not draw in the mythological images associated with them, and so they appear as simple star patterns. Piccolomini included stars from **Ptolemy**'s first through fourth magnitudes, omitting the fainter fifth magnitude stars, and used different star symbols for each of the magnitude classes. The stars were also labeled a, b, c, d, *etc*., usually in order of their brightness. The accompanying text helps to explain the particulars about each constellation, including the legends associated with them. In the individual maps the constellations are drawn to fill the page and, therefore, the different maps are not to the same scale. They are also drawn so that the traditional constellation pattern is most recognizable and so the direction of north varies from one map to the next. There is also a lack of a coordinate grid on the maps; no coordinates are listed on the subsequent star tables, and little attention is paid to the accuracy of star positions with respect to each other. As a result, *De le stele fisse* was not of much use to professional astronomers, but this is not surprising as Piccolomini was writing for a more popular audience.

Some sources incorrectly list 1578 as the year of Piccolomini's death.

Pickering, Edward Charles

Born **Boston, Massachusetts, USA, 19 July 1846**
Died **Cambridge, Massachusetts, USA, 3 February 1919**

Edward Pickering created the world's largest programs in photometric, photographic, and spectroscopic stellar research. These programs helped American astronomy to attain a dominant role within the discipline by the early 20th century.

Pickering was the son of Edward and Charlotte (*née* Hammond) Pickering. The Pickering family had deep roots in Massachusetts; Edward's ancestor John Pickering had emigrated from England to Salem in 1636. Edward was born into a family well connected with people of influence in Boston. He attended Boston Latin School, but his interest in science developed during studies at Harvard College's Lawrence Scientific School. On his graduation at age 19, Pickering taught mathematics at the Lawrence School for 2 years before becoming an instructor in physics at the Massachusetts Institute of Technology [MIT]. At the age of 22, he was appointed Thayer Professor of Physics at MIT, and in 1874, he married Elizabeth Wadsworth Sparks, daughter of former Harvard president Jared Sparks. The couple had no children. Upon the death of **Joseph Winlock**, Pickering was named the fourth director of the Harvard College Observatory, an office he assumed on 1 February 1877. He would remain the observatory's director until his own death. Initially named Phillips Professor, Pickering would be renamed Paine Professor of Astronomy when that position was created in 1887.

Pickering is remembered as a pioneer in the new science of astrophysics. On becoming director of the observatory, he decided not to focus on the astronomy of stellar positions and motions, a research field that occupied many of the large observatories of the day. Instead, he began by emphasizing a still undeveloped field, the measurement of the brightnesses of stars. In 1884, Pickering published *Harvard Photometry*, a catalog of the visual magnitudes of 4,260 stars. In this and later works, Pickering adopted British astronomer **Norman Pogson**'s proposal that a difference of five magnitudes should correspond to a brightness ratio of 100 times. The Pogson scale was soon universally adopted, in part because of Pickering's advocacy. *Harvard Revised Photometry*, a catalog of the visual magnitudes of 9,110 stars brighter than magnitude 6.5, followed in 1908. A supplement to this catalog included measurements of the magnitudes of 36,682 additional stars.

In order to achieve worldwide coverage of the sky, it was necessary for Pickering to establish an observing station in the Southern Hemisphere. Pickering's brother, **William Pickering**, helped found Harvard's Boyden Station at Arequipa, Peru, in 1891. The bulk of the Peruvian photometric observations, however, were acquired and reduced by another member of the observatory staff, **Solon Bailey**. Rather than employing the technique of an artificial comparison star, Pickering's early photometric measurements were chiefly conducted by the polarization method, wherein the magnitudes of two stars were visually compared.

The magnitudes in *Harvard Revised Photometry* are visual magnitudes. His brother, however, convinced Pickering of the advantages of astronomical photography, after sensitive dry emulsions for photographic plates were developed. Many stars could be recorded on a single exposure, and the photograph became a permanent record that could be examined at leisure. Starting in the 1880s, the Harvard College Observatory also pioneered the development of photographic photometry. With data-collection facilities located in both hemispheres, the observatory accumulated an unmatched archive of photographic plates of the heavens. In 1903, Pickering published the first *Photographic Map of the Entire Sky*, a set of 55 photographs that showed stars as faint as the 12th magnitude.

Variable stars were another focus of research at the Harvard College Observatory under Pickering's directorship. In 1881, he proposed a system for classifying the types of variables that were known. Later, Pickering's assistant, **Henrietta Leavitt**, discovered the period–luminosity relationship among Cepheid variable stars, by examining photographs of the Small and Large Magellanic Clouds obtained at Harvard's southern station. Bailey likewise employed photography to discover more than 500 variable stars in globular clusters. When Pickering assumed the directorship, only some 200 variable stars were known. At the time of his death, however, more than 3,000 variable stars had been discovered at the observatory, almost all by photographic methods.

Pickering provided technical support and encouragement to **William Olcott** after the latter founded the American Association of Variable Star Observers [AAVSO] in 1911. The early AAVSO had a membership that included professional astronomers like **Anne Young** as well as amateur astronomers.

Pickering initiated routine patrol photography of the sky with wide-field cameras. These patrol photographs provide an important record of the appearance of the sky in times past and are another of Pickering's legacies.

Under Pickering's directorship, the observatory carried out spectroscopic investigations that were perhaps even more important than its photometric programs. In 1885, Pickering initiated a program of objective prism spectroscopy. A thin prism was placed in front of the objective lens of a wide-field telescope. The images of many stellar spectra could then be recorded on a single photographic plate. In 1889, he reported the discovery of the first spectroscopic binary star, ζ Ursae Majoris.

When Pickering began this spectroscopic work, several systems had already been proposed for classifying stellar spectra. These systems, based primarily on visual observations, had stars grouped into only a handful of spectral types. Yet, all of them proved inadequate to the wealth of details revealed by the new photographic surveys. At Harvard, new classification schemes were developed for the thousands of stellar spectra acquired by the objective prism surveys.

The first Harvard spectral catalog, the *Draper Memorial Catalogue*, was published in 1890, and classified 10,351 stars into 15 spectral types. The second Harvard catalog, initiated by Pickering's assistant **Antonia Maury**, abandoned the original Draper scheme and substituted 22 groups represented by Roman numerals. Maury's system incorporated further subdivisions based on the widths of certain spectral lines. However, the next Harvard catalog, produced by **Annie Cannon**, returned to an elaboration of the Draper scheme. It was this catalog that introduced the now familiar sequence of spectral types, OBAFGKM, along with their decimal subdivisions. Pickering lobbied for acceptance of this classification system at the 1910 meeting of the International Union for Cooperation in Solar Research. A committee on the classification of stellar spectra was formed, which gave support to the Harvard system. That system gained worldwide acceptance, and was the forerunner of the MKK spectral classification system widely used today.

In 1911, Pickering began a more ambitious program in the spectral classification of stars, which culminated in publication of the *Henry Draper Catalogue*. Therein, Cannon classified the objective prism spectra of some 225,300 stars of the ninth magnitude and brighter. Although the bulk of her classification work was completed by 1915, publication of the *Henry Draper Catalogue* was completed only after Pickering's death by his successor, **Harlow Shapley**.

Abundant recognition came to Pickering during his lifetime. Among his awards were two Gold Medals from the Royal Astronomical Society, a knighthood of the Prussian Order *Pour la Mérite*, and the Bruce Medal of the Astronomical Society of the Pacific. He received honorary degrees from six American and two international universities. At the age of 27, he was elected to the National Academy of Sciences. Pickering played a role in the formation of the American Astronomical Society [AAS] (founded in 1899) and in 1905 was elected its second president, a post he likewise held until his death.

When Pickering was chosen president of what was then called the Astronomical and Astrophysical Society of America [AASA], the organization had met for only 6 years. During his long presidency, the society changed its name to the AAS and became a more effective instrument for fostering the development of an increasingly professional science. Pickering presided over the establishment of numerous research committees that, with varying degrees of success, attempted to encourage cooperation among astronomers and to establish professional standards within the discipline. From its inception, the AAS was an organization that served chiefly the interests of professional astronomers. Pickering was sympathetic to amateurs, but during his presidency, the society's membership and direction were firmly consolidated in professional hands.

While Pickering himself performed the bulk of measurements for his visual photometric surveys, numerous women assistants helped to carry out the photographic and spectroscopic programs he supervised. The Harvard College Observatory under Pickering's tenure has been likened to a factory system of mass production, with Pickering as the observatory's chief executive officer. Pickering saw astronomy as a field in which women could make important contributions to science. Yet, most of the women hired under Pickering's directorship were consigned to routine work in the reduction of astronomical data. Even so, his assistants Maury, Leavitt, Cannon, and **Williamina Fleming** were among the most important women astronomers of their time.

Pickering never abandoned his belief in the importance of securing large collections of astronomical data. Toward the end of his life, this emphasis caused friction with some younger astronomers who emphasized research programs driven by astrophysical questions over data gathering. Even these critics, however, appreciated the significance of Pickering's data and its ready availability to the astronomical community.

Pickering's papers (comprising 68 linear feet) are in the Harvard University Archives.

Pickering, William Henry

Born **Boston, Massachusetts, USA, 15 February 1858**
Died **Mandeville, Jamaica, 16 January 1938**

William Pickering influenced the selection of mountaintop sites for astronomical observatories in the Western Hemisphere, pioneered the application of photography to astronomy, and was a noted popularizer of the discipline. His later works concerned visual observations of the Moon and planets, but in this regard, he strayed progressively further from mainstream science.

Pickering was descended from a notable New England family; his parents were Edward and Charlotte (*née* Hammond) Pickering. His older brother, **Edward Pickering**, was appointed director of the Harvard College Observatory, [HCO] in 1877. William graduated from the Massachusetts Institute of Technology in 1879 and taught physics there until 1883. In 1887, he was named an assistant professor at HCO. But while retaining this title until his retirement in 1924, Pickering fashioned for himself an eclectic and peripatetic career.

Pickering and his brother were the first to recognize the favorable seeing conditions that existed on California's Mount Wilson in 1889. He subsequently mounted Harvard's Boyden refractor at the site and conducted photographic studies. Roughly a decade elapsed before **George Hale** performed similar tests at Mount Wilson, prior to establishing his solar and astronomical telescopes on the mountain's peak. In 1891, meanwhile, Pickering reerected the Boyden telescope at Arequipa, Peru, to further his brother's photometric and photographic program on Southern Hemisphere stars. There, he devised a standard scale (from 1 to 10) for rating the atmospheric seeing conditions.

But the routine acquisition of data proved unsuitable for Pickering, whose attention was directed instead toward visual studies of the planets, particularly Mars. After being recalled to Massachusetts, Pickering became acquainted with **Percival Lowell**, and was soon commissioned by him to establish an observatory near Flagstaff, Arizona. Pickering thus played a role in the founding of three American observatories, and demonstrated the advantages of arid, high-altitude conditions for the optimization of astronomical research.

Pickering's early success with dry-plate emulsions convinced his brother of the enormous potential of photographic methods for astronomical data collection. This opportunity was soon exploited by Edward as one of three great programs that he established at Harvard. On behalf of the observatory, Pickering then undertook an expedition to Jamaica in 1899. Finding its atmospheric conditions suitable, he returned the following year with a 12-in. refractor of 135-ft. focus. With it, Pickering secured some of the finest images then obtained of the Moon's surface, which were published in his photographic atlas (1903).

From his lunar studies, Pickering argued for the volcanic origins of most lunar surface features. He concluded that the rival impact theory could not explain the uniform circularity of craters. In support of this hypothesis, Pickering amassed geological evidence from places as widely separated as the Hawaiian Islands and the Azores, and drew from it what he believed to be convincing analogies for the volcanic nature of the Moon's features. On the basis of albedo changes that he observed during the course of each lunar "day," Pickering advanced suggestions that either hoarfrost, or some type of vegetation, could explain the apparent phenomena, despite the absence of any measurable lunar atmosphere.

Much of Pickering's later life was devoted to the search for a trans-Neptunian planet. Starting in 1907, he predicted the existence of no less than seven unseen worlds over the next 24 years. Names for Pickering's hypothetical planets bore letters of the alphabet, starting with "Planet O." He employed a simplified graphical process to analyze the measured residuals of Uranus and Neptune. While none of Pickering's hypothetical planets were found to exist, his search nonetheless catalyzed a similar investigation at Lowell Observatory, from which the eventual discovery of Pluto was announced in 1930.

Pickering's most notable discovery, on photographic plates taken at Peru, concerned Saturn's ninth satellite (Phoebe) and his demonstration of its retrograde orbit. Phoebe was the first planetary satellite found to possess this property. For his investigations of the Saturnian system, Pickering was awarded the Lalande Prize of the Paris Academy of Sciences in 1905 and the Janssen Medal in 1909. Nonetheless, his scientific methods remained largely those of the 19th century. Pickering's visual observations and highly speculative theories were greeted with increased skepticism and ostracism by 20th-century astronomers.

Pickering was married to Anne Atwood; the couple had two children. A crater on the Moon bears his name.

Pigott, Edward

Born **England or France, 1753**
Died **Bath, England, 27 June, 1825**

Edward Pigott's chief claim to fame is as one of the founders of the study of variable stars.

Pigott was the son (probably the oldest) of Nathaniel Pigott and Anna Mathurina de Beriol. Nathaniel was the grandson of William, Eighth Viscount Fairfax; Edward's full name is sometimes given as Edward Fairfax Pigott. Little is known of Edward's early life and formal education, although he appears to have acquired a good knowledge of French. A portrait in the Junior School of Ampleforth College, Yorkshire, England, long believed to be of Edward Pigott (and published as such) may, in fact, be that of a relative, Gregory.

Nathaniel Pigott was a surveyor and astronomer. Edward's interests in these subjects were probably stimulated by helping his father. They observed the 3 June 1769 transit of Venus together from Caen, France (where they then lived), and many years later, the 3 May 1786 transit of Mercury from Louvain, Belgium. In 1771, the family moved to Wales.

Edward Pigott surveyed the region of the Severn estuary in 1778/1779, discovered a nebula in Coma Berenices in 1779, and the short-period comet D/1783 W1. He also made observations of the satellites of Jupiter and studied the method of longitude determination by lunar transits and is believed to have observed the great comet of 1807.

In 1781 the family moved to Bootham, Yorkshire, where father and son constructed an observatory. There, Edward began a partnership with **John Goodricke**, discoverer of the periodicity of the light variation of Algol (β Persei). Pigott himself discovered the variability of η Aquilae on 10 September 1784. By early December of the same year, he had determined its period to be 7 days, 4 hours, 38 minutes, about 24 minutes longer than the accepted modern period. Piggott tried to set up a photometric system so that he could estimate the variations in stellar brightness more precisely.

It was not until the 17th century, after the application of the telescope to celestial observation, that astronomers began to accept that the brightness of some stars varied. Pigott and Goodricke were the first to show that stellar variability is often periodic. Pigott has some claim to be regarded as the founder of the study of stellar variability. In 1786, he published a catalog of 50 variable stars writing, "these discoveries may, at some future period, throw fresh light on astronomy." Later he announced the variability of the stars now known as R Scuti and R Coronae Borealis. During a lull in the Napoleonic wars, Pigott returned to the continent but was caught by a renewal of hostilities and detained for a while at Fontainebleau, where, nevertheless, he managed to write a new study of the period of R Scuti and tried to explain stellar variability in terms of a model of rotating spotted stars. He also inferred the existence of "dark stars" and surmised that aggregations of such objects might account for phenomena like the "Coal Sack." Pigott was apparently released from detention through the good offices of Sir Joseph Banks. Although Pigott knew Banks and both the **Herschels** (**William** and **John**), and published some 20 papers in the *Philosophical Transactions of the Royal Society of London*, he does not seem to have received much recognition for his work during his lifetime. He is known to have retired to Bath and appears to have withdrawn from astronomical work by the end of his life.

Pingré, Alexandre-Guy

Born **Paris, France, 4 September 1711**
Died **Paris, France, 1 May 1796**

Alexandre Pingré was a diligent observational astronomer, calculator, and noted historian of astronomy. Pingré's parents sent him to the college of Senlis directed by the regular canons of the Congregation of France (the Génovéfains). A good student, he entered the Congregation at age 16. By 1735 he was a teacher of theology in the college. Because of the persecutions against the Jansenistes, Pingré was dismissed from his chair and sent away from Paris to obscure colleges to teach grammar. Fortunately, in Rouen, Pingré met the surgeon Claude-Nicolas Le Cat who, in 1749, asked him to join—as an astronomer—the academy he had founded there. Thus, at the age of 38, Pingré undertook his first scientific work by calculating the lunar eclipse of 23 December 1749; 4 years later he observed the transit of Mercury on 6 May 1753. The Académie royale des sciences in Paris then named Pingré a correspondent of **Pierre-Charles Le Monnier**, and his congregation called him to Paris, to the abbey of Sainte-Geneviéve, where the abbot installed a small observatory and offered him some instruments. In Paris Pingré met Le Monnier, who assigned him the calculations for the four-volume *Etats du Ciel à l'usage de la marine*, which appeared from 1754 to 1757. Later, **Joseph-Jérôme Lalande** integrated this nautical almanac into the *Connaissance des temps*. In 1756, Pingré became a member of the academy.

For the second edition (1770) of the *Art de vérifier les dates* of **Nicolas La Caille**, Pingré calculated the solar eclipses up to 1900 and later (1787) the eclipses in the Northern Hemisphere for 10 centuries before our era. Pingré designed several sundials in Paris. At the request of the Provost of the Guilds, he created in 1764, on the tower-column of the former Hôtel de Soissons, a very original sundial, cylindrical with several horizontal stilettos.

In 1760, the academy designated Pingré to observe the 1761 transit of Venus from Rodrigue Island in the Indian Ocean. He also made three voyages to examine the marine chronometers of Berthoud and Le Roy. During one of these voyages, he observed the 1769 transit of Venus from Cap François in Santo Domingo, Haiti. From the numerous observations of the transit received in Paris, Pingré deduced a solar parallax of 8.8″.

In 1769, Pingré was named astronomer–geographer in the place of the deceased **Joseph Delisle**. At the same time he was chancellor of the University, librarian of the Sainte-Geneviéve Library, and a member of the Académie de marine.

Besides his regular observations, Pingré wrote lengthy works, interrupted from time to time by his travels. Beginning in 1757, he undertook research on comets from Antiquity. This large historical and theoretical work, *Cométographie*, was published in two volumes in 1783/1784. From 1756, he worked on a history of 17th-century astronomy at the request of Le Monnier, who passed to him the manuscripts of **Ismaël Boulliau**. Pingré completed this work at the age of 80. Jerôme de Lalande reported on it to the academy in 1791 and then, with Le Monnier, undertook its publication. Upheaval during the Revolution halted printing. The manuscript was located by **Camille Bigourdan** in the archives of the Paris Observatory; Bigourdan published it in 1901.

At Lalande's request Pingré translated the *Astronomiques* of **Manilius**, a Latin poet of the Augustan century, and a poem by **Aratus**. During the Revolution, with the suppression of the academies, Pingré remained the librarian of Sainte-Geneviéve but with few resources. With the establishment of the Institut National in 1795, he was elected to the astronomy section, attending meetings almost until his death.

A regular canon of Sainte-Geneviéve, Pingré was also a dignitary of freemasonry, being an active correspondent with the lodges of Bourbon Island (now Réunion). His leisure activities included reading (in particular Horace in Latin), music, and, at the end of his life, botany. Esteemed as a scientist, he was also a man of great goodness, modesty, and piety.

Pişmiş, Paris Marie

Born **Istanbul, (Turkey), 1911**
Died **Mexico City, Mexico, 1 August 1999**

Paris Pişmiş was the first formally trained astronomer in Mexico. She was born into an Armenian family living in Istanbul, Turkey. In defiance of her parents' wishes and native tradition, she became one of the first women in Turkey to attend Istanbul University, earning her Ph.D. in mathematics in 1937, under the supervision of professors **Erwin Freundlich**, who was then in Istanbul as a refugee from the Nazi persecution, and Richard von Mises. Pişmiş worked as a research assistant at the Istanbul University Observatory from 1935 to 1937.

Before World War II, Pişmiş traveled to the United States to pursue postdoctoral studies. She worked as an assistant astronomer at the Harvard College Observatory (1938–1942). There, she met astronomers **Harlow Shapley**, **Bart Bok**, **Sergei Gaposhkin**, **Cecilia Payne Gaposhkin**, and **Donald Menzel**. Pişmiş also met Félix Recillas, a Mexican mathematician and an astronomy student who became her husband in 1942. In that year, she moved with him to Mexico and joined the staff of the newly created Tonantzintla Observatory in Puebla, where she worked alongside **Guillermo Haro**, who became the observatory's director. Pişmiş started teaching astronomy to students of physics and mathematics. Her two children, Elsa and Sevín Recillas, who also became scientists, were born during that time.

After visiting appointments at Princeton University and Yerkes Observatory, Pişmiş moved to Mexico City in 1948 and joined the Observatorio Astronómico Nacional de Tacubaya, part of the Universidad Nacional Autónoma de Mexico [UNAM], which is now the Instituto de Astronomía. She spent most of her time on research, teaching, and advising students. At UNAM, Pişmiş taught formal courses in astronomy, and transmitted her passion for doing scientific research to many students (*e. g.*, Arcadio Poveda, Eugenio Mendoza, Enrique Chavira, and others).

Pişmiş was also a restless traveler and was engaged with different groups doing astronomical research all over the world. She was always interested in new ideas and new techniques. She was invited to lecture at many scientific institutions and universities, traveling to Istanbul, Heidelberg, Ankara, Byurakan, the Canary Islands, Paris, Buenos Aires, and so forth.

Pişmiş made significant contributions in observational and theoretical astronomy. She discovered 20 open stellar clusters and three globular clusters that are named for her. She was among the first to study the kinematic behavior of the gas associated with hot young stars, introducing the Fabry–Perot interferometric technique to Mexico. Pişmiş studied the effects of interstellar absorption in the observed distribution of star clusters. She performed the first photometric observations of young stellar clusters carried out in Mexico. She also worked theoretically to explain the origins of spiral structures in galaxies and the observed galactic velocity fields. Toward the end of her life, Pişmiş became interested in the morphology and kinematics of the so called mildly active galactic nuclei. Her scientific output totaled more than 100 research articles.

Another of Pişmiş's major contributions was to foster the publication of Mexican astronomical journals. She was a member of the board of editors of the *Revista Mexicana de Astronomía y Astrofísica*, from its foundation in 1974 untill her death. She was editor of the *Boletín de los Observatorios de Tonantzintla y Tacubaya*, from 1966 to 1973. Pişmiş was likewise editor of the proceedings of the International Astronomical Union Colloquium 33 (*Observational Parameters and Dynamical Evolution of Multiple Stars*) in 1975. She supervised the edition of three volumes of the *Astrophotometric Catalogue of Tacubaya* (1966).

Pişmiş was a member of the International Astronomical Union, and was appointed Mexico's representative to that organization. She was a member of the Royal Astronomical Society, the American Astronomical Society, and the Academia Mexicana de Ciencias. She received a science teaching award from UNAM, plus honorary doctorates from the same institution and from the Instituto de Astrofísica, Óptica y Electrónica.

Paris's former student, Deborah Dultzin, wrote:

> Listening to her lectures, learning to observe with her, and later on, being initiated into the wonderful world of scientific research work by her, was an inspiring experience. She spoke about a scientist's life as something wonderful for a woman, and one could see that she really enjoyed it.

Pişmiş was interested not only in science, but also in all aspects of culture. Fluent in several languages, she loved literature, painted, played the flute and piano, and was also a good singer and dancer. She inspired admiration in all those who knew her, and was a role model for women in science all over Mexico and beyond. In collaboration with her grandson, Gabriel Cruz-González, Pişmiş prepared an autobiography, *Reminiscences in the Life of Paris Pişmiş: A Woman Astronomer* (1998).

Plana, Giovanni Antonio Amedeo

Born **Voghera, (Lombardy, Italy), 6 November 1781**
Died **Turin, Italy, 20 January 1864**

Mathematical physicist and astronomer Giovanni Plana wrote more than 100 memoirs dealing with mathematical analysis, geodesy, astronomy, celestial mechanics, and heat theory, including his most important work, the theory of the lunar movements. Plana was the son of Antonio Maria Plana and Giovanna Giacoboni. From 1796, Plana studied in Grenoble, France, where he met and befriended Stendhal (Henry Beyle). In 1800, Plana entered the École Polytechnique where **Joseph Lagrange** taught analysis and mechanics, Gaspard Monge taught geometry, and **Pierre de Laplace** taught astronomy. He also became friends with **Siméon-Denis Poisson**. In 1803, Plana became professor of mathematics at the Turin Artillery School, located in Alessandria, and became professor of astronomy at Turin University in 1811. Before assuming the responsibilities of his chair, Plana practiced astronomy at the Brera Astronomical Observatory in Milan under the scientific direction of **Barnaba Oriani**. In 1816, he became director of the Turin Astronomical Observatory. In 1817, Plana married Alessandra Maria Lagrange, a niece of the great mathematician.

In Milan in 1811, Oriani proposed to the young astronomer **Francesco Carlini** some research in the theory of the Moon, probably on Laplace's suggestion. Plana was involved with this project and collaborated closely with Carlini, at least until 1820, when they won a prize of the Paris Académie des sciences. The prize, promoted by Laplace in 1818, was to be assigned to whoever succeeded in the construction of lunar tables based solely on the law of universal gravity. (The prize was shared with **Charles Damoiseau**.) Despite the prize, Laplace criticized the memoir of Carlini and Plana. A bitter dispute ensued. Plana determined the tone of the dispute, perhaps remembering the discussions in Grenoble when the young students sided excitedly with Lagrange, *homme à principes*, or with Laplace, *homme à théorèmes.* In the end, Laplace admitted that the two Italian astronomers were more accurate than him. The Académie des sciences published Damoiseau's memoir but not that of Carlini and Plana, who decided to publish a complete theory of the Moon. But the collaboration was complicated and, in the end, Plana decided to continue his work alone, which was published in 1832 in three big volumes.

Plana's work is considered a milestone in celestial mechanics. The theory was derived solely from the principle of universal gravitation and borrowed only the essential data from the observations. Plana's lunar theory had completed Laplace's program, along the road drawn by **Isaac Newton**, for one of the most complex celestial phenomena.

In 1825 and 1827, Plana and Carlini published the data of their observations obtained by the measurement of the mean parallel (45°) linking the French geodesic net to the northern Italian one, from Bordeaux to Fiume (today Rijeka), crossing the Alps. They were also able to explain the anomalies of Giovanni Battista Beccaria's measurements of the meridian arc between Mondovì and Andrate, as they noted the deviation of the plumb line due to the presence of high mountains.

In 1822, Plana inaugurated the new Turin Observatory and the new instrument, a meridian circle of Reichenbach. He published the results of his 1822, 1823, 1824, and 1825 observations and his theoretical considerations on astronomical refraction. Other astronomical memoirs dealt with Foucault's pendulum, the movement of a body launched from the Moon to the Earth, and comets.

Plana won the Copley Medal of the Royal Astronomical Society. He was president of the Turin Accademia delle Scienze, foreign member of the Académie des sciences, and corresponding member of the most important European academies. Plana's archives are in Turin in the Accademia delle Scienze. Plana's letters to Carlini about the theory of the Moon and other subjects are in the Archives of the Brera Astronomical Observatory.

Plancius, Petrus

Born **Dranoutre, (Belgium), 1552**
Died **probably Amsterdam, The Netherlands, 1622**

Petrus Plancius is known as a cartographer and globe maker, and also as a Calvinist theologian and Bible scholar. Plancius's education took him to England and France; he subsequently moved north from Flanders during the Dutch Wars of Independence and settled in the Netherlands. His interest in missionary work arose from his religious convictions, and gave impetus to his cartographic activities, both celestial and terrestrial.

Plancius's 1589 celestial globe, published with **Michael van Langren**, included Southern Hemispheric stars that had not been previously depicted, namely *Crux*, *Triangulum Antarcticus*, and the *Nubeculae Magellani*. He encouraged **Pieter Keyser** and Frederick de Houtman to make further observations of the southern skies during the voyage of the *Hollandia* to the East Indies in 1595–1597. These observations supplied the data for the formation of 12 further constellations, which appeared on Plancius's globe of 1598 published by Hondius and which were subsequently adopted by **Johann Bayer**. On a globe published in 1612 with Pieter van den Keere, Plancius added another eight constellations, in between old ones. Some of these, of biblical reference, have not survived; others such as Monoceros, Camelopardalis, and Columba have endured.

Planman, Anders

Born **Hattula, (Finland), 1724**
Died **Pemar, (Finland), 25 April 1803**

Anders Planman observed the transits of Venus in 1761 and 1769 for the Swedish Academy of Sciences. Planman, the son of lieutenant Pehr Planman and Ingeborg Leufstadius, was born in a Swedish family in Finland (then part of Sweden). He studied in Åbo (Turku) and Uppsala, where he became associate professor (*docent*) in astronomy in 1758. In 1763, Planman became a professor of physics in Åbo, where he remained until his retirement in 1801. He was a member of the Science Society at Uppsala (*Vetenskapssocieteten*) and from 1767 of the Royal Swedish Academy of Sciences.

Planman's most important contribution in the field of astronomy came with the transits of Venus in 1761 and 1769, which he observed in the far north of Finland. Planman's expeditions were financed by the Academy of Sciences in Stockholm, and they were part of a larger effort by Swedish astronomers to contribute to the measurement of the solar parallax, which they did to an extent second only to Britain and France. Though his own 1761 measurements were somewhat uncertain, Planman was given the task of calculating a value for the parallax based on all the data received by the academy. This work resulted in values between 8.2″ and 8.7″. As a preparation for the transit in 1769, Planman developed a new method to calculate the parallax, and his own observations in 1769 were considered among the best in Europe. He now found the parallax to be 8.5″. Planman participated in discussions concerning the possible existence of an atmosphere on Venus and also on the much-debated issue of the reliability of the observations carried out by **Miska Höll** in northern Norway (Vardöhus).

By making an observational effort great enough to command the attention of all of Europe, and by giving Planman the main responsibility of handling its observational data, the Academy of Sciences created a platform for Planman that for a few years made him an international authority on the important question of the solar parallax. Otherwise his scientific life was uneventful.

Plaskett, Harry Hemley

Born **Toronto, Ontario, Canada, 5 July 1893**
Died **Oxford, England, 26 January 1980**

Harry Plaskett made observational and theoretical contributions to the understanding of stellar atmospheres and solar physics, especially through studies of spectral line formation, solar granulation, and the recognition of large-scale mass movements on the Sun's surface. Son of **John Plaskett** and Rebecca Hemley, Plaskett graduated from Ottawa Collegiate School before enrolling at the University of Toronto, where he was awarded his B.A. degree in 1916. During World War I, Plaskett served in the Canadian Field Artillery and rose to first lieutenant among his brigade in France. Afterward, he spent a year at Imperial College, London, in the laboratory of spectroscopist **Alfred Fowler**.

Returning to his native land, Plaskett spent eight years (1919–1927) as a research astronomer at the newly established Dominion Astrophysical Observatory in Victoria, British Columbia, where his father was director. At the time, its 72-in. reflector was the second largest telescope in the world. In 1921, Plaskett married Edith Alice Smith; the couple had two children.

Plaskett was then called to Harvard University (1928–1932), where he served as lecturer, associate professor, and professor of astrophysics. In 1932, Plaskett was chosen as the Savilian Professor of Astronomy at Oxford University, a post that he retained until his retirement in 1960. At Oxford University, he built up a "school" of solar physics that produced a long line of research students. Plaskett had two solar telescopes with spectrographs constructed there, and campaigned (starting in 1946) for a large, modern reflecting telescope in the British Isles. This ambition was realized (after his retirement) with the completion of the Isaac Newton telescope at Herstmonceux in 1967.

Plaskett's research involved analysis of the Sun and stars by means of spectroscopy and spectrophotometry. He was the first to identify four lines of ionized helium in the spectra of O-type stars and deduced their corresponding temperatures of excitation, according to the ionization theory of **Meghnad Saha**. This work led to a new understanding and classification of these very hot stars. Plaskett likewise measured the absorption profiles of the so called magnesium "b" lines in the solar spectrum, as a function of their position on the Sun's disk. These measurements constituted the first practical tests of the relative strengths of scattering versus absorption in the Sun's atmosphere and significantly improved the theory of spectral line formation. Plaskett's detailed study of the phenomenon of solar granulation provided convincing evidence that these small-scale structures were manifestations of Bénard convection cells arising in the photosphere's outer layers. Finally, Plaskett's studies of the Sun's rotation led to his announcement of large-scale velocity fields and especially meridional currents on its surface. He recognized the importance of hydrodynamic considerations to the explanation of such motions, which served as a precursor to later work in solar oscillations and helioseismology.

Plaskett was elected a fellow of the Royal Society of London, and served as secretary (1937–1940) and president (1945–1947) of the Royal Astronomical Society [RAS]. Like his father, Plaskett was awarded the Gold Medal of the RAS (1963) and delivered the Halley Lecture at Oxford University (1965). From 1932 to 1935, he served as president of the International Astronomical Union's [IAU] commission on spectrophotometry. Saint Andrews University conferred an honorary doctorate upon him (1961).

Plaskett, John Stanley

Born **Hickson, (Ontario, Canada), 17 November 1865**
Died **Esquimalt, British Columbia, Canada, 17 October 1941**

Canadian astronomer John Plaskett is probably best remembered for his role in the establishment of the Dominion Astrophysical Observatory and the building of its 72-in. telescope, briefly the largest in the world. But he also showed (together with **Otto Struve**) that the material that produces stationary absorption lines in the spectra of spectroscopic binaries is truly interstellar and not just circumstellar.

Plaskett was one of a number of children of Ontario farmers Joseph and Annie P. Plaskett, and his father's death when he was only 16 forced him to defer his own education until some of the younger children had been taken care of. He married Rebecca Hope Hemley in 1892, and the elder of their two sons, **Harry Plaskett**, followed in his father's footsteps, eventually becoming Savillian Professor of Astronomy at Oxford University. Trained as a mechanic, John Plaskett acquired some engineering experience in Ontario and Schenectady, New York, USA, and entered the University of Toronto as an assistant to the professor of physics and as a mature student, earning his BA in physics and mathematics in 1899 at the age of 33. He was hired initially at the Dominion Observatory in Ottawa primarily as Mechanical Superintendent, but immediately set to work to establish an astrophysics department, install a number of new instruments, and initiate several new research programs, including solar rotation and radial–velocity measurements of stars.

Plaskett and **William King**, by then director of the Dominion Observatory at Ottawa, soon became dissatisfied with the 15-in. refractor available to them and set out to persuade the Canadian government to fund a 72-in. reflector, somewhat modeled on the Mount Wilson 60-in. telescope, but with innovations of Plaskett's own (like the central hole in the primary mirror for the Cassegrain focus) adopted in later large reflectors. They succeeded by 1913, and a 72-in. reflector was ordered from Warner and Swasey. Plaskett became the founding superintendent (later director) of the Dominion Astrophysical Observatory in Victoria, British Columbia, retiring in 1935, but continuing to serve as a consultant on astronomical instrumentation, particularly for the McDonald Observatory 82-in. telescope, until his death.

Plaskett's leadership had a major role in the development of Canadian excellence in the measurement of stellar velocities and their interpretation. His own work included collaboration with Joseph Pearce on radial velocities of hot, bright stars, which confirmed the work of **Bertil Lindblad** and **Jan Oort** on the rotation of the Milky Way. The investigations with Struve showed, first, that there is gas that is truly interstellar and, second, that it shares the rotation of the galactic stellar system. He was part of the International Astronomical Union commissions on variable stars, stellar classification, and radial velocities, reflecting the unusual breadth of his accomplishments. Plaskett's 1939 drawing of the Milky Way, making clear the relationships among the disk, bulge, halo, and globular clusters is widely reproduced even now.

Plaskett received the Gold Medal of the Royal Astronomical Society, of which he was a fellow, the Rumford Medal of the American Academy of Arts and Science, the Henry Draper Medal of the National Academy of Science, and the Bruce Medal of the Astronomical Society of the Pacific. He was active in the Royal Astronomical Society of Canada and the American Astronomical Society and was a fellow of the Royal Society of Canada and a recipient of its Flavelle Medal. Plaskett received honorary degrees from Toronto, Pittsburgh, British Columbia, McGill, and Queen's universities.

Plato

Born **Athens, (Greece), *circa* 428 BCE**
Died **Athens, (Greece), 348/347 BCE**

Plato's astronomy, though never systematized like that of **Eudoxus** or **Aristotle**, continued to influence readers for millennia, through the beauty and coherence of his images and myths.

Plato was born as Aristocles to Ariston and Perictionê, in one of the wealthiest Athenian families, descended from Solon's brother through his mother. He had two older brothers, Glaucôn and Adeimantos, a sister Potonê, and a younger half-brother Antiphôn. Well-educated, Plato in his early 20s came under the influence of Socrates, upon whose execution he left Athens, traveling especially to south Italy and Syracuse. He returned to Athens around 390 or 385 BCE and founded his school in the grove sacred to the hero Akademos. In the 360s BCE Plato again visited Syracuse twice, vainly attempting to teach philosophy to its tyrant Dionysios II. He was unmarried but well loved by his students.

The pervasive dramatic irony of his dialogs, his own express preference for probable accounts, plus millennia-deep scholarship continue to challenge Plato's readers. Certain ideas recur, and may rather confidently be attributed to Plato (not just to characters in the dialogs), but many details may simply be decorative.

Plato discusses astronomy in six dialogs – *Phaedo*, *Republic* (books 7 and 10), *Politicus*, *Timaeus*, *Laws* (books 7 and 12), and *Epinomis* – composed in about that order over a generation. The first three weave astronomy into myth, and all six show a steadily growing appreciation of astronomy. Plato always sought to reveal cosmic design, penetrate phenomena to hidden mathematical reality, and inspire students to contemplate higher truths. Thus, and also because contemporary celestial observations eluded any coherent account, Plato preferred theory over observation.

The 6th-century commentator **Simplicius** reported that **Sosigenes** in the 2nd century quoted **Eudemus** (in the generation after Plato) as saying that Plato's astronomical program was to find regular circular motions of the planets to explain their apparent irregular motions. **Geminus** attributed that program to the

Pythagoreans, who said that even in human affairs, noble men do not alter speed or course, so one must hypothesize celestial uniformity, while **Plutarch** claimed that Plato saved astronomy from reproach by subordinating natural laws to divine principles.

In the *Phaedo*, equilibrium holds the spherical Earth centered in the spherical heaven. Earth is very large, with dimples filled by water, mist, and air, in which people gather like ants around frog ponds; atop the highest peaks lies Earth's true surface exposed to the surrounding bright, clear *aithêr*, through which the stars move.

In the *Republic*, Plato first insists on the utility of astronomy, then its importance in education: The proper goal of astronomical study is to direct the mind *via* theoretical exercise away from the mutable world to the eternal world of truth, just as number and geometry do, and music should. A mythic celestial mechanics completes the *Republic*, in which the whole *kosmos* is a spindle (hung from a rainbow-hued pillar of light), its whorl formed of eight nested whorls, representing the fixed stars and the seven "wanderers" (*planetai*). The outermost whorl, broad and "spangled" with stars, rotates the same as the spindle itself; the seven inner whorls revolve gently in the opposite direction. The eighth (innermost) lunar whorl moves the fastest, illuminated by the next (seventh) and brightest solar whorl. That and the next two (the sixth Venus and fifth Mercury) all move together, with the next greatest swiftness, and so on in descending order out to the second (Saturn). The third (Jupiter) is the whitest – Venus is almost as white, and the fourth (Mars) is ruddy and "recycling" (probably because although Jupiter and Saturn retrograde about once per year, and Venus and Mercury follow the Sun, Mars traverses more than a full circuit of the zodiac between retrogradations). This planetary order – Moon, Sun, Venus, Mercury, Mars, Jupiter, and Saturn outermost – persists in later works. Each whorl has upon it a Seirên singing a single tone, all eight in harmony. The spindle lies in the lap of the goddess Necessity, around whom sit the three Fates: Clotho turning the outer whorl, Atropos turning the seven inner whorls, and Lachesis playing with both. (Plato omits planetary names, and the well-known zodiacal inclination; no one has convincingly explained the whorl-widths – outermost widest, then Venus, Mars, Moon, Sun, Mercury, Jupiter, and Saturn narrowest.)

The myth in the *Politicus* tells that the revolution of the whole Universe affects the course of earthly events, and alters its direction at great intervals. Plato proposed that time is created by the rotation of the *kosmos*, and that when the *kosmos* reverses, so too time reverses in its course.

The *Timaeus* gives a different model, not physical but fundamentally mathematical and deeply religious. The whole divinely ordered *kosmos* is a living spinning spherical creature pervaded by soul. The world-soul contributes to a band, half the length of which, called the "Same," forms the celestial equator moving all the fixed stars with the same motion, while the other half, called the "Other," being divided lengthwise into seven parts, corresponds in a way never completely described to a pair of interleaved geometric series 1, 2, 3, 4, 8, 9, 27, and to the seven planets. Venus and Mercury remain close to the Sun, due to an otherwise unspecified "contrary power." Each planet has its own soul, the cause of its unique motion, and is thereby an "instrument of time." Mere mortals do not understand their motions and periods, but all planets together completing their cycles marks a "perfect" year of the *kosmos*, whose value scholars have spilt much ink vainly computing. Each fixed star is spherical, with a soul whose motion is axial rotation. The Earth herself is wound round the *kosmic* pole, and by resisting the rotation of the whole (unlike the planets) remains the unmoved "guardian of day and night." The *Timaeus*, with its theory of matter founded on the Platonic solids, provided a geometric cosmological model that carried an enormous influence through the time of the Renaissance.

In the *Laws*, astronomy is considered to be useful (for better regulation of the civic calendar), just as arithmetic and surveying are otherwise useful, as well as for mental exercise and training. But the members of the all-powerful Nocturnal Council must study astronomy to learn the primacy in time of soul and the order and divinity of the stars, for only such men are fit for such high rank. True astronomical education will inculcate deep faith, rather than the disbelief caused by the soulless astronomy of mere bodies of stone. (Plato here alluded to **Anaxagoras** and **Democritus**.) Indeed, it is only by asserting that the planets do not truly wander that the wise and devout man may validly study astronomy without committing blasphemy, because the Sun and all stars are ensouled and self-moved.

All ancient philosophers accepted the deeply Platonic *Epinomis*, but some modern scholars have denied his authorship. It argues that astronomy provides the best education for statesmen, and that the celestial bodies are worship-worthy beings through whom we learned number. The stars are fiery-bodied living beings, proven very large, and the Sun "leads" Mercury and Venus.

Plato's world-soul in harmony with all parts of the Universe offered a benign and humanocentric *kosmos*, whose appeal only Epicureans sought to resist before the modern period. Plato's approval of the musical harmony of the stars (which he may have intended as decoration, not definition), and his belief that the planets were divinities worthy of worship, ensured that astrology would be hard to resist, but his insistence that astronomy, with mathematics and music, were the highest studies of which the human mind is capable ensured their survival across centuries when little else did.

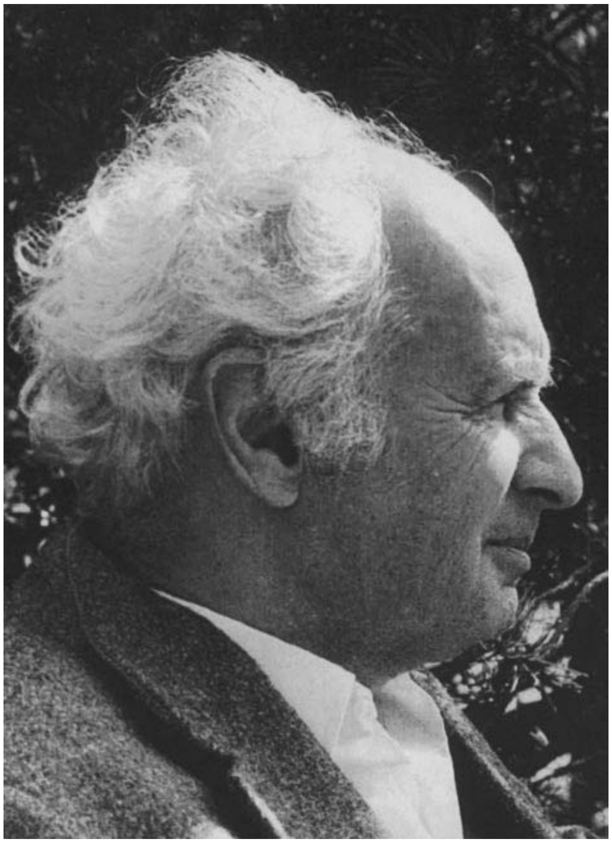
Plaut, Lukas

Born **Kumamoto, Japan, 5 June 1910**
Died **Haren, the Netherlands, 4 October 1984**

Lukas Plaut investigated the intrinsic properties and space distribution of variable stars and eclipsing binaries. He was one of the identical twins born to Joseph Plaut and Katharina Lewy. Plaut received his primary education in Japan and at the Real-Gymnasium of München, Germany



(1925–1929), and attended the Friedrich Wilhelm University in Berlin from 1929 until spring 1933, where he studied variable star astronomy with **Paul Guthnick** at Babelsberg Observatory. Because of his Jewish parentage, Plaut was expelled from the observatory in April 1933, and so he moved to Leiden Observatory in the Netherlands, then under the directorship of **Willem de Sitter**. Here he earned a bachelor's degree (1936), a master's degree (1938), and a doctorate in 1939, with thesis on photographic photometry of two variable stars, guided by **Ejnar Herzsprung**. Occupation of the Netherlands by the German army in 1940 forced Plaut to move first to Groningen (the Kapteyn Laboratory, followed by a modest teaching job), then to a labor camp, and finally to the concentration camp in Fürstenau, Germany.

After liberation of the Netherlands, Plaut returned to Groningen, as a member of the staff of the Kapteyn Laboratory (1945–1964) and as professor of astronomy (1964–1975). There he carried out the work that led to two impressive publications. One, in 1950, was a critical compilation of the orbital elements of 117 eclipsing binaries. The next one, in 1953, was based on the compilation. It presented a thorough discussion of the frequency distribution of the orbital elements (*Groningen Publications* Numbers 54 and 55).

In 1953, at a conference on coordination of galactic research (published as International Astronomical Union Symposium Number 1, 1955), **Walter Baade** proposed a large, systematic survey of faint variable stars of the RR Lyrae type in order to explore the stellar population in the interior regions of the Galaxy, and to arrive at an improved estimate of the distance of the galactic center. Plaut undertook the execution of the program at the Kapteyn Laboratory, which came to be known as the Groningen–Palomar survey of faint variable stars. For four areas at low and intermediate latitudes, carefully chosen in consultation with Baade, Plaut collected long series of photographic plates with the Palomar Schmidt telescope from 1956 to 1959. The variables were detected with an instrument specially designed at the Kapteyn Laboratory by J. Borgman, based on the principle of eliminating all nonvariable stars in the field by combining a negative and a positive photographic image. Observational data and provisional analyses of the about 2,500 variables detected were published by Plaut in the years 1966–1973. The final outcome of this impressive project was the joint paper by Plaut and **Jan Oort**, dealing with the determination of the distance of the galactic center – 8.7 kiloparsecs – and the space distribution of the various types of variable stars in the region within 5 kiloparsecs from the galactic center.

After retirement, Plaut attempted to continue research, but the effects of the persecution and humiliation he had undergone between 1933 and 1945, led to mental disturbances and gradual lack of contact with the world.

A nearly complete set of Plaut's publications, as well as many of his notebooks used for lectures and research, is kept in the archives of the Kapteyn Institute of Groningen University.

Pliny the Elder

Born **Novum Comum, Gallia Cisalpina, (Como, Italy), 22 or 23**
Died **Stabiae, (Campania, Italy), August 79**

Pliny's *Natural History* described the known state of astronomy and astrology, and was influential for 1,000 years or more.

Pliny's *Natural History*, in 37 volumes, contained, he wrote, "twenty thousand noteworthy facts obtained from one hundred authors … with a great number of other facts in addition that were either ignored by our predecessors or have been discovered by subsequent experience." This composition was Pliny's last, for the natural spectacles that he so admired led him to his death: As commander of the Imperial Fleet at Misenum, he had set sail partly for a closer look at the eruption of Mount Vesuvius, and partly to rescue those stranded by the same eruption. Landing at Stabiae, he judged the situation safe enough to bathe, sup, and snore through the night. But just before dawn, Pliny was awakened for immediate evacuation. The exertion and excitement must have proven too much for the corpulent, unfit asthmatic: Arriving at the beach, he fell down and died, apparently from a heart attack.

Pliny was born in an equestrian family – whose status gave access to a public service career. His sister married a wealthy landowner and bore a son – Pliny the Younger – whom the Elder adopted as his own. Apart from the Elder's own writings (only his *Natural History* is extant), the Younger's letters to the historian Tacitus supply our best observations of Pliny's life, death, and person.

Before the *Natural History*, Pliny had composed at least six other works on several topics – grammar, oratory, history, cavalry technique, and a biography – and had followed a distinguished military and government career. He was well traveled and a close observer of all that went on around him.

Pliny shunned most of the material luxuries common to his time, preferring instead to study and write, and to quietly enjoy natural phenomena. His effort was to become educated in everything, as he saw the Greeks to be, but he noted that the Greek mastery of individual subjects had produced no single work summarizing the whole. So Pliny took this task – the unification of the whole *enkuklios paideia*, "all-encompassing learning" – upon himself.

Pliny's survey became an encyclopedia, the *Natural History*. Its coverage is necessarily superficial and in many places wrong, but it is neither sterile nor wholly uncritical: Pliny stated and judged his sources, often expressing wonder, surprise, or doubt. Setting aside the introductory and bibliographical Book I, the *Natural History* opens with astronomy and cosmology in Book II. Pliny began with a generally Stoic overview of the cosmos, earlier investigations into its nature and size, and its arrangement. Although he gave some relative dimensions of its parts, he dismissed attempts upon its overall dimensions as "madness, downright madness." Eliminating theology from the study of nature, Pliny rejected inquiry into God's existence, shape, and form as "a mark of human weakness." Divinity, he retorted, belongs to that which *obviously* governs the rest of the cosmos: the Sun.

Having set theology apart from astronomy, Pliny went on to describe planetary motion and eclipses quantitatively, giving periodicities and ranges of motion in coordinate systems that are unfortunately inconsistent and unspecified. He stated the order of the geocentric planetary orbits, and the interplanetary spacings according to Pythagorean harmonic theory, which he immediately rejected as "a refinement more entertaining than convincing." But the planetary order was justified by its ability to explain, at least qualitatively, the planetary elongations and speed variations. Planetary motions are governed by orbital curvature and solar rays, the Sun clearly being, Pliny observed, the governing power of the cosmos, controlling the planets from their midst and the Earth from above.

Pliny's treatment of astrology is noteworthy for its detail and balance: While Pliny certainly believed in astrological influence, he was unhesitant in denouncing astrologers. He enumerated biological evidence for celestial influence: Certain plants bloom or move according to the Sun. "Persistent research" showed that the Moon influences shellfish growth, ant activity, and eye diseases in cattle. Storms can be caused by the stars, and winds by the Sun, and the various winds arise on dates measured by stellar risings and settings. Despite this, Pliny considered astrologers mistaken in assigning individual stars to individual people, and he thought it implausible to attribute chance to stellar influence: Because stellar motions are predetermined, such "chance" would not be chance at all.

Why all this attention to astronomy and astrology, in a culture that valued practical engineering and government so much more than theoretical science? Pliny gave two reasons: to combat superstitious fears of gods and nature, and because astronomy and astrology genuinely do influence life, especially through agriculture. Pliny devoted a book to astronomical farming calendars, giving content from the Greeks and Babylonians, noting their disagreements on astronomy and also on what farmers should do at different times of the year. Despite these disagreements he considered them useful, given the absence of any simpler, nonastronomical system.

The shallowness of Pliny's *Natural History* – hardly avoidable in any single-author encyclopedia – did not prevent its long-lived influence on the astronomy of several important medieval writers, particularly **Martianus Capella** and **Bede**, and hence on all who studied their works in subsequent centuries. This tradition perpetuated Pliny's planetary data and, perhaps more importantly, his doctrine that solar rays govern planetary movement. Overall, Pliny's *Natural History* became widely used for general education. Around the 12th century, his solar-ray doctrine ceded ground to element-based theories of Aristotelian and Platonist origin. The absence of epicycles in Pliny's planetary system inspired further rejection of his astronomy in the Renaissance, compounded by growing awareness of his unreliability more generally. In recent decades he is read as representative of knowledge not in our day, but in his own.

The rest of Pliny's works are lost. They include a work *De iaculatione equestri* (On horseback javelin–throwing); the 20-volume *Bella Gemaniae* (German Wars); the 6-volume *Studiosi* on oratorial training; the 8-volume grammar, *Dubius sermo*; a two-volume biography of his patron, *De vita Pomponi Secundo*; and 30 volumes on the *History of Rome*.

Plummer, Henry Crozier Keating

Born **Oxford, England, 24 October 1875**
Died **Oxford, England, 30 September 1946**

Henry Plummer, who served as Andrews Professor of Astronomy and Astronomer Royal of Ireland, conducted valuable research on variable stars and stellar motions. He is commemorated in Plummer models for the distribution of stars in globular clusters and other spheroidal systems. Plummer was the eldest son of William Edward Plummer, an astronomer and then senior assistant at the Oxford University Observatory, and Sara Crozier. The elder Plummer later became director of the Observatory of the Mersey Docks and Harbour Board and reader in astronomy at the University of Liverpool. Henry Plummer's education began at Saint Edmund's School, Oxford, and continued at Hertford College under a scholarship. He took first class honors in Mathematical Moderations and Finals, as well as the Open Mathematical Scholarship and a second class in Final Honours School of Natural Science (physics). Plummer then spent a year as a lecturer in mathematics at Owen's College, Manchester, before returning to Oxford in 1900 to spend a year as assistant demonstrator at the Clarendon Laboratory.

In 1901, Plummer accepted the position of second assistant in the University Observatory under the directorship of **Herbert Turner**. By this time, he had published several papers on astronomy and been elected a fellow of the Royal Astronomical Society [RAS]. Despite its low salary, the post offered him his first opportunity to work professionally in astronomy. With the exception of a year spent as a fellow at the Lick Observatory (1907), where he worked on spectroscopy, Plummer remained at the University Observatory until 1912. There, he coordinated its participation in the International *Carte du Ciel* Astrographic Chart and Catalogue, and investigated systematic errors in the positions of images on photographic plates. During this time, Plummer also produced a number of papers on other topics.

In 1912, Plummer succeeded **Edmund Whittaker** as Andrews Professor of Astronomy at the University of Dublin and Astronomer Royal of Ireland. He was placed in charge of Dunsink Observatory, which, owing to poor funding, could make only one serious contribution to astronomy, that being the observations of variable stars. But the observatory's location in the secluded countryside was not conducive to Plummer's lifestyle; he was a bachelor and was described as a "townsman." Added to that were the political troubles that arose in Ireland after the end of World War I. As a result, he faced the very difficult decision of giving up his career in astronomy in 1921 in favor of returning to England as chair of mathematics at the Artillery College, Woolwich (later the Military College of Science), a post he held until his retirement in 1940.

Plummer's responsibilities at the military college left him little time for astronomy. Nonetheless, he remained tied to the astronomical community and while at Woolwich managed to publish about a dozen astronomical papers. Plummer regularly attended meetings of the RAS and was elected the Society's vice president (1936–1937) and president (1939–1941). He had been elected a fellow of the Royal Society in 1920, just prior to his departure from Ireland. In 1924, Plummer broke his lengthy solitude by marrying his longtime friend Beatrice Howard. The couple did not have any children. In 1940, upon his retirement, he and Beatrice returned to Oxford where, in 1942, he gave the Halley Lecture. Beatrice died in the spring of 1946, from which Plummer never fully recovered.

Plummer's contributions to astronomy were many and varied. His first published work describes a graphical method of solving Kepler's equation. A scan of Plummer's early papers reveals topics as varied as using projective geometry to solve binary star orbits, measuring occultations of stars by the Moon, compensating for errors in a siderostat, and studying images formed by parabolic mirrors. Two of his papers on comet 2P/Encke discredited the then-current model of solar-radiation pressure as the cause of its anomalous acceleration. Plummer's work on the *Astrographic Catalogue* not only flexed his mathematical muscle but also displayed his skill with astronomical equipment. His most remembered text, *An Introductory Treatise on Dynamical Astronomy* (1918), was a significant contribution to celestial mechanics and planetary theory. Plummer returned to this subject again in 1932 after learning of numerical investigations carried out at the Copenhagen Observatory.

By far Plummer's most prolific areas of research were studies of variable stars and of stellar motions. At Dunsink Observatory, Plummer and his assistant, Charles Martin, conducted photometric observations of variable stars, in conjunction with measurements of their radial velocities. Plummer showed that eight of those stars, including ζ Geminorum, could not be spectroscopic binaries, as had been assumed, because their atmospheres displayed radial pulsations. This was among the first evidence gathered for the theory of pulsations in classical Cepheid variables, a theory developed more fully by **Arthur Eddington**.

In 1911, Plummer derived an expression for the spatial distribution of stars in globular clusters and their apparent two-dimensional representations on photographic plates. From this relationship, he concluded that most clusters had condensed from primitive spherical nebulae while maintaining convective equilibrium. Plummer also began a lengthy study of the parallaxes of B- and A-type stars in the Milky Way. His results showed a relatively simple way to estimate the parallax of a star from known values of its proper motion and radial velocity. More importantly, he emphasized a distinction between the two principal velocity fields of stars in the Milky Way system: (1) those that are moving parallel to the plane of the galactic disk, and (2) those that exhibit a more spherical (or random) distribution. After Plummer's death, these two dynamical systems were recognized as related to the two stellar populations defined by **Walter Baade**, for which any model of galaxy formation must account.

Plummer was also very interested in the history of science. In 1939, he was asked by the Royal Society to edit the complete works of **Isaac Newton** before the tercentenary of Newton's birth (1942). Unfortunately, World War II put most of the project on hold, and it remained incomplete on Plummer's death. (It was eventually completed by the Society.) At the Society's triple centenary celebration of Newton, **Galileo Galilei**, and **Edmond Halley** on 9 October 1942, Plummer delivered the address on Newton. His 1942 Halley Lecture was entitled, "Halley's Comet and Its Importance."

Plutarch

Born **Chaironeia, Bœotia, (Greece), *circa* 45**
Died ***circa* 125**

Though most famous for his biographies, Plutarch also wrote a dialog on the Moon, in which the participants discuss the Moon's appearance and possible habitability, and how it is able to remain in orbit. Plutarch is best known as a biographer, but none of his contemporaries seems to have written a biography about him – nearly all that we know about Plutarch comes from clues in his own writings. Plutarch lived in a time of peace and contemplation, and seems to have spent most of his life in or near his beloved hometown. He did, though, manage to travel widely: He studied at Athens under the Peripatetic philosopher Ammonius of Lamptrae. He served his town as building commissioner and archon, and participated in a diplomatic mission to the Roman proconsul. Plutarch's travels took him throughout Greece, and he ventured as far as Alexandria, Asia Minor, north Italy, and Rome. In Rome, Plutarch spent about 15 years attending to matters of state, but also lectured on philosophy, probably in Greek, for he never found time to learn Latin. His social circle embraced Rome's most prominent, among whom Mestrius Florus gave him Roman citizenship with an official Roman name, Mestrius Plutarchus. On returning from Rome, Plutarch became a priest at Delphi (near Chaironeia), where he apparently remained until the end of his life. Two inscriptions there testify to his presence: One under a statue of Hadrian, and one under a statue of Plutarch himself. Though both statues have been destroyed, the inscriptions, plus a third inscription at Chaironeia, indicate the esteem in which Plutarch was held.

Plutarch's fame originates in his abundant and eloquent writings. Most famous is the *Lives of Famous Men*, a collection of parallel biographies that contrasts the virtues and vices of Greece's and Rome's prominent public figures. Less famous are 78 essays collected as the *Moralia*, of which about 12 are thought to be written by other authors. The *Moralia* are, as their name suggests, mostly of moral tone. Some of them, such as the dialog *De facie in orbe lunae apparet* (on the Moon's face) present scientific topics for nontechnical readers.

In *De facie*, six interlocutors discuss what might lie behind the Moon's uneven appearance. The discussion presents viewpoints from several Greek schools – including the Academics, Epicureans, Peripatetics, and Stoics – and considers astronomy, cosmology, geography, and the optics of reflection. The interlocutors weigh the several philosophical viewpoints against each other for physical plausibility, after which one of the interlocutors summarily concludes that the face is due to topographical features in its Earth-like terrain. The conversation then turns to whether the Moon might be so Earth-like as to be habitable, what kinds of plants and animals might live there, and why they would not fall off. There is also some discussion of whether the lunar beings are terrestrial souls who, by being either deceased or not yet born, lack bodies. Understandably, in debates on extraterrestrial life and the plurality of worlds, *De facie* was routinely cited well into early modernity.

Other highlights of *De facie* include discussion on how the heavy Moon can remain aloft. One proposed explanation seems tantalizingly close to modern thought: Comparing the Moon's revolutions to a stone whirled in a sling, Plutarch writes, "the moon is saved from falling by its very motion and the rapidity of its revolution … for everything is governed by its natural motion unless it be diverted by something else." There is a description of a total solar eclipse, one of only a few from classical times that mentions stars appearing in the darkness, and perhaps the only classical description of the temperature drop and the solar corona.

Along with the rest of his writings, *De facie* remained influential for centuries after Plutarch wrote it. It has been copied, edited, and emulated by many with scientific motives, the last of whom included **Johannes Kepler**. Kepler was strongly attracted to Plutarch's discussion on lunar habitation: *De facie* is an important influence behind Kepler's *Somnium* on lunar astronomy. Some of Plutarch's other writings include astronomical material, too, in particular his expansions on **Aratus**'s *Phænomena* and a commentary on **Hesiod**'s *Works and Days*. These have received less attention than *De facie*, which, since Kepler's day, has received little attention indeed.

Poczobut, Marcin [Martin Poczobutt]

Born **Slomiank, (Lithuania), 30 October 1728**
Died **Daugavpils, (Latvia), 17 November 1810**

Lithuanian astronomer Marcin Poczobut directed the astronomical observatory at Vilnius University and contributed to the refinement of cartography in Eastern Europe. He was born in the Gardinas region of Lithuania. His father, Kazimier Odlanicki Poczobut, came from a noble family once promoted to *bojar* by King Sigismund I in 1536. His mother was Helena Hlebowicz.

Poczobut became a Jesuit in 1745 and followed that society's tenets until it was banned in 1773. After his graduation from Vilnius University in 1751, he continued studies of Greek, Latin, and mathematics at Prague University. He studied next in France and Italy from 1761 to 1763, where he acquired much of his knowledge of mathematics and astronomy. Upon returning to his homeland, Poczobut was appointed professor of mathematics and astronomy (1764) and later rector of Vilnius University (1780–1799). As third director of the university's astronomical observatory (1764–1808), he added new instruments, including a sextant of 6-ft. radius (1765) and a mural quadrant of 8-ft. radius (1777). To obtain this equipment, Poczobut traveled to England and France, visiting the Greenwich and Paris observatories.

With the large sextant, Poczobut measured the precise length and width of Vilnius for the first time. In recognition of this work, King Stanislaus II bestowed upon him the title of Royal Astronomer (1767), and likewise honored the observatory. Poczobut made other contributions to geodesy and cartography. He determined the geographic coordinates of some 20 points in Lithuania and Latvia, and together with Jan Sniadecki, submitted a plan of dividing Lithuania, Poland, and White Russia into 400 quadrangles. He directed the work of A. Rostanas, J. Bistrickas, and others. Poczobut also participated in K. Perthes's cartographic work in western Lithuania and Courland (now part of Latvia).

Poczobut conducted regular astronomical observations, the most famous of which involved some 60 precise positions of the planet Mercury, from which **Joseph de Lalande** calculated an improved orbit of the planet. In 1766, Poczobut published a book about eclipses of the Moon, which compared data from the observatories of Paris, Vilnius, Warsaw, Krakow, and London.

In 1777, Poczobut asked the French Academy of Sciences to honor the last Polish monarch, King Stanislaus (Poniatowski) II, with a constellation. For this, he selected a V-shaped group of stars mentioned in **Ptolemy**'s *Almagest* that lay just outside of Ophiuchus. The designation did not last, but Poniatowski's bull may still be found on some older star charts; the bull's head is formed by the stars 67, 68, and 70 Ophiuchi.

For a brief time, Poczobut was a member of the provisional government of Lithuania formed in Vilnius during the 1794 rebellion against the Russians. Along with 18 others, he signed the Proclamation of the Lithuanian Supreme Council on 30 April 1794.

Poczobut exhibited extraordinary interest in the first minor planet, (1) Ceres, discovered in 1801. During his 73rd year, Poczobut reportedly "continued to search for and tirelessly observe this body with such persistence and effort that he lost consciousness several times." After Ceres was designated by the sign of a sickle, Poczobut sang its praises with a Latin distich, translated as: "Whoever taught the sickle to cut the stalks of standing corn/The toothed sickle shall become for you the garland of Ceres."

Ancient Egypt was another subject of Poczobut's fascination. He published two papers on the probable age of the Dendera zodiac, recovered from the temple of Hathor by Napoleon Bonaparte's armies and transported to the Louvre.

In 1808, Poczobut resigned as head of the Vilnius Observatory and moved to a monastery. The Polish poet Adam Mickiewicz mentioned him in his epos, *Pan Tadeusz*. He wrote that Poczobut was a priest and astronomer who had finished his life in peace and silence.

Poczobut was named a Knight of the White Eagle and was a recipient of the Order of Saint Stanislaus. He was elected a member of the Royal Society of London (1769) and a corresponding member of the French Academy of Sciences (1781).

Poe, Edgar Allan

Born **Boston, Massachusetts, USA, 19 January 1809**
Died **Baltimore, Maryland, USA, 7 October 1849**

Edgar Allan Poe's *Eureka* has gained attention because of its potential affinity with what in the late 20th century emerged as the standard "Big-Bang" cosmology.

Poe was the second child of actors David Poe and Elizabeth Arnold Poe, both of whom died before their son turned three. Poe then became the foster son of Fanny Allan and her husband, John Allan, a businessman in Richmond, Virginia. Although best known as a writer of haunting poems and exquisitely plotted fantastic tales, Poe has gained attention in the history of astronomy for his speculative but seemingly prescient cosmogony, which opened a cosmic narrative unfolding from a singular "primordial particle."

In 1848, a year before his premature death, Poe published *Eureka: A Prose Poem*, dedicated to **Alexander von Humboldt**, German author of the multivolume treatise *Kosmos*. In *Eureka*, Poe sets out "to speak of the physical, metaphysical and mathematical – of the material and spiritual universe – of its essence, its origin, its creation, its present condition and its destiny." While assuming (Newtonian) absolute space, Poe distinguishes "the universe of stars" from "the universe proper," and propounds an intriguing evolutionary account of the former, the sidereal Universe. The plot begins with "a particle absolutely unique, individual, undivided," and it evolves accordingly from that singularity: "From that one particle" are "irradiated spherically – in all directions – to immeasurable but still to definite distances in the previously vacant space – a certain inexpressibly great yet limited number of unimaginably yet not infinitely minute atoms."

Some have seen Poe as pointing toward a solution to Olbers's paradox (Harrison), or even toward the anthropic cosmological principle as an explanation for the large size of the Universe (Cappi). Strictly speaking, Poe's "primordial particle" was speculative, nonscientific, and perhaps merely a curiosity. On a broader historical canvas, however, it stands as a noteworthy mid-19th-century example of the impulse to offer an evolutionary account of cosmic history, and as a perennial example of the longing of the human imagination to tackle questions concerning the physical origin of the Universe.

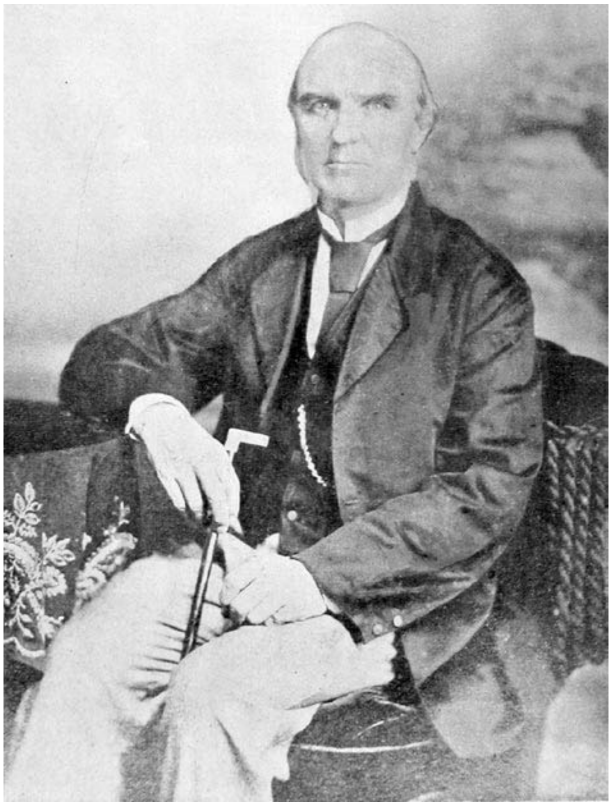
Pogson, Norman Robert

Born **Nottingham, England, 23 March 1829**
Died **Madras, (India), 23 June 1891**



Norman Robert Pogson discovered eight asteroids and 20 variable stars but is usually remembered for his recommendation leading to the adoption of a standard value of the photometric constant, which standardizes the old Greek magnitude system of stellar brightnesses.

Although his father, George Pogson, an established hosiery manufacturer, intended a career in business for his son, Norman developed an early interest in science. It is likely that his mother Sarah's intuitive understanding of this saved him from a Dickensian existence as an apprentice in the textile business. Pogson was twice married, first to Elizabeth Jane Ambrose. They had 11 children. Elizabeth died of cholera in 1869. He then married Edith Louisa Stopford in 1883. She bore him three children. A daughter of his first wife, Elizabeth Isis Pogson, served her father as assistant at the Madras Observatory from 1873 to 1881. She later became Meteorological reporter for Madras. Elizabeth was first proposed for fellowship in the Royal Astronomical Society in 1886, being admitted at last in 1920.

A family friend, **John Hind**, an assistant at George Bishop's South Villa Observatory in London, recommended Pogson's appointment as assistant at South Villa in 1851. Less than a year later he accepted an assistantship at the Radcliffe Observatory, Oxford, under the directorship of **Manuel Johnson**. Pogson's main duty was to make routine observations of stellar positions with the meridian circle, but his enthusiasm was such that he made additional observations even outside the required working hours. Johnson lent Pogson's services to **George Airy** for the Astronomer Royal's famous Harton Colliery experiments to measure the density of the Earth in 1854. Pogson's painstaking attention to detail made a positive impression on the Astronomer Royal. During his Oxford years, Pogson began actively searching for asteroids and monitoring variable stars. The French Academy of Sciences awarded him the Lalande Medal for his discovery of the minor planet (42) Isis in 1856.

That same year Pogson proposed the adoption of a light ratio of 2.512 (the fifth root of 100) for two stars that differ in brightness by one magnitude. The resulting magnitude scale eventually became an international standard after both Harvard and Potsdam observatories adopted it for their photometric programs in the 1870s.

Pogson's desire for more freedom in his astronomical activities brought him into conflict with Johnson. In the mid-1850s he gained the attention of gentleman–scientist John Fiott Lee, who maintained a private observatory at Hartwell House near Aylesbury, Buckinghamshire. Lee offered Pogson the directorship of the Hartwell Observatory, and Pogson accepted. The position provided more freedom of action but was not considered to be of professional standing, a status Pogson ardently desired. On Johnson's death, Pogson applied unsuccessfully for the Radcliffe Observership; a year later, with the support of Airy and Sir **John Herschel**, he was appointed government astronomer at the Madras Observatory in South India.

What first appeared to secure professional recognition for Pogson eventually led to the total eclipse of his career. In a remote location, the Madras Observatory was in disrepair when Pogson arrived, and the astronomer's salary proved inadequate to support his family in India. The government denied him any additional assistance in running the facility, and contemplated its closure more than once during his tenure. Pogson's oversensitive personality did not aid his cause. A quarrel with the Royal Astronomical Society over a planned survey of southern stars soured his relations with the British scientific community. His observations of the solar eclipse of 1868 – he had been one of the first to observe the bright line spectrum in the corona – did not receive due credit because the Indian government authorized the printing of only three copies of his report.

Pogson labored on, embittered by his relations with officialdom and mourning his first wife and eldest son, both of whom died in Madras. He withheld publication of meridian circle observations and telegraphic longitude determinations. Finally, in 1884 a sympathetic governor of Madras, Sir Mountstuart Elphinstone, encouraged Pogson to publish his results. Elphinstone also proposed him for fellowship in the Royal Society, but the application failed. Thereafter, Pogson ceased regular observation, although he remained government astronomer until his death from liver cancer. At the time of his death, he was widely, if mistakenly, considered to have been a scientific nonentity.

Pogson was in fact one of the great visual observers of his time. A pioneer of variable star astronomy, he toiled for many years over an atlas of variables comprising charts of some 60,000 stars. **Edward Pickering** arranged for a grant from the Bruce Fund to support publication of the atlas, but Pogson died before he was able to complete the project. Fragmentary results were finally published in 1908 in the *Memoirs of the Royal Astronomical Society*.

Poincaré, Jules-Henri

Born **Nancy, Meurthe–et–Moselle, France, 29 April 1854**
Died **Paris, France, 9 July 1912**

The French mathematician and philosopher Henri Poincaré made contributions to a wide range of scientific problems, including many in celestial mechanics. Poincaré came from an eminent French intellectual family. His father was professor of medicine at the University of Nancy, and an uncle inspector-general of roads and bridges in France. His cousin, Raymond Poincaré, was a lawyer, statesman, and president of the French republic during World War I, and his sister married the philosopher Emile Boutroux. Henri Poincaré was happily married to the great granddaughter of the zoologist Etienne Geoffroy Saint-Hilaire.

From infancy, Poincaré experienced bad health, including diphtheria at age five. His motor coordination was poor, he had great difficulty learning to write, and he found drawing impossible. Poincaré was not able to read from a blackboard, but his memory was such that he could memorize mathematical formulae and theorems upon hearing them, and remember the exact contents of books after a single reading.

Poincaré studied at the École Polytechnique and the École Supérieure des Mines (School of Mines), both in Paris. His inability to draw was a problem for a potential engineer, but he revealed himself as a brilliant student and genius in mathematics. After graduating as a mining engineer, Poincaré earned a doctorate in mathematical sciences at the Paris Faculty of Sciences, with a thesis on differential equations. Appointed professor of mathematics at the University of Caen in 1879, he moved to the University of

Paris 2 years later, where he held the chair of experimental physics until his death. Considered the last universalist in mathematics, Poincaré published more than 500 papers and 30 books on nearly all branches of pure and applied mathematics, including theoretical physics and mathematical astronomy.

In 1889, Poincaré received a prize offered by King Oscar II of Sweden and Norway for work on the stability of orbits in the *n*-body problem (in which more than two gravitating point masses mutually interact). This was on the advice of German mathematician Karl Weierstrass, who pointed out that, although Poincaré had not solved the problem in full generality, his results "inaugurated a new era in the history of celestial mechanics." Poincaré developed new mathematical techniques to approach the *n*-body problem and showed that there is no analytical solution already for the case of three bodies: The orbits can have very irregular and chaotic form. Thus Poincaré's work was a predecessor of modern chaos theory as applied, for instance, to the mutual perturbations of the orbits of the outer planets.

Poincaré summarized his research on celestial mechanics in his fundamental work *Les méthodes nouvelles de la méchanique céleste* (three volumes, published 1892–1899) and his more practical *Leçons de méchanique céleste* (1905–1910). He applied the results of his study of the equilibrium of rotating fluid bodies (*Figures d'équilibre d'une masse fluide*) to the problem of the origin of the Solar System (*Leçons dur les hypotheses cosmogonique*). He concluded that the planets could not have formed from rotating bodies that contracted as they cooled (as implied in the hypothesis of **Pierre de Laplace**) because the rotating mass would separate into two distinct, unequal masses. The process may be relavant to the formation of binary stars. Poincaré also applied the method to the rings of Saturn. In 1906, his mathematical investigations of electromagnetism yielded results analogous to those put forward some months earlier by **Albert Einstein** in his special theory of relativity.

Besides his purely scientific work, Poincaré wrote some very accessible books on the philosophy of science and mathematics. These books became very popular and were translated into many languages. For his literary talent, he was elected member of the Académie française in 1908, while he was already member of the Académie des sciences, the Royal Society, and many other academies and scientific societies.

Poisson, Siméon-Denis

Born **Pithiviers, (Loiret), France, 21 June 1781**
Died **Paris, France, 25 April 1840**

Siméon-Denis Poisson's greatest contribution to astronomical and physical theory, the Poisson bracket, was generated by the mathematical development of perturbation calculation for the Solar System. He is also remembered for poisson statistics, appropriate for samples with small numbers of members, as often happens in astronomy.

Poisson came from a modest family background. His father, a former soldier, had purchased a low-ranking administrative post in Pithiviers. In 1817, he married Nancy de Bardi, an orphan born in England to *émigré* parents.

The French Revolution, which Poisson supported enthusiastically, made it possible for him to advance to the presidency of the district. Poisson was guided by his father toward those professions to which access had been made easier by First Republican social legislation. Thus, enrolled in the École Centrale of Fontainebleau, he took advantage of his instruction to obtain first place in the national competitive examination to enter the new École Polytechnique, to which he was admitted in 1798.

At the école, Poisson impressed the eminent **Pierre de Laplace** and his colleague, **Louis Lagrange**, with his intelligence, industriousness, and perspicacity. With formidable mathematical talent and enjoying the steady support of the highly placed Laplace, Poisson advanced rapidly to positions of increasing responsibility and eminence: instructor at the École Polytechnique upon his graduation in 1800; deputy professor in 1802; professor of analysis and mechanics in 1806; astronomer at the Bureau des longitudes in 1808; professor of mathematics at the newly established Faculty of Sciences at the Sorbonne; and culminating in election as member of the physics section of the elite Institut de France in 1812.

J. Heilbron terms the mathematical worldview within which Poisson worked as the first modern "standard model." It interpreted physical law as the operation of weightless, "imponderable" fluids, two each for electricity and magnetism, one for heat, one for light, and one for the newly discovered infrared radiation. These imponderables were believed to operate in a manner analogous to gravity, as inspired by the delicate experiments of Charles-Auguste de Coulomb demonstrating how the attraction between static electrical charges varied, as did gravitational attraction, with the inverse square of their separation. Laplace was the leader of this enterprise and Poisson his outstanding disciple.

In the analysis of perturbations, one may begin with the positions of a number of celestial bodies, all mutually attracting one another gravitationally, along radius vectors. If we call the number of vectors r, their attraction will satisfy r second-order differential equations, which can be written in the generalized coordinates introduced by Lagrange. Whether or not these equations are analytically soluble, the integrals of the set of differential equations depend upon $2r$ arbitrary constants. In a supplement to Book VIII of Laplace's *Mécanique céleste* that appeared in 1808, Lagrange developed the implications of Poisson's observation, reported to the Academy of Sciences early that year, that the $2r$ arbitrary constants must satisfy r physical constraints: Specifically, Lagrange proved that in the presence of a perturbation that forces the arbitrary constants to be treated as functions of time, the derivatives of the desired functions with respect to time are the solutions of a linear system in which the coefficients of the unknowns are independent of time.

Using a mathematical transformation, Poisson, in 1809, then extended and generalized Lagrange's result, modifying the variables so that they retain the same form – the Poisson bracket – even upon the introduction of the perturbation function. In the following decades William Rowan Hamilton and Carl Jacobi used the Poisson bracket as an essential element in their geometric reformulation of the dynamical equations of physics, and in the 1920s, Paul Dirac identified the Poisson bracket as crucial in the mathematical structure of Werner Heisenberg's novel quantum mechanics. It is of interest to note that Poisson also anticipated the δ-function made famous by Dirac's employment of it.

Poisson also attempted to complete a didactic presentation of the "standard model" in a series of clearly written and widely read textbooks. He assumed the positions of examiner of graduating students at the École Militaire in 1815 and that of the École Polytechnique the following year. He was named to the Royal Council of the university, the highest educational consultative body in the restored monarchy in 1820.

Another work of Poisson that is of great significance to astronomy is his *Recherches sur le mouvement des projectiles dans l'air* (1839), which first discussed in print the importance of a term, discovered by his doctoral student Gustave Gaspard de Coriolis, to correct for the deviations from the law of motion arising from a rotating frame of reference. A decade later this work inspired the striking experiment of the Foucault pendulum, which demonstrates in a dramatic way the Earth's rotation on its axis. Poisson, however, chose not to mention Coriolis's name. By the time of his death, Poisson had published some 300 papers and books.

Poisson was elected foreign associate of the Royal Society of London in 1818 (and received its Copley Medal in 1832); he was a member of virtually all the academies of the day from Boston to Saint Petersburg. That this adherent of the First Republic was honored by the empire and made a Peer of France by the Orleanist monarchy in 1837 is evidence of his political discretion.

Pond, John

Born **London, England, 1767**
Died **Blackheath, (London), England, 7 September 1836**

John Pond, England's sixth Astronomer Royal, raised the observing program at the Royal Greenwich Observatory to a new standard of excellence. The son of a well-to-do retired businessman, Pond developed an interest in astronomical observations while being tutored at home by **William Wales**, who had served as astronomer and conavigator to Cook on the second voyage of the *HMS Resolution*. As a teenager Pond detected errors in Greenwich observations. After enrolling at age 16 as a chemistry student at Trinity College, Cambridge, he withdrew before completing his degree because of ill health. Sent abroad to warmer climates to recuperate, Pond made astronomical observations during his travels.

Upon his return to England in 1798, Pond began making astronomical observations from his private observatory near Bristol, at Westbury in Somerset, with an altazimuth refractor equipped with 2½-ft.-diameter circles designed by Edward Troughton, one of England's leading makers of scientific and astronomical instruments. Pond's work proved that the Greenwich Observatory quadrant had been deformed by age. This work, published in the *Philosophical Transactions of the Royal Society* in 1806, led to his election the following year as a fellow of the society as well as the institution of a program by **Neville Maskelyne**, the fifth Astronomer Royal, to upgrade Greenwich's instrumentation.

Following marriage in 1807, Pond established his home in London, where he continued working in astronomy using excellent instruments whose construction was supervised by Troughton. After his appointment in 1811 as Astronomer Royal when Maskelyne retired, Pond devoted most of the next quarter-century to upgrading the equipment, staff, and procedures of the Greenwich Observatory. Troughton had designed a new mural circle, ordered by Maskelyne, which enabled Pond to obtain the data for his 1813 catalog of the north-polar distances of 84 stars. The observations made with the circle in 1813/1814 also enabled Pond to challenge the accuracy of claims by **John Brinkley**, the first director of the Dublin Observatory, to have detected stellar parallax of a number of fixed stars. Not only was Pond's assertion that effects of parallax could not be detected with contemporary instruments later proved right, but also his challenge helped stimulate **Friedrich Bessel**'s subsequent successful work in that field. During Pond's tenure, Troughton designed for the Greenwich Observatory a new transit instrument and a 25-ft. zenith telescope, which were erected in 1816 and 1833, respectively. Before ill health forced Pond to retire in 1835, he completed his crowning achievement, a catalog of 1,113 stars, observed more precisely than ever before, which was published in 1833. He is best remembered, however, for beginning the fundamental modernization of the national observatory, a task carried on with zeal by his successor **George Airy**, who regarded Pond as the "principal improver of modern practical astronomy."

Pons, Jean-Louis

Born **Peyre, (Hautes-Alpes), France, 24 December 1761**
Died **Florence, (Italy), 14 October 1831**

Jean-Louis Pons was the world's most successful visual discoverer of comets. Born into a poor family, Pons did not leave his mark on the astronomical community until 1801, when he logged his first discovery of a comet on 11 July. Pons's discovery (c/1801 N1), which he shared with **Charles Messier**, proved to be Messier's last. During his lifetime, Pons discovered or codiscovered a total of 37 comets. Of these, 26 are credited to his name.

In 1789, Pons gained a post as concierge at the Observatory of Marseilles and received instruction on the telescope from the astronomers. He was a fast learner and soon was allowed to observe with all the instruments. His favorite telescope was one with a 3° field of view. (This suggests a magnification around 15×.) Pons was known to possess an extraordinary ability to remember the star fields he had observed and thus to recognize changes within them.

In 1813, Pons was promoted to assistant astronomer and in 1818, assistant director of the Marseilles Observatory. In that year, he received the first of three Lalande Prizes for his discovery of three comets. **Joseph de Lalande**, director of the Paris Observatory, established the Lalande Prize in 1802, awarded each year for the outstanding achievement in astronomy. Pons's receipt of three Lalande Prizes may itself be unequaled.

On 26 November 1818, Pons discovered a comet that was later shown by German mathematician and astronomer **Johann Encke** to follow an elliptical orbit. Moreover, Encke demonstrated that Pons's comet (now designated 2P/1818 W1) was identical to that observed in 1786 by **Pierre Méchain** (2P/1786 B1) and in 1795 by **Caroline Herschel** (2P/1795 V1). The comet's orbital period is a scant 3.3 years, and Encke correctly predicted its return in 1822. For this reason, the comet is known today as 2P/Encke, although Encke himself always referred to it as Pons's comet. On account of gases that are vented from its rotating nucleus, the comet's orbital period decreases by about 2.5 hours per revolution. With its short period and one of the smallest perihelion distances (0.3 AU), comet 2P/Encke has perhaps evolved more rapidly than other periodic comets. It is associated with the annual Taurid meteor shower.

In 1819, Pons was appointed director of the observatory at the Royal Park La Marlia, near Lucca, Italy. He was called to that post by the widow of the former King Louis of Etruria, Duchess Maria Luisa of Bourbon, on the advice of Baron **János von Zach**, also of the Marseilles Observatory. In 1821, Pons received a second Lalande Prize, this time shared with Joseph Nicholas Nicollet, for discovering additional comets from his new observatory. After the Duchess died in 1824, Pons was invited to become director of the Florence Observatory by the Grand Duke of Tuscany, Leopold II. There, he found a total of seven more comets, and was awarded his third Lalande Prize in 1827, shared with **Jean Gambart**. Pons also received a Silver Medal from the Royal Astronomical Society for his discovery of two comets in 1822, at the same time that Encke was awarded the society's Gold Medal.

After 1827, Pons's eyesight began to fail, and he was forced to stop observing in 1831. Although he had no formal training in astronomy, Pons was a remarkable observer and shared the astronomical stage with many well-known scientists. Although possessing enormous patience and perseverance, Pons did not record the positions of his comets with much precision, making it more difficult for others to confirm his discoveries. While some comet discoveries are still made by visual means, most new comets are found today using photographic and electronic (charge–coupled device) imaging techniques. He is commemorated with a crater on the Moon's surface.

Pope Sylvester II

➔ **D'Aurillac, Gerbert**

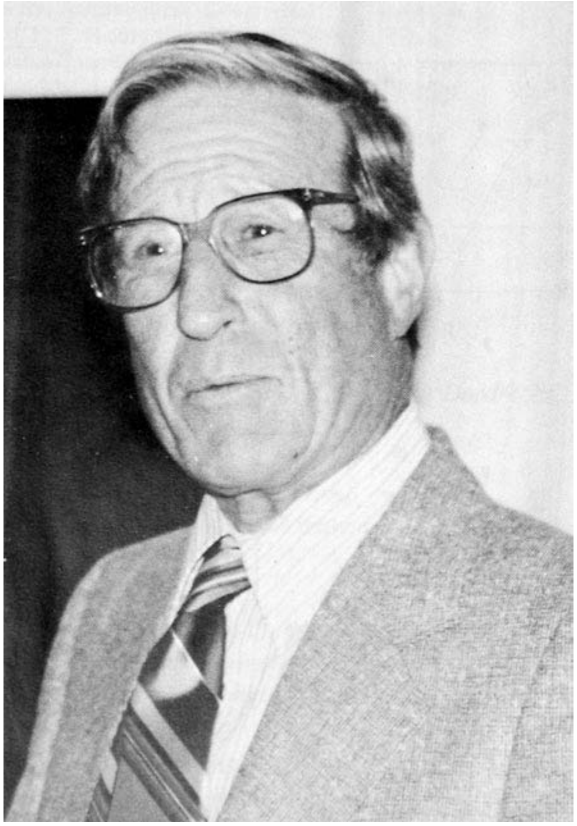
Popper, Daniel Magnes

Born **Oakland, California, USA, 11 August 1913**
Died **Los Angeles, California, USA, 9 September 1999**

Daniel Popper excelled in determining the properties of stars in binary systems. Much of modern stellar astrophysics is built on the foundation of stellar luminosities, radii and spectral types as a function of mass as determined by Popper.

The Popper family of Oakland, California, had already produced several community leaders by the time Daniel Popper received his AB and Ph.D. degrees at the University of California at Berkeley in 1934 and 1938, respectively. During this period, Popper's first published article, with **Lawrence Aller** and Alfred Mikesell, was on the spectrum of Nova Herculis 1934. His dissertation under **Arthur Wyse** was on the spectrophotometry of Nova Lacertae 1936. In this study, Popper correctly identified the greatly broadened lines of hydrogen and other common elements. In a third early paper on exploding stars, this time on supernova 1937C, Popper correctly differentiated the greatly broadened spectral lines in that object from those observed in Nova Herculis and Nova Lacertae, a difference that was not understood for an additional 40 years.

Although he began his career by working on exploding stars (novae and supernovae), Popper soon moved onto **Henry Norris Russell**'s "Royal Road to the Stars" – the study of eclipsing binary stars – and this is what turned out to be his life's work. Popper's early career featured short assignments at a number of locations beginning with a Martin Kellogg Fellowship at Eastman Kodak,



in Rochester, New York. There, he met his future wife, Catherine Salo; they were married in 1940 and had one son. On the recommendation of Lick Observatory director **William Wright**, Popper landed a job as resident astronomer at the newly dedicated McDonald Observatory in West Texas in 1939, remaining there for 3 years. After a year at Yerkes Observatory (1942–1943) Popper returned to Berkeley to join the war effort at the Radiation Laboratory, returning to Yerkes/University of Chicago as an instructor and then assistant professor at the end of World War II.

Popper was hired by the University of California at Los Angeles [UCLA], when that institution formed a new astronomy department in 1947, and remained there for the rest of his career. As a guest investigator at the Mount Wilson and Palomar observatories, one of his first results was the direct measurement of the gravitational redshift of a white dwarf, 40 Eridani B; his results agreed with the prediction of the general theory of relativity within the uncertainties inherent in the theory and the measurements.

Early in Popper's career, there was no real understanding of what today is thought of as stellar evolution. That understanding was gained in the 1940s, 1950s, and 1960s beginning with **Hans Bethe**'s idea that stars are powered by nuclear fusion reactions in their cores. Popper devoted his career to providing very accurate masses, radii, and luminosities of many pairs of stars (eclipsing binaries). Such systems are critical to understanding stellar evolution because both stars have the same age; determination of their properties provides perhaps the most critical tests of the theory of stellar evolution.

When Popper began his work, he soon came to realize that many of the previous spectroscopic workers had not recognized important subtleties inherent in the interpretation and measurement of eclipsing binary spectrograms and in the analysis of their light curves. He came to mistrust the accuracy of most of the earlier work – with good reason. Popper conveyed his misgivings forcefully to the astronomical community in a series of 18 articles entitled "Rediscussion of Eclipsing Binaries." In his published work, he established the guiding principles and detailed procedures needed to achieve accurate results. Following Popper's lead, this field of study advanced to routinely produce accuracies of better than 1% in both masses and radii.

One of Popper's few extended stays away from UCLA came in 1964 when, on a National Science Foundation Senior Research Fellowship, he worked on the inauguration of the stellar intensity interferometer program in Narrabri, New South Wales, Australia. While there, Popper helped the program focus on establishing accurate stellar temperature scales.

Popper was honored as the 1984 Karl Schwarzchild Lecturer of the Astronomische Gesellschaft.

Poretsky, Platon Sergeevich

Born **Elizavetgrad (Kirovograd, Russia), 15 October 1846**
Died **Zhoved, (Chernigov Guberniya), Russia, 22 August 1907**

Platon Poretsky was a Russian mathematician and astronomer who developed a strong interest in mathematical logic. Poretsky, son of an army doctor, graduated from the department of physics and mathematics at Kharkov University. In 1870, he was awarded a fellowship by the department of astronomy and worked as an astronomer at the Kharkov Observatory. In 1876, Poretsky moved to Kazan University, where he was appointed its chief astronomical observer. There, he conducted meridian observations of stars in a zone assigned to the Kazan Observatory and published two volumes on the results.

In 1886, Poretsky defended a master's thesis that addressed the nature of errors associated with the observatory's meridian circle. Its theoretical part dealt with reducing the number of equations and unknowns in systems of cyclical equations relating to practical astronomy. But by a decision of the Department of Physics and Mathematics, Poretsky was awarded a doctorate in astronomy instead, based on the extraordinary quality of his work. He then became a *Privatdozent* (lecturer) in spherical trigonometry at Kazan University. Poretsky was also appointed secretary and treasurer of the physical–mathematical section of the Kazan Society of Natural Scientists (1882–1888) and supervised the publication of its *Proceedings*.

In succeeding years, Poretsky developed a deep interest in the emerging discipline of mathematical logic and became the first Russian scientist to lecture on the subject in 1888. His publications on mathematical logic (from 1884 until his death) were extensive and focused on the elaboration of Boolean algebras, on the study of the logics of classes and propositions, and the application of logical methods to the theory of probability. His influence on the development of mathematical logic was substantial, as is evidenced, for example, in the works of Archie Blake and Louis Couturat. Poretsky's poor health, however, forced him to take early retirement in 1889.

Poretsky's mathematical papers are preserved in the Kazan University Archives.

Porter, John Guy

Born **Battersea, (London), England, 5 November 1900**
Died **Hailsham, (East Sussex), England, 13 September 1981**

John Porter was a sophisticated astronomical computer as well as a dedicated astronomical educator. While a schoolteacher of mathematics and chemistry, he devoted himself as an amateur astronomer to computational astronomy, becoming the director of the British Astronomical Association [BAA] Computing Section in 1937. Porter became an expert on the computation of the orbits of meteors. By the end of World War II, Porter had refined his skills in this area so extensively that he was awarded a Ph.D. for his research on the orbits of meteors and comets. After the war, Porter and **John Prentice** were invited to join (Sir) **Alfred Lovell** at Jodrell Bank Observatory where they assisted in the analysis of radar observations of meteor streams. They showed from velocity profiles that meteors were members of the Solar System and not interstellar particles. Porter's book, *Comets and Meteor Streams*, spelled out these techniques for general use.

By 1949, Porter's reputation in computation was well established. He joined the staff of Her Majesty's Nautical Almanac Office at Herstmonceux, where he was responsible for computing the *Nautical Almanac and Astronomical Ephemeris*. Porter continued to lead the BAA Computing Section from this new venue, though many of his efforts on behalf of the *BAA Handbook* and other projects were by then nearly anonymous.

As a member of the International Astronomical Union, Porter served as president of Subcommission 20A on Orbits of Comets, and as chairman of the Working Group on Orbits and Ephemerides of Comets from 1955 to 1964. After a series of short-term appointments at Yale University in New Haven, Connecticut, USA, and then at the Jet Propulsion Laboratory in Pasadena, California, USA, Porter and his wife retired to Hailsham in about 1962. After his retirement, Porter published a comprehensive catalog of the most reliable orbits of 583 periodic comets observed between 240 BCE and 1965.

Quite apart from the successful career outlined earlier, Porter had a second equally successful career as a popularizer of astronomy. His first radio broadcast, delivered in 1946 on the discovery of Neptune, led to a series of popular weekly broadcasts that extended 15 years. Porter also developed a short series of television programs on astronomy for children, but he preferred the relative anonymity conferred by radio.

Porter was the recipient of the Walter Goodacre Medal and Gift of the BAA in 1965 and of the Jackson Gwilt Medal and Gift of the Royal Astronomical Society in 1968.

Porter, Russell Williams

Born **Springfield, Vermont, USA, 13 December 1871**
Died **Pasadena, California, USA, 22 February 1949**

Arctic explorer, artist, and telescope maker Russell Porter was the cofounder of the amateur telescope making movement in the United States and architectural draftsman of the 200-in. Hale Telescope at Palomar Mountain.

Porter studied civil engineering at the University of Vermont and architecture at the Massachusetts Institute of Technology [MIT] but abandoned his coursework to pursue arctic exploration under the influence of admiral **Robert Peary**. Porter served as surveyor, astronomer, and artist on the ill-fated Fiala–Ziegler Expedition that failed to reach the North Pole (1903–1905). He also surveyed and mapped Mount McKinley in Alaska, but did not reach its summit.

Following these adventures, Porter temporarily settled at Port Clyde, Maine, where he married Alice Belle (1907); the couple had two children. There, he constructed his first telescopes and observatories, employing new optical and mechanical designs for instruments having fixed eyepieces. During World War I, he performed optical work at the United States National Bureau of Standards and was an instructor in design at MIT.

Porter published a quartet of drawings (1916) in *Popular Astronomy* that he labeled "Moonscapes." These depicted what an observer would see, if transported to the lunar surface in the vicinity of the crater Gassendi. Porter noted that "having himself spent many years above the Arctic Circle," he "was struck by a strange likeness of the moon's general aspect to our own polar regions." In turn, he completed "A New Projection of the Moon," depicting its appearance as if each point were simultaneously experiencing sunrise – a clever aid to helping the novice observer.

In 1919, Porter returned to his birthplace as an optical associate at the Jones and Lamson Machine Company. The following year, he founded the Amateur Telescope Makers of Springfield, whose clubhouse (Stellafane) on nearby Breezy Hill became the focus of the group's astronomical activities. The "Springfield" mounting was another of that group's innovations. A 1921 article written by Porter, "The Poor Man's Telescope," caught the attention of *Scientific American* assistant editor **Albert Ingalls**. A three-part series of articles, prepared and illustrated by Porter, launched the amateur telescope making movement, whose early phase culminated in publication of the three-volume classic, *Amateur Telescope Making, Book One, Two, and Three*.

In 1928, Porter was hired by **George Hale** to assist with the design of the 200-in. reflector on Palomar Mountain. Porter's earlier invention of the split-ring equatorial mounting was eventually incorporated into the Hale telescope (completed in 1948). Working only from blueprints, Porter produced the exquisite series of "cutaway drawings" of the giant reflector that revealed its intricate construction. He also designed the site-survey telescopes used in testing the Palomar seeing conditions, the new astrophysics laboratory at the California Institute of Technology, plus the mounting and dome for its Schmidt telescope. Additional freelance work included conceptual drawings of the Griffith Observatory, Los Angeles, and the star projector constructed by the Morrison Planetarium, San Francisco.

Porter was awarded honorary doctorates by two Vermont institutions: Norwich University (1946) and Middlebury College (1949). A crater on the Moon has been named for him.

Posidonius

Born **Apameia, (Syria), 135 BCE**
Died **Rhodes, (Greece), 51 BCE**

Posidonius is responsible for an early measurement of the circumference of the Earth.

Posidonius was from a Greek family though he was born in Syria. He was raised in the Greek tradition and completed his education in Athens under the great Stoic philosopher Panaetius of Rhodes. His name is sometimes listed as Posidonius of Apameia, while at other times it is listed as Posidonius of Rhodes. The former obviously refers to the place of his birth, while the latter refers to the place where he ultimately taught.

Presumably, the influence of Panaetius is what brought Posidonius to Rhodes. Sometime after 100 BCE he is known to have become the head of the Stoic school at Rhodes, where he taught both **Cicero** and Pompey (the Great). In 86 BCE, Posidonius was sent as an envoy to Rome, where he met Gaius Marius, the Roman politician and general. It is also probable that it was around this time that he first met Pompey, who later visited him in Rhodes and became his pupil for a time. It is a remarkable testament to his abilities that we know as much about him as we do, as only fragments of his own writings have survived.

Posidonius is chiefly remembered for providing a value for the circumference of the Earth. There were, in fact, four attempts to measure the circumference of the Earth between the time of **Aristotle** and that of **Ptolemy**. Posidonius estimated that the distance from Rhodes to Alexandria was 5,000 stadia. (According to some estimates, a stade is roughly 185 m, though the one used by Posidonius may have been shorter.) He then observed that if the star Canopus was exactly on the horizon at Rhodes, then it was 1/4 of a sign (1/4 of 30°) about the horizon at Alexandria. This meant that the circumference of the Earth had to be 240,000 stadia, the accuracy of which depends on the value of the unknown stade. His result, whether based on observation or, more likely serving as an illustration, was likely a bit too large and not as accurate as that of **Eratosthenes**, but Posidonius's methods were a precursor to understanding the concept of latitude. It is interesting to note that later scholars indicate that Posidonius actually used different values both for the distance from Rhodes to Alexandria and for the height at which the star Canopus rose above the horizon. Both numbers as given earlier are actually incorrect for that approximate date. (Obviously, the distance never changes, but precession has changed Canopus's position from Posidonius's time.) Posidonius also made an estimate of the size of the Sun, but for its calculation used a value for the size of the Earth different from the one he had himself computed, thereby revealing something of his own convictions about their accuracy.

Most of our knowledge about Posidonius's astronomy comes to us from **Cleomedes**. Posidonius also showed a great interest in the earth sciences, having developed theories of clouds, mist, wind, rain, lightning, earthquakes, frost, hail, and rainbows in a work on *Meteorology*.

Pouillet, Claude-Servais-Mathias-Marie-Roland

Born **Cusance, (Doubs), France, 16 February 1790**
Died **Paris, France, 13 June 1868**

Mathias Pouillet (the name by which he was known) provided the first precise measurements of solar radiation, which he performed with instruments of his own design. Pouillet was the second of ten children of Ignace Denis Pouillet, a papermaker, and of Marie Françoise Rolland. He is said to have attended the lycée of Besançon, before he went to the collège of Tonnerre (Yonne), where he spent 2 years as a teacher of mathematics and where he received his baccalauréatit in 1811. Pouillet then became a student at the École Normale Supérieure, Paris from 1811 to 1813, where he earned his *licence ès sciences*, and he stayed on there as a tutor until 1815, subsequently becoming a *maître de conférences* in physics in the same establishment until 1822. In the meantime, he had earned the *agrégation pour les sciences* (in 1819). From 1817 to 1826, Pouillet also acted as a deputy teacher for the astronomer **Jean–Baptiste Biot** at the Faculté des sciences of Paris. In 1820, Pouillet was appointed professor at the Collège Bourbon (now the Lycée Condorcet), a post he held until 1829, and from 1826 to 1838 also assistant professor at the Faculté des sciences of Paris. He married Henriette Pichon in 1827, and in the same year he was invited to become the tutor of several children of the future king of France, Louis-Philippe.

Pouillet held very important positions at the Conservatoire (then royal) des Arts et Métiers: He was professor and assistant director from 1829 to 1832 (and also teacher of physics at the École Polytechnique for a year in 1831) and administrator (which in fact meant director) from 1832 until 1849, when he was dismissed because of the events of 13 June: an attempted revolt organized by A. A. Ledru-Rollin on the premises of the Conservatoire that Pouillet had not been able to control. In 1838, after the death of the incumbent, P. -L. Dulong, Pouillet held the chair of physics at the Faculté des sciences. He was compulsorily retired in 1852 because he refused to swear an oath of allegiance to the imperial government that took power after the coup d' état of 2 December 1851. He had lost both his children a few years earlier. Deeply affected by these personal and professional tragedies, he devoted his last years to the Académie des sciences and to experimental research, which he mainly carried out in his cottage at Épinay-sur-Seine.

Throughout his scientific career, Pouillet was a much-appreciated teacher of physics, lucid in his theoretical lectures and adept in the art of demonstrating experiments at whatever level he was teaching. A number of his lecture texts were printed in 1828, and he published his famous book *Éléments de physique expérimentale et de météorologie* during the years 1827–1830. A popular version of it was first published in 1850. As a member of the Société d'Encouragement pour l'Industrie Nationale, Pouillet also took an important part in reports on industrial exhibitions and many civil engineering works.

Pouillet carried out researches in various fields that were published as about 40 memoirs from 1816 onward, especially in the *Comptes rendus* of the Académie des Sciences. These dealt with optics, electricity, magnetism, meteorology, photography, photometry, thermal phenomena, and even with studies on the laws of population. In optics he investigated diffraction phenomena. In electricity, he improved the measurement of weak currents by means of his tangent and sine galvanometers. This allowed him in 1837 to verify very accurately Ohm's laws, which had been originally expounded in 1827.

Pouillet's astronomical research was mainly concerned with the measurement of solar radiation and the determination of the atmospheric effects on the recorded values. In 1824, he submitted a letter on the subject to the Académie des sciences through Dulong, and the same year he read a paper before the academicians. In 1838, Pouillet presented a substantial memoir in which he described the pyrheliometers he had designed for the purpose and reported the results of his observations. The data he obtained led to the first successful determination of a "solar constant," which he defined as the flux of total solar radiation received by a surface perpendicular to the Sun rays, for a mean Sun–Earth distance, at the upper limit of the atmosphere. He obtained a value of 1.7633 cal min^{-1} cm^{-2} (*i. e.*, 1,228 W m^{-2}), which turns out to be only 10% lower than the modern value, and hence better than the much overestimated values later given by Jules Violle in 1875 (2.54) and by Alexei Hansky in 1897 (3.4). In 1856, Pouillet designed an instrument he called an *actinographe*, which allowed him to record on a strip of photographic paper the effect produced by the intensity of the image of the Sun as it moved along the strip during the day. J. Stefan successfully used these actinometric observations together with Violle's ones to derive a value for the surface temperature of the Sun.

Pouillet was made a *Chevalier* of the Légion d'honneur in 1828, and an *Officier* in 1845. Meanwhile he had been elected a member of the Académie des sciences in 1837. He served several terms as a deputy for the French department of Jura and sat in the National Assembly from 1837 to 1848 on the government side.

Pound, James

Born **Bishop's Canning, Wiltshire, England, 1669**
Died **Wanstead, (London), England, 16 November 1724**

James Pound made useful observations of Jupiter, Saturn, and the solar parallax, though he is remembered chiefly for the effects of the encouragement and astronomical training he provided to his nephew, **James Bradley**. Pound was educated at Oxford University from 1687 to 1694, when he received both his BA and his MA. By 1697, he had also obtained a medical degree and took orders in the Anglican Church. From 1699, he served as a chaplain in India, where he survived a massacre in 1705. In 1706, Pound returned to England, and was appointed as rector of Wansted in Essex the following year. He was elected to the Royal Society on 30 November 1699. On 14 February 1710, he married Sarah Farmer, a widow; they had a daughter, also named Sarah, born in 1713. After Pound's wife passed away in 1715, Pound was married in October 1722 to Elizabeth Wymondesold, who had a considerable fortune.

Pound made several astronomical observations in 1715, reporting his findings in *Philosophical Transactions*. In 1717, he mounted a 123-ft. focal length objective made by **Christiaan Huygens**; he used this "aerial" telescope to observe Saturn, its moons and rings, and also Jupiter with its satellites. Pound was one of the few observers who made significant contributions using this difficult form of telescope. **Isaac Newton** incorporated Pound's observations into the third edition of his *Principia*; **Pierre de Laplace** used his data to calculate Jupiter's mass.

Pound's financial circumstances enabled him to fund Bradley's education and astronomical interests. He made many observations with Bradley, and furthered his career by introducing him to **Edmond Halley** and **Samuel Molyneux**. Pound visited the latter regularly at his observatory in Kew. In 1717, Pound and Bradley attempted to measure the solar parallax, concluding that the Sun's distance lies between 93 and 125 million miles. The following year, Pound observed the components of the double star γ Virginis in order to determine a stellar parallax, a task Bradley continued in his observations of γ Draconis, which led to Bradley's discovery instead of the aberration of starlight in 1729. Together, Pound and Bradley also observed the opposition of Mars (1719) and the transit of Mercury on 29 October 1723.

Poynting, John Henry

Born **Monton, (Greater Manchester), England, 9 September 1852**
Died **Birmingham, England, 30 March 1914**

John Poynting was a physicist, mathematician, and inventor. He was the youngest son of Reverend T. Elford Poynting and Elizabeth Long. He attended Owens College, Manchester, and Trinity College, Cambridge (1872–1876), and was elected fellow of Trinity College in 1878. He was appointed professor of physics at the Mason College Birmingham (later University of Birmingham) in 1880 and remained there until his death. He married Maria Adney in 1880 and had a son and two daughters.

Poynting is well known for the Poynting vector, which describes the rate at which energy is carried by electromagnetic radiation. It was first introduced in his paper "On the Transfer of Energy in the Electromagnetic Field" (1884). He was also known for his discovery that infrared radiation causes small particles that orbit the Sun to spiral toward and plunge into the Sun. This idea was later developed by the American physicist **Howard Robertson** and is known as the Poynting–Robertson effect. Poynting also invented a method for finding the absolute temperature of celestial objects. He calculated the mean density of the Earth and made a determination of the gravitational constant. The results were published in *The Mean Density of The Earth* (1894) and in *The Earth: Its Shape, Size, Weight and Spin* (1913).

The Cambridge University Press published Poynting's *Collected Scientific Papers* in 1920. His other works include *The Earth* (1913) and *The Pressure of Light* (1910). Poynting was awarded the Adams Prize of Cambridge for his essay on *The Mean Density of The Earth* in 1894. He received the Hopkins Prize of the Cambridge Philosophical Society (1903) and the Royal Medal from the Royal Society (1905).

Prager, Richard

Born **Hanover, Germany, 30 November 1883**
Died **Boston, Massachusetts, USA, 20 July 1945**

German variable-star astronomer Richard Prager compiled a three-volume catalog of variable stars and their literature, which was the primary source of information on these between 1925 and 1949. He was educated at Hamburg (1901) and Göttingen (1903) universities, receiving a Ph.D. from Berlin in 1908 and holding a position as an assistant at the Berlin Academy of Sciences for the next year. In 1909, Prager accepted a position as a section chief at the Observatorio Astronomico Nacional in Santiago de Chile, where he worked with **Friedrich Ristenpart** during the latter's abortive attempt to rejuvenate the facility. There Prager made a number of measurements of positions of Solar System objects including 139 of comet 1P/Halley during its 1910 appearance.

Returning to Germany in 1913, Prager was first assistant and then observer at the Berlin–Babelsbürg Observatory, being appointed professor in 1916. Together with **Paul Guthnick**, he exploited the then revolutionary potassium iodide cell to perform precision photoelectric photometry of variable stars. Of Jewish ancestry, Prager was imprisoned by the Nazis at Potsdam in 1938, but released to immigrate to London when the British Home Office accepted his application for asylum at the urging of the British astronomical community. He lectured to the Royal Astronomical Society in January 1939 before going on to Harvard College Observatory under a program for displaced scholars (in which **Harlow Shapley** played a significant part). Prager carried out some mathematical work for the navy during World War II, but he never entirely recovered from the physical hardships of imprisonment and separation from his family, and died after a succession of illnesses.

Prager's three volumes of *Geschichte und Literature des Lichtwechsels der Weranderlichen Sterne*, the last published in English from Harvard in 1941 as *History and Bibliography of the Light Variations of Variable Stars*, were superceded only after 1949, when, at the request of the Commission on Variable Stars of the International Astronomical Union, Boris V. Kukarkin and **Pavel Parenago** took up the task of compiling and evaluating the literature on this important astronomical subject. Prager served as secretary of the Astronomische Gesellschaft (the German astronomical society) from 1930 to 1936, but was debarred from membership in the International Astronomical Union because Germany was not permitted to join until after World War II.

Prentice, John Philip Manning

Born **Stowmarket, Suffolk, England, 14 March 1903**
Died **Stowmarket, Suffolk, England, 6 October 1981**

John Prentice discovered the Giacobinid (Draconid) meteor shower and Nova DQ Herculis 1934, but his main contributions to astronomy came through his careful supervision of the British Astronomical Association [BAA] Meteor Section for over 30 years. Prentice played an important role in establishing radar observation as a primary technique for studying meteors.

A lawyer by profession, Manning Prentice (as he was known to his friends) acquired an interest in astronomy as a schoolboy. He first began observing the Moon and planets with a small refractor, and later meteors with his naked eye. After joining the BAA in 1919, Prentice continued his meteor observations and was appointed leader of the BAA Meteor Section in 1923, holding that position until 1954.

In 1915, Reverend Martin Davidson (1880–1968) pointed out that the orbit of the short-period comet 21P/Giacobini – Zinner passed close enough to that of the Earth that it might result in a meteor shower on about 10 October each year. No such activity was seen until **Andrew Crommelin** calculated that on 10 October 1926 the orbits of the comet and the Earth would intersect. Acting on Crommelin's prediction, Prentice took up a routine watch the previous evening and was rewarded with the observation of a strong meteor shower – Prentice estimated meteors appeared at a rate of 17 per hour for one observer – with a radiant very near that projected by Davidson. **William Denning** published a similar conclusion about this shower at an earlier date than Prentice, but priority for the discovery clearly belongs to Prentice as the earliest observer. A spectacular return of the Giacobinid meteor shower in 1933, when the Earth crossed the comet's orbit 80 days after the passage of the comet (as opposed to 19 days before the comet's passage in 1926), confirmed not only the relationship of the shower with the comet but also revealed that the duration of the shower was sharply limited to only 4½ hours. The zenith hourly rate for the

1933 Giacobinid shower was estimated at between 4,000 and 6,000 meteors per hour. Unfortunately, the skies were cloudy in England, and the information on this shower was provided by Reverend William Frederick Archdall Ellison (1834–1936) at the Armagh Observatory and by observers on the European Continent.

Prentice's familiarity with the night sky was an important prerequisite for his program of meteor observation and also contributed to his discovery, early on the morning of 13 December 1934, of a nova in the constellation of Hercules. While taking a break from his tiring routine of meteor counting, Prentice noticed something wrong in the appearance of the head of Draco. The problem was quickly traced to an interloping star that was promptly reported to the Royal Greenwich Observatory. Prentice's expeditious reporting facilitated valuable premaximum spectroscopic observation of Nova DQ Herculis. An independent discovery of this nova was made within hours at Delphos, Ohio, by another amateur astronomer, **Leslie Peltier**.

In June 1937, Prentice married Elizabeth Mason Harwood; their union resulted in the birth of four children. The resulting obligations, as well as those associated with his leadership in the congregation of the Stowmarket Congregational Church, must have increased the burden of his avocational interests, but Prentice's zeal for observation remained comparatively undiminished. A further complication arose as a result of the bombing of the church in 1941. For 14 years thereafter, Prentice shouldered a heavy burden as he led the membership's effort to rebuild the structure and preserve the integrity of the congregation. Prentice was active as a leader of youth activities in the church and served as a lay minister and church secretary as well.

After World War II, (Sir) **Bernard Lovell** contacted Prentice and his BAA meteor section for assistance in tracing the relationship between meteor activity and apparently spurious radar signals, interference that could not be traced to cosmic-ray activity. During the Perseid shower in August 1946, Prentice traveled to Jodrell Bank to assist with the correlation of radar signal reception with the appearance of specific meteors; the correlation was immediately evident. Prentice and **John Porter** worked with Lovell and others at Jodrell Bank to apply this technique to good advantage in investigations of meteor streams during daylight hours, and streams of meteors too faint to be seen with the naked eye at night.

In 1935, the BAA and American Association of Variable Star Observers honored Prentice for his discovery of Nova DQ Herculis by awarding him their Walter Goodacre Medal and D. B. Pickering Medal, respectively. In 1953, the Royal Astronomical Society honored his work on meteors with the award of its Jackson-Gwilt Gift and Medal while the University of Manchester conferred an honorary master of arts degree on Prentice in that same year.

➜ **Pèlerin de Prusse**

Pritchard, Charles

Born **Alberbury, Shropshire, England, 29 February 1808**
Died **Oxford, England, 28 May 1893**

Reverend Charles Pritchard pursuaded astronomers to take accurate positional measurements from photographic plates. Pritchard was the fourth son of William Pritchard. He married Emily Newton in 1834 and Rosalind Campbell in 1858.

Pritchard was educated at Merchant Taylors' and Christ's Hospital schools, then Saint John's College, Cambridge. He graduated first in 1830 and then received an MA from the same institution in 1833. Pritchard became a fellow of Saint John's College in 1832 and an honorary fellow in 1886. He earned another MA from Oxford in 1870 and a DD in 1880. Pritchard was named a fellow of New College in 1883.

Pritchard had a successful career as headmaster of Clapham Grammar School, London (1834–1862). He was particularly noted for his teaching of mathematics and sciences. Pritchard also equipped the school with a small observatory. Upon his retirement to the Isle of Wight he became involved in the current controversies between science and religion. Pritchard was opposed to Darwinism and used his scientific accomplishments in defense of the Christian religion. He was subsequently appointed as Hulsean Lecturer (Cambridge) in 1867 and then as Savilian Professor (Oxford; at age 62) from 1870 to 1893.

At Oxford, Pritchard oversaw a complete renovation of the observatory, obtaining new instruments and appointing competent assistants. He engaged the observatory in a number of research projects of specific duration. Pritchard started work on a study of lunar libration using photography; however, this work was not successful and was never published. He compiled a catalog of star magnitudes using a wedge photometer; this was published as the *Uranometria nova Oxoniensis* (1885). Pritchard embarked on a program to measure stellar parallax using photography. He also committed the Oxford Observatory to the *Carte du Ciel* project, obtaining a suitable telescope and initiating the survey.

Pritchard was awarded the Gold Medal of the Royal Astronomical Society in 1886 and a medal of the Royal Society in 1892. He was a fellow of the Royal Astronomical Society from 1849 (its president from 1866 to 1868), fellow of the Royal Society from 1840, and also a fellow of the Geological Society and Cambridge Philosophical Society.

Letters and some other papers by Pritchard are kept in the Library of the Royal Astronomical Society.

Proclus

Born **Byzantium (Istanbul, Turkey), *circa* 411**
Died **Athens, (Greece), 17 April 485**

Head of the Athens Academy in the 5th century, Proclus promoted astronomy in mathematics, cosmology, physics; in empirical observation and instrumentation; and in higher education, proposing that celestial objects have their own self-movement in free space, that our system can be heliocentric, and that cosmic space consists of pure light. He was the last major thinker of Antiquity, and also the one who systematized Greek knowledge in the form it was transmitted to Islam and western Europe.

Proclus' Greek–speaking parents, Patricius and Marcella, moved from Byzantium to Xanthus, a district of Lycia in Asia Minor, probably by 415. Proclus studied rhetoric, Roman law, and Latin at Alexandria. He visited Byzantium at the time of the revival of advanced schools inspired by the Athenian-born Empress Eudocia (425). There he experienced a momentous conversion to Athenian philosophy. On his return to Alexandria, Proclus studied **Aristotle** and mathematics, which included astronomy. He then traveled to Athens (430), where he was quickly embraced by the leaders of the Neoplatonic "academy," and studied the philosophy of Aristotle, **Plato**, and other Greek thinkers. Proclus rose to become head of the premier center of higher learning of the Roman Empire at the age of 25. Around 450, he traveled for a year's sabbatical to the region of Lydia in Asia Minor, to avoid persecution by the Christian authorities. His chief surviving book on astronomy was written just after this trip. In Athens, Proclus pursued a career as a teacher, author, administrator, and influential figure within the empire, which left his followers in awe, as recorded by his biographer, Marinus. The biography concludes with a valuable reference to two solar eclipses at Athens, one precisely observed (14 January 484) and one predicted (19 May 486).

Proclus' integration of astronomy and physics with his metaphysics freed scientific thinking from constraints owed to Aristotle and **Ptolemy**. But he was not just a theoretician. He promoted practical and empirical knowledge, for they combine critical reasoning with direct perception of the appearances of reality. Proclus' chief astronomical treatise, the outline *(Hypotyposis) of the Astronomical Hypotheses*, contains a detailed description of how to construct and calibrate the spherical armillary astrolabe, and how to make observational measurements of the Moon and the stars; he noted the existence of optical binary stars. He also refers to the use of Heron's water clock to measure the Sun's diameter, to the meteoroscope instrument, and to the actual construction of ephemerides tables. He made some of the last reliable astronomical observations of Antiquity (475).

Proclus' views on astronomy are part of his responses to the core questions: How much can the appearances of things tell us about their deep nature? What is the nature of reality? For Proclus the celestial objects are "self-substantiated" agents with the power to move freely of their own accord. They orbit according to their own natural, unimpeded motion, and move in the three dimensions of free space without the need of celestial spheres. Proclus further proposed that every fixed star and planet must have its own spin around its axis. He went so far as to suggest that the Earth itself is like a star, and if it were not for the inertness characteristic of its predominant physical property, it should move circularly.

Proclus advanced the heliocentric view. He accepted that the celestial bodies revolve around the Earth as center but only in their capacity as earth-like bodies. Since it is their self-power that really matters, they should be arranged around the center of most power: the Sun. The Sun is also in the middle of a system consisting of the five observed planets, the Moon, and the Earth's four elements. Further, Proclus speculated that every planet has its own group of attendant "satellites."

Proclus poured scorn on astronomers such as Ptolemy, who believed that inventing epicyclic and eccentric spheres could explain away the apparent irregular movement of the planets and the Sun and the Moon. Proclus took these irregularities seriously, as problems challenging us to reconcile our current level of understanding with that proper to deeper reality. He also rejected **Hipparchus**' discovery of the "precession," as described by Ptolemy, and Ptolemy's interpretation that the precession involves a backward movement of all the stars. For Proclus the stars are fixed in their constellations and do not precess. Proclus' *Outline of the Astronomical Hypotheses* contained the only critical evaluation of Ptolemy in antiquity, and rejected his speculations on many counts.

Proclus also rejected Aristotle's fifth element for the heavens. For Proclus the heavens have the same four constituents (fire, air, water, and earth) as the Earth, but in a different state of matter. This contains the "summits" of all the elements, where the properties of fire prevail. He concluded that the celestial bodies must have some Earth properties also, to be opaque (as in eclipses) and have gravity. Above all, he asserted that there is one science for both the heavens and Earth, not separate ones.

In cosmology, Proclus was the first to propose that space must be a three-dimensional body of a special kind that allows normal bodies to coexist with it. He speculated that there is a cosmic space, a body of pure, invisible light, in which the entire Universe is immersed.

Proclus instilled astronomical interest in his students, including Marinus, his successor at the Athenian School; **Ammonius**; and Ammonius' brother **Heliodorus**. The latter records Proclus' observation of an occultation of Venus by the Moon (475) from Athens. Ammonius' students **Simplicius** and the Christian **John Philoponus** wrote the major commentaries on Aristotle, but followed Proclus on the rejection of Aristotelian physics, and accepted most of his views on the celestial bodies and the elements.

Through the Byzantine emigrés Gemistos Plethon and John Bessarion, Proclus and Ptolemy spread to Renaissance Europe. By the 16th to 17th centuries Proclus' mathematical and astronomical achievements gained wide recognition. Proclus' *Commentary on Euclid* was highly regarded and discussed in **Galileo Galilei**'s circle. **Nicolaus Copernicus** cited it in the *Revolutions of the Heavenly Spheres*, and **Johannes Kepler** did likewise in the *Harmonices Mundi* (1619). Kepler quoted Proclus repeatedly and praised him as a true precursor of the heliocentric theory.

Proclus' name has been given to a lunar crater near the Sea of Tranquillity.

Proctor, Mary

Born **Dublin, Ireland, 1862**
Died **probably London, England, 1957**

Mary Proctor never became a professional astronomer, but was widely known for numerous articles and books on the subject.

Proctor was the daughter of **Richard Proctor** and his first wife, Mary (*née* Mills) Proctor. Mary's father was a well-known astronomer, lecturer, and writer, born in London and a graduate of Saint John's College, Cambridge. It was from him that Mary acquired her astronomical knowledge and her love for writing. From an early age, she took pride in the care of his library; as a young woman, she arranged his letters and corrected the galley proofs of his books. She graduated from the College of Preceptors at London in 1898.

Proctor's mother died in 1879. When her father remarried in 1881, the Proctor family immigrated to America and settled in Saint Joseph, Missouri. Proctor studied writing and assisted her father in the production of a new journal, *Knowledge*, which he founded and edited that same year. Among her earliest published writings was a series of articles on comparative mythology. She also began a secondary career as a lecturer on astronomy, following a very successful appearance at the World's Columbian Exposition at Chicago in 1893. Proctor's ambition to write a book was first realized with the 1898 publication of *Stories of Starland*, which was adopted by the New York City Board of Education. She attended classes at Columbia University and taught astronomy in private schools.

Many of Proctor's articles and books were aimed at younger audiences, and Proctor became known as the "children's astronomer." Her literary works included *Wonders of the Sky*, *Everyman's Astronomy*, *The Romance of Comets*, *Legends of the Stars*, and *Half-Hours with the Summer Stars*. Her books were easy to read, accurate, informative, and well illustrated. Proctor was widely respected by professional astronomers, and in 1898 was elected to membership in the American Association for the Advancement of Science. She was elected a fellow of the Royal Astronomical Society in 1916.

In *The Book of the Heavens*, published in 1924, Proctor wrote: "Some of my readers may become great astronomers; for that reason I have [included] … accounts of … some leading observatories of the world [so] that boys and girls may see astronomers of today at work." She never married. A 12-mile diameter lunar crater has been named for her.

Proctor, Richard Anthony

Born **Chelsea, (London), England, 23 March 1837**
Died **New York, New York, USA, 12 September 1888**

Richard Proctor was principally an expositor of science, especially astronomy. He wrote prodigiously on the latter topic, and gained considerable fame through his articles and books. In 1854, Proctor worked as a clerk in the London Joint Stock Bank. A year later, he enrolled at King's College, London, where he studied theology and mathematics. Proctor graduated in 1860 from St. John's College, Cambridge, as 23rd Wrangler. That year he also married his first wife, Mary Mills.

"A few months after leaving Cambridge," Proctor tells us, "in my quiet home at Ayr, free of all anxieties about maintenance (for I had inherited ample means), I began in a very modest and quiet way the study of some astronomical matters, to which my attention had been attracted by two books picked up at a book stall in Glasgow." His first published article took him 6 weeks to prepare. "Often I would not complete more than four or five lines in a day with which I was satisfied, so that … my work went on very slowly indeed." The piece, entitled "Colours of Double Stars," appeared in *Cornhill Magazine* (1865).

As a form of therapy, following the death of his eldest son, Proctor undertook a "work which would occupy me," he wrote, "for at least a year." In due course, his first astronomical treatise, *Saturn and Its System*, was completed (1865). This contained the first popular account of **James Maxwell**'s theory of the discrete nature of the planet's ring system.

Although commercially unsuccessful at first, the book established Proctor's reputation among those best equipped to judge its merits, and in 1866 he was elected a fellow of the Royal Astronomical Society. That same year, however, Proctor suffered a serious financial crisis when the New Zealand bank, in which the bulk of his assets were invested, collapsed.

Out of necessity, Proctor taught mathematics at the Military School, Woolwich. But by the autumn of 1867, he had definitely settled on a literary career. Passing "through experiences enough to age a man ten years in as many weeks," Proctor eventually succeeded, and in 1872 became one of the secretaries of the Royal Astronomical Society, and editor of its journal, the *Monthly Notices*. From that time onward, his output was prodigious and diverse.

It was Proctor's intention to produce original works that formed a standard embodiment of the astronomical knowledge of the last quarter of the 19th century. His exhaustive account of the Venus transits of 1874 and 1882 was characterized by one biographer as "the best popular exposition of the nature and use of that phenomenon that has yet appeared." Proctor wrote, in all, around 57 books, his last being *Old and New Astronomy* (1892), a large treatise on which he reported, "I intend … putting into final form the results of my studies, now scattered through my essays, lectures and magazine articles." This was left unfinished at the time of Proctor's death, but enough materials had been assembled that his friend, **Arthur Ranyard**, could complete the task.

In 1867, Proctor prepared a map of Mars from the 1864–1865 drawings by Reverend **William Dawes**. Employing considerable cartographic skills, he applied names to supposed continents, seas, bays, and straits, thus showcasing current beliefs about physical conditions on the planet. A small forked bay-like marking, named after Dawes (now Sinus Meridiani), was adopted as the Martian prime meridian. Proctor also deduced an extremely accurate rotation period of Mars, from historic drawings of the red planet. In 1870, Proctor plotted the positions and proper motions of roughly 1,600 stars. As a result, he found that certain clusters shared a common direction of travel through space, a phenomenon he dubbed "star drift." Around 1873, Proctor conjectured that the craters of the Moon were impact features and not the result of volcanic eruptions. It would be decades before this idea gained wider acceptance.

Proctor's first wife, Mary, died in 1879. He then went on a 2-year lecture tour of the United States. In 1881, Proctor met and married the widow of Robert J. Crawley; the couple settled in Saint Joseph, Missouri (her hometown). That same year, he founded the popular science magazine *Knowledge*, and continued as its editor until his death from yellow fever. One year earlier, Proctor and his wife had moved to Orange Lake, Florida. His daughter, **Mary Proctor**, followed in her father's footsteps and published many popular books on astronomy. A crater on Mars has been named in Proctor's honor.

Ptolemy

Flourished **Alexandria, (Egypt), second century**

Hundreds of years of Greek geometrical astronomy were systematized, with rigorous demonstrations and proofs, by Claudius Ptolemaius. His intent was to do for applied mathematics what Euclid had done for pure mathematics (geometry). Ptolemy produced handbooks containing all that was known about astronomy, optics, geography, astrology, musical theory, geometrical constructions using spherical projection, the structure and size of the Universe, and mechanics. Although his primary goal was to summarize what was already known, Ptolemy also advanced astronomical knowledge so far as to earn for himself a reputation as the greatest astronomer of the ancient world. He showed how, based upon observation and empirical data, geometrical models could be constructed that simulated nature. His astronomical textbook surpassed all that had gone before and dominated future astronomy for well over a millennium. In replacing much of previous astronomy, however, Ptolemy helped cause the loss of a vast body of earlier data.

Of the man himself almost nothing is known. His recorded observations purportedly were made – some assert they were fabricated – between the 9th year of Hadrian's regime (125) and the 4th year of Antoninus Pius (141) "in the parallel of Alexandria." Most writers assume that Ptolemy worked in Alexandria, Egypt, but according to **Olympiodorus the Younger**, a philosopher teaching in Alexandria in the 6th century, Ptolemy worked for 40 years at Canopus, a town 15 miles to the east of Alexandria (and hence in the same parallel). One tradition even has it that Ptolemy in 147 erected in the temple of Seraphis at Canopus a pillar to commemorate

his discoveries. Wherever he actually resided, Ptolemy rightly is associated with Alexandria, whose library provided him with the observations of his predecessors, upon which he constructed his great synthesis.

Ptolemy's mathematical systematic treatise of astronomy, *The Mathematical Syntaxis*, soon attracted the appellation *megiste*, the Greek adjective for "greatest," which was transliterated into Arabic. With the addition of the definite article *al*, Ptolemy's complete exposition of mathematical astronomy became, upon passing from Arabic into Medieval Latin, the *Almagest*. Ptolemy's treatise was lost in the west soon after its completion, but was copied and studied in the Byzantine Empire. Manuscript versions in the original Greek and dating from the 9th century are extant, as are Arabic translations dating from the 11th century and later. So is a Latin translation from Arabic made in 1175. This was rendered, in 1515, into the first printed version of the *Almagest*.

The *Almagest* begins with a brief introduction to the nature of astronomy and a presentation of the necessary trigonometric theory and spherical astronomy. Then come theories of the Sun and the Moon, an account of eclipses, discussion of the fixed stars, and finally a discussion of the planets. The motivation underlying Ptolemy's study is found in an epigram:

> I know that I am mortal and the creature of a day; but when I search out the massed wheeling circles of the stars, my feet no longer touch the Earth, but, side by side with Zeus himself, I take my fill of ambrosia, the food of the gods.

Ptolemy proposed to begin with reliable observations and attach to this foundation a structure of ideas using geometrical proofs. Had he completely replaced the Greek deductive geometrical science he inherited with an inductive observational procedure, the result would have been a scientific revolution. However, determining the reliability of observations other than from their agreement with the very theory that were to be used to confirm proved a major problem for Ptolemy.

Ptolemy sought to explain the apparent irregularity of the Sun's motion as a combination of regular circular motions (defined as motions that cut off equal angles in equal times at the center of the circle). In the eccentric hypothesis, the circle carrying the Sun was not centered on the Earth, and thus regular motion as viewed from the center of the Sun's orbit appeared irregular when viewed from the Earth. In the epicycle hypothesis, a small circle (the epicycle) had its center fixed on a large circle (the deferent), and the combination of their regular motions was irregular. In the case of the Sun, either hypothesis could produce the observed motion. The hypotheses were interchangeable in a mathematical sense, though not in a physical sense.

Ptolemy next presented a table of the motions of the Moon and showed that the eccentric circle and the epicycle hypotheses could produce the same appearances. He reported lunar observations of greater accuracy than ever made before, using an astrolabe, which he described in detail.

To reproduce the more complex movements of the planets, Ptolemy found it necessary to employ both hypotheses simultaneously. Furthermore, difficulties in matching theory to observation eventually forced Ptolemy to violate his own definition of uniform circular motion. The violation would become one of the major causes of dissatisfaction with Ptolemy's system, leading to **Nicolaus Copernicus**' revision and revolution 14 centuries later.

In several instances in the *Almagest*, reported observations match corresponding theory more accurately than could be expected of random observations subject to probable errors, and Ptolemy is thus suspected of having fabricated the purported observations. There exists, however, a close agreement between Ptolemy's numerical parameters and modern observational values, so Ptolemy must have had a large, if unreported, body of real observations from which he derived his accurate parameters. Once a theory and its quantitative parameters were determined from a large body of real observations, Ptolemy next might have selected from among the observations a few in best quantitative agreement with the theory and then presented these examples to illustrate – not necessarily to determine, or to prove – the theory. Furthermore, Ptolemy was working within the tradition of Greek geometrical astronomy originally concerned almost totally with geometrical procedure and very little, if at all, with specific numerical results. The objective of the *Almagest* could have been didactic. Ptolemy may not have intended to deceive his readers, but he was less than candid concerning the manner in which he arrived at his results and was most remiss if his conduct is judged against the ethics of modern science.

Another question involving Ptolemy and his astronomy is whether the many circular motions compounded to determine the trajectory of a planet had a physical reality. Did Ptolemy envision actual physical structures in the heavens carrying around the planets? Or were his planetary theories merely means of calculating the apparent places of the planets without pretending to represent the true system of the world? His lunar theory predicted the Moon's positions in longitude and latitude accurately but greatly exaggerated the monthly variation in the Moon's distance from the Earth. Hence, the argument goes, Ptolemy could not have intended that the theory be interpreted realistically. In one of his other books, however, Ptolemy showed a concern with the physical world. In the *Planetary Hypotheses* he nested the mechanism of circles for each planet inside a spherical shell between adjoining planets. And a passage in the *Almagest* is susceptible to the interpretation that a construction in the heavens made not of wood, nor of metal, nor of other earthly material, but of some divine celestial material offering no obstruction to the passage of one part of the construction through another, controlled the motions of the planets.

After all is said – the charges of fraud leveled, the scientific shortcomings revealed, and the unanswerable questions exhausted – the historical influence and significance remain. Ptolemy's *Almagest* was the culmination of Greek astronomy, unrivaled in Antiquity, surpassing all that had gone before, and not itself surpassed for some 1400 years, until the time of Copernicus.

Puiseux, Pierre-Henri

Born **Paris, France, 20 July 1855**
Died **Fontenay, Jura, France, 28 September 1928**

Pierre Puiseux produced a series of studies on the Moon, addressing its motion, its surface, and its internal structure. He was the son of Viktor Puiseux (1820–1883), an astronomer and mathematician as well as a member of the Academy of Sciences, and of Laure Louise Jeannet (died: 1858). In 1865, Puiseux began to attend the high school in Saint-Louis; in 1875, he became a university student at the École Normale Supérieure, where he received his Ph.D. in mathematical sciences in 1879. On 20 June 1883, he married Laurence Elisa Marie Béatrice Bouvet, with whom he had seven children. Puiseux was well-known as a mountain climber. He succeeded in several first ascents and contributed to the exploration of several mountains in France, Switzerland, Sweden, and Italy. He frequently published mountaineering articles in *Annuaire du Club alpin français* as well as in the journal *Montagne*.

Puiseux worked his way up the career ladder at the Observatory of Paris, starting as a student astronomer (1879) before taking the positions of assistant astronomer (1881), associate astronomer (1885), astronomer (1904), and, after his retirement in 1917, honorary astronomer. From 1880, he lectured at the Faculty of Science in Paris, since 1897 as a honorary professor. In 1904, Puiseux was appointed to a lectureship in celestial mechanics.

In his dissertation of 1879, Puiseux analyzed the secular acceleration of the Moon. As an astronomer at the observatory, he devoted his studies to the photography of celestial bodies, to the realization of an international celestial map, and to the analysis of the Moon's topography and libration. He was sent abroad for scientific missions several times, for example, to Fort-de-France (Martinique) in 1882 for the observation of the transit of Venus, and to Cistierna (Spain) in 1905 for the observation of a solar eclipse. In addition to his books on the internal structures of the Earth and the Moon, and his photographic atlas of the Moon, Puiseux wrote numerous treatises published in *Annales de l'Observatoire de Paris*, in *Comptes-rendus de l'Academie des sciences*, and in the *Bulletin de la Société Astronomique de France*.

From 1906 to 1917, Puiseux supervised the photographic mapping of the sky. In 1907 and 1910, he served as secretary at the congresses of the International Union for Solar Research, which took place in 1910 at Mount Wilson Observatory in California. In 1909, he participated as the secretary at an international conference for the edition of celestial maps.

Puiseux was awarded the Valz Prize of the Academy of Sciences in 1892, the Lalande Prize of the Astronomical Society of France in 1896, and the Janssen Prize of the Academy of Sciences in 1908. He became knight of the Legion of Honor in 1900, president of the Astronomical Society of France in 1911, member of the Astronomy Section of the Academy of Sciences in 1912, associate member of the Royal Astronomical Society in 1917, and honorary president of the French Alpine Club. In 1935, a crater on the Moon was named for Puiseux to credit his scientific achievements (latitude 27°.8 S, longitude 39°.0 W, diameter 24 km).

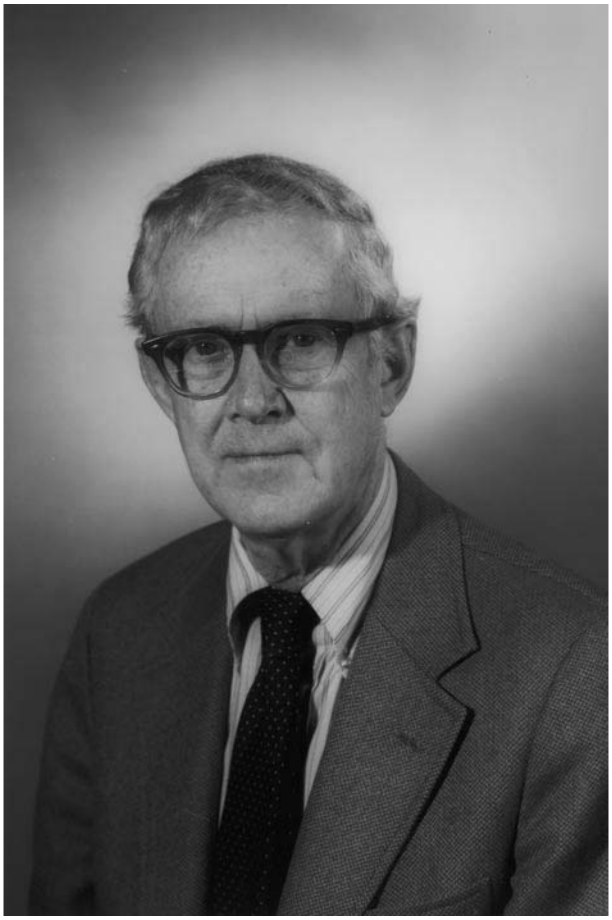
Purcell, Edward Mills

Born **Taylorville, Illinois, USA, 30 August 1912**
Died **Cambridge, Massachusetts, USA, 7 March 1997**



American experimental physicist Edward Purcell is honored within astronomy for the 1951 discovery, with his student Harold C. Ewen, of the 21-cm line of neutral hydrogen, which had been predicted in 1944 by Henk C. van de Hulst, but it was for the 1945 discovery of nuclear magnetic resonance [NMR] that he shared the 1952 Nobel Prize in Physics with Felix Bloch, who had demonstrated the same phenomenon at nearly the same time, using a different technique.

Edward Purcell was the son of Elizabeth Mills, a high school Latin teacher, and Edward A. Purcell, the manager of the Taylorville telephone exchange (and later of the Illinois Southeastern Telephone Company). He probably owed some of his laboratory skills to very early familiarity with electrical equipment, including the magnetos of old crank telephones. Purcell earned a BS in electrical engineering at Purdue University in 1933, spent a year as a foreign exchange student at the Institute of Technology in Karlsruhe, Germany, and entered the Physics Department at Harvard University in 1934. He married Elizabeth Busser, who had also been an exchange student in Germany. Purcell received his Ph.D. in 1938 with a thesis on a spherical condenser mass spectrograph, carried out under Kenneth Bainbridge, but was also introduced to the quantum theory of magnetism by John H. van Vleck.

Purcell was appointed an instructor in the Harvard Department of Physics in 1938, rising through the ranks to assistant professor in 1941, associate professor in 1946, full professor in 1949, and the endowed Gerhard Gade University Professorship in 1961. The first, and probably most distinguished, of his Harvard Ph.D. students was Nicolaus Bloembergen (Nobel Prize in Physics, 1981; Gerhard Gade Professor Emeritus and professor of optical sciences at the University of Arizona). He continued to make significant contributions in the area of NMR until about 1955. The Purcells raised two sons, Frank and Dennis.

During World War II, Purcell worked full-time at the Massachusetts Institute of Technology's [MIT] Radiation Laboratory. He headed the Fundamental Development Group responsible for X-band and K-band radar techniques. Purcell contributed to two volumes of the well-known *MIT Radiation Laboratory Series*.

The associate director, I. I. Rabi, arranged numerous discussions and lectures at the end of the war, to assist the scientists at the Radiation Laboratory in their return to physics research and academic life. Purcell, Henry C. Torrey, and Robert V. Pound discussed the transitions of water molecules in the microwave K-band, as well as the nuclear spin magnetic resonance transitions, observed by Rabi and coworkers with molecular beam techniques. They conceived of the idea of looking for NMR in condensed matter. A literature search revealed that C. J. Gorter in the Netherlands had attempted to detect this phenomenon earlier without success. In December 1945, the three MIT scientists demonstrated the proton magnetic resonance at about 30 MHz in a magnetic field of about 7,000 oersted. They had borrowed the large electromagnet used by J. C. Street for cosmic ray research, in a shed adjacent to the Lyman Laboratory of Physics at Harvard.

Somewhat by accident, Purcell had heard of the van de Hulst prediction of a spectral feature produced by neutral hydrogen when the spin of the electron flips from parallel to antiparallel with the spin of the proton, and suggested a search for it to Harold C. Ewen, who was looking for a thesis topic where he could apply his background in microwave engineering. Ewen built a state-of-the-art microwave radiometer, and they put it at the focus of a small horn antenna, pointed at the sky from the top floor of the Lyman Laboratory of Physics. When the Milky Way passed overhead, the effective radiation temperature at 21 cm increased, leading to recognition of the predicted feature on 25 March 1951. Ewen and Purcell shared the 1988 Tinsley Prize of the American Astronomical Society for their discovery. The line is of enormous continuing importance in astronomy, because it enables us to trace out the amounts and motions of the most abundant element in the Universe, even when there are no stars nearby to light it up.

Van de Hulst was visiting Harvard at that time. Together with Professor **Jan Oort** and a microwave engineer C. H. Mueller, he had been working for some time on the same problem. They used a radio telescope antenna in the Netherlands that had belonged to the Germans during World War II. The Dutch group had experienced an experimental setback caused by a fire. When van de Hulst notified the group of the discovery at Harvard by Ewen and Purcell, they were quickly able to confirm it. Purcell asked the editor of the magazine *Nature* to postpone the publication of the letter he and Ewen had submitted, so that the results of the Dutch group could appear simultaneously. Purcell also had correspondence with Australian radio astronomer **Joseph Pawsey**, so three short announcements appeared in *Nature* **168**, 356 (1951) at the same time.

Purcell remained interested in astronomy to the end of his career, working on the properties of interstellar dust particles in the 1960s and 1970s and on the orientation of rotating dust grains in the magnetic field of interstellar space with **Lyman Spitzer, Jr**.

His wide-ranging intellectual curiosity is evident from two other scientific explorations outside the field of astronomy. He spent considerable time in the search for the magnetic monopole postulated by **Paul Dirac**. Purcell told the author that his unpublished notes on this subject would read like a fable "Hunt for the Unicorn." No evidence for the existence of the magnetic monopole has been found to date.

Purcell's interest in bacterial locomotion met with much more success. It was the result of collaboration with Howard C. Berg, who had been a junior fellow in the Society of Fellows at Harvard, while Purcell was a senior fellow. Berg demonstrated that *E. coli* bacteria move not by a reciprocal motion of their flagella (tails), but rather by a helical twisting motion. Purcell realized that viscous forces completely dominate inertial effects. It is the hydrodynamic regime of low Reynolds number. His paper and popular talk "Life at Low Reynolds Number" bear witness to his superb teaching ability and physical insight. Berg and Purcell received the biological Physics Prize of the American Physical Society in 1984.

In addition to undertaking wide-ranging research, Purcell was an outstanding teacher, receiving the 1968 Oersted Medal of the American Association of Physics Teachers and writing an outstanding textbook on electricity and magnetism and a series of short articles illustrating order-of-magnitude (envelope back) calculations of many different physical phenomena. He was a member of the Science Advisory Board for the US Air Force and of the Presidential Science Advisory Committee [PSAC] under presidents Eisenhower, Kennedy, and Johnson. Purcell received the National Medal of Science in 1969, and was elected to the United States National Academy of Sciences, the American Philosophical Society, and the Royal Society (London) as a foreign honorary member. He served as president of the American Physical soceity in 1969.

Pythagoras

Born **Samos, (Greece), *circa* 570 BCE**
Died **Metapontum or Croton (Crotone, Calabria, Italy), *circa* 480 BCE**

Pythagoras was a curious combination of a charismatic guru and mathematical genius, who founded an influential movement characterized by belief in reincarnation, moral and religious purity, and a predilection for numerical explanation. The Pythagorean doctrine that the nature of things consists in mathematical structure led both to **Plato**'s theory of forms and to Greek astronomers' lasting preference for simple, constant motion.

Born the son of Mnesarchus, a gem engraver, the young Pythagoras traveled widely for many years, acquiring both scientific information and religious lore. He is reported to have heard **Thales** and **Anaximander** and to have studied with Egyptian priests and with the Chaldeans. These undoubtedly encouraged his mathematical and astronomical interests. On the religious side, Pythagoras associated with Zoroasterism or the Magi, was initiated into numerous mysteries, and went into the cave on Mount Ida with Epimenides, a famous Cretan miracle-worker. **Heraclitus**, a champion of the empirical search for natural regularities and despiser of omnivorous polymathy, accused Pythagoras of patching together an idiosyncratic pseudo-wisdom from these eclectic sources.

Returning to Samos when he was about 40 and finding the rule of the tyrant Polycrates disagreeable, Pythagoras immigrated to Croton. An eloquent speaker, he quickly achieved prominence, preaching virtue, self-control, and a simple lifestyle to various audiences, including – contrary to custom – married women apart from their husbands and boys apart from their parents. He established a quasi-religious, quasi-philosophical organization, under whose leadership the city prospered so conspicuously that Pythagoreans rose to power in several neighboring cities. Pythagoreans were divided into a larger body of *acusmatici* (hearers) and a smaller inner circle of *mathematici* (learners) who adopted a moderately ascetic life characterized by mathematical and astronomical research, secret doctrines, abstinence from animal food, communal living, and various purificatory rituals connected with belief in reincarnation. Around 500 BCE Kylon, a rejected applicant to the order, led a coup in which many prominent Pythagoreans were assassinated. Pythagoras escaped, finding refuge in Metapontum. He is variously said to have lived to the age of 80, 90, or 100, and may have returned to Croton.

Although **Diogenes** disputed it, most likely Pythagoras, like Socrates and Jesus, wrote nothing. Because Pythagoreans kept their more innovative doctrines secret and honorifically attributed later discoveries to the founder, identifying a doctrine as Pythagoras's own is highly conjectural. Clearly he instituted a way of life based on a core of distinctive cosmological and anthropological beliefs. Pythagoras is reported to have been the first to call the Universe *kosmos* (although **Anaximander** certainly used the term), meaning that it is an ordered whole. The Universe is not mindless matter but a living god, breathing in the surrounding emptiness. Human souls are alienated portions of the divine world-soul, immortal but repetitively embodied in various forms, including nonhuman species. Pythagoras taught the kinship of all life; accordingly, he regarded the animal sacrifices pervasive in Greek religion as parricidal. Pythagoreans even avoided eating anything that seemed to contain soul, such as fava beans.

Pythagoras, using the monochord, discovered that the musical scale instantiated certain whole-number ratios: the octave (2:1), the fifth (3:2), and the fourth (4:3). Because the integers in these ratios add up to ten, ten was regarded as the perfect number and the key to all mathematical truth. He evidently generalized the idea that music consists of numbers to everything else. (**Aristotle** wrote that the Pythagoreans claimed that all things – perceptible objects, souls, and even moral qualities – *are* numbers.) There are two fundamental principles: limit and unlimited. The cosmos and its contents are products of the imposition of limit on the unlimited, various kinds of thing being distinguished by different numerical formulae. Various qualities, including moral virtues, are just special types of mathematical harmony. Living an orderly, nonviolent, scholarly life insures better rebirths and eventual reunion with the cosmic soul. Pythagoras called this manner of living "philosophy" and himself a "philosopher," originating a sense of those terms subsequently adopted by Plato. Pythagoreans allegedly suppressed the proof that the hypotenuse of a right triangle whose other sides were numbers (*i. e.*, integers) could not be a number, since this anomaly contradicted their thesis that all things, including spatial magnitudes, are numbers. Plato subsequently avoided the problem by constructing the cosmos from geometrical, rather than arithmetical, units.

In applying his seminal discovery to astronomy, Pythagoras imputed musical form, as well as mathematical order, to the heavens. The idea behind the doctrine of the "harmony of the spheres" seems to be that the movements of such huge objects must make sounds; and, as the pitch of a vibrating string varies with its length, the pitch of a celestial object varies with the radius of its orbit. Pythagoras may have assigned the same three ratios he identified for strings to the stars, the Sun, and the Moon. Later Pythagoreans assigned other musical ratios to each of the known planets. We do not hear this celestial music because it is omnipresent and invariant, and our auditory apparatus only detects vibratory change. Obviously, music is temporal, and time itself seems to be a serial order of events. For Pythagoreans, time consists in the repetitive orbitings of the celestial bodies, themselves embodiments of harmonious numerical arrangements. In later Antiquity the "harmony of the spheres" was mostly a curiosity; but Pythagoras's belief that heavenly bodies must move in a constant and mathematically elegant way, despite observational evidence to the contrary, continued to dominate astronomical theory. The centuries-long project of "saving the appearances" of planetary retrograde motion by hypothesizing uniformly rotating nested spheres (**Eudoxus**, Aristotle) or a combination of uniformly rotating deferents and epicycles (**Apollonius**, **Hipparchus**, **Ptolemy**, even **Nicolaus Copernicus**) testifies to the persistence of Pythagoras's preference for uniform motion.

Q

Qabīṣī: Abū al-Ṣaqr ˁAbd al-ˁAzīz ibn ˁUthmān ibn ˁAlī al-Qabīṣī

Flourished **(Iraq), second half of the 10th century**

Qabīṣī, an astronomer and astrologer, came from one of two villages called Qabīṣa in Iraq. He studied **Ptolemy**'s *Almagest* under ˁAlī ibn Aḥmad al-ˁImrānī of Mosul, a mathematician and teacher, and dedicated several works (nos. 2, 3, 4, and 6, as given below) to Sayf al-Dawla, the Ḥamdānid Emir of Aleppo between 945 and 967. Otherwise, details of Qabīṣī's life are little known.

Qabīṣī's extant works are the following:

(1) A commentary on **Farghānī**'s *Kitāb al-fuṣūl* (also referred to as *Kitāb fī jawāmiˁ ˁilm al-nujūm*).
(2) A treatise on the distances and volumes of the planets (*Risāla fī 'l-abˁād wa-'l-ajrām*). This treatise provides distances and volumes for the planets other than those of the Sun and the Moon, which had already been given in the *Almagest*. Qabīṣī's account of Mercury was quoted twice by **Bīrūnī** in his *al-Qānūn al-masˁūdī* (Vol. X, Chap. 6).
(3) Book on the introduction to astrology (*Kitāb al-mudkhal ilā ṣināˁat aḥkām al-nujūm*), comprising five chapters. Qabīṣī's most famous work, this book is preserved in several Arabic manuscripts and in a Latin translation of which there are more than 200 manuscripts as well as 12 editions printed between 1473 and 1521. His text was the main book used in universities in the medieval Latin world where astrology was taught as part of the curriculum in medicine.
(4) A treatise for the examination of astrologers (*Risāla fī imtiḥān al-munajjimīn*). This treatise contains 30 astronomical or astrological questions and answers. Qabīṣī divides astrologers into four categories according to their intellectual level: The complete astrologer; the one who knows facts such as the shape of the celestial sphere but can not prove them; the astrologer who accepts things uncritically, like a blind man – the majority of astrologers fall into this category; and one who does not know anything about astronomy and astrology, relying only upon the operations of instruments.
(5) A work on the conjunction of the planets in the zodiacal signs and their prognostications for the revolutions of the years is attributed to Qabīṣī in Latin (*De coniunctionibus planetarum in duodecim signis et earum pronosticis in revolutionibus annorum*).
(6) A mathematical work in Arabic on numbers.

Qabīṣī wrote several other works that are not extant. We know of them because he refers to them in his surviving works. These include a treatise on the size of the Earth, referred to in (2) and (6) as *Risāla fī masāfat al-arḍ*, part of which is quoted at the end of (6); a book on the explanations of astronomical tables, referred to in (2) as *Kitāb fī ˁilal al-zījāt*; a book on affirming the validity of astrology, referred to in the preface of (3) as *Kitāb fī ithbāt ṣināˁat aḥkām al-nujūm*, which was a response to the criticism of astrology by ˁAlī ibn ˁĪsā, an astronomical instrumentmaker of the 9th century; *Kitāb fī al-namūdārāt*, *i. e.*, a book on the *namūdār*s, the method to fix a person's ascendant when the time of birth is unknown, referred to in the fourth chapter of (3); and a book referred to in the introduction of (4) as *Shukūk al-Majisṭī* (Doubts on the *Almagest*).

Qāḍīzāde al-Rūmī: Ṣalāḥ al-Dīn Mūsā ibn Muḥammad ibn Maḥmūd al-Rūmī

Born **Bursa, (Turkey), *circa* 1359**
Died **Samarqand, (Uzbekistan), after 1440**

Qāḍīzāde al-Rūmī was known for his works in mathematics and astronomy, which were used extensively as teaching texts. He left his native Bursa, where his grandfather had been a prominent judge and his father an eminent scholar, and traveled to Persia in order to gain a higher level of proficiency in the philosophical and mathematical sciences. His nickname indicates his family's standing (Qāḍīzāde = son of the judge) and his origins (Rūmī = from what had been part of the eastern Roman Empire). He studied with many learned scholars in Khurāsān and Transoxiana, among whom was the famous theologian **al-Sayyid al-Sharīf al-Jurjānī** at the court of Tīmūr in Samarqand. Qāḍīzāde, however, felt that Jurjānī was deficient in the mathematical sciences. After Tīmūr's death, Qāḍīzāde found both a student and a patron in Tīmūr's grandson **Ulugh Beg**, also in Samarqand.

Qāḍīzāde joined a group of scholars in the circle of Ulugh Beg that taught mathematics and astronomy, as well as other sciences. He became the head of the madrasa (school) of Samarqand, and Ulugh Beg often attended his lectures. Qāḍīzāde also became one of the directors of the Samarqand Observatory after the death of **Jamshīd al-Kāshī** in 1429, and he undertook its observational programs assisted by **ʿAlī al-Qūshjī**, who continued the program after Qāḍīzāde's death.

Qāḍīzāde was not known for his innovations or creativity. He was most famous for his commentaries on **Maḥmūd al-Jaghmīnī**'s astronomical compendium entitled *al-Mulakhkhaṣ fī ʿilm al-hay'a al-basīṭa* (1412) and **Shams al-Dīn al-Samarqandī**'s geometrical tract *Ashkāl al-ta'sīs* (completed: 1412); the large number of extant manuscripts of both commentaries indicates their enduring popularity as teaching texts. Therefore, it is not surprising that one also finds supercommentaries on Qāḍīzāde's commentaries written by many scholars–teachers including Sinān Pāshā (died: 1486), **ʿAbd al-ʿAlī al-Bīrjandī** (died: 1525/1526), **Bahā' al-Dīn al-ʿĀmilī** (died: 1621), and Qāḍīzāde's student **Fatḥallāh al-Shirwānī** (died: 1486). All of these individuals continued the tradition established at Samarqand, thereby disseminating the mathematical sciences throughout Ottoman and Persian lands. Also noteworthy is that the marriage of Qāḍīzāde's son to Qūshjī's daughter would eventually sire the famous Ottoman astronomer–mathematician **Mīram Čelebī** (died: 1525).

A number of other astronomical works are sometimes attributed to Qāḍīzāde, including a supercommentary on Ṭūsī's commentary (*taḥrīr*) of the *Almagest* and a treatise on the sine quadrant, but it is not clear which of these are authentic. The ascription of a commentary (*Sharḥ*) on **Naṣīr al-Dīn al-Ṭūsī**'s major astronomical work *al-Tadhkira fī ʿilm al-hay'a* (Biblioteca Medicea Laurenziana or. MS 271) to Qāḍīzāde is certainly not correct; this manuscript is actually an incomplete copy of the commentary by Jurjānī.

Among Qāḍīzāde's mathematical works is a treatise on determining the value of sin 1°, for which he seems to have relied heavily on the work of Kāshī. Qāḍīzāde's only philosophical or theological work is a supercommentary on **Athīr al-Dīn al-Abharī**'s *Hidāyat al-ḥikma*, although he intended to write a refutation of parts of Jurjānī's famous commentary on the Persian ʿAḍud al-Dīn al-Ījī's (*circa*: 1281–1355) *Mawāqif.*

Qāsim ibn Muṭarrif al-Qaṭṭān: Abū Muḥammad Qāsim ibn Muṭarrif ibn ʿAbd al-Raḥmān al-Qaṭṭān al-Ṭulayṭulī al-Qurṭubī al-Andalusī

Flourished **Cordova, (Spain), 10th century**

Qāsim ibn Muṭarrif al-Qaṭṭān may well represent the earliest astronomers in Islamic Spain (al-Andalus) of whom we have knowledge. Though known as a reciter of the Quran (*muqri'*) and traditionalist with the sobriquet *al-shaykh al-ra'īs* (Principal Shaykh), only one of his works is extant, a study of cosmological and astronomical subjects. However, in the biographical dictionaries there is no reference to Qaṭṭān's interest in cosmology or astronomy. From what we know of the lives of his teachers, we can deduce that he was born at the end of the 9th or the beginning of the 10th century. An analysis of Qaṭṭān's work offers only two chronological details: a quotation from **Maslama al-Majrīṭī** and the following statement in the title of the star table: "We found its longitude in the ecliptic in the year 300 of the Hijra" (912–913).

If the attribution is correct, Qaṭṭān's work, entitled *Kitāb al-hay'a* (Book on cosmology), would be the first extant Andalusī treatise on astronomy. The only known manuscript is preserved in the Süleymaniye Library in Istanbul (Carullah Efendi 1279, folios 315r–321v). The work is a compendium of all the Andalusī cosmological and astronomical knowledge of the time and draws upon a variety of traditions. The most prominent is that of eastern Islam, which flourished in the 10th century after successfully combining the old cosmology and astronomy of Greece and India. There are also echoes of an old Latin astrological tradition, still in use in the Iberian Peninsula.

The text consists of 30 numbered and five unnumbered chapters. The unnumbered chapters differ from the others in several aspects and do not seem to belong to the work. The chapters are as follows: 1–8: signs of the Zodiac and lunar mansions; 9–11: planets and cosmographical subjects; 12: stars; 13–16: Moon and Sun; 17–27: subjects related to the calendar, *i. e.*, years, months, days, hours (22 and 23 are devoted to clocks); and 28–30: description of the cosmos, both the superlunary and sublunary world. The other five chapters – the ones without numbering – deal with the Sun, the Moon, and terrestrial latitudes. Some of the chapters that purport to explain the physical structure of the cosmos show a clear dependence on **Aristotle**, while others draw upon **Ptolemy**, in particular on his *Planetary Hypothesis*, which very probably reached the author through the *Kitāb al-aʿlāq al-nafīsa* of the eastern geographer Abū ʿAlī Aḥmad ibn ʿUmar ibn Rustah.

The clocks described are a sundial, the description of which coincides almost word for word with the one found in the *Kitāb al-asrār fī natā'ij al-afkār* (Biblioteca Medicea Laurenziana, MS Misc. Or 152, folio 47r), explicitly attributed to **Ibn al-Ṣaffār**, one of Maslama's disciples. This clock is unlike extant Islamic clocks, although we know of at least two texts that describe a similar instrument (the *balāṭa* described in the *Zīj* by **Ibn Isḥāq al-Tūnisī** and the one in the commentary to the *Mišná* by **Maimonides**). These clocks seem to date back to biblical times. The second one, called *thurayya*, is a "fire clock" because the hours are indicated by the burning of oil. A description of a similar clock is found in a work by a certain Yūnus al-Miṣrī. Qaṭṭān's clock derives from a clock calculated for Baghdad, which probably reached al-Andalus through Tunis, perhaps thanks to the well-known epistolary relationship between Ḥasdāy ibn Shaprut of Cordova, and the Tunisian **Dunash ibn Tamīm**.

The star table contains 16 stars. It is a standard table of the kind that accompanies a treatise for constructing an astrolabe, although, in view of the errors found, it was probably derived from a reading of the coordinates of an instrument calculated for Cordova, namely ecliptic coordinates (longitude and latitude) and the degree of the zodiac that rises with a star and diurnal arc. It is the first star table documented in al-Andalus and is clearly influenced by **Battānī** and Maslama.

In a number of chapters there are signs that the author does not have a thorough understanding of the field. However, the work is important because it demonstrates the emergence of astronomical and cosmological knowledge from a range of traditions in 10th-century al-Andalus, the period in which science was beginning to develop in this area. Although the author is Andalusī, the manuscript is eastern, suggesting that it reached a fairly wide readership. The text is largely nonspecialist and was probably used in the nonscientific circles in which the author undoubtedly moved.

Qaṭṭān al-Marwazī: ʿAyn al-Zamān Abū ʿAlī Ḥasan ibn ʿAlī Qaṭṭān al-Marwazī

Born **Marw (Merv, Turkmenistan), 1072/1073**
Died **Marw (Merv, Turkmenistan), October 1153**

Qaṭṭān al-Marwazī was a prominent scholar of the 11th and 12th centuries, whose only extant work, a treatise on astronomy, entitles him to be ranked among the leading observational astronomers of his age. He was born in Marw, an ancient city in Persia, which had become by then one of the most prosperous cities of Great Khurāsān, a vast and flourishing province on the eastern borders of the Islamic world and home to many outstanding scientists, philosophers, religious scholars, saints, and mystics. At the time Marw had ten large public libraries, one of them housing 12,000 books.

Living in a city with a rich cultural milieu, Qaṭṭān al-Marwazī grew up to become an expert in many fields of science and wisdom. Like other erudite and encyclopedic savants of the Islamic Middle Ages, he wrote books in most areas of knowledge including astronomy, medicine, prosody, engineering, and literature. His writings were regarded highly among the learned circles of Marw. Though well versed in different disciplines, Qaṭṭān al-Marwazī's main occupation was medicine.

Sources describe Qaṭṭān al-Marwazī as a master of Greek sciences and an ardent exponent of Greek philosophy. Being a student of Lawkarī, who himself was a student of Bahmanyār, the most distinguished disciple of **Ibn Sīnā**, Qaṭṭān al-Marwazī belongs to the third generation of scholars who have fully benefited from the Avicennian tradition.

None of Qaṭṭān al-Marwazī's numerous writings, however, have survived save a book on astronomy written in Persian and entitled *Gayhānshenākht* (Knowledge of the Cosmos). According to the author, the book was so titled because "he who understands this book will have a coherent knowledge of the configuration of the cosmos, and its system will be clear to him." The book, however, is not confined to cosmology in the proper sense of the term, but, as is usual for the works of its genre in the Islamic tradition, covers a wider range of subjects such as the configuration of the Earth and certain topics in geography. Therefore, it falls within the context of cosmographical works. Furthermore, the treatise also includes what we usually find in the works dedicated to the calendar and issues related to the "passage of time." The book, therefore, comprises a range of topics from the celestial movements, eccentrics and epicycles, apogees, planetary sectors, the ecliptic, the fixed stars, lunar and solar eclipses, the meridian, and the azimuth to the sizes of the Earth and other planets, chronology, and even some minor hints regarding astrology.

Gayhānshenākht may thus be placed within the corpus of what was known as *hay'a basīṭa*, *i. e.*, plain or simplified astronomy. These works were simplified forms and summaries of astronomy that gave a coherent and unified account of the discipline. The main audience for such works were ordinary, educated people for whom astronomy had a greater appeal than other sciences, in part because of its applications in religious matters, and in part because it dealt with the realm of the unknown. Therefore, despite the fact that Arabic was the prime language of science and letters throughout Islamdom, Qaṭṭān al- arwazī, out of an inner obligation, chose to write a simple and easy-to-understand book on astronomy in Persian for the educated public and for beginners who wished to have a share of the art.

Qaṭṭān al-Marwazī seems to have been involved in other aspects of astronomy. His status as an observational astronomer is well established by the fact that he mentions in several places his engagement with astronomical measurements. Furthermore, Qaṭṭān al-Marwazī claims to have written other books on astronomy, including a *zīj* or astronomical handbook, which requires direct participation of the observer. Nevertheless, his interest was not limited to pure astronomy, a science that in his view "is based on certitude and demonstration" and "into which no discrepancy shall find a way." He shows interest in astrology as well, which for him is "a science of analogy and conjecture." By this, however, Qaṭṭān al-Marwazī does not mean to belittle astrology but rather to place each within its own proper domain, since he promises to write a book on that subject, too.

Despite the very little information available to us about the man and his works, we may conclude that Qaṭṭān al-Marwazī was one of the most prominent scientific figures of his time. In a series of correspondences between him and Rashīd al-Dīn Waṭwāṭ, himself a great literary figure of his age, Rashīd al-Dīn Waṭwāṭ does not fail to acknowledge him as "a scholar for whom not even a minute replica can be found across either east or west" even though the author is being accused by Qaṭṭān al-Marwazī of plundering his library. Furthermore, his stature as a great astronomer may be substantiated by the fact that two centuries later Ibn Taymiyya, a renowned religious scholar in Damascus, singles out Qaṭṭān al-Marwazī's name as someone very skillful in astronomy, while discussing the question of lunar crescent visibility.

A clan of the Turkish Ghuzz (Oghuz) tribe from eastern Asia invaded Marw. Being taken captive, Qaṭṭān al-Marwazī is said to have shouted words of insult at his captors, which led to his tragic death. They tortured him to death by filling his mouth with soil.

Qian Lezhi

Flourished **China, 5th century**

Qian Lezhi, an astronomer of the Liu-Song dynasty (420–479) of the Southern Dynasties (420–589), made detailed armillary spheres that replicated the motion of the sky. About his life we know nothing except that he was the *Taishiling*, the highest official of the Imperial Bureau of Astronomy and Calendrics.

In 436, by command of the emperor, Qian Lezhi made a copper armillary sphere. Historical materials about the device show that the "armillary" was not a real armillary sphere, but a celestial globe demonstrating the apparent motions of celestial bodies. The device was constructed mainly of rings, with a small sphere in the center representing the Earth. Both diameters of the equatorial and ecliptic rings were 6.08 *chi*. (One *chi* equaled about 24 cm during this period.) The circumference of each ring was 18.26 *chi*. One *du* in the sky – ancient Chinese divided the circle into 365 *du* – corresponded to 0.05 *chi* along the circumference of the rings. There was a polar axis paralleling the rotation axis of the Earth. Semicircular rings representing the longitudes of the lunar mansions connected vertically to the equatorial ring. In the area of the North Celestial Pole, the Big Dipper and pole star were shown, but sources do not mention how they were fixed on the device. It is possible that dots representing the Big Dipper and the pole star appeared at the corresponding places. The Sun, the Moon, and five planets (Venus, Jupiter, Mercury, Mars, and Saturn) were fixed on the ecliptic ring.

Besides this device, there was a clepsydra or waterclock connected to the celestial globe, which was also driven by water from the water clock so that the celestial part of the globe moved synchronously with the rotation of the Earth. Therefore, the device could demonstrate the apparent motion of celestial bodies.

Qian Lezhi's thoughts on the design of the instrument were apparently influenced by astronomers **Zhang Heng**, and especially, Ge Heng (3rd century). Ge Heng made an "armillary sphere," which was actually also a moving celestial globe, with an unmoving sphere representing the Earth installed inside the globe itself.

In 440, Qian Lezhi made another, smaller "armillary sphere" that was 2.2 *chi* in diameter. On the surface of the sphere, the lunar mansions and other asterisms were indicated, and the Sun, Moon, and five planets were fixed on the ecliptic. In ancient atlases such as those of **Gan De**, **Shi Shen**, and Wu Xian, the stars were indicated by black dots. Adapting **Chen Zhuo**'s method, Qian Lezhi used white, black, and yellow pear shapes. Some sources say that other color combinations, such as red, black, and white, were used.

Quetelet, Lambert Adolphe Jacques

Born **Ghent, (Belgium), 22 February 1796**
Died **Brussels, Belgium, 17 February 1874**

Lambert Quetelet became one of the most influential social statisticians of the 19th century, but is also remembered for his studies of meteor showers and their apparent radiants.

Quetelet was the son of François-Augustin-Jacques-Henri Quetelet and Anne Françoise Vandervelde. He was educated at the lyceum of his native town. In 1815, when that school was converted to the College of Ghent, he was appointed a professor of mathematics. In 1819 Quetelet was awarded the institution's first Ph.D., for a dissertation on the theory of conic sections. That same year, he was appointed professor of mathematics at the Athenaeum of Brussels, and was soon elected to the Royal Academy of Sciences and Arts. Quetelet was married in 1825; he and his wife had two children.

During the 1820s, Quetelet began a campaign to found an observatory in Belgium. Upon this suggestion, he was commissioned to go to Paris and study the practice of astronomy under **Dominique Arago**, director of the Paris Observatory. While there in December 1823, Quetelet observed a subdivision in the A-ring of Saturn, using the observatory's 10-in. achromatic refractor. He also learned probability theory from Jean Baptiste Joseph Fourier and **Pierre de Laplace**. Belgium's Royal Observatory was not completed until 1833, although Quetelet served as its director after 1828. There, he gave special attention to meteorological and geophysical observations.

Following the very intense Leonid meteor shower of 12/13 November 1833, Quetelet's attention was directed toward the occurrence and annual periodicity of meteor showers. In March 1837, he predicted the return of the Perseid meteors during the coming August. That same year, Quetelet produced the first catalog of historical sightings of this shower. Over time, he amassed more than 300 records of the appearance of this and other suspected meteor showers. Quetelet, however, was not alone in his recognition of the Perseid meteors. Two Americans, Connecticut bookseller **Edward Herrick** and Cincinnati physician **John Locke**, had independently documented the shower's annual nature. Quetelet is also regarded as the codiscoverer of the Orionid and Quadrantid meteor showers.

Quetelet's other astronomical (and meteorological) observations included numerous solar and lunar eclipses, planetary and stellar occultations, the aurora borealis (and its magnetic anomalies), comets, asteroids, and bolides. He determined the longitude difference between Brussels and other European observatories by means of telegraph signals. A catalog of more than 10,000 stars, observed by Quetelet and his associates between 1857 and 1878, was published by his son Ernest in 1887.

Quetelet's most famous work, *On Man and the Development of His Faculties: A Treatise on Social Physics* (1835), laid the foundations of sociology and introduced his concept of the "average man." In 1853, he organized the first international statistics conference and was appointed its president. Toward the end of his life, Quetelet published several histories of the physical and mathematical sciences in Belgium. At the time of his death, he was regarded as Belgium's most revered scholar.

Qunawī: Muḥammad ibn al-Kātib Sīnān al-Qunawī

Born **Probably Istanbul, (Turkey)**
Died **Istanbul, (Turkey), *circa* 1524**

Muḥammad al-Qunawī, astronomer and *muwaqqit* (timekeeper), lived in Istanbul and pioneered the Turcification movement of the Greco–Hellenic and classical Islamic astronomical literature. Very little is known about his life. However, Qunawī's name indicates that he came from Qunya (Konya, Turkey). Sīnān, his father, served in the Ottoman State Chambers as a scribe, and so he became known as Ibn Kātib Sīnān, *the son of Sīnān the Scribe*.

In his work entitled *Kitāb al-Aṣl al-muʿaddil,* Qunawī states that "he had met all the important astronomers of the time" (Istanbul Archeology Museum, MS 1255/4, 156b). These would have been from among his Ottoman intellectual circle of friends and students who had studied both the astronomical works of **ʿAlī al-Qūshjī**, thus connecting them with the mathematical–astronomical tradition of Samarqand, and the achievements of *ʿilm al-mīqāt* (astronomical timekeeping) of classical Islam, which had reached its apex with the works of **Khalīlī** and **Ibn al-Shāṭir** in 14th-century Damascus.

After completing his education, Qunawī worked for some time as the official *muwaqqit* in several religious institutions including the New (Yeni) Mosque in Edirne. In this capacity, he offered several works in the service of various Sultans: his *Hadiyyat al-mulūk* to Sultan Bāyazīd II, his *Faḍl al-dā'ir* to Sultan Selīm I, and his *Mīzān al-Kawākib* to Sultan Süleymān I (the Magnificent).

Qunawī wrote 11 books on astronomy: seven in Arabic and four in Turkish. Thus his works were not confined to the Turkish-speaking areas of Istanbul, the Balkans, and Anatolia, but could be used in Arabic-speaking areas, such as Cairo, Egypt, as well. Qunawī's works in Turkish provide us with insight into the growing needs of the Ottoman state bureaucracy. In fact, the word *al-Ihkwān* (usually meaning "brothers"), mentioned in the title of his Turkish book *Hadiyyat al-ihkwān,* actually refers to the *muwaqqit*s, who were part of this bureaucracy. Qunawī's Turkish writings helped inculcate an attitude among Ottoman astronomers that contributed to the translation of the Hellenic and Islamic astronomical heritage from Arabic and Persian into Turkish from the beginning of the 16th century onward and paved the way for the Turcification of the language of astronomy.

Most of Qunawī's works were devoted to timekeeping and astronomical instruments. He was thus following one particular tradition of Islamic astronomy whereby it was "in service" to religious, administrative, and social needs of Islamic civilization that placed a high value on precise calculations (dependent upon the mathematical sciences, especially astronomy) and instruments for attaining them. These were used for regulating the prayer times, determining the *qibla* or local direction to Mecca, and ascertaining the beginning and the end of important national and religious days and months (*e. g.*, the month of Ramadan). Each locality needed its own set of tables and calculations, and Qunawī's were for the capital city of Istanbul. Among his achievements, he simplified the standard usage of astronomical instruments, especially quadrants (*al-rubʿ al-mujayyab, rubʿ al-muqanṭarāt*, and *rubʿ al-dā'ira*), and he invented a new method for astronomical calculations in his *al-Aṣl al-muʿaddil.* Qunawī also translated the introductory part of Khalīlī's *mīqāt* tables (which provided solutions to all the standard problems of spherical astronomy for all latitudes) under the title *Tarjamah-i jadāwil-i āfāqī* or *Tarjamah-i risāla fī al-awqāt al-khamsa wa-jadāwil al-raṣad.* To the group of tables that Khalīlī prepared for each degree of latitude, he added a special table for an unknown location at latitude 40° 30′ N.

In the preface to his *Tarjamah-i jadāwil-i āfāqī*, Qunawī says "some of our sons wanted, from this poor man, to learn about sine tables; and so we translated this work into Turkish ..." (Süleymaniye Library, Ayasofya MS 2594, 1b). This is an indication that he was teaching astronomy courses in the *muwaqqithāne*s (timekeeping institutions attached to mosques) and that the language for learning and education was Turkish.

Qunawī's Arabic work entitled *Mīzān al-kawākib* contains time calculation tables by means of stars; the tables have over 500 pages, and include nearly 250 million registers. The main tables show the time from sunset (evening) to sunrise, dawn, and midday for a degree of solar longitude and full vertical rise. One can simply observe a star reaching the last point instantly and also read its rise from a different table prepared by the author; one can enter solar longitude through the rise on the main table and determine the nighttime. According to D. King (1986, p. 248), these tables represent an original Ottoman contribution in determining the astronomical time *via* tables.

After his death, Qunawī's works were developed further by **Muṣṭfā ibn ʿAlī al-Muwaqqit**, the chief astronomer to Sultan Süleymān the Magnificent.

Qūshjī: Abū al-Qāsim ʿAlāʾ al-Dīn ʿAlī ibn Muḥammad Qushči-zāde

Born **probably Samarqand, (Uzbekistan)**
Died **Istanbul, (Turkey), 1474**

ʿAlī al-Qūshjī was a philosopher–theologian, mathematician, astronomer, and linguist who produced original studies in both observational and theoretical astronomy within 15th-century Islamic and Ottoman astronomy. He contributed to the preparation of **Ulugh Beg**'s *Zīj* at the Samarqand Observatory, insisted on the possibility of the Earth's motion, and asserted the need for the purification of all the scientific disciplines from the principles of Aristotelian physics and metaphysics.

Qūshjī was the son of Ulugh Beg's falconer, whence his Turkish name Qushči-zāde. He took courses in the linguistic sciences, mathematics, and astronomy as well as other sciences taught by scholars in the circle of Ulugh Beg. These included **Jamshīd al-Kāshī**, **Qāḍīzāde al-Rūmī**, and Ulugh Beg himself. It has been claimed that he was also taught by **al-Sayyid al-Sharīf al-Jurjānī**; if so, Qūshjī would have been quite young.

In 1420, Qūshjī secretly moved to Kirmān where he studied astronomy (*circa* 1423-1427) with Mollā Jāmī as well as the mathematical sciences. Upon his return to Samarqand *circa* 1428, Qūshjī presented Ulugh Beg with a monograph *(Ḥall ishkāl al-muʿaddil li-l-masīr)* in which he solved the problems related to Mercury; Ulugh Beg was reported to have been quite pleased. Sources say that Ulugh Beg referred to Qūshjī as "my virtuous son" (= "ferzend-i ercümend" [Nuruosmaniye MS 2932, f. 2b]). Indeed, after the death of Qādīzāde, it was Qūshjī whom Ulugh Beg commissioned to administer the observational work at the Samarqand Observatory that was required for his *Zīj* (astronomical handbook). Qūshjī, often referred to as "ṣāḥib-i raṣad" (head of observation), contributed to the preparation and correction of the *Zīj*, but it is unclear to what extent and at what stage. This question becomes especially problematic in view of Qūshjī's criticisms of it, and his pointing out of mistakes, in his *Sharḥ-i Zīj Ulugh Beg* (Commentary on Ulugh Beg's *Zīj*).

Upon Ulugh Beg's death in 1449, Qūshjī, together with his family and students, spent a considerable time in Herat where he wrote his theological work, *Sharḥ al-Tajrīd*, a commentary to **Naṣīr al-Dīn al-Ṭūsī**'s work *al-Tajrīd fī ʿilm al-kalām,* which he presented to the Timurid Sultan Abū Saʿīd. After Abū Saʿīd's defeat by Uzun Ḥasan in 1469, Qūshjī moved to Tabrīz where he was welcomed by the latter. It is said that Qūshjī was sent to Istanbul to settle a dispute between Uzan Ḥasan and Mehmed the Conqueror; after accomplishing the mission, he returned to Tabrīz. However, around 1472, Qūshī, together with his family and students, left permanently for Istanbul either on his own or because of an invitation from Sultan Mehmed.

When Qūshjī and his entourage approached Istanbul, Sultan Mehmed sent a group of scholars to welcome them. Sources say that in crossing the Bosporus to Istanbul, a discussion ensued about the causes of its ebb and flow. Upon arrival in Istanbul, Qūshjī presented his mathematical work entitled *al-Muḥammadiyya fī al-ḥisāb* to the Sultan, which was named in his honor.

Qūshjī spent the remaining two to three years of his life in Istanbul. He first taught in the Ṣaḥn-i Thamān Madrasa (founded by Sultan Mehmed); then he was made head of the Ayasofya Madrasa. In this brief period, Qūshjī educated and influenced a large number of students, who, along with his writings were to have an enormous impact on future generations. He was buried in the cemetery of the Eyyūb mosque.

Qūshjī, especially when compared with his contemporaries such as Kāshī and Qāḍīzāde, was a remarkable polymath who excelled in a variety of disciplines including language and literature, philosophy, theology, mathematics, and astronomy. He wrote works in all these fields, producing books, textbooks, and short monographs dealing with specific problems. His commentaries often became more popular than the original texts, and themselves became the subject of numerous commentaries. Thousands of copies of Qūshjī's works are extant, many of which were taught in the madrasas.

Qūshjī's philosophy of science, which had important repercussions for the history of astronomy, is contained in his commentary to **Ṭūsī**'s *Sharḥ al-Tajrīd.* Besides being one of the most important theological works in Islam, Qūshjī lays down the philosophical principles of his conception of existence, existents, nature, knowledge, and language. As for the mathematical sciences, Qūshjī in general tried to free them from hermetic–Pythagorean mysticism and to provide an alternative to Aristotelian physics as the basis for astronomy and optics. He sought to define body (*jism*) as being predominantly mathematical in character. Qūshjī claimed that the essence of a body is composed of discontinuous (atomic) quantity while its form consists of continuous (geometrical) quantity. When a body is a subject of the senses, it then gains its natural properties (qualifications).

One consequence of Qūshjī's anti-Aristotelian views was his striking assertion that it might well be possible that the Earth is in motion. Here Qūshjī followed a long line of Islamic astronomers who rejected **Ptolemy**'s observational proofs for geostasis; Qūshji, though, refused to follow them in depending on **Aristotle**'s philosophical proofs, thus opening up the possibility for a new physics in which the Earth was in motion. Qūshjī's views were debated for centuries after his death, and he exerted a profound influence on Ottoman–Turkish thought and scientific inquiry, in particular through the *madrasa* and its curriculum. His influence also extended to Central Asia and Iran, and it has been argued that he may well have had an influence, either directly or indirectly, upon early modern European science to which his ideas bear a striking resemblance.

Qūshjī wrote five mathematics books, one in Persian and four in Arabic. His *Risāla dar ʿilm al-ḥisāb* (Persian), written during his stay in Central Asia (along with his enlarged Arabic version of this work, *al-Risāla al-Muḥammadiyya fī al-ḥisāb*), were taught as a mid-level textbook in Ottoman *madrasas*. In these works, in accordance with the principles he laid down in the *Sharḥ al-Tajrīd*, he tried to free mathematics from hermetic–Pythagorean mysticism. As a result, Ottoman mathematics took on a practical character, which hindered traditional studies such as the theory of numbers.

In the field of astronomy, one of Qūshjī's most important contributions is in the observational program for the *Zīj-i Ulugh Beg* and in his corrections to the work, both before and after publication. In addition, he has nine works on astronomy, two in Persian and seven in Arabic. Some of them are original contributions while others are pedagogical. In his theoretical monograph entitled *Ḥall ishkāl al-muʿaddil li-l-masīr*, Qūshjī criticizes and corrects opinions and ideas pertaining to Mercury's motions mentioned in Ptolemy's *Almagest*. Another work is his *Risāla fī anna aṣl al-khārij yumkinu fī al-sufliyayn* that deals with the possibility of using an eccentric model for Mercury and Venus, which, as he says, goes against both Ptolemy and **Quṭb al-Dīn al-Shīrāzī**.

Qūshjī's *Risāla dar ʿīlm al-hay'a* (Persian), written in Samarqand in 1458, was commonly used as a teaching text; there exist over eighty manuscript copies of it in libraries throughout the world. It was also translated into Turkish. Two commentaries were written on it, one by **Muṣliḥ al-Dīn al-Lārī**, the other by an anonymous author. Lārī's commentary was widely taught in Ottoman *madrasas*. Qūshjī's *Risāla* was also translated into Sanskrit and thus represents the transmission of Islamic astronomy to the Indian subcontinent. Qūshjī wrote an enlarged version of the work in Arabic under the name *al-Fatḥiyya fī ʿilm al-hay'a,* which was presented to Sultan Mehmed in 1473. This work was taught as a middle-level textbook, and was commented on by Gulām Sinān (died: 1506) and Qūshjī's famous mathematician-astronomer great-grandson **Mīram Čelebī**. It was also translated into Persian by Muˁīn al-Dīn al-Ḥusaynī and into Turkish by Seydî Ali Reîs. In the *Risāla* and the *Fatḥiyya*, Qūshjī followed the principles he had laid down in his *Sharḥ al-Tajrīd* and excluded an introductory section on Aristotelian physics that had customarily introduced almost all previous works of this kind.

Quṣṭā ibn Lūqā al-Baˁlabakkī

Born **Baˁlabakk, (Lebanon), probably *circa* 820**
Died **(Armenia), probably *circa* 912–913**

Quṣṭā ibn Lūqā (Constantine, son of Loukas), a scholar of Greek Christian origin working in Islamic lands in the 9th century, did work in astronomy that included translations of Greek astronomical works and original compositions. In addition, he composed and translated mathematical, medical, and philosophical works. Quṣṭā's scholarly reputation extended far and wide, and he was noted for his scientific achievements (especially in medicine, where his authority surpassed **Ḥunayn ibn Isḥāq** according to the bibliographer Ibn al-Nadīm [died: *circa* 990]). He reportedly collected Greek scientific manuscripts from Byzantine lands; his translations and revisions of these formed an important part of his scholarly activities. Qusṭā was fluent in Greek (as well as Syriac), as demanded by his scientific translations, and he also mastered Arabic, a language in which he produced many original scientific compositions. Quṣṭā's scholarly career, which was centered in Baghdad, is notable for his association with numerous patrons, who are particularly important for establishing his biography as well as the chronology of his work. These include various members of the ˁAbbāsid caliphal family, government officials, and a Christian patriarch; the most likely interpretation of the evidence places the bulk of his work in the second half of the 9th century.

The scientific works of Qusṭā include several astronomical compositions, which cover both the theoretical and the practical aspects of astronomy. The best known are:

(1) *Kitāb fī al-ˁamal bi-ʾl–kura al-nujūmiyya* (On the use of the celestial globe; with some variations as to title), which contains 65 chapters and was widely disseminated through at least two Arabic recensions as well as Latin, Hebrew, Spanish, and Italian translations;
(2) the extant astronomical work, *Hayʾat al-aflāk* (On the configuration of celestial bodies; Bodleian Library MS Arabic 879, Uri, p. 190), which is one of the earliest compositions in theoretical (*hayʾa*) astronomy;
(3) *Kitāb al-Madkhal ilā ˁilm al-nujūm* (Introduction to the science of astronomy – astrology);
(4) *Kitāb al-Madkhal ilā al-hayʾa wa-ḥarakāt al-aflāk wa-ʾl-kawākib* (Introduction to the configuration and movements of celestial bodies and stars);
(5) *Kitāb Fī al-ˁamal bi-ʾl-asṭurlāb al-kurī* (On the use of the spherical astrolabe; Leiden University Library MS Or. 51.2: *Handlist*, p. 12); and
(6) *Kitāb Fī al-ˁamal bi-ʾl-kura dhāt al-kursī* (On the use of the mounted celestial sphere).

The two introductory astronomical titles (3 and 4), reported in the lists of Ibn al-Nadīm's *Fihrist* and Ibn Qifṭī (died: 1248), respectively, are not extant, unless the latter is the same as the theoretical work mentioned in (2). F. Sezgin suggests that these two works are the same; however, they are listed as two distinct titles by Ibn Abī Uṣaybiˁa (died: 1269). Work (5) is sometimes questioned as a work by Qusṭā but seems to represent a variation in title of (1). Although E. Wiedemann (1913) treats (6) as an independent work, it also seems to be a variation in title of (1). This leaves Qusṭā with at least four distinct astronomical compositions, two of which (1 and 2) are extant.

Qusta's works also include translations of the so called Little Astronomy or "Intermediate Books" (*Kutub al-mutawassiṭāt*), texts studied after Euclidean geometry in preparation for Ptolemaic astronomy. Extant among these are the Arabic versions of **Theodosius**'s *Spherics* (*Kitāb al-Ukar*) and **Autolycus**'s *Rising and Setting* [*of Fixed Stars*] (*Kitāb al-Ṭulūˁ wa-ʾl-ghurūb*). In addition to other extant translations, such as Hero of Alexandria's "On the Raising of Heavy Objects" (*Fī rafˁ al-ashyāʾ al-thaqīla*), Qusṭā is associated with Arabic versions of **Aristotle**'s *Physics* as well as the later commentaries of Alexander of Aphrodisias and **Philoponus** on certain of their books. This dual translation program fits well with his statements about the "cooperation" of natural philosophy and geometry in optics as a mixed mathematical science, a genre to which astronomy and mechanics also belong.

R

Rāghavānanda Śarman

Flourished **Rāḍha, Bengal, (India), 1591–1599**

Rāghavānanda Śarman was a Brāhmaṇa who followed the Saurapakṣa school of astronomy. He composed several astronomical works in the late 16th century, including the *Viśvahita*, a set of astronomical tables whose epoch is 1591; the *Dinacandrikā*, another set of astronomical tables whose epoch is 1599; and the *Sūryasiddhāntarahasya*, a commentary on the *Sūryasiddhānta*, written in 1591. Little is known of these three works though they have been published.

Raimarus Ursus

➤ **Bär, Nicholaus Reymers**

Rainaldi, Carlo Pellegrino

➤ **Danti, Egnatio**

Ramée, Pierre de la

➤ **Ramus, Peter**

Ramus, Peter [Petrus]

Born **Cuts, (Oise), France, 1515**
Died **Paris, France, 26 August 1572**

Peter Ramus rejected scholasticism and outlined new ways to view and to teach knowledge, influencing astronomy's transition from medieval to modern form. He was born in an impoverished noble family originally from Liège. There appears to have been little that was unusual about Ramus's early education. At around 12, after two unsuccessful attempts to enter the University of Paris, he enrolled at the Collège de Navarre, where he earned money working as a servant to wealthier peers. Having to attend school as a day student, however, meant that Ramus did not complete his master of arts until he was 21. Of special benefit was the friendship that Ramus then forged with his later patron, Charles de Guise, who was to become Cardinal of Lorraine and, eventually, of Guise. The support of Guise disappeared after Ramus's conversion to Protestantism around 1562, but the long and active intervention of the cardinal on Ramus's behalf was responsible for much of the fame he gained during his life.

Ramus's career began sedately enough as an instructor at the Collège du Mans, but he soon moved, with his longtime collaborator in rhetoric, Omer Talon, to the Collège de l'Ave Maria, also in Paris. There, in 1543, Ramus published the first of many attacks on Aristotelian and scholastic education that would make him notorious and that led directly or indirectly to his death. Ramus's assertion that the medieval approach to learning, with its long tradition of minutely analyzing and carefully commenting on selected classical authors, was bankrupt proved scandalous to the faculty of Paris, and in short order they secured a ban on his teaching of dialectic (the rhetorical practice of logical principles).

This edict simply led Ramus to concentrate his efforts on the instruction of eloquence and mathematics. He was forced to teach himself the latter subject, since it had been minimal in his university curriculum. But taken together, the two apparently disparate disciplines reveal exactly how much of Ramus's work remains entrenched in premodern modes of thought. To Ramus, the study of numbers and the study of literature were but two aspects of one unified and coherent body of knowledge, which in all its facets was directed only at "disputing well," as he put it in his 1543 *Structure of Dialectic*.

The prospects of Ramus began to improve in 1545 when he was invited to become an instructor at the more prestigious Collège de Presles, where Talon again joined him. Ramus was shortly thereafter promoted to principal of the school and in 1547, following the succession of Henry II to the throne and the subsequent elevation of Charles de Guise in the estimation of the court, all restrictions on Ramus's teaching were lifted; he was left entirely free to comment on the whole range of university subjects. In 1551, he was made a *regius* professor of eloquence and philosophy – the only time these two fields were combined under one title. In 1565, he was chosen dean of the *regius* professors, who came collectively to be called the Collège de France and who, as a body, had been intended by Francis I to represent a humanistic alternative to the resolutely scholastic education of the University of Paris. After this, his fortunes began to decline, falling slowly at first and then precipitously. Suspected even in the late 1550s of being a secret Protestant, Ramus had to flee Paris for Fontainebleau under royal protection during the religious troubles of 1562. He returned in 1563, but having made his conversion public in the intervening year, Ramus entered the city this time without the critical support of Guise. Harried by a growing number of antagonists, Ramus left Paris again in 1567 and again took refuge with a sympathetic member of the royal family.

From 1568 to 1570, Ramus toured the prominent Protestant centers of learning in Germany and Switzerland. During these years, too, he began to broaden his vision of pedagogical reform and wrote on subjects ranging from theology to astronomy. He found the academic atmospheres of Heidelberg and Geneva, though, uncertain at best and returned to Paris for the last time in 1570. The royal family, especially the queen mother, continued to defend Ramus publicly, but he was murdered during the Saint Bartholomew's massacre.

Ramus does not very directly affect the history of astronomy, but his work was influential throughout the 17th and 18th centuries in Europe and America in a surprising number of ways. The topical organization of many modern encyclopedias can be traced to his interest in systematic thought, and **Francis Bacon**'s search for an inductive method is in part attributable to his own youthful interest in Ramus's writing. Primarily, Ramus advocated a regular approach to the study of any given subject. He believed that all realms of knowledge could be construed schematically, and that any discipline of learning would conform to three "laws" of universality, homogeneity, and generality. In other words, a "natural method" of learning would be observably true in every posited application of the art or science, specific in its description, and arranged in such a way as to exhibit the general truths on which it was based.

Ramus considered astronomy a branch of physics and, as such, part of the quadrivium of the university curriculum. Characteristically, he did develop a chart of physics, in which the stars (still very much after the manner of **Aristotle**) were classed as elements of constant simple matter, opposed to the immaterial essences of God and intelligence. Beyond this, Ramus seems merely to have appreciated astronomy as an application of mathematics, though he was critical of both **Nicolaus Copernicus** and **Ptolemy** for propounding their respective theories of the Solar System without observation. Copernicus thus had violated the first law of method. It is, in the end, one of the most telling marks of Ramus's influence that **Johannes Kepler** later claimed, with evident pride, that his own work had at last satisfied the demands of Ramus on astronomy.

Raṅganātha I

Flourished **Kāśī, (Vārānasi, Uttar Pradesh, India), 1603**

Raṅganātha I was born into a family of astronomers; his father was Ballāla. Raṅganātha I wrote a popular Sanskrit commentary, the *Gūḍhārthaprakāśikā* (1603), on the anonymous *Sūryasiddhānta* (10th or 11th century), one of the most popular astronomical works in Sanskrit. Raṅganātha I's son, Munīśvara, was also an astronomer and composed a Sanskrit astronomical treatise, the *Siddhāntasārvabhauma* (1646), along with a commentary on the *Siddhāntaśiromani* of **Bhāskara II**.

The *Sūryasiddhānta* was the fundamental text of the Saura School, one of four principal schools of astronomy active during the Hindu classical period (late 5th to 12th centuries). Those editions of the *Sūryasiddhānta* that have come down to us, including the first English translations, are mostly based on Raṅganātha I's text, and so have acquired considerable influence.

Rañganātha II

Flourished **Kāśī, (Vārānasi, Uttar Pradesh, India), 1640 or 1643**

Rañganātha II was born into a rival family of astronomers sharing the same name as **Rañganātha I**; his father was Nṛsiṃha. He wrote a Sanskrit astronomical work, the *Siddhāntacūdāmaṇi* (1640 or 1643), along with a number of other astronomical and mathematical works. Rañganātha II's father had written a commentary on the anonymous *Sūryasiddhānta* (10th or 11th century). Rañganātha II's brother, **Kamalākara**, likewise composed a Sanskrit astronomical treatise, the *Siddhāntatattvaviveka* (1658).

The *Siddhāntacūdāmaṇi* consists of 12 chapters and covers many of the standard topics discussed in Hindu astronomy of the classical period (late 5th to 12th centuries). It is also based on the *Sūryasiddhānta*.

Rañganātha II also composed the *Bhañgīvibhañgīkaraṇa*, a detailed work on the theory of planetary motions that criticized an earlier work of Munīśvara, son of Rañganātha I. Rañganātha II's astronomical writings included the *Lohagolakhaṇḍana*, a work on the celestial sphere, and the *Palabhākhaṇḍana*, a guide to determining terrestrial latitudes from observations of the stars.

Rankine, William John Macquorn

Born **Edinburgh, Scotland, 5 July 1820**
Died **Glasgow, Scotland, 24 December 1872**

Scottish railroad engineer William Rankine, among many other activities ranging over science and engineering, wrote down in 1869 a set of equations connecting the density, pressure, and temperature of gases on the two sides of a shock wave. These were generalized in 1887 by Pierre Henri Hugoniot (1851–1897) and, in the form of the Rankine–Hugoniot relations, can be used to describe, for instance, propagation of a supernova remnant moving into the interstellar medium at a speed faster than that of sound.

Ranyard, Arthur Cowper

Born **Swanscombe, Kent, England, 21 June 1845**
Died **London, England, 14 December 1894**

Arthur Ranyard not only observed the features of the Sun but also interpreted other solar observations in order to understand the sun's physical characteristics. He moved to London at an early age, and studied mathematics at University College, London, and Pembroke College, Cambridge. As a student, Ranyard and George de Morgan (son of **Augustus de Morgan**, the well-known mathematician) played a leading role in the founding of the London Mathematical Society. After taking a Cambridge law degree, Ranyard was called to the Bar at Lincoln's Inn, and practiced as a barrister for the rest of his life. He became a member of the Royal Astronomical Society in 1863, and served as its secretary in 1873.

Despite his success at law, astronomy was always Ranyard's avocation and true passion. He was especially interested in the Sun, and his diligence and high intelligence helped him rise quickly above the level of a *dilettante*. He traveled, at his own expense, to view several solar eclipses, including one in 1870 viewed from Sicily, and another in August 1878 from Cherry Creek (near Denver), Colorado, USA, which Ranyard observed with **Charles Young**'s party. The next year, he published his most important work on solar eclipse observations.

On the basis of his comprehensive review of historical eclipse observations, Ranyard discovered that the form of the extended and much-attenuated outer atmosphere of the Sun, the corona, varied with the sunspot cycle. As **Agnes Clerke** put it:

> "When sun-spots are numerous, the corona appears to be most fully developed above the spot-zones, thus offering to our eyes a rudely quadrilateral contour. The four great luminous sheaves forming the corners of the square are made up of rays curving together from each side into 'synclinal' or ogival groups, each of which may be compared to the petal of a flower."

At sunspot minima, the corona has a more shapeless, roughly circular, and amorphous appearance.

Ranyard mounted another expedition to Sohag, in Upper Egypt, for the eclipse of 17 May 1882. Totality lasted only 74 s, but was memorable because of the unexpected appearance of the solar-eclipse comet X/1882 K1, seen and photographed during the eclipse and never seen again.

Yet Ranyard was not primarily an observer; rather, he was a keen student of historical records made by others. His analysis of these observations was frequently highly perceptive and produced new results or cleared up long-standing enigmas. For instance, he and **John Hind** independently debunked the notion, based on a single drawing by the German amateur Johann Pastorff, that the great comet C/1819 N1 had been visible in transit in front of the Sun.

His work on periodicities related to the sunspot cycle led him to take an interest in Jupiter. Its cloud markings were subject to occasional outbreaks; were these related, possibly, to the sunspot cycle? Ranyard was a member of a group organized in March 1876 by the Royal Astronomical Society for the study of Jupiter. (Other members included **William Huggins**, William Noble, Alexander Lindsay, **Laurence Parsons**, and **Thomas Webb**.) Ranyard concluded from examining all the observations then available that deeper tinges of color and the eruption of equatorial "porthole" markings seemed more likely to appear during years of sunspot minima. This was a pioneering effort, based on insufficient data; unfortunately, it has not been borne out by modern studies.

After the death of the prolific astronomy popularizer **Richard Proctor** in 1888, Ranyard produced revised editions of some of Proctor's works, such as his *Old and New Astronomy*, and became editor of *Knowledge*, a London illustrated scientific magazine that had been founded by Proctor. In this role, he introduced large-scale photogravure reproductions of astronomical photographs, including reproductions of many of **Edward Barnard**'s pioneering wide-angle photographs of the Milky Way obtained at Lick Observatory, California, USA, with the Willard portrait lens. In commenting on the wild and mysterious dark markings revealed in these photographs, Raynard first perceived that they were best explained by assuming the existence of masses of dark absorbing matter rather than as holes or gaps in the star clouds. In making this suggestion, he departed from the view that had been hitherto maintained by **William Herschel** and **John Herschel**. It was a major breakthrough, but its time had not yet come. Indeed, Barnard himself continued to struggle with the nature of the dark markings for many years before finally convincing himself that Ranyard's explanation had to be the correct one.

In 1893, Ranyard accompanied Barnard on the latter's triumphant Grand Tour of the Continent following his discovery of the fifth satellite of Jupiter. Barnard found that even when suffering from hay fever, as he did on the train from Boulougne to Paris, Ranyard never lost his politeness. When the two men visited **Camille Flammarion** at Juvisy, Ranyard became so much a part of the occasion that Flammarion remarked that he was "a perfect Frenchman." He was as much appreciated for his personal charm as for his perceptive knowledge of astronomy. Soon after his return from Europe, Ranyard was taken ill. He died of cancer.

Rauchfuss, Konrad

Born **Frauenfeld, Thurgau, Switzerland, *circa* 1530**
Died **Strasbourg, (Bas-Rhin), France, 26 April 1600**

Konrad Rauchfuss is best known as a mathematician, and his name is connected with the astronomical clock in the cathedral of Strasbourg.

Petrus Dasypodius, the father of Konrad, was one of the Swiss humanists; he taught at the school of Johannes Sturm in Strasbourg, wrote humanistic treatises, and held lower church positions. His son studied at this academy with Christian Herlinus and became professor there in 1558.

Rauchfuss devoted himself mainly to the teaching of mathematics. He recognized early the low level of knowledge and teaching of mathematics in his time, and he decided to translate into Latin the basic Greek mathematical texts. He edited and commented on works by Euclid, Heron of Alexandria (his favorite author), **Ptolemy**, and then propositions of the works by **Theodosius of Bythinia**, **Autolycus**, and Barlaamo. A remarkable textbook *Analyseis geometricae sex librorum Euclidis* (1566) contains the proofs of the first six books of Euclid's *Elementa*; Rauchfuss wrote it together with his teacher Herlinus. The numerous textbooks of Rauchfuss were in use for many years at many European universities.

Rauchfuss's astronomical clock in the cathedral of Strasbourg replaced the original one from 1352 to 1354. That clock had been taken down about 1550, and nothing was left from it. After several reconstructions and improvements in the following centuries, today's clock still follows the principal design by Rauchfuss, and contains some original parts. The Rauchfuss clock was installed in the cathedral between 1571 and 1574, and Rauchfuss described it in detail in the book *Heron mechanicus* (Basel, 1580). A remarkable portrait of **Nicolaus Copernicus**, painted on the clock by Tobias Stimmer (1539–1582), confirms that Rauchfuss appreciated Copernicus's work, but he never became an adherent of the Copernican cosmological system.

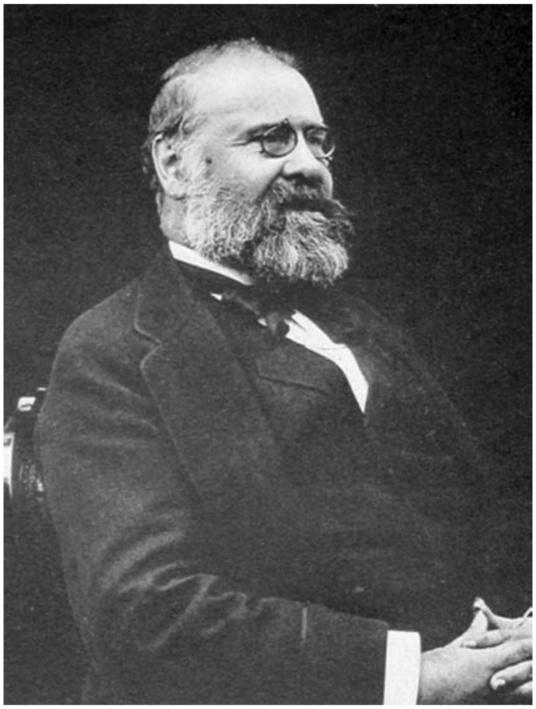
Rayet, Georges-Antoine-Pons

Born **near Bordeaux, Gironde, France, 12 December 1839**
Died **Floirac near Bordeaux, Gironde, France, 14 June 1906**



Georges Rayet was a French astronomer who, with **Charles Wolf** at the Paris Observatory in 1867, detected a class of rare, exceptionally hot stars whose spectra show strong broad emission lines of helium, carbon, and nitrogen. Wolf–Rayet stars, as they are known after their discoverers, are about twice the size of the Sun, and have a rapidly expanding outer shell – the source, it is thought, of the emission lines. The residual hydrogen envelopes of these stars have been stripped away (by stellar winds or mass transfer), revealing their deeper layers. Many central stars of planetary nebulae are of this type.

Rayet had no formal schooling until the age of 14, when his family moved to Paris. He was admitted to the École Normale Supérieure (1859); he graduated with a physics degree in 1862 and taught for a year before obtaining a post in the new weather forecasting service set up by **Urbain Le Verrier** at the Paris Observatory. In 1873, its operation was entrusted to him, but within the year the two men disagreed over storm forecasts, and Rayet was dismissed. He then lectured on physics at the Faculty of Sciences of Marseilles, and in 1876 was appointed professor of astronomy at Bordeaux.

Following a government initiative to build several new observatories, Rayet was asked to undertake a survey of the history and instrumentation of the world's observatories. He was subsequently offered the directorship of the observatory to be built at Floirac. From 1879, he held this position in tandem with his Bordeaux appointment. Having installed modern astrometric equipment at Floirac, Rayet organized a program of positional measures of stars, nebulae, and the components of binary systems.

Rayet's first collaboration with Wolf occurred in 1865 when they photographed an eclipse of the Moon. On 20 May of the next year, the pair noted bright emission lines, widened into bands, in the continuous spectrum of a nova (T Coronae Borealis, the first nova to be examined spectroscopically). In the following year, they made the observations that would immortalize their names in the Wolf–Rayet stars, when they discovered a similar appearance in the spectra of three eighth magnitude stars in Cygnus.

In 1868, Rayet undertook responsibility for the spectroscopic work on an expedition to the Malay Peninsula to observe a total eclipse of the Sun. With Wolf, Rayet also made significant observations of comet C/1874 H1 (Coggia), and observed the total solar eclipse of 1905 from Spain. He was an enthusiastic supporter of the International *Carte du Ciel* Astrographic Chart and Catalogue, and in the year before his death published the first volume of the *Catalogue photographique de l'Observatoire de Bordeaux*.

Raymond of Marseilles

Flourished **(France), 1141**

Raymond was among the earliest Latin scholars to adapt Arabic science to the needs and requirements of a well-educated Latin-reading public. While not making translations himself, he was well acquainted with Arabic texts translated in Toledo, in the fields of astronomy, astrology, and probably alchemy.

The works that can be securely attributed to Raymond are three substantial texts that refer to each other. The first is *Liber cursuum planetarum*, an adaptation to the meridian of Marseilles of the astronomical tables originally drawn up for the meridian of Toledo and translated from, or based on, Arabic sources. Raymond's adaptation was made in 1141 and is accompanied not only by his own explanation on how to use the tables (*regula*), but also by a long essay justifying the study of astronomy and, in particular, astrology. This essay begins with a substantial poem, and the essay itself quotes liberally from classical sources and the church fathers. The second work is *Liber iudiciorum*, a handbook of judicial astrology, based on 12th-century translations from Arabic of astrological works by **Abu Maʿshar, al-Qabisi**, and Sahl ibn Bishr, and on earlier Latin material attributed to "Argaphalau" and **Ptolemy**. The third is *Liber de astrolabio*, a text on the construction and use of the astrolabe.

Raymond was not an innovator, and his astronomical and mathematical competence is not outstanding. Nevertheless, his work had considerable influence in the 12th century, especially in England, where a version of the *Liber iudiciorum* was prepared for Robert, Duke of Leicester, and where **Roger of Hereford** adapted the tables of Marseilles for his local meridian.

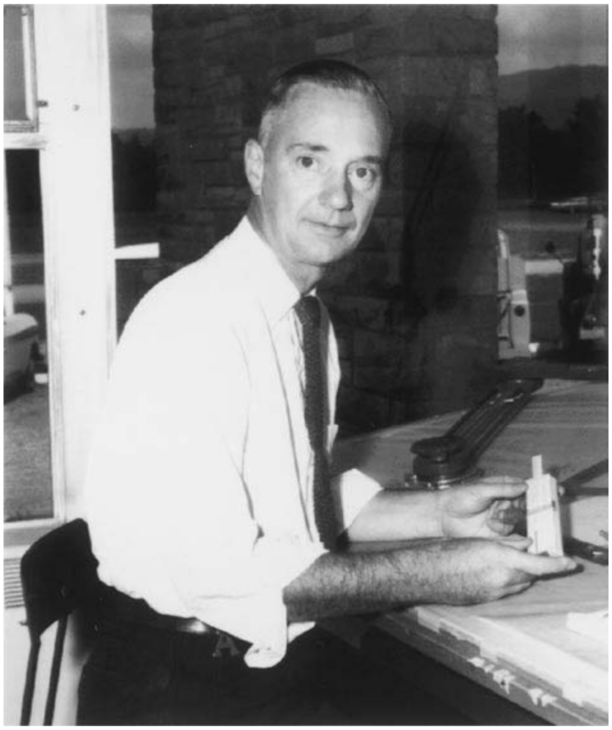
Reber, Grote

Born **Chicago, Illinois, USA, 22 December 1911**
Died **Tasmania, Australia, 20 December 2002**

Grote Reber was the first person who knowingly built a radio telescope. With it, Reber pioneered the exploration of the sky at radio wavelengths, locating the first known discrete radio objects, Cygnus A and Cassiopeia A.

Reber's father, Schuyler Colfax Reber was a lawyer and part owner of a canning factory, while his mother, Harriet (*née* Grote) Reber taught elementary school where Grote grew up in Wheaton, Illinois, a suburb of Chicago. Among Harriet's pupils in the seventh and eighth grade at the Longfellow school in Wheaton was **Edwin Hubble**, with whom Reber later corresponded. At the time of his graduation with a BA in electrical engineering from the Armour (now Illinois) Institute of Technology in 1933, Reber was already interested in **Karl Jansky**'s 1932 discovery of radio emission from our Galaxy. Reber sought employment at the Bell Laboratories, Holmdell, New Jersey, in order to work with Jansky. Unsuccessful in that strategy, Reber accepted employment with various manufacturers of electronic equipment in the Chicago area.

After failing to interest others in his plans to follow up on Jansky's work, Reber, an amateur radio enthusiast (call letters W9GFZ), decided to build his own dish antenna in order to achieve a higher angular resolution than that of Jansky's rather broad-beamed rotating antenna. Jansky made observations at a wavelength of 14.6 m (a frequency of 20.53 MHz). Reber realized that observing at a higher frequency would also facilitate a higher angular resolution and, if the radiation was of thermal origin, stronger signals.



Reber financed and designed the telescope himself and, with little assistance, constructed it in the 4 months from June to September 1937 at his mother's home. The telescope, a meridian transit instrument consisting of a wooden frame with a galvanized iron reflecting surface 9.6 m in diameter with a focal length of 6.1 m, was able to observe declinations between −32.5° and +90°. Reber also designed and built the antenna feeds and receivers; his work as an engineer for radio manufacturing firms in Chicago gave him access to state-of-the-art technology.

Reber first observed in 1938 at a wavelength of 9 cm (3,300 MHz), close to the shortest wavelength possible at the time, and then with a more sensitive receiver at 33 cm (910 MHz) in late 1938 and early 1939. Observations of various parts of the Milky Way, the Sun and other bright stars, and planets were unsuccessful, which, as Reber characteristically put it, was "rather dampening to the enthusiasm." His lack of success did, however, indicate that the radio emission was not thermal. It is now known that radio emission at centimeter and meter wavelengths is predominantly produced by synchrotron radiation.

Reber designed a new receiver to operate at 187 cm (162 MHz). Early observations with this receiver suffered from human electrical interference, primarily automotive ignitions. To minimize these problems, Reber worked during the day, slept in the early evening, and observed after midnight. By early April 1939, it was clear that Jansky's cosmic static was coming from the Galaxy. The trend of stronger emission near the galactic center seen by Jansky was confirmed, but Reber's efforts to detect individual celestial objects including the Sun were not successful.

Reber's results, like Jansky's before him, were readily accepted for publication in the *Proceedings of the Institute of Radio Engineers*. Reber also submitted his results to the *Astrophysical Journal*; however the editor, **Otto Struve,** accepted Reber's paper only after astronomers from the University of Chicago visited Wheaton to inspect his equipment. Even then, when Reber's paper was published in 1940, the section considering theoretical aspects of his results was removed!

After Reber improved the sensitivity of his receiver, his survey of the sky undertaken between early 1943 and mid-1944 confirmed that diffuse radio emission came from the galactic plane, but that there were also several peaks of emission: one in Cassiopeia, which is now known to be the galactic supernova remnant Cassiopeia A, and a broader peak in Cygnus, later resolved into the radio galaxy Cygnus A and the galactic Cygnus X complex. Observations of the Sun in September 1943 found it to be an intense source of radio emission. Reber's 1944 papers in the *Proceedings of the Institute of Radio Engineers* were the first published reports of radio emission from the Sun; he was unaware of classified earlier detections of the Sun during the war of which that by **James Hey** is best known. Reber found that near the maximum of the 11-year solar cycle, the Sun was not only very bright at radio wavelengths but, as a series of observations at 62.5 cm (480 MHz) from mid-1946 onward revealed, it was also the source of intense, short-lived bursts of radio emission.

News of Reber's discoveries reached the Dutch astronomer **Jan Oort**, who was one of the few who fully appreciated their significance. Oort realized that radio observations, unlike optical observations, did not suffer from obscuration caused by dust and gas, and would provide a powerful probe if a spectral line at radio wavelengths could be found. Oort assigned the problem to Hendrik van de Hulst, who discovered that neutral hydrogen had a potentially detectable hyperfine transition at 21 cm (1400 MHz). Van de Hulst met Reber in 1945, and while it was not clear that the line would be detectable, Reber started preparing his telescope to observe at that frequency.

In 1947, Reber accepted a position with the National Bureau of Standards [NBS] in Washington; his work in Wheaton came to an end. Reber moved his telescope to Sterling, Virginia, and then in 1959 moved it again to the National Radio Astronomy Observatory at Green Bank, West Virginia, where it remains to this day. The telescope now sits on an azimuth rail that had been designed and built but never installed in Wheaton. Reber attempted to generate interest in his design for a 220-ft. (67-m) radio telescope, but was again ahead of his time. The United States' interest in radio astronomy lagged behind Australia's, the Netherland's, and the United Kingdom's.

In 1951, Reber left the NBS and moved to Hawaii. This move marked the beginning of his long association with Research Corporation, a private foundation for the advancement of science established in New York in 1912. Reber installed antennas on the 10,020-ft. summit of the Haleakala volcano on the island of Maui. There he used the Lloyd's mirror interferometric technique in which a reflection off water acts as the second mirror pioneered by John Gatenby Bolton (1922–1993) and colleagues in Australia. Observations were attempted at frequencies near 20, 30, 50, and 100 MHz. However, anomalies introduced by the ionosphere rendered the first three frequencies unusable. At 100 MHz, the bright radio sources Cas A and Cyg A were detected and considerable asymmetry inferred for both sources from the differences in their rising and setting interferometric patterns.

Having discovered the important role of the ionosphere in low-frequency observations, Reber moved in 1954 to Tasmania, near the south magnetic pole, where ionospheric effects were known to be much smaller. He collaborated with Graeme Reade Anthony "Bill" Ellis (born: 1921) to determine the lowest frequency at which they could detect extraterrestrial radio emission. They were able to observe several times at 0.91 MHz, and on three occasions for half an hour or so at 0.52 MHz during the 1954/1955 solar minimum. Reber then built an array of 192 dipoles covering 223 acres and carried out a survey of the sky between February 1963 and May 1967 at 144 m (2.1 MHz). Reber found that the radio appearance of the sky at these longer wavelengths is the inverse of that at shorter wavelengths, with the sky being brighter at the galactic poles, and darker at the galactic center. Reber's very low frequency observations were confirmed (albeit with lower angular resolution) by observations with the Radio Explorer Satellites in the late 1960s and 1970s. The radio darkening toward the galactic plane is thought to arise from absorption by plasma in our galaxy.

Reber returned to Tasmania in the 1970s after a 4-year stay at the Ohio State University, which had awarded him an honorary Doctor of Science degree in 1962. Reber was also honored with the Henry Norris Russell Lectureship from the American Astronomical Society and the Catherine Wolfe Bruce Award from the Astronomical Society of the Pacific in 1962, the Elliot Cresson Gold Medal from the Franklin Institute in 1963, the Karl G. Jansky Lectureship of the National Radio Observatory in 1975, and the Jackson-Gwilt Medal and Gift of the Royal Astronomical Society in 1983.

The self-professed stubbornness with which Reber persevered through many months of unsuccessful observing in Wheaton also attended his refusal to accept the Big-Bang model of the expanding Universe. He favored an interpretation of redshift in terms of energy loss due to multiple Compton scatterings, although this theory can be readily falsified. However, it was Reber's determination to succeed in spite of initial setbacks that ensured that radio astronomy would develop into a thriving, fundamental field of research, and that opened the door to the possibility of astronomical observation at many other nonvisual wavelengths.

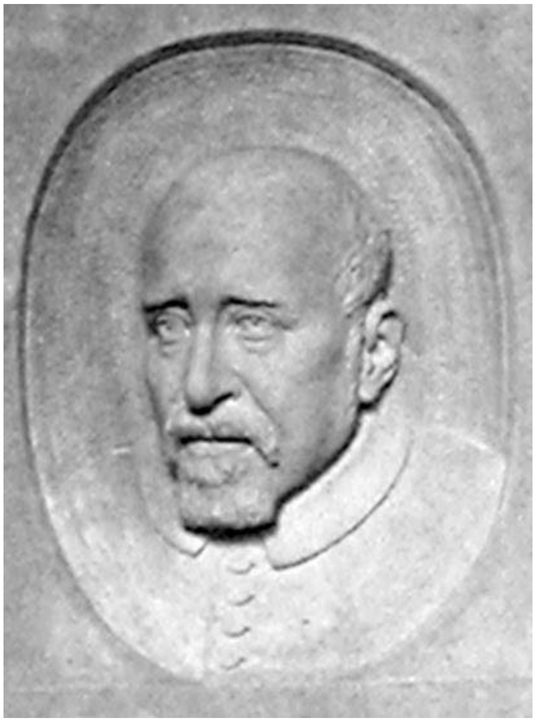
Recorde, Robert

Born **Tenby, (Dyfed), Wales, *circa* 1510**
Died **Southwark, (London), England, 1558**



Robert Recorde was the first writer in English on arithmetic, geometry, and astronomy.

Recorde was the son of Thomas Recorde and Rose Johns (or Jones). He received his BA and was elected fellow of All Souls College, Oxford University, in 1531. Recorde then moved to Cambridge, where he studied mathematics and medicine, and graduated with an MD at the University of Cambridge in 1545. He may have returned to Oxford University to teach mathematics, rhetoric, anatomy, music, astrology, and cosmography, but details are lacking. In fact, it seems that his reputation as a teacher rests on the views expressed in his treatises about how best to teach mathematics. Recorde moved to London where he practiced as a physician from 1547. In 1549 he was comptroller of the Mint at Bristol. The same year he became entangled in political intrigues and was accused of treason by William Herbert; this marked the beginning of a permanent quarrel with Herbert that had serious consequences for Recorde's later career. In May 1551 he was appointed general surveyor of the mines and money by the king. Recorde died in the King's Bench prison for failure to pay a penalty in a libel suit that Herbert had brought against him, yet left a little money to relatives in a will that was admitted to probate on 18 June 1558.

Recorde seems to have been a polymath who collected historical and other ancient manuscripts. His major claim to fame rests on his precociousness in mathematics, and he was the first to introduce algebra into England. Recorde's *Pathway to Knowledge* (1551) contains the first use of the term "sine" in English, and it also has a woodcut portrait of Recorde. He introduced a number of arithmetical symbols into English, and his works in mathematics remained standard authorities until the end of the 16th century.

The *Pathway*, subtitled "First Principles of Geometry," explains solar and lunar eclipses and contains a list of astronomical instruments. The *Castle of Knowledge* (1556) is the first comprehensive treatise on astronomy and the sphere to be printed in English, containing Ptolemaic astronomy in an elementary form with a brief, favorable reference to the Copernican theory. On the basis of this reference, some have considered him the first in England to adopt the Copernican system. Probably because this is an elementary text, Recorde cautioned students against rejecting the theory until they are more advanced in the study of astronomy. Still, he implied that the new theory could save the phenomena as well as the older system. The *Castle* is based on **Ptolemy**, **Proclus**, **John of Holywood**, and **Oronce Finé**, but Recorde examined the standard authorities, correcting their textual errors. There are also a number of other works that are no longer extant but that he referred to in the *Castle*. Among these is *The Treasure of Knowledge* (1556), probably on the higher part of astronomy.

Recorde is important primarily as an educational theorist. He insisted on a definite order in the study of the various branches of mathematics. He emphasized simple explanation of fundamental ideas, deferring demonstration to a later stage. Recorde used the dialog form along with visual aids and applications to practical problems. From a historiographical point of view, he is also important for his critical use of authorities and sources. When one considers the Renaissance reverence for ancient authorities, Recorde's caution is exemplary. He is in this regard representative of the more cautious acceptance of **Aristotle** that one finds, especially among English authors in the 16th century. After praising Ptolemy for his diligence, Recorde continues:

> yet muste you and all men take heed, that both in him and in al mennes workes, you be not abused by their autoritye, but evermore attend to their reasons, and examine them well, ever regarding more what is saide, and how it is proved, then who saieth it: for autoritie often times deceaveth many menne."

It seens as if several generations of English students were introduced to mathematics by his writings, thus his reputation as the founder of the English school of mathematical writers.

Rede, William

Born **England, *circa* 1320**
Died **England, *circa* 1385**

William Rede's chief astronomical work was a recomputation of the Alfonsine Tables for the Oxford meridian, epoch 1340. These Oxford tables enjoyed wide circulation during the 14th and 15th centuries. He also lectured on the *theoria planetarum* and calculated horoscopes for his Merton colleague John Ashenden.

Rede was raised from childhood by Nicholas of Sandwich, a wealthy landholder in the south of England. Rede came up to Oxford in the mid-1330s; he was a fellow of Merton College between 1344 and 1357, where he was a protégé of the astronomer **Simon Bredon**. From the late 1350s onward, Rede held a number of church offices, and was elected Bishop of Chichester in 1368. A significant benefactor of Merton College, he gave it over 100 books, a collection of mathematical instruments, and funds for construction of the Mob Quad library.

Redman, Roderick Oliver

Born **Rodborough near Stroud, Gloucestershire, England, 17 July 1905**
Died **Cambridge, England, 6 March 1975**

Roderick Redman designed and built a variety of astronomical instruments, applied them to problems in solar and stellar spectroscopy, and revitalized optical astronomy at Cambridge University after World War II. He was the only son and the eldest of four children of Roderick George and Elizabeth Miriam (*née* Stone) Redman. His father, who ran an outfitter's shop inherited from his own father, had left school at age 11, but felt strongly that his son, at least, should receive a full education. Redman senior was an active member, choirmaster, and organist of the Stroud Baptist Church, and Redman junior acquired a lifelong interest in music, being himself a fine organist.

Educated at Marling School, Stroud, Redman won an Open Exhibition in mathematics and physics to Saint John's College, Cambridge, and began his studies there in 1923 at the age of 18. He took the mathematical *tripos* with distinction in 1926, gaining a number of valuable studentships including the Isaac Newton Studentship. He was taken on as a research student by Sir **Arthur Eddington** to work on a theoretical problem in dynamical astronomy, obtaining his Ph.D. in 1930.

Following a traveling studentship at the Dominion Astrophysical Observatory in Victoria, British Columbia, Canada, Redman was appointed assistant director of the Solar Physics Observatory, Cambridge, under **Frederick Stratton** in 1931. Redman remained in Cambridge until 1939, occupied mainly with solar spectroscopy and spectrophotometry. He then moved to South Africa, as chief assistant at the Radcliffe Observatory, Pretoria. Unfortunately, with the outbreak of World War II, the observatory's 74-in. telescope under construction in England, which he had hoped to use, was left incomplete. Redman, however, made the best of what was available to him – the finder on the new telescope's mounting – to perform a valuable photometric program in collaboration with the Royal Observatory at the Cape.

In 1946 Redman was elected a fellow of the Royal Society, and in 1947 was invited to return to Cambridge University as professor of astrophysics and director of the combined University Observatory and Solar Physics Observatory. These two institutions, though on the same site, had different histories; they were now merged to form the Cambridge Observatories. Redman thus inheriting the posts of both Eddington and Stratton.

Redman's first task was a radical modernization. Old instruments were replaced by two new telescopes – a 16-in. Schmidt camera and a 36-in. reflector – and a new solar outfit with a Babcock grating spectrograph. Under Redman's directorship, Cambridge University was transformed into a leading center for astrophysical research, and he himself, a perfectionist in everything he touched, became a highly valued adviser on various national and international bodies. His own fields of activity included successful observations of four total solar eclipses in the course of his scientific life, the last being those of 1952 in Khartoum, where under ideal weather conditions he obtained exceptionally fine high-resolution spectra of the chromosphere, and of 1954 in Sweden.

Among the instruments Redman designed and built were a solar monochrometer, a slit spectrograph that could take a rapid series of coronal images during solar eclipse, a Fabry photometer (at Radcliffe), and, before leaving Cambridge for Pretoria, the spectrograph for the 74-in reflector. In the postwar period, he contributed to the design and construction of a photon-counting photometer and an assortment of narrow-band spectrometers used by his students, who included a large fraction of those who passed through the Cambridge Observatories during his directorship. His research results with these included the demonstration that the residual flux at the centers of strong solar absorption lines was much less than had previously been thought; several determinations of the temperature of the chromosphere; and a database of velocities for single and binary stars later useful as velocity standards and for studies of galactic dynamics.

An early campaigner for British telescopes at better sites than Cambridge, Redman participated in the site testing that led to the location of the Anglo–Australian Observatory and served as a consultant to the Anglo–Australian Telescope Board. He served the Royal Astronomical Society in every capacity except treasurer, and including president (1959–1961). He was president of several commissions and working groups of the International Astronomical Union, was a member of the council of the Royal Society (1953–1954), and held a variety of positions of responsibility in his college (Saint John's) and the astronomical community. He was director of the observatories and, very briefly, of the integrated Institute of Astronomy until his retirement in 1972.

Redman was survived by his Canadian wife, Kathleen, (*née* Bancroft), whom he married in 1935, and their four children.

Regener, Erich Rudolph Alexander

Born **Schleussenau near Posen (Poznań, Poland), 12 November 1881**
Died **Stuttgart, (Germany), 27 February 1955**

Physicist Erich Regener conducted research on cosmic rays and was the first to outfit a V-2 rocket for taking measurements in the upper stratosphere. Regener, son of a Royal land surveyor, attended Gymnasia in Bromberg, Marienburg (West Prussia), Stargard (Pommern), and yet again in Bromberg, and concluded his school years by sitting for his *Abitur* (final exam) in 1900. He then studied chemistry and physics at the Friedrich Wilhelm University in Berlin. Working under the supervision of Emil Warburg, he was awarded a Ph.D. in 1905 for a dissertation on the influence of ultraviolet radiation on the oxygen–ozone equilibrium. Regener was twice married, first to Victoria Mintschin and then to Gertrud Heiter. He had two children by his first wife.

From 1906 to 1913, Regener worked as an assistant at the Military Technical Academy in Berlin-Charlottenburg. In 1909, he qualified as a lecturer at the University of Berlin by completing a *Habilitationsschrift* (thesis) in nuclear physics, using α particles to determine the elementary electric charge, a subject that Heinrich Rubens had encouraged him to pursue. In 1912, he was appointed honorary professor and, in 1914, succeeded Richard Börnstein as full professor of physics and meteorology and head of the Physics Institute at the Agriculture College in Berlin. Concurrently, Regener taught physics at the Berlin Veterinarian College. From 1915 to 1918, he worked in the battlefields, first as an X-ray field-technician, and after 1917, as an assistant to Fritz Haber, where he was conducting research on gas warfare at the Kaiser Wilhelm Institute. In 1920, Regener became full professor of physics and director of the Physical Institute at the Technische Hochschule in Stuttgart, where he remained active until 1937 and, after the war, from 1945 until his retirement in 1951.

In 1937, Regener was removed from his civil service position because his first wife, Victoria, was a Russian-born Jew. She and his two children were forced to emigrate; the couple was later reunited. (After Victoria's death in 1949, Regener remarried.)

To continue his work, Regener obtained support from the Kaiser Wilhelm Gesellschaft and established the organization's research facility for studies of the stratosphere at Friedrichshafen, on the shores of Lake Constance. Here, he successfully led the institute during the war years by obtaining contracts and money from the National Ministry of Aviation and the German Research Institute for Aviation. After the war, Regener's facility became associated with the new Max Planck Gesellschaft and in 1952 became known as the Max Planck Institute for the Physics of the Stratosphere. The institute was moved to Lindau after Regener's death and was one of the two founding organizations underlying the contemporary Max Planck Institute for Aeronomy.

Regener continued experimental practices that his teacher, Rubens, had been using. His *Habilitationsschrift* led him to undertake research on radioactive compounds and to devise ways of making the trajectories of such radiation visible. Regener's interest in radiation was expanded in the 1920s to involve cosmic radiation. The significance of cosmic rays for astronomy was already apparent, although its corpuscular nature was not yet established. Regener studied the absorptivity of this radiation and performed measurements both at great depths underwater (in Lakes Constance and Alpsee), and at great heights in the atmosphere (up to 30 km). He developed ballooning techniques and automatic meteorological equipment by which it became possible to study other characteristics of the upper atmosphere (composition, moisture, temperature), which were of interest to the emerging aviation industry. With measurements of the ozone concentration in the stratosphere, Regener returned to one of the themes in his dissertation.

Regener endeavored to have his automatic meteorological equipment reach ever-greater heights. He explicitly stressed the advantage and superiority of unmanned meteorological balloons over more expensive manned balloons. In making this argument, he anticipated the contemporary discussion between supporters and opponents of manned space flights. Plans for launching measurement equipment from a balloon located 30 km above the ground were laboratory-tested in 1938, but never successfully realized.

In 1942, Regener and his colleagues Erwin Wilhelm Schopper and Hans Karl Paetzold were given the assignment of developing a scientific application for the V-2 rockets being constructed at the military research facility in Peenemünde, a village on the Baltic coast. In January 1945, instruments were installed in the nose of a rocket (the Regener container), but it was never launched. Portions of the instruments, however, were subsequently taken to the United States, where the first high-altitude research rockets were flown in 1946 from White Sands, New Mexico. In the final years of his life, Regener planned to send measurement equipment into the upper atmosphere using the French Véronique rocket, but he did not live to see the launch.

Régis, Pierre-Sylvain

Born **La Salvetat de Blanquefort, (Lot-et-Garonne), France, 1632**
Died **Paris, France, 1707**

Pierre Régis was a proponent of Cartesian philosophy and astronomy. Educated at the Jesuit College at Cahors, and at the University of Paris in theology, he taught at Toulouse and Montpellier, until he succeeded **Jacques Rohault** in Paris in 1680. He was admitted to the newly reformed Académie royale des sciences in 1699.

Régis was a student and follower of Rohault, a very popular lecturer, and one of the principal defenders of an experimentally grounded version of **René Descartes**'s natural philosophy. Régis's *System of Philosophy* of 1690, while based broadly on Descartes, is an eclectic mix of Descartes, **Pierre Gassendi**, and Rohault's probabilistic version of Cartesianism; after Rohault's 1671 *Treatise* it was the most important systematic popularization of Cartesian natural philosophy. The second and third books of Part II of the *System* are devoted to cosmogony and astronomy, and take as their starting point Descartes's theory of vortices.

Régis's one contribution to Cartesian cosmology is in the area of terrestrial gravity, which was a key element in the defense of vortex theory. Descartes had accounted for weight in terms of the complex dynamics of fluid matter around the Earth, which had the effect of pushing bodies toward the center. The theory had been further developed by **Christiaan Huygens** and Rohault. Régis questioned whether Rohault's account of the circulation of fluid matter would actually explain the pushing of bodies toward the center, arguing that it would instead push the body toward some point on the axis between the center of the Earth and the center of the parallel on which the bodies were situated.

Regiomontanus

➔ **Müller, Johann**

Regius, Hendrick

Born **Utrecht, The Netherlands, 29 July 1598**
Died **Utrecht, The Netherlands, 19 February 1679**

Henricus Regius was one of **René Descartes'** first disciples, and one of the principal representatives of Cartesianism in the Netherlands, but his polemical style and intransigent approach soon brought him into conflict with the authorities. He studied in Franeker, Groningen, Leiden, Paris, Montpellier, Valence, and Padua. He taught medicine at the University of Utrecht from 1638.

Descartes showed Regius the material he had intended to publish as *The World*, and Regius had probably based his lectures on this material. In 1646, Regius published his *Fundamenta physices*, which offered a form of Cartesian natural philosophy stripped of the metaphysical foundations that Descartes had provided to legitimate his approach in his *Principles of Philosophy* (1644). Descartes had provided a detailed physical defense of a cosmological system in which the cosmos was indefinitely extended, and comprised an indefinite number of Solar Systems, each with its own planetary system. Although Regius' principal concern was with physiology, he did offer a complete system, so included Cartesian cosmology in Part II of the *Fundamenta*. Even though his account of cosmology here hardly strays at all from that of Descartes, he presented the system as a whole in a way that Descartes considered incautious and superficial, opening up Cartesianism to objections that Descartes' own carefully presented formulations had been designed to avoid. However, in his public dispute with Regius, Descartes was forced to clarify a number of elements of his natural philosophy, although none of these bore directly on cosmological issues.

Regnerus

Frisius, Gemma Reinerus

Reichenau, Hermann von

Hermann the Lame

Reinhold, Erasmus

Born **Saalfeld, (Thuringia, Germany), 22 October 1511**
Died **Saalfeld, (Thuringia, Germany), 19 February 1553**

Erasmus Reinhold is best known for his preparation of the Prutenic Tables, calculated from **Nicolaus Copernicus**'s heliocentric theory.

Reinhold's father Johann (1479–1558) studied in Leipzig and Cologne. He served in the Chancellory of George, Duke of Saxony, and as secretary to the Abbot of the Benedictine monastery at Saalfeld, and held various civic offices in Saalfeld, including that of Mayor. Johann Reinhold prospered sufficiently to enable his son to go from the *Stadtschule* (municipal school) in Saalfeld to Wittenberg University, where he dedicated himself primarily to the study of mathematics under Jacob Milichius. After graduation, Erasmus Reinhold was made professor of higher mathematics (*i. e.*, astronomy). He was elected dean of the philosophical faculty on repeated occasions and, in 1549–1550, rector of the university. Reinhold enjoyed a certain advancement through his close relationship to Philipp Melanchthon.

The most significant of Reinhold's publications were his commentary on the planetary theory of **Georg Peurbach** (1542, and subsequent editions); a textbook for the more advanced study of astronomy that he certainly based on his own lectures; a small work, *De Horizonte*, that appeared as supplement in a number of impressions of **John of Holywood**'s *Libellus de sphaera* (as printed in Wittenberg); and above all the *Tabulae Prutenicae* (Prutenic Tables). Reinhold was the most influential astronomer in Protestant Germany.

Through his fellow professor **Rheticus** Reinhold in Wittenberg had a very early opportunity to acquaint himself with the heliocentric system of Copernicus. Immediately upon its appearance, Reinhold worked his way attentively through Copernicus's *De revolutionibus orbium coelestium*. Following a partial recalculation of observational data (where Copernicus had made several mistakes) and on the basis of Copernicus's improved elements for planetary orbits, the constant of precession, the length of the year, and the obliquity of the ecliptic, as well as his own theory of lunar motion and approach to triangulation (among other factors), Reinhold produced new planetary tables. After many years of work, they appeared first in Tübingen in 1551, commissioned by Melanchthon and Duke Albert of Prussia, and named *Tabulae Prutenicae* in honor of the latter.

Reinhold did not endorse the heliocentric system, but recognized that the mathematical theory of this system represented a significant advance in relation to new observational data. He made no statement on the question of the physical reality of the heliocentric system; as a strongly "classically" minded astronomer, adhering to the conceptual model of a division between physics and astronomy, he did not accept that such a theory raised any problem. For Reinhold the question was irrelevant as he subscribed to the traditional scientific concept of astronomy "saving the appearances."

The Prutenic Tables rendered the heliocentric system operable for practical astronomy, in particular for the calculation of calendars and horoscopes. From the 1570s, Reinhold's tables were one of the most important astronomical tables, and they were instrumental in Copernicus being generally recognized, from the end of the 16th century, as one of the most important astronomers. The accuracy of the planetary positions as calculated proved, with time, to be a significant factor in the acceptance of the totality of the heliocentric system, rather than just its mathematical parameters. (Subsequently, larger errors became evident once again, as **Johannes Kepler** and others showed.) The tables were significant for the furtherance of the heliocentric world-system, even though Reinhold himself always recognized the geocentric.

Reinhold's brother Johannes became professor of mathematics in Greifswald in 1549, but died in 1552. Reinhold's son, Erasmus Jr. (1538–1592) studied mathematics and medicine in Wittenberg under the care of Melanchthon, and then in Jena, and became doctor of medicine and municipal doctor in Amberg and Saalfeld. Later he became *Bergvogt* (mountain steward) to the Elector of Saxony, and wrote works on land surveying as well as calendars, which appeared regularly for many years in Erfurt.

Reinmuth, Karl Wilhelm

Born **Heidelberg, (Germany), 4 April 1892**
Died **Heidelberg, (Germany), 6 May 1979**

Before the advent of automated search techniques, Karl Reinmuth became the world's most successful asteroid hunter. He discovered a total of 389 minor planets, including some of the first known to exist outside of the main asteroid belt.

A lifelong resident of Heidelberg, Reinmuth studied at the Ruprich-Karls University. His doctoral thesis (1916), entitled "Photographische Positionsbestimmung von 356 Schultzschen Nebelflecken," reported on the position determinations of 356 nebulae, originally cataloged in 1875 by Herman Schultz of Uppsala.

Reinmuth joined the staff of the Königstuhl Observatory near Heidelberg as a volunteer in 1912, working under the supervision of director **Maximillian Wolf**, the first astronomer to apply photographic techniques to the discovery of asteroids. Reinmuth located his first new minor planet, (796) Sarita, on 15 October 1914. Upon Wolf's death, Reinmuth was appointed director of the Königstuhl Observatory in 1932 and served in that capacity until his retirement in 1957.

After World War I, Reinmuth was given responsibility for resuming a sky survey begun by Adam Massinger, another of Wolf's assistants. Massinger had been urged to compile a photographic record of more than 4,000 objects included in **John Herschel**'s *A General Catalogue of Nebulae and Clusters of Stars* (1864). Photographic plates from the Heidelberg Observatory, some dating back to 1900, were used in this collection. The project was halted by the outbreak of war; Massinger was killed in battle at Ypres. Reinmuth continued working on the project until it was completed in 1924.

In 1926, Reinmuth published the catalog entitled *Die Herschel-Nebel nach Aufnahmen der Königstuhl-Sternwarte*. Despite its German-language title, the volume listed the approximate dimensions, position angles (where relevant), and partial descriptions in English of the objects (chiefly galaxies) originally given by Herschel. At that time, Reinmuth's catalog was the only such listing that contained position angles of galaxies in the northern heavens.

Between 1919 and 1937, Reinmuth discovered all of the Trojan asteroids (seven) recognized during that period. Trojan asteroids have nearly circular orbits and are located at the leading or trailing Lagrangian points (L4 and L5) of Jupiter's orbit. During a routine asteroid patrol, Reinmuth discovered a faint comet on 22 February 1928 now known as 30P/Reinmuth.

During the 1930s, a competition of sorts developed between Reinmuth and **Eugène Delporte**, of the Belgian National Observatory at Uccle, in the discovery of Earth-approaching asteroids. Following Delporte's detection of minor planet (1221) Amor in 1932, Reinmuth recorded the trail of a nearby, rapidly moving asteroid whose orbit was found to cross that of the Earth. It was given the name (1862) Apollo, after the Greek Sun god. Reinmuth's discovery proved to be the first object in a class of asteroids sharing similar orbital properties. Apollos are one of three classes of Earth-approaching asteroids, along with the Amors and Atens, whose perihelion distances lie inside the orbit of Mars. Apollo-type asteroids have semimajor axes (a) that are greater than or equal to 1 AU and perihelion distances (q) that are less than or equal to 1.017 AU. Reinmuth discovered another member of the Apollo class of minor planets, (69230) Hermes, which remained "lost" by astronomers until its accidental rediscovery in 2003. For over 50 years, Hermes held the close-approach record of only 800,000 km from Earth.

In 1980, evidence was presented by physicist **Luis Alvarez** and colleagues that an asteroid's collision with the Earth was responsible for the Cretaceous–Tertiary extinction of the dinosaurs. Consequently, the potential danger of near-earth asteroids [NEAs] has been taken far more seriously by astronomers than in Reinmuth's day. Automated search techniques enable the discovery of NEAs to be made at a remarkable pace – a feat that surely would be the envy of Reinmuth.

Reinmuth is commemorated with the naming of minor planet (1111) Reinmuthia.

Renieri, Vincenzio

Born **Genoa, (Italy), 30 March 1606**
Died **Pisa, (Italy), 5 November 1647**

A friend and disciple of **Galileo Galilei**, Vincenzio Renieri is best remembered for his work on the satellites of Jupiter. Although little is known about his early life, Renieri joined the Olivetan Order in 1623, which initially took him to Rome and a decade later to Siena, where he met Galilei (1633). Thereafter, Renieri made frequent visits to Arcetri and soon became an intimate friend of Galilei. Working closely with Vincenzio Viviani, Renieri was given the task of continuing Galilei's observations of the satellites of Jupiter and improving the computational tables. To that end, Galilei entrusted Renieri with all of his papers dealing with Jupiter's satellites, which were to be perfected and sent to the States-General of Holland as the basis for determining longitude at sea. Having accepted the chair in mathematics at Pisa (previously held by Dino Peri and earlier still by Galilei), Renieri continued to supplement Galilei's observations while improving his methods.

Unfortunately, Renieri published only one work, the *Tabulae mediceae secundorum mobilium universales* (Florence, 1639). Although the title is tantalizing, Renieri's widely discussed tables for Jupiter's satellites were not published during his lifetime. **Jean-Baptiste Delambre**, among others, garbled the story about Renieri's sole publication, the *Tabulae mediceae*, not only indicating it was published before his fourth birthday but also questioning whether Renieri's satellite observations ever existed. The *Medicean Tables* say nothing about the Medicean satellites; instead, they represent a typical effort to improve **Johannes Kepler**'s *Rudolphine Tables* for the planets. Deploring the gross errors in earlier ephemerides (Ptolemaic, Alphonsine, Prutenic), Renieri claimed a simpler method for calculating longitudes by means of a two-step procedure, which he applied first to the superior planets, then to the inferior. His treatment of planetary latitudes is similar but more complicated. Renieri concluded by comparing his results (for the middle terrestrial latitudes), arguing that his tables were superior to the Rudolphine, Tychonic, Danish, and Landsbergian.

In the end, Renieri's observations of Jupiter's satellites were not printed until the mid-19th century. Although the Grand Duke of Tuscany ordered the ephemerides published (later echoed by his brother, Prince Leopold), Renieri died prematurely, and his manuscript was lost. (A questionable report suggests it was stolen by one Giuseppe Agostini.) The loss was unfortunate, as the synodic periods Renieri supplied were remarkably accurate, clearly superior to values given by **Simon Mayr** and other contemporaries. **Alexandre Pingré** indicates Renieri had an excellent telescope but made many observations with a mediocre quadrant. Several of Renieri's observations are cited in **Giovanni Riccioli**'s *Almagestum novum* (pt. I) .

Respighi, Lorenzo

Born **Cortemaggiore, (Emilia-Romagna, Italy), 7 October 1824**
Died **Rome, Italy, 10 December 1889**

Alongside **Angelo Secchi** and **Giovanni Schiaparelli**, Lorenzo Respighi can be considered the most important Italian astronomer of the second half of the 19th century. He was a pioneer in solar spectroscopy.

Respighi completed his early studies in Parma and his higher studies at the University of Bologna, where he obtained his degree *ad honorem* in philosophy and mathematics in 1847. At age 18, he was inducted into the Accademia delle Scienze of Bologna, and four years later he became a permanent member of the Accademia Benedettina. In 1849, Respighi was appointed as substitute to the chair of mechanics and hydraulics at Bologna. In 1851, he was appointed professor of optics and astronomy, a chair vacant for 3 years, and in 1855 he was also named director of the Astronomical Observatory. Respighi held these positions until 1864, when he was dismissed for refusing to take an oath of loyalty to the government of the Kingdom of Italy, which succeeded the papal government in Bologna.

Respighi moved to Rome in 1865, and in August of that year Pope Pius IX appointed him professor of optics and astronomy at the University of Rome La Sapienza and director of the Roman Observatory at the Capitol, a post he held until his death.

Respighi's scientific work began with a mathematical opus entitled *Principi del calcolo differenziale*, which **Augustin Cauchy** presented at the Académie des sciences in Paris. He subsequently became interested in positional astronomy, geodetic astronomy, and instrumental astronomy, but his main focus was physical astronomy (spectroscopy) and he is considered one of the pioneers in this field of study in Italy. In positional astronomy, Respighi compiled three catalogs, published between 1877 and 1884, of the mean declinations of over 2,500 stars at the 1875.0 epoch. Each star was observed several times using Ertel's meridian circle at the Bologna Observatory, both directly and applying the new method for observing zenithal stars by reflection in a basin of mercury. During these observations, he did extensive research into the aberration of light, conducting experiments using a water-filled telescope. He also conducted experiments on the variation of the speed of light in a vacuum, again with Ertel's meridian circle, using a thick piece of glass made specifically for this purpose with numerous air bubbles inside. Respighi also observed planets and comets, discovering three comets (C/1862 W1, C/1863 G2, and C/1861 Y1). In geodetic astronomy, Respighi determined the latitude of the Bologna Observatory and the absolute declination value for the city, as well as the latitude of the Capitol Observatory and of the prime meridian of Monte Mario in Rome. He also studied meteorology, writing several dissertations on the climate of Bologna, in which he reduced and discussed the meteorological and magnetic data accumulated by the Bologna Observatory in 45 years of observations (1814–1859).

Respighi's most important astrophysical researches involved stellar scintillation and the study of solar physics. Between 1869 and 1885, he conducted systematic observations of the border of the Sun, using the method invented by **William Huggins** in 1869. Known as "the widened slit method," it entailed placing the slit of the spectroscope tangential to the border of the Sun, widening the slit to include the entire height of the solar prominences, and placing a piece of red glass in front of the eyepiece. Respighi also studied the relationship between sunspots and solar prominences, deducing that at the points of the border of the Sun where a sunspot occurs or disappears, the chromosphere looks thinner. In 1870, he participated in the Italian expedition to observe the solar eclipse in Sicily, and in 1873 he began a series of measurements of the diameter of the Sun to study its variations in relation to the sunspot cycle. Lastly, Respighi noticed that the spectral lines over the sunspots look widened and deformed, a phenomenon that was later studied by

George Hale and is due to the Zeeman effect. He also studied the spectrum of the aurora borealis and compared this spectrum to the one of zodiacal light.

When head of the Capitol Observatory, Respighi engaged in a long dispute with Secchi about who had invented the use of the objective prism to study the stellar spectra and the nature of sunspots. He discovered that on the instrument invented by **Joseph von Fraunhofer** in 1815, the angle of refraction was too large, so it could not be used for spectra. Thus, Respighi had a prism made with an angle of refraction of just 12° and mounted it on the equatorial telescope at the Capitol. With this instrument, on 15 February 1869, he was able to show French physicist **Marie Cornu** the excellent stellar spectra he had obtained. The instrument used by Respighi spread rapidly and became one of the chief aids in astrophysics. With Secchi, **Pietro Tacchini**, **Giuseppe Lorenzoni**, and A. Nobile, in 1871 Respighi helped establish the Italian Society of Spectroscopists, although he rarely participated actively due to his disagreement with Secchi.

Respighi was a member of the European Commission for the Degree and of the Royal Superior Commission of Weights and Measures. Likewise, he was a member of numerous academies, such as the Accademia delle Scienze of Bologna, the Accademia dei Lincei, the Italian Society of Science known as the Società dei XL, the Geneva Society of Physics and Natural History, and the Royal Society of London. He was conferred with the Order of Saints Mauritius and Lazarus, the Order of the Crown of Italy, and the Military Order of the Portuguese Crown.

Respighi's manuscripts are in the Historical Archives of the Department of Astronomy of the Bologna University and in the Historical Archives of the Rome Astronomical Observatory in Monte Porzio.

Rheita, Antonius Maria Schyrleus de Schyrle [Schierl, Schürle] Johann Burchard

Born **Reutte, Tyrol, (Austria), 1604**
Died **Ravenna, (Italy), 1659 or 1660**

Antonius de Rheita was a telescope maker, observer, and supporter of the Tychonic system. He described the bands of Jupiter and developed the compound eyepiece.

Rheita was born in a noble family; "de Rheita" was derived from his birthplace. Rheita was educated in the Augustinian abbey of Indersdorf, Bavaria. On 14 October 1623, he enrolled at the University of Ingolstadt, where optics and astronomy were taught in the tradition of **Christoph Scheiner** and **Johann Cysat**. Three years later, Rheita left without a degree to become a Capuchin monk in the monastery of Passau, taking the name Antonius Maria. In 1636, he left Passau to become reader in philosophy at the Capuchin monastery of Linz. There, he met Philipp Cristoph von Sötern, the elector of Trier, for whom he worked for several years. In 1642, Rheita was in the Capuchin monastery of Cologne, where he conducted astronomical research and constructed telescopes that would result in his first publication, *Novem stellae circa Jovem visae, circa Saturnum sex, circa Martem nonnulla* (Nine stars seen [or observed] around Jupiter, six around Saturn, several around Mars), in 1643. That year, he met the instrument and telescope maker Johann Wiesel in Augsburg, where Rheita presumably was to give support to the nearby Bridgettine monastery in Altomünster of his brother Elias. One year later, Rheita was in Antwerp to prepare the publication of his main work *Oculus Enoch et Eliae*, before returning, in 1645, to Trier, again in the service of Sötern until the latter's death in 1652.

In those years, Rheita ran a workshop that produced telescopes for, among others, the Archbishop-Elector of Mainz. In Belgium to prepare a new edition of his *Oculus Enoch et Eliae* in 1653, he was informed of accusations against him by the Inquisition. Imprisoned in Bologna and later in Ravenna, Rheita's plans to build an observatory in Mainz would never materialize. On 27 November 1659 or 14 November 1660 (depending on the source used) he died, in unclear circumstances, in confinement.

In his *Oculus Enoch et Eliae*, Rheita defended the Tychonic world system, criticizing the Copernican system as established by **Philip Lansbergen**. In this he followed Scheiner and Cysat, and his friend and supporter Eryceus Puteanus. Defending the physical reality of the geoheliocentric world system was part of Rheita's contribution to the Counter-Reformation.

Rheita also published a map of the Moon in his *Oculus Enoch et Eliae*. With the exception of **Francesco Fontana**'s unpublished lunar drawings of 1629 and 1630, this was the first map to present the Moon south up, as seen through a telescope consisting of two convex lenses. However, Rheita's map was uninfluential.

Rheita's main contribution to astronomy was in the field of telescope design. In his 1643 work *Novem stellae circa Iovem, circa Saturnum sex, circa Martem nonnullae* Rheita claimed to have discovered a number of new satellites of the superior planets. In particular, on 29 December 1642, he said he discovered five satellites of Jupiter, above the four satellites already discovered by **Galileo Galilei** in 1610. The letter spread very rapidly to Paris**. Pierre Gassendi** published his answer together with Rheita's letter in April 1643. Gassendi correctly claimed that the new satellites were fixed stars. Rheita argued that those satellites could only be revealed by his recently invented binocular telescope. *Oculus Enoch et Eliae* referred to the binocular telescope, with Henoch and Elias each symbolizing one eye. With the same instrument, Rheita observed the bands on Jupiter, as he announced in a letter of 18 June 1651 to the Elector of Mainz.

More important for telescope design was the compound eyepiece, developed in collaboration with Wiesel around 1644. In 1611, **Johannes Kepler** had already introduced a third convex lens, that is, an erector lens, to reinvert the image seen through his telescope; it consisted of two convex lenses. Rheita's telescope consisted of four convex lenses, one objective lens and three ocular lenses. (Rheita introduced a field lens beside an erector lens.) The focal point of the objective lens coincided with the focal point of the third ocular lens. The introduction of the third ocular lens allowed overcoming the main problem of the telescopes of the first half of the 17th century: the limitation placed on magnifications by the progressive restriction of the field of view. Moreover, Rheita discovered that the angle of view was a function of the diameter of the ocular lenses. As a consequence, the ocular lenses were often made larger than the objective lens, resulting in an inversion of the trumpet shape of the tube with respect to earlier telescopes. The compound eyepiece also limited chromatic aberration.

Rheita's design of telescopes became known throughout Europe, mostly through telescopes produced by Wiesel in Augsburg. The same design was soon used in England by Richard Reeve (of Hartlib's circle), in Holland by **Christiaan Huygens**, in Italy by **Giuseppi Campani,** and in France by another Capuchin monk, Chérubin d'Orléans. Rheita in his book suggested that polishing on paper glued into a spherical mould would allow for precise polishing of spherical lenses of long focal lengths. This new polishing technique, together with the compound eyepiece, allowed for longer and longer telescopes, and the astronomical discoveries that went along with it, during the second half of the 17th century.

Rheticus

Born **Feldkirch,Vorarlberg, (Austria), 16 February 1514**
Died **Kassa (Košice, Slovakia), 4 December 1574**

Georg Rheticus was among the first to adopt and spread the heliocentric theory of **Nicolaus Copernicus**.

Georg von Lauchen, later known as Rheticus, was born in an Austrian town near the Swiss border. His father, Georg Iserin, was the town doctor and a government official; he taught his son until 1528, when he was tried on a charge of sorcery, convicted, and beheaded. One of the consequences of this execution was that his name could no longer be used; therefore, Georg's mother, an Italian noblewoman named Tommasina de Porris, reverted to her maiden name. Since "de Porris" means "of leeks" in Italian, Rheticus preferred to translate it into German "von Lauchen." Later, he took the additional name of Rheticus, after the ancient Roman province of Rhaetia in which he had been born.

Rheticus studied first at the Latin school in Feldkirch, then at the Frauenmünsterschule in Zürich until 1531. In 1533 he matriculated from the University of Wittenberg, where he received the title of *magister artium* in 1536. Soon afterward, thanks to Philipp Melanchthon's support, Rheticus was appointed to teach arithmetic, geometry, and astronomy at the University of Wittenberg.

In October 1538, Rheticus went on leave to visit leading astronomers and mathematicians: **Johannes Schöner** in Nüremberg, **Peter Apian** in Ingolstadt, Joachim Camerarius in Tübingen, and Copernicus in Frombork (Frauenburg). In September 1541, Rheticus went back to Wittenberg, where he was elected dean of the arts faculty. A few months later he was offered a post as professor of higher mathematics at the University of Leipzig, where he began teaching in October 1542.

In 1545, Rheticus left Leipzig to study abroad. After making a short stay in Feldkirch, he spent some time in Italy. Toward the end of 1546, he suffered a severe mental disorder in Lindau, a town on Lake Constance; this aroused some unfounded rumors about his death. But his health recovered to allow Rheticus to teach mathematics and astronomy at Constance for 3 months in late 1547. Then he studied medicine in Zürich with Konrad von Gesner.

In February 1548, Rheticus went back to Leipzig, where, with Melanchthon's influence, he was made a member of the theological faculty. In this period he was deeply engrossed in his university duties and sent many books to the press, among them a Latin translation of Euclid's *Elements* (1549), a calendar and ephemeris (1550), and the *Canon doctrinae triangulorum* (1551), which was the first publication to contain all the six trigonometrical functions. In April 1551, Rheticus was accused of having a homosexual affair with one of his students, and the consequent scandal compelled him to escape from Leipzig. His friends, such as Melanchthon, stopped supporting him, and he was tried in his absence by a town court. Rheticus was condemned to 101 years of exile, and all his possessions in Leipzig were impounded.

After leaving Leipzig, Rheticus spent some time at Chemnitz, before establishing himself in Prague. In 1551/1552 he studied medicine at the University of Prague. In 1553 Rheticus made a trip to Vienna, and the following year he moved to Kraków, Poland, where he remained for 20 years as a practicing doctor, though he continued to devote himself to mathematics and astronomy. In this period he worked on the trigonometric tables, projected and constructed astronomical instruments, and carried out astronomical observations and alchemy experiments.

In 1574 Rheticus left Kraków and went to Kassa (Kosice), by request of the local magnate Johannes Ruben. Here he was visited by Valentine Otho, who was at that time a student of mathematics at the University of Wittenberg. Rheticus died shortly afterward. He left an unfinished manuscript, which was then completed by Otho and published with the title of *Opus palatinum de triangulis* (1596); another book, the *Thesaurus mathematicus*, was edited by Bartholomeo Pitiscus (1613). Thanks to these posthumous works, Rheticus can be considered one of the most important authors of trigonometrical tables.

Rheticus was among the first to adopt and spread the heliocentric theory of Copernicus. Rumors of this hypothesis had reached Rheticus at Wittenberg. In May 1539 he traveled to Poland to visit Copernicus, and ended up staying at Frombork for 2 years, during which time he was able to persuade Copernicus to let him study the virtually completed *De revolutionibus*. Rheticus became enthusiastic over the heliocentric theory and tried to convince Copernicus to publish it. Since his efforts were rewarded with no success, Rheticus wrote a brief summary of the theory, which was published in Danzig at the beginning of 1540, explicitly authorized by Copernicus, under the title of *Narratio prima de Libris Revolutionum eruditissimi viri et mathematici excellentissimi, reverendi Domini Doctoris Nicolai Copernici Torunnaei Canonici Varmiensis* (First report on the Books of the Revolutions of the learned gentleman and distinguished mathematician, the Reverend Doctor Nicolaus Copernicus of Torun, Canon of Warmja).

Rheticus's booklet, written in the form of a letter to Schöner, was the first illustrated account of Copernicus's heliocentric theory. The *Narratio prima* is not, however, a pure summary of *De revolutionibus*; it has a different structure. First of all, Rheticus explained the questions about the motion of the fixed stars and the precession of the equinoxes: Curiously, therefore, at the beginning of his booklet he did not speak of the three motions of the Earth, but introduced them at the end. Rheticus's expository method was contrary to that used by Copernicus. While the latter started from the statement that the Earth moves and then tried to demonstrate it by analyzing the apparent motions of the stars, Rheticus expounded these motions of the stars in order to be able to assert that the motions of the Earth are the unique way of explaining them. This expository order was a consequence of the pedagogical aims that Rheticus wanted to achieve, but perhaps there is also another reason: Rheticus seemed to underline that the apparent motions of the stars and those of the Sun, which the astronomical tradition had considered as separated matters, are strictly correlated and can be coherently explained only by assuming a moving Earth. For many decades the *Narratio prima* remained the best popularization of the heliocentric theory. The first edition of 1540 was enthusiastically received, and a second edition was published in Basel less than a year later. The *Narratio* was reprinted as an appendix of Copernicus's *De revolutionibus* in 1566 and of **Johannes Kepler**'s *Mysterium cosmographicum* in 1596.

Probably as a result of the *Narratio's* success, when Rheticus left Frombork in 1541, Copernicus allowed him to take a complete copy of *De revolutionibus* to arrange for its publication. Rheticus entrusted publication of the manuscript to Johann Petrius in Nüremberg, but he could not supervise the entire work and left oversight of the printing to a Lutheran theologian, **Andreas Osiander**, who made some unauthorized additions to the manuscript. When Rheticus received the first copies of the printed book in April 1543, he saw that the title had been changed: Instead of *De revolutionibus*, the printed version read *De revolutionibus orbium coelestium*. The worst change, however, was the insertion of an anonymous preface, which affirmed that the book contained a mere mathematical hypothesis, not a description of the real universe. Rheticus suspected that Osiander had made the changes and probably did not approve; however, he did not take an official position against the preface, since perhaps he considered it a way of making the heliocentric theory more acceptable for ecclesiastics and theologians.

Ricci, Matteo

Born **Macerata, (Marche, Italy), 6 October 1552**
Died **Beijing, China, 11 May 1610**

Matteo Ricci carried out an astonishingly successful mission to Chinese scholars during which he greatly improved the maps of China and introduced Euclidean geometry and trigonometry there.

Ricci's parents were Giovanni Battista Ricci and Giovanna Angiolelli. Matteo entered the Jesuit order in 1571, and after his courses in rhetoric, philosophy, and theology he studied mathematics at the Roman College under **Christoph Clavius**.

In 1577 Ricci departed Rome to join the Jesuits working in China and arrived there in 1583, where he worked for 27 years. He first opened a residence in Nanking for himself, his fellow Jesuits, and his scientific instruments. (For a time suspicious landlords would drive Ricci and his companions from their dwellings, until they hit on the plan of renting haunted houses; then no one bothered them.) Gradually Ricci was welcomed to the academies and gained many influential friendships. Later he became the court mathematician in Beijing, and there he stayed for the rest of his life.

Jesuits were practically the sole source of Chinese knowledge about western astronomy, geometry, and trigonometry. Appointments in the Astronomical Bureau provided the Jesuits with access to the ruling elite, whose conversion was their main object. Mathematical and astronomical treatises demonstrated high learning and proved that the missionaries were civilized and socially acceptable.

Matteo Ricci brought trigonometry to China, where it had remained in primitive form until the Jesuits came. Ricci's successors, **Ferdinand Verbiest** and **Johann Schall von Bell**, used geometric and trigonometric concepts to bring about a revolution in the sciences of astronomy, the design of astronomical instruments, mapmaking, and the intricate art of making accurate calendars.

The Jesuits were inveterate mapmakers and were continually traveling around the empire of China, even though travel conditions were quite inconvenient. The *Philosophical Transactions of the Royal Society* recounts 52 such journeys by Ricci and Verbiest alone.

Ricci designed and displayed a great world map, which brought about a revolution in traditional Chinese cosmography. For the first time the Chinese had an idea of the distribution of oceans and landmasses. This was the beginning of his major contribution to the diffusion of knowledge through his more than 20 works in Chinese on such topics as mathematics and astronomy.

For 20 years Ricci tried to reach the emperor in person, but the emperor was a recluse not accustomed to seeing even his own people. Then, unexpectedly, the emperor summoned Ricci and his companions to inquire about a ringing clock brought to him by the Jesuits. His own scientists had failed to fix it when it stopped. Since the emperor could not receive these foreigners in person, he had an artist draw full-length portraits of them, so that they could have a vicarious interview.

Another opportunity was occasioned by an eclipse of the Sun: The prediction of the expected time and duration made by the emperor's own Chinese astronomers differed considerably from the Jesuit prediction. When the latter prediction proved correct, the place of the Jesuit mathematicians was secure. It is interesting that the Jesuits taught the Chinese the heliocentric theory, unaware that **Galileo Galilei**'s trial had taken place, and it had been forbidden by Rome to be taught as a proven fact. There was a more than 5-year lag in communications.

Ricci's books *Geometrica Practica* and *Trigonometrica* were translations of Clavius's works into Chinese. In 1584 and 1600 he published the first maps of China ever available to the west. As author, the Chinese geometrical works for which Ricci is remembered were books on the astrolabe, the sphere, measures, and isoperimetrics. But especially important was his Chinese version of the first six books of Euclid's *Elements*, which was written in collaboration with one of his pupils and entitled *A First Textbook of Geometry*.

The prestige Ricci gained in the highest cultural spheres by his wisdom, scientific knowledge, and capacity for philosophical speculation won him a hearing when he spoke of the gospel message. Without any trace of superiority in his manner, he used a process of dialog that was characterized by an esteem and respect for everyone. Ricci's success was due to his personal qualities, his complete adaptation to Chinese customs (choosing the attire of a Chinese scholar), and his authentic knowledge of mathematics, physics, and astronomy. (His works included Chinese texts on religious and moral topics, as well as writings on scientific topics.) It is still possible to visit Ricci's 8-ft.-high tomb in the Beijing suburbs.

Riccioli, Giovanni Battista

Born **Ferrara, (Italy), 17 April 1598**
Died **Bologna, (Italy), 25 June 1671**

Giovanni Riccioli was a pioneer in lunar astronomy who first named craters and mountains on the Moon for scientists. He also perfected the use of the pendulum for time measurement.

Riccioli entered the Jesuit order in 1614, and studied rhetoric, philosophy, and theology in Parma and Bologna. During this period he began his studies in astronomy.

Riccioli published one of the earliest books on astronomy: *Almagestum Novum* (Bologna, 1651). His chapter concerning the Moon contains two large maps (28 cm in diameter), one of which shows – for the first time – the effects of librations and introduces new lunar nomenclature. Almost all of his names for lunar objects are still in use today. It is the first map to name craters and mountains for scientists and prominent people instead of abstract concepts. A copy of Riccioli's lunar map stands at the entrance to the lunar exhibit at the Smithsonian Institute, and was described in detail in the *Philosophical Transactions* of the Royal Society. It was meticulously drawn by another Jesuit, **Francesco Grimaldi**.

Jesuit astronomers in Rome such as Riccioli had a great advantage over others because they were able to gather information from their former pupils spread out across the globe, in places as disparate as South America, Africa, China, Japan, and India. There were many Jesuit astronomical observatories throughout the world that efficiently gathered data concerning lunar and solar eclipses as well as transits of Venus. By the time of the (temporary) suppression of the Jesuit Society in 1773, no fewer than 30 of the world's 130 astronomical observatories were run by Jesuits. This information enabled Riccioli to compose a table of 2,700 selenographical objects, incomparably more accurate than anything previously known.

Riccioli also made many important measurements in order to refine his existing astronomical data, such as the radius of the Earth and the ratio of water to land on its surface. He compiled star catalogs and described sunspots, the movement of a double star, and the colored bands of Jupiter.

In physics, Riccioli went beyond the preliminary work of **Galileo Galilei** and succeeded in perfecting the pendulum as an instrument to measure time, thereby laying the groundwork for a number of important later applications. Riccioli once persuaded nine of his fellow teachers to count 87,000 oscillations over the course of a day, enabling him to identify an error of three parts in a thousand. In his book *God and Nature*, David Lindberg notes that it was Riccioli, not Galilei, who first accurately determined the rate of acceleration of a falling body. Noting the collaborative efforts of Jesuits, he argues that Jesuit scientists, rather than the Academia del Cimento or the Royal Society, formed the first true scientific society. **Athanasius Kircher**, for example, in his ability to collect observations from a worldwide network of informants was more than a match for **Marin Mersenne** in Paris or Henry Oldenburg in London, and he published this information in massive encyclopedias, which were indispensable in disseminating scientific data and theories.

Riccioli contributed also to geography, publishing tables of latitude and longitude for many different locations. This facilitated later developments in cartography.

Riccò, Annibale

Born **Modena, (Italy), 15 September 1844**
Died **Rome, Italy, 23 September 1919**

Annibale Riccò carried out an exhaustive study of solar prominences, of which he amassed over 20,000 observations, and deduced the existence of the solar wind.

Riccò was educated at the University of Modena, where he received his bachelor's degree in mathematics (1866) and doctorate in natural sciences (1868). He also earned a degree in civil engineering from the Polytechnic Institute of Milan (1868) and began his career as an architect.

Riccò's involvement with astronomy began as an observatory assistant at Modena. In 1872, he cofounded the Society of Italian Spectroscopists, whose efforts were devoted chiefly toward an improved understanding of the Sun. Temporarily an instructor of physics at Naples, Riccò was subsequently appointed an astronomer at the Royal Observatory in Palermo. In 1885, he founded an observatory at Catania, and in 1890 became director of the Catania Observatory and Mount Etna Observatories and acquired the chairmanship of astrophysics at the University of Catania. Riccò held these posts for the remainder of his life.

Riccò's data revealed the solar prominences to be of two principal types, either quiescent or active. He was among the first to argue that dark "filaments," which appeared superimposed on the solar disk, were themselves prominences. In 1892, Riccò demonstrated that delays of roughly forty to forty-five hours occurred between the crossings of sunspots on the solar meridian and resulting terrestrial magnetic disturbances. Particles emitted by the Sun, and whose existence Riccò inferred, are now recognized as the "solar wind."

Riccò oversaw the Catania Observatory's involvement with the International *Carte du Ciel* Astrographic Chart and Catalogue project, and attempted, albeit unsuccessfully, to photograph the Sun's corona without an eclipse from the top of Mount Etna with American astronomer **George Hale** (1894). Perhaps in relation to his solar studies, Riccò observed numerous bright comets, including C/1908 R1 (Morehouse) and 1P/1909 (Halley). In 1899, he became coeditor, and in 1905, editor, of the *Memoire della Società degli Spettroscopisti Italiani*, founded by **Angelo Secchi** and **Pietro Tacchini**. Riccò traveled abroad to witness several total solar eclipses.

Riccò's solar research netted him some prestigious awards, including the Royal Prize of the Accademia dei Lincei, and a Knight of the Crown of Italy. Riccò was thrice elected an executive officer of the International Union for Cooperation in Solar Research [IUCSR] and, in 1919, a vice president of its successor, the International Astronomical Union [IAU]. Both appointments reflected his strong commitments toward fostering solar research and international scientific cooperation.

Richard of Wallingford

Born **England, *circa* 1291**
Died **England, *circa* 1335**

Richard of Wallingford is probably best remembered for the astronomical clock he designed for the abbey of Saint Albans. He also wrote books about astronomical instruments and about trigonometry.

Richard was born in either 1291 or 1292 to William, a blacksmith, and Isabella. William died when Richard was 10, whereupon Richard was adopted by William de Kirkeby, Prior of Wallingford. He attended Oxford for 6 years, graduating with an AB degree, then assumed the monastic habit at Saint Albans. He was ordained deacon in 1316 and priest in 1317. His abbot sent him back to Oxford, where he studied for 9 years and received a Bachelor of Divinity degree in 1326.

In the same year the presiding abbot died, and Richard was elected the new abbot of Saint Albans. Despite contracting leprosy at about that time, which led to blindness in one eye and later robbed him of his power of speech, Richard was nonetheless a strong abbot. He brought Saint Albans out of debt, quelled riot among the townspeople, and survived internal struggles that led to a papal inquisition.

Richard's greatest achievement was the clock that he designed and had built for the abbey. It was the first purely mechanical clock of which there is a complete record. It not only struck the hours of the day, but also indicated the positions of the Sun, Moon, and planets, as well as lunar phases and solar eclipses; it may also have had a tidal dial. It was a clock of unprecedented complexity and accuracy for its time and was unsurpassed in quality for the next 200 years. When King Edward III chided him for building a clock instead of more churches, Richard replied that many abbots could build churches, but after he was dead, no one could complete the work of the clock. The clock itself is no longer in existence, a victim of the dissolution of the monasteries in the 16th century.

While studying at Oxford, Richard produced several works of mathematics and astronomy that are also remarkable for their time. The *Quadripartitum* and *de Sectore* comprised the most comprehensive compendium of trigonometry in Europe before the end of the 1400s. This also was the first instance where trigonometry was separated from its applications (*e. g.*, astronomy) and dealt with in an abstract manner. Richard wrote the *Exafrenon*, a treatise on the prediction of weather and natural events that were believed to be governed by planetary influence. He also wrote two manuscripts devoted to astronomical instruments he invented. The *Albion* described his version of an *equatorium* to calculate planetary positions and eclipses. It was a completely new design with few moving parts, and capable of very accurate predictions. Versions of the albion were created by Simon Tunsted, **John of Gmunden**, and **Johann Müller** (Regiomontanus), and it was influential in the design of the later instruments of **Johannes Schöner** and **Peter Apian**. The *Rectangulus*, made from seven straight rods, rather than the disks and rings of typical armillaries, was an observational instrument that also allowed one to directly transform coordinate systems. Since it was based on straight lines, it could be constructed more easily and accurately, but it was more difficult to read than the armillary or torquetum.

Richaud, Jean

Born **Bordeaux, Gironde, France, 1 October 1633**
Died **Pondicherry, (India), 2 April 1693**

French Jesuit missionary Jean Richaud made the first astronomical discoveries from India using a telescope. In 1689, he observed that the stars α Centauri and α Crucis are in fact double. (The binary nature of α Crucis had been independently noted by fellow Jesuit Jean de Fontenay, at the Cape of Good Hope, 4 years earlier.)

Richer, Jean

Born **France, 1630**
Died **Paris, France, 1696**

Giovanni Cassini sent Jean Richer to South America in order to witness the 1672 opposition of Mars. Richer's observations, and those made simultaneously at the Paris Observatory, were used to refine the length of the Astronomical Unit. While in present-day French Guyana, Richer measured that a pendulum swung more slowly than at Paris. He attributed this to weaker gravitational acceleration near the Equator, in accordance with the Newtonian theory of an oblate Earth.

Riḍwān al-Falakī: Riḍwān Efendi ibn ʿAbdallāh al-Razzāz al-Falakī

Born **Cairo, (Egypt)**
Died **Cairo, (Egypt), 7 August 1711**

Riḍwān Efendi al-Falakī was an Egyptian–Ottoman astronomer known for his production of astronomical tables as well as various instruments and globes. He was also noted for the many students that he trained. There is little information on his birth, youth, and education. However, we know that Riḍwān al-Falakī studied in Cairo and received his astronomical education from distinguished scholars. Indeed, he never left Cairo except in 1680, when he visited Mecca for the *ḥajj* (pilgrimage). Besides writing on astronomy, Riḍwān al-Falakī wrote a number of books on mathematics and geometry. According to the sources on Ottoman astronomy, his works were so abundant that the drafts of his books were considered a camel's load. At the request of the timekeeper Ḥasan Efendi, in 1700 and 1701 he prepared spheres and astronomical devices upon which he marked the Arabic names of stars that he located through observation. Among Riḍwān al-Falakī's many students in astronomy, only Yūsuf al-Jamāli (the servant of Ḥasan Efendi) is known.

The titles of 17 of Riḍwān al-Falakī's astronomical works are known, most of which are extant. All were written in Arabic. Several works are adaptations of the work done at the Samarqand

Observatory under **Ulugh Beg**. His *Zīj al-mufīd ˁalā uṣūl al-raṣad al-jadīd al-Samarqāndī*, or *al-Zīj al-Riḍwānī*, is an astronomical handbook with tables based on *Zīj-i Ulugh Beg* but adapted for Cairo's latitude. It consists of four parts in addition to an introduction and various tables. Riḍwān al-Falakī's *al-Durr al-farīd ˁalā al-raṣad al-jadīd* is possibly a commentary written on Ulugh Beg's *Zīj*; it contains an introduction, 12 sections, and a conclusion. *Asnā al-mawāhib fī taqwīm al-kawākib* is another work he adapted from *Zīj-i Ulugh Beg* for Cairo's latitude.

Riḍwān al-Falakī is also known for his works on timekeeping. Of these, probably the most extensive is *Dustūr uṣūl ˁilm al-mīqāt wa-naṭījat al-naẓr fī taḥrīr al-awqāt*. Other treatises treat eclipses, lunar-crescent visibility, sundials, and Jupiter–Saturn conjunctions. For a listing of his works, see Ihsanoğlu *et al.* (1997), and Rosenfeld and Ihsanoğlu (2003).

Ritchey, George Willis

Born **Tuppers Plains, Ohio, USA, 31 December 1864**
Died **Azusa, California, USA, 4 November 1945**

George Ritchey may arguably be called the most visionary and yet least appreciated designer and user of large telescopes in early-20th-century America. Although Ritchey has become well known for the Ritchey–Chrétien telescope design, developed along with French astronomer Henri Chrétien, roughly half a century was to elapse before its innovative traits gained widespread acceptance. At the same time, however, Ritchey was among the first astrophotographers to demonstrate the true potential of the modern reflecting telescope. While employed at the Mount Wilson Observatory, California, Ritchey produced remarkable photographs of astronomical objects, especially of the "spiral nebulae." It was in these spiral nebulae, then considered to be merely clouds of gas or dust, that Ritchey discovered faint novae, suggesting that they were in fact galaxies external to the Milky Way. A perfectionist in much of his work, Ritchey was perhaps the foremost optician and instrument maker of his day. Yet, it was also Ritchey's curse that he could be a difficult and sometimes temperamental person to work with. He tended to be secretive and possessive of his techniques, over optimistic in some of his claims, and dismissive of others' ideas. As a result, Ritchey's personal disputes with **George Hale** and others cost him much of his well-deserved reputation.

Ritchey was born into a small farming community. His father was a skilled and, at times, fairly prosperous furniture maker. Although the family had its high and low points, Ritchey succeeded in gaining a reasonably good education for the times. He graduated from Hughes High School in Cincinnati, Ohio (1881), and entered the School of Design at the University of Cincinnati the following year. It was during this time that Ritchey became interested in astronomy, and he was doubtless lucky to be living so near to one of the oldest observatories in America, the Cincinnati Observatory. Between 1882 and 1887, Ritchey was in and out of school as his ambitions to become an astronomer competed with economic reality. He married Lillie May Gray in 1885; the couple was to have two children. While attending classes, Ritchey worked part-time at the observatory, in a small home shop where he built his first telescope, and at the family furniture business. It was for economic reasons that Ritchey left college and became an industrial-arts instructor at the Chicago Manual Training School in 1888. However, the move to Chicago turned out to be Ritchey's great opportunity to become an astronomer.

Ritchey met Hale in 1890, and both realized that they could be of use to one another. Ritchey, who had also taken up photography as a hobby, was an occasional visitor and contract employee at Hale's Kenwood Physical Observatory. The subsequent establishment of the University of Chicago's Yerkes Observatory resulted in Ritchey being hired by Hale as a full-time optician and observer. Both Ritchey and Hale had come to the conclusion that the days of the unchallenged superiority of the refracting telescope were over, and that large reflectors, cheaper to build for their aperture and not susceptible to chromatic aberration, represented the future of large astronomical telescopes.

While still employed at the Chicago Manual Training School, Ritchey worked on a number of projects for Hale, including a 24-in. mirror for a special solar telescope, and perfected his mirror-making techniques on smaller instruments for himself. Ritchey's first major project at the Yerkes Observatory was the construction of a 24-in. $f/4$ Newtonian reflector. This short focal length telescope, expressly built for astrophotography, was considerably "faster" than any normal refracting telescope of the same aperture and much larger than special photographic lenses then available. It had a wide field of view, and could record faint nebulosity with much shorter exposures than competing instruments.

Ritchey proved to be more than just an optician, and with the 24-in. and other telescopes at Yerkes, began his career as an astrophotographer. For a time, he challenged **Edward Barnard** and others with his published photographs of star clusters, nebulae, and the Moon. Many journals and astronomy texts of the time were graced by his photographs. It was during this time that Ritchey began publishing a number of scholarly articles, *e. g*., on his design for an improved mounting system for large telescope mirrors, and reports of his observations, including those changes observed in the nebulosity around Nova Persei (1901). These changes are now considered to be the first observation of a light echo.

Ritchey's next project was a 60-in. reflecting telescope, originally intended for a "western station" of Yerkes Observatory that instead became the Mount Wilson Observatory. It was with the 60-in. that he began his series of photographic observations of the Moon, planets, nebulae, star clusters, and most importantly, the spiral nebulae. In 1910, Ritchey reported that his photographs of spirals (like M81) revealed "soft star-like condensations" that he called nebulous stars. Adopting this condensation model, he concluded that his photographs "strongly oppose, if they do not effectually preclude, the theory that the spiral nebulae are distant systems of stars like our Milky Way." Starting in 1917, however, Ritchey began to discover novae associated with the spirals, and later identified them on plates taken back in 1909. This evidence seemingly contradicted his earlier stance against the spirals as independent stellar systems. As a result, it was largely left to Lick Observatory astronomer **Heber Curtis**, and Mount Wilson Observatory astronomer **Edwin Hubble**, to correctly conclude that the spiral nebulae were in fact external galaxies.

Ritchey's greatest achievement, yet also the project that would see his downfall, was the mirror of the 100-in. Hooker telescope at Mount Wilson Observatory. Construction of this telescope (the largest attempted up to that time) was begun in 1906 but only completed in 1919. The project was plagued with problems and controversies from the beginning. There was considerable difficulty in procuring a high-enough quality glass disk to suit Ritchey, who advocated, and conducted extensive experiments on, the concept of a lightweight, cellular mirror. Ritchey also objected to using a domed observatory, preferring a lightweight, roll-off structure that would eliminate the detrimental effects to atmospheric steadiness caused by the release of heat absorbed by a conventional masonry building during the day. His seemingly endless testing, experimenting, and arguments over design concepts cost him the support of Hale and others. In the end, his personal disputes with Hale also cost him his job at Mount Wilson Observatory and tarnished his reputation in the astronomical community. With the completion of the 100-in. telescope, Ritchey had produced another superb mirror. Yet, he was effectively shut out of Hale's next great telescope project – the 200-in. Mount Palomar reflector. Ritchey was to spend the next several years either working on projects in France, or in semiretirement.

As early as 1910, Ritchey met French astronomer and optician Henri Chrétien. Ritchey and Chrétien recognized the inherent flaws of Newtonian and Cassegrainian optical designs, namely the increase of the aberration called coma toward the edge of the field of view. It causes stars to appear as elongated, comet-shaped blurs. Together, they developed the Ritchey–Chrétien telescope (employing hyperbolic primary and secondary mirrors) that corrected this flaw and potentially produced near-perfect star images in photographs. But Ritchey's loss of reputation, caused by his disputes with Hale, cast serious doubts on the new type of telescope. Given a laboratory at the Paris Observatory, Ritchey completed a prototype of the new design, a 0.5-m (20-in.) reflector, in 1927. Yet, American astronomers virtually ignored the potential benefits offered by the Ritchey–Chrétien design.

In 1930, Ritchey returned to the United States and eventually obtained support to construct a 1-m (40-in.) Ritchey–Chrétien reflector for the United States Naval Observatory. But plagued by poor weather conditions at its original site in Washington, the instrument languished until the telescope was reerected at Flagstaff, Arizona, where its design was thoroughly vindicated. Starting in the 1960s, many of the largest optical telescopes constructed have employed the Ritchey–Chretien design.

Excluded from all aspects of the 200-in. Palomar reflector, Ritchey nonetheless continued to produce designs of giant reflecting telescopes, up to 8-m aperture, none of which was ever built. Yet, he had contributed toward many important developments, both observationally and instrumentally, in early-20th-century astronomy. His principal legacies remain the 60- and 100-in. reflectors at Mount Wilson Observatory. While some of Ritchey's ideas concerning large telescopes seemed radical during his lifetime, many have since come into standard practice in modern astronomical instrumentation. The Ritchey–Chrétien telescope, lightweight cellular mirror, the stress-reducing mirror cell, and even the concept of the "observatory environment," have since been adopted by the astronomical community that, under Hale's influence, had once excluded Ritchey.

Rittenhouse, David

Born **Paper Mill Run near Germantown, Pennsylvania, (USA), 8 April 1732**

Died **Philadelphia, Pennsylvania, USA, 26 June 1796**

David Rittenhouse, a noted self-educated man of many dimensions, rose from obscure beginnings as a clock- and scientific instrument-maker in Norriton, Pennsylvania, to prominence in the world of science as an effective observational astronomer and experimental scientist.

The origin of Rittenhouse's clockmaking knowledge is unclear, though it is certain that he inherited a chest of tools from a maternal uncle, and that his father purchased the additional tools he originally needed to enter the trade of clockmaking. The tall clocks Rittenhouse made in the roadside workshop he opened in Norriton around 1749, if not unusual in their mechanism, nevertheless were masterpieces of craftsmanship. In three he included small orreries, and in the period 1767–1771 he designed and built two large vertical orreries. One of these was purchased by the Pennsylvania General Assembly for the College of Philadelphia (later the University of Pennsylvania), the other by the College of New Jersey (now Princeton University).

Indeed, it was his clockwork orreries and telescopes that led Rittenhouse to astronomy and ultimately brought him to the attention of the scientific community in Philadelphia. Four years after his marriage to Eleanor Coulston on 20 February 1766, he and his family took up residence in Philadelphia. Eleanor died giving birth to the second of two children; David remarried in 1772, this time to Hannah Jacobs.

However, it was the transit of Venus in 1769 that turned Rittenhouse to serious observational astronomy, and earned him a place among the world's astronomers. He had previously taught himself mathematics and physical sciences by reading, mostly from **Isaac Newton**'s *Principia.* For the transit, Rittenhouse first prepared a proposal to the Philosophical Society in which he recommended that the society establish two stations to observe the transit. He volunteered to equip a station at Norriton as one of the two sites. After the society approved his plan, Rittenhouse constructed a transit telescope (possibly the first telescope made in America), in addition to an equal-altitude instrument and an 8-day clock, all for use at Norriton.

The observational techniques Rittenhouse reported were of greater significance than the data he obtained, more for their inventiveness than for their innovation. For instance, around 1785 he resolved the difficulty in lining up his meridian telescope on a distant mark by installing a collimating lens system enabling him to use a much closer mark. Such a lens system was not new, so he cannot be credited with its origin, but his inventiveness was showcased. The same can be said of his use of spider web in his telescope, for he did not know that it had been previously used by **Francesco Fontana**.

In Philadelphia, Rittenhouse established an astronomical observatory and made many astronomical observations, provided data for almanacs, and lectured on astronomy. In 1786, he published a paper describing his invention and study of a plane transmission grating, in this case a series of closely spaced fine wires wrapped on frames. Using one of these frames he observed up to six orders of diffracted spectra, measured the angular displacement of each, and from the data developed a workable theory of diffraction to account for his observations, but he took the experiments no further. It would be left for **Joseph von Fraunhofer** and Augustin Fresnel to carry them forward.

Rittenhouse also took part in the Mason–Dixon survey of the boundary between Pennsylvania and Maryland (1763), and carried out surveys of other state and colonial boundaries, as well as canals and rivers, usually with instruments of his own construction. He served in various capacities during the Revolution, and in 1792 became the first director of the United States Mint. He was one of the earliest members elected to the American Philosophical Society and succeeded Benjamin Franklin as president of the society (1791). Rittenhouse was elected a foreign member of the Royal Society of London (1795).

Ritter, Georg August Dietrich

Born **Lüneburg, (Niedersachsen, Germany), 11 December 1826**
Died **Lüneburg, (Niedersachsen, Germany), 26 February 1908**

August Ritter, a pioneer in the theory of stellar structure, obtained fundamental results by applying the relatively recent laws of thermodynamics, as enunciated by Rudolf Clausius and **William Thomson** (Lord Kelvin), to a gaseous model of the Sun. He took up the problem where **Jonathan Lane** had left it and carried the mathematical development forward to where **Robert Emden** could turn it into a fully developed theory of a perfect gaseous sphere.

The entire subject of solar physics in the period from 1870 to 1890 was in a state of rapid flux, invigorated by the prospect of investigating the physical constitution of the stars by means of spectral analysis. Ritter's highly mathematical contributions, coming from a relatively unknown faculty member at a small polytechnic school, found few appreciative readers at the time.

Ritter began his studies in 1843 at the polytechnic school in Hanover, and continued them at Göttingen University, where he received his Ph.D. in 1853. He then returned to the Hanover polytechnic school as an instructor in 1856. Ritter was subsequently appointed a professor of mechanics at the Aachen Technische Hochschule when it opened in 1870. Some idea of his circumstances there is suggested by the testimony of Otto Lehmann, who came to Aachen in 1883 from the larger secondary school at Mühlhausen. The space for research at Aachen was so small that Lehmann could not find room for the limited apparatus he brought with him. It took him far longer to do research at Aachen, he claimed, but he felt compensated by the increased time he had there for research.

In a series of 18 papers published between 1878 and 1883 in the leading German physics journal, *Annalen der Physik*, and in a separate textbook of 1879, Ritter employed a meteorological model to derive the fundamental differential equations regulating both a thermodynamically stable gaseous sphere heated by gravitational contraction and one subject to cyclical pulsations. He showed that stable convective currents acting throughout the sphere produced a temperature gradient inversely proportional to its radius.

A 1939 assessment by **Subrahmanyan Chandrasekhar** characterized Ritter's investigations as "a classic [,] the value of which has never been adequately recognized," in which "almost the entire foundation for the mathematical theory of stellar structure was laid by him" (1939, pp. 178, 179). Astronomers **Otto Struve** and Velta Zebergs pointed out that Ritter's 1879 paper on the theory of radial pulsations in stars was advanced long "before the [observed] variation in radial velocity [among classical Cepheids] was known." More importantly, Ritter had derived a "relation between density and period of pulsation" that "remarkably closely approximates the observations" (1962, p. 314).

Ritter, Johann Wilhelm

Born **Samitz, (Chojńow, Poland), 16 December 1776**
Died **Munich, (Germany), 23 January 1810**

German chemist, physicist, and physiologist Johann Ritter came to work at Jena with **Alexander von Humboldt** in 1795. His subsequent career and life were brief and chaotic, partially owing to issues of philosophy of science then under bitter discussion in Germany. In 1801, while at the court of the Duke of Gotha and Altenberg, Ritter discovered that paper soaked in a solution of silver iodide was blackened most by the radiation coming from the Sun just slightly off the end of the spectrum beyond the last visible violet light. Ritter was, therefore, the discoverer of ultraviolet radiation, the year after **William Herschel** discovered infrared from its heating power.

Roach, Franklin Evans

Born **Jamestown, Michigan, USA, 23 September 1905**
Died **Tucson, Arizona, USA, 21 September 1993**

American spectroscopist and photometrist Frank Roach was for many years the world expert on how bright the sky is at night and the various sources that contribute to the brightness. He was the oldest of four children of optometrist Richard F. Roach and Norwegian immigrant Ingeborg (*née* Torgerson) Roach and was educated in the public schools of Wheaton, Illinois (including the high school also attended by **Edwin Hubble** and **Grote Reber**), and Highland Park, California. Roach started on a premedical curriculum at Wheaton College, and won a scholarship to the University of Michigan, but decided to use it to finish a bachelor's degree immediately rather than a medical degree involving a longer period of education that his family could ill afford. A succession of temporary, nonscientific jobs continued to interrupt Roach's education, but he succeeded in completing, at the University of Chicago, an MS in 1930, with a thesis on absorption lines of ionized sulfur in stellar spectra and a Ph.D. in 1934 with a thesis on red and near-infrared stellar spectra, both under the direction of **Otto Struve** who had, in 1932, succeeded **Edwin Frost** as director of Yerkes Observatory. In 1932, Roach was sent to Perkins Observatory, Ohio, where he used their 69-in. telescope to develop and use a spectrograph intended for the new McDonald Observatory, a Chicago–Texas collaboration.

Roach was appointed as the first astronomer stationed at McDonald Observatory and, while there, collaborated with **Christian Elvey** on photographic photometry of reflection nebulae, his first venture into accurate measurements of faint, extended sources. During his time as associate professor of astronomy at the University of Arizona, beginning in 1936, Roach continued both stellar spectroscopy (mastering the details of atomic physics essential for understanding diffuse skylight) and photometry with Elvey. During World War II, Roach was first a member of the California Institute of Technology rocket program, working at Eaton Canyon near Pasadena and then at what became the United States Naval Ordnance Test Station [NOTS], China Lake. Though he was reassigned to work on high-explosives research in connection with the Manhattan Project, Roach returned to NOTS after the war, where he established with Elvey a pioneering night-sky research group. After a year in Paris (1951/1952) collaborating with **Daniel Barbier**, the French expert on night-sky emission, Roach moved to the National Bureau of Standards [NBS], in Boulder, Colorado. He established, in 1961, another night-sky observatory on Mount Haleakala, in Hawaii, and moved there after his 1966 retirement from the NBS.

Roach provided the standard photometer against which all the others were calibrated during the International Geophysical Year (1958), acted as an advisor to astronauts on what they could reasonably expect to see in space and how to interpret it, and was part of the scientific team for the "Scientific Study of Unidentified Flying Objects" conducted by the University of Colorado in 1967, under contract to the United States Air Force.

Roach's greatest achievement, however, remained the identification of the various sources of diffuse skylight. These include the glow of ionized atoms in the Earth's atmosphere (in layers that, as he showed, moved up and down through the day and night and the seasons), aurorae (atomic glows driven by particles coming from solar flares), faint stars, and sunlight reflected by dust in the plane of the Solar System (zodiacal light). His 1973 book, *The Light of the Night Sky*, written with Janet L. Gordon (who had been part of the University of Arizona astronomy department during his time there), continues to be cited on the subject. Unfortunately, of course, the skies we see now are very much brighter than those Roach measured because of the increased input of artificial light, reflected back by high-lying dust (some of which is also artificial). In the course of his career, Roach published more than 100 papers.

Gordon and Roach were married in 1977, following the death of his first wife, Eloise Blakslee, who had been the daughter of a Yerkes Observatory photographer. Roach received a Department of Commerce Gold Medal in recognition of his outstanding work on upper-atmosphere physics.

Roberts, Alexander William

Born **Farr, (Highland), Scotland, 4 December 1857**
Died **Alice, (Eastern Cape), South Africa, 27 January 1938**

Using light curves he derived from his own very precise visual photometry, Alexander Roberts pioneered the computation of eclipsing binary-star orbits, shapes, and densities. Roberts demonstrated, simultaneously with **Henry Norris Russell**, that the components of some of these stellar systems are tenuous, low-density stars with gigantic diameters.

Roberts's father apparently died while Alexander was an infant as only his mother's maiden name, Ann Campbell, is known. The family moved from Farr to Leith, where Roberts received his education at the Saint James Schools, and further preparation for a career in teaching at Moray House and the Watt Institution and School of Arts. After completing his education, in 1878 Roberts accepted a teaching post at Wick, Caithness, where he apparently met his future wife, Elizabeth Dunnett. In 1881, he matriculated at the University of Edinburgh for further education.

At an early age, Roberts read a copy of **James Ferguson**'s *Astronomy Explained on Sir Isaac Newton's Principles* and thereafter contemplated an astronomical career. In 1882, he applied for a position as an assistant at the Edinburgh Observatory, but in response received a discouraging letter from **Charles Smyth**, the Astronomer Royal for Scotland. Instead, after graduating from the university, Roberts accepted a call to missionary teaching at the Free Church Mission College in Lovedale, Cape Colony, South Africa. Roberts arrived at Lovedale in July 1883 and was followed a year later by Elizabeth; they were married in 1884 and had three children.

After settling in Lovedale, Roberts took up his avocational interest in astronomy. After some preliminary recreational observing, he made an accurate determination of the latitude of his observing station. The next step of his orientation was to map the night skies, which he did carefully with an old theodolite and binoculars. Roberts noted not only the position of each visible star but also numbered each star in a sequence that represented their relative brightness. In this familiarization process, Roberts revisited each chart a day, a week, or a month later, each time reranking the stars according to their brightness. Using this process he discovered a number of new variable stars. By 1891, when construction of his observatory was completed, Roberts's orientation to the southern night skies was also complete, and he began to pursue serious astronomical research. With the encouragement of **David Gill**, director of the Royal Observatory, Cape of Good Hope, Roberts began to observe southern variable stars. By 1894, he had discovered a number of additional variable stars so that the total of his discoveries had grown to 20. As the number of known variable stars in the southern skies grew, Gill recommended that Roberts pay particular attention to eclipsing binary stars, of which Algol was the best-known example.

As his observing program matured, Roberts considered the conditions that might influence the accuracy of his observations, for example, the effect of position angle of the variable star and comparison stars in the field of view, and also the influence of relative proximity to the variable star and the comparison star in the field of view to his nose. After these effects were noticed, Gill arranged for the donation of a special photometer by Sir John Usher. Roberts conducted an exhaustive series of observations with this special photometer in which the field of view could be rotated to six different fixed positions. Using the Usher photometer, then a wedge photometer on loan from Oxford University, and later a 4-in. meridian photometer on loan from Harvard College Observatory, Roberts conducted his variable star photometry program with unprecedented levels of precision for visual observations.

For nearly 30 years, Roberts was among the most prolific and exacting variable star observers in either hemisphere. Roberts determined the orbital elements and absolute dimensions of eclipsing binaries from an analysis of their light curves. Because of his confidence in the precision of his light curves, Roberts took the extra steps necessary in computing the orbits of binary stars to demonstrate that their shape was that of oblate spheroids as had been suggested theoretically by **George Darwin** and **Jules Poincaré**. Roberts took the process a step further, and computed the relative diameters and masses of the individual stars in some of these systems. From these data, he concluded that the stars were distended and tenuous objects. In contrast, Russell reached similar conclusions based only on the combined mass of the binary pairs and did not venture the computation of the masses of individual stars.

Roberts's style of reporting for his results was to prepare accurate light curves reflecting his observations, and to draw theoretical conclusions based on his mathematical analysis of the light-curve data. Thus his reporting, in the leading astronomical journals of the times, was fairly compact and did not include his reduced observations. Eventually, Roberts had accumulated over a quarter of a million observations; professional colleagues urged him to publish his reduced data. Around 1915 or so, the reality of his dilemma began to sink in. In order to accommodate requests, from the likes of **Edward Pickering** and **Ejnar Hertzsprung**, Roberts would have to give up observing and spend his full effort at reduction and tabulation of his results. The data reduction effort was as monumental as the effort that had been invested in making the observations. At Pickering's request, Roberts prepared his observations for publication, but unfortunately the format in which he presented his data was not acceptable to Harvard College Observatory for publication in their *Annals*. Though he appealed for assistance from Pickering, Hertzsprung, and others, Roberts insisted that the work was his alone; he was unwilling to train natives to help with this effort, likely for lack of the financial resources with which to pay them for their work. Tragically, Roberts's massive accumulation of data remained unpublished at the time of his death. The data are now held by the American Association of Variable Star Observers and will eventually be reduced and added to their archives, a fitting home for this valuable resource. Well known in the field of binary-star astronomy in his era, Roberts's published work is well cited by authorities in and after his time including **William Campbell** and **Zdněk Kopal**.

In 1893, Roberts was placed in charge of a 3-year program for training South African born teachers in a new normal school at Lovedale. Over the next 27 years, he trained over 4,000 natives, and became well known throughout the colony as a result of the efforts of this large corps of teachers. Through these extensive contacts, Roberts became increasingly involved in South African race relations. In 1920, South African Prime Minister Jan Smuts appointed Roberts to represent the interests of native Africans in the all-white Senate, which Roberts did with distinction. Roberts also served on a number of commissions investigating various problems including a racially charged riot in Port Elizabeth and the Bondelzwarts rebellion in southwest Africa. While the 1920s saw the end of Roberts's own astronomical research, he used his position in government to support the establishment of the University of Michigan's Lamont-Hussey Observatory at Bloemfontein. He also worked to promote astronomy among South Africans. He lectured widely and corresponded with young enthusiasts. **Alan Cousins** was one of the future South African astronomers inspired by Roberts's personal influence.

The first recipient of an honorary Doctor of Science degree from University of the Cape of Good Hope (now the University of South Africa), Roberts was also elected fellow of the Royal Astronomical Society, the Royal Society of Edinburgh, and the Royal Society of South Africa. He served as president of the South African Association for the Advancement of Science in 1913, as president of the Astronomical Society of South Africa in 1927 and 1928, and as a South African delegate to the 1925 International Astronomical Union General Assembly held at Cambridge, England.

Roberts's personal papers are deposited in the Cory Historical Library of Rhodes University.

Roberts, Isaac

Born **Groes, (Clwyd), Wales, 27 January 1829**
Died **Crowborough, (East Sussex), England, 17 July 1904**

Isaac Roberts, a pioneer astrophotographer, demonstrated that long exposures in large, well-mounted reflecting telescopes could record details of nebulae not visible to the naked eye. His photographs of the Andromeda, Orion, and many other nebulae surpassed all prior efforts.

The son of a farmer, Roberts moved with his family to Liverpool, England, where his father, William Roberts, took a position as bookkeeper in 1835. Roberts received only an elementary education. The remainder of his great store of knowledge was self-acquired.

In 1844, Roberts was apprenticed to a local building firm for a period of 7 years. After his apprenticeship, he remained with the firm, eventually becoming its manager. When the owners of the firm died, Roberts was retained by the families to supervise the closing of the company. Roberts then opened his own building firm, enjoying considerable success as a hard-working and diligent businessman. He took every possible opportunity to increase his knowledge, principally by means of study at the Mechanics Institute, which emphasized natural philosophy and experimental methods of investigation. In 1875, he married Ellen Anne Cartmell; their marriage was childless and ended by her death. By 1888 Roberts had amassed sufficient funds to retire. He then began to take part in the scientific work which had long fascinated him.

Interested in geology during his working days, Roberts became a fellow of the Geological Society, and wrote several papers that are still of interest today. But after a few years, he turned to astronomy and worked in that field for the remainder of his life.

Astrophotography was not new when Roberts came upon the scene. But, in 1878, when dry photographic plates were introduced, Roberts was among the first to realize the implications of the new emulsion for astronomy. An astronomical photograph need not end when all of the stars and nebulous details visible to the eye are recorded. The exposure could be continued, with more light accumulated on the plate to register fainter objects.

In 1879 Roberts purchased a 7-in. Cooke refractor, which he mounted in his private observatory at Maghull, near Liverpool. He began his experiments in astrophotography with this telescope. At first he intended to produce a photographic star atlas, and toward that end attended the 1887 organizational meeting for the *Carte du Ciel* project in Paris. The magnitude of the effort impressed Roberts, but he eventually decided not to participate in it.

At this time, **Andrew Common** had produced a magnificent photograph of the Orion nebula that won a Gold Medal from the Royal Astronomical Society [RAS] in 1884. Unfortunately, no one seemed to be following up in this exciting new field. Since Roberts had achieved some success in photographing nebulae and clusters, he decided that this avenue was the one through which he could make the most effective contribution.

Roberts ordered a 20-in. silver-on-glass reflector from the firm of **Howard Grubb**. The 100-in.-focal-length instrument was mounted equatorially with a very accurate clock drive. Plates were exposed at the mirror's prime focus, in order to preserve as much light as possible. Roberts added a novel touch to the mounting. In the place of a counterweight, he mounted the 7-in. refractor. It was an odd-looking arrangement, but it worked, and Grubb sold several other instrument-pairs in this style.

After a lengthy period of adjustment, the photographic results began to flow. The first exceptional images were of the Orion nebula and the Pleiades. The Orion exposure revealed more detail and extended the image to six times the area of Common's prize-winning picture. The image of the Pleiades revealed photographically, for the first time, the nebulosity that envelopes this brilliant cluster. Roberts exhibited these images at the January 1886 meeting of the RAS. He reported having taken over 200 images of objects outside the Solar System during 1885. For 15 years, Roberts regularly exhibited his latest photographs at the RAS meetings.

Roberts was active in the organization of astronomers during this period. He played a role in the formation of the Liverpool Astronomical Society [LAS], but objected to the rapid expansion of that organization into one of worldwide scope. He withdrew from active participation in the LAS, but was later active in the formation of the British Astronomical Association.

Roberts's greatest photographic achievement was a 4-hour exposure of the Andromeda nebula (known today as the Andromeda Galaxy). This image was presented to the RAS in 1888. It recorded photographically, for the first time, the spiral nature of the nebula. The image caused quite a sensation. It compares well with modern images of this galaxy. Though he did not know it, he had resolved a number of individual stars in the gigantic spiral.

In 1890 Roberts moved to Crowborough, Sussex, seeking a location with more favorable observing conditions. The new observatory was 780 ft. above sea level. He found the atmosphere to be much steadier at Crowborough. At the new location, Roberts employed a professional astronomer, **William Franks**, as his observer; and most of the observational work at Crowborough was carried out by Franks.

In 1896, Roberts went on an eclipse expedition to Norway. His party did not see the eclipse, but while on the trip he did meet **Dorothea Klumpke**, a San Francisco native and a professionally trained astronomer working on the *Carte du Ciel* project at the Paris Observatory. Roberts and Klumpke were married in 1901. The second Mrs. Roberts moved her professional astronomical activities to Roberts's observatory at Crowborough. The two collaborated on astronomical projects, mainly the analysis and publication of his plates, until Roberts's death.

Roberts died suddenly. On the morning of his death he had been working on his plates. Four years later his ashes were entombed in a stone monument in Birkenhead cemetery near Liverpool. The monument is fascinating; it includes engravings of some of his most important photographs. After settling his estate, Dorothea returned to Paris, where she continued to be active in astronomy. She maintained control of Roberts's photographic plates, making them available to other astronomers for research purposes. In 1928, to commemorate the centenary of Roberts's birth, she published a two-volume photographic atlas based on his work.

The failure of the Great Melbourne Telescope in the 1860s had cast a pall over the suitability of the reflecting telescope for astronomical work. However, over the years, Roberts had the opportunity to experiment with many cameras and telescopes. He saw that the future of observational astronomy lay with big reflectors, and took every opportunity to describe and explain this fact to other astronomers. By the time of his death, his assertions had borne fruit not only through his own work, but also that of **George Ritchey** with his 24-in. Newtonian reflector at Yerkes Observatory, and **James Keeler** with the 36-in. Crossley Reflector at Lick Observatory. The giant instruments erected by Ritchey and **George Hale** at Mount Wilson Observatory bore witness to the value of Roberts's early assessment of the reflector's potential, as did the welter of smaller reflectors installed in most contemporary observatories in the first half of the 20th century. Roberts's work played no small part in this revolution.

Roberts was an avid musician. He sang with the Liverpool Philharmonic Choral Society. He was fluent in the Welsh language. Toward the end of his life he became an agnostic, expressing the view that revealed religion had no place in the Universe that he had explored. Politically, Roberts was a liberal, and he was active in education reform.

During his career as a scientist, Roberts received numerous medals and honors. Among these were election to the Royal Society (1890), an honorary Doctor of Science from Trinity College, Dublin (1892), and the Gold Medal of the Royal Astronomical Society (1895). A crater on the Moon has been named Roberts to honor both Isaac Roberts and **Alexander Roberts**, a South African amateur variable star astronomer.

Robertson, Howard Percy

Born **Hoquiam, Washington, USA, 27 January 1903**
Died **Pasadena, California, USA, 26 August 1961**

American mathematical physicist Howard ("H.P.") Robertson is honored by the names of the Poynting–Robertson effect (of light on small dust particles) and the Robertson–Walker metric, which describes the curvature of space–time within the framework of general relativity. He was the oldest of five children of a family of modest means, whose father died when he was 15. Nonetheless, all the children attended the University of Washington, where Robertson earned a bachelor's (1922) and a master's (1923) degree.

At the University of Washington, Robertson came under the tutelage of the famous mathematician and relativist, Eric Temple Bell. They had a tempestuous and engaging intellectual relationship, which they both valued highly over the years.

Two years later, Robertson obtained his Ph.D. from the California Institute of Technology (Caltech). His thesis was entitled "On Dynamical Space–times which contain a Conformal Euclidean 3-space," and ran a mere 38 pages in length. While at Caltech, he interacted with the mathematical physicists, Paul S. Epstein and Harry F. Bateman.

The next 2 years were spent studying in Göttingen and Munich, Germany as a National Research Fellow. Robertson returned to Caltech as an assistant professor in 1927. From 1929 to 1947 he was at Princeton University, again returning to Caltech as a professor in 1947. From 1940 to 1943, Robertson served with the National Defense Research Council, and was with the London Mission of the Office of Scientific Research and Development from 1943 to 1946. From 1944 to 1947, he was an expert consultant to the Office of the Secretary of War. He was awarded the United States Medal of Merit in recognition of his wartime services to his country.

After World War II, Robertson was a much-sought-after scientific advisor to numerous branches of government and industry, and he was very effective in applying science to military strategy and tactics. In this capacity he was the chief scientific advisor to general M. Gruenther, then the Supreme Allied Commander in Europe (1954–1956). From 1956 to 1960, Robertson was a member of the Defense Science Board. He was also the chief science advisor to the second and third directors of the Central Intelligence Agency, admiral Sidney W. Souers and general Hoyt S. Vandenberg. Robertson was a trustee of the Systems Development Corporation, the Institute for Defense Analysis, and the Carnegie Endowment for International Peace. He was also a director of the Northrop Aviation Corporation.

Robertson was endowed with exceptional mathematical powers coupled with a deep insight into physical processes. His early scientific efforts were concerned with the study of differential geometry, in which he was strongly influenced by the work of Bell, Luther Eisenhart, Oswald Veblen, and **Herman Weyl**. In 1931, for example, he translated Weyl's classic tome, *The Theory of Groups and Quantum Mechanics*, into English. He also published works on quantum mechanics, notably a short paper in *The Physical Review* pointing out the connection between uncertainty in the simultaneous measurement of two noncanonical variables and the commutation properties of their associated operators (1929). He also made a seminal contribution (1940) to T. von Karman and L. Howarth's theory of isotropic turbulence by applying invariant theory to the categorization of the velocity correlation tensors that feature prominently in their equations.

Robertson's best-known contributions were in the theory of relativity and its applications to cosmology. He developed the theory of uniform cosmological spaces, *i. e.*, spaces with spatial isotropy and homogeneity, and deduced the form of the line element common to all these spaces (1929). These have subsequently been called Robertson–Walker spaces. Robertson was deeply intrigued by the consequences of the observed red shift–distance relationship, which led to an extensive and long-lasting working association with **Edwin Hubble**, **Milton Humason**, and **Richard Tolman**.

Robertson is also well known for his work on the absorption and re-emission of light by a particle revolving around the Sun (1937). His fully relativistic treatment of the problem superseded **John Poynting**'s (1903) classical formulation, and in fact led to a significant quantitative correction to the classical result. Robertson's calculations indicated the presence of a tangential drag that acts to reduce the angular momentum of the body, causing it to spiral in toward the Sun. The effect is important for small dust particles, and implies that the immediate neighborhood of the Sun should be cleared of these particles on astrophysically interesting timescales. This process is commonly referred to as the Poynting–Robertson effect.

Robertson had a long-standing fascination with sports cars, and was well known for his fast driving on the Caltech campus and in the surrounding area. In early August of 1961 he was involved in a high-speed automobile accident. He died from a pulmonary embolism brought on by the injuries sustained in the accident.

Robinson, Thomas Romney

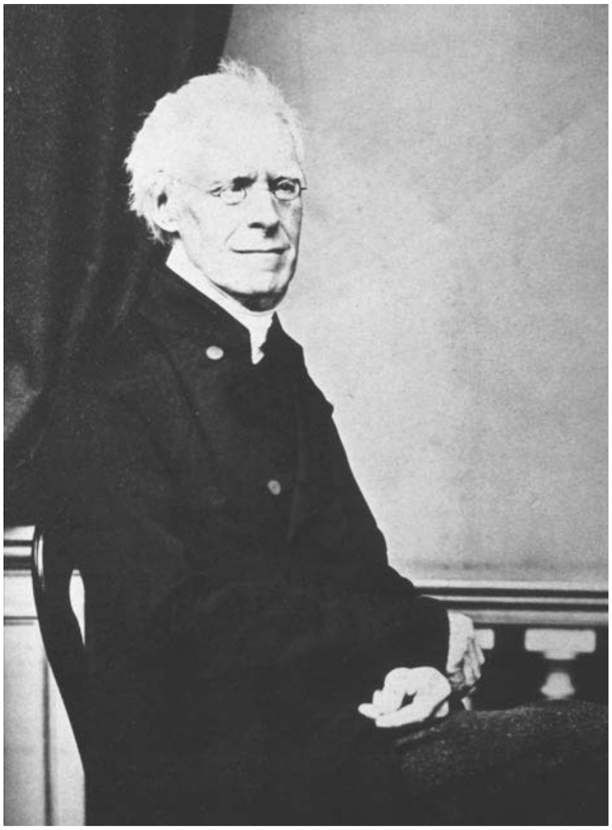
Born **probably Lawrencetown near Bainbridge, Co. Down, (Northern Ireland), 23 April 1792**
Died **Armagh, Ireland, (Northern Ireland), 28 February 1892**

Thomas Romney Robinson (sometimes John Thomas Romney Robinson) was director of Armagh Observatory for more than 58 years. A child prodigy, he became one of the most respected practical astronomers of his time. He is remembered for the anemometer design that bears his name.

Romney Robinson (as he is commonly referred to) was the eldest son of Thomas Robinson, an English portrait painter, and his wife Ruth Buck. Thomas named his son after his mentor, George Romney, and set up business in Dublin about 1790. Later the family moved to County Down, and then in 1801 settled in Belfast where Romney attended Belfast Academy.

Robinson was precocious, being able to read poetry by three and to write verse by five. By the age of 12 a volume of his poems was published in Belfast with a list of 1,600 subscribers. He showed an interest in the machinery used in the linen and shipbuilding industries and experimented with chemistry and electricity. Robinson entered Trinity College, Dublin, in January 1806 and graduated in 1810, the year of his father's death. He gained fellowship in 1814. Robinson was elected a member of the Royal Irish Academy in 1816 and read papers on high-temperature furnaces and electricity. He lectured in Trinity College as deputy to Bartholomew Lloyd, the professor of natural and experimental philosophy, and provided his students with a useful textbook in his *System of Mechanics* (1820).

However, Robinson found that teaching left him with little time for research. He was a close friend of **John Brinkley**, the Andrews' Professor of Astronomy and director of Dunsink Observatory. In 1821 he relinquished his fellowship, married, took holy orders, and became the rector of the parish of Enniskillen, County, Fermanagh. In 1823 Robinson was appointed director of Armagh Observatory, and the following year he was appointed vicar of the parish of Carrickmacross, which was closer to Armagh.



Armagh Observatory had been established by the (Anglican) Church of Ireland in 1790 but had not attained much distinction under its first two directors, James Archibald Hamilton and William Davenport. Robinson set the observatory on a productive course. Thanks to the generosity of the primate, Lord John George Beresford, Robinson was able to commission badly needed new instruments. He ordered a transit instrument and a mural circle from Thomas Jones, a leading London instrumentmaker. The new transit was in place by 1827, and observations began on a program of positional measurements. The publication of the transit observations for the years 1828, 1829, and 1830 was funded by Beresford. The mural circle was delivered in 1831 but did not come into operation until late in 1834.

The third instrument that Robinson commissioned was a 15-in. reflecting telescope of an innovative design, which was highly significant for the future development of telescope technology. It was a Cassegrain, rather than a Newtonian, telescope, then the standard. It was the first large reflecting telescope to be mounted equatorially with a clock drive. The primary mirror of speculum was supported by a novel lever support system to avoid distortion. The maker was **Thomas Grubb** who, as engineer to the Bank of Ireland in Dublin, was well known for his machines for printing banknotes. Early in 1833, Robinson approached Grubb to see if he would make an equatorial mount for the 13.3-in. objective by Chauchoix of Paris, which had been purchased by **Edward Cooper** for his private observatory at Markree Castle, County Sligo. Cooper's telescope was installed in April 1834, and the 15-in. telescope was installed at Armagh Observatory the following year. With the staunch support of Robinson, Grubb and his son **Howard Grubb** went on to establish a telescope-making firm of international renown.

Robinson was closely associated with **William Parsons**'s ambitions to build large reflectors at Parsonstown (Birr). In November 1842, accompanied by his friend Sir **James South**, Robinson witnessed the casting of the speculum mirror for the great 6-ft. telescope and described the scene in graphic detail in the *Proceedings* of the Royal Irish Academy. He advised Rosse to adopt an equatorial mount but the latter opted for a universal joint arrangement that was less demanding mechanically.

By February 1845 the great telescope was nearly finished, and Robinson returned to Birr, accompanied once again by South. After waiting for fine weather, the first observations were made on 10 March, and 40 nebulae from **John Herschel**'s catalog were examined. The following month, Robinson reported in glowing terms on the performance of the telescope to the Royal Irish Academy.

Robinson's experience of observing with large telescopes at Birr convinced him that there was a need for a large reflector in the Southern Hemisphere. In 1849, when Robinson was president of the British Association, the association proposed that the government should provide the Cape Observatory with a large reflector. A Southern Telescope Committee was formed, and a proposal for a 4-ft. Cassegrain reflector by Grubb on a German equatorial mount was made in 1853, but was rejected by the government. The project was revived in 1862 when the State of Victoria in Australia decided to erect a large telescope in Melbourne. After prolonged negotiations, which also involved the offer of a gift of a telescope from **William Lassell**, the State of Victoria ordered the telescope from Grubb in February 1866. The telescope was built in Dublin and delivered to Melbourne in 1869. Unfortunately, the resources of the Melbourne Observatory were not sufficient to maintain the speculum mirror in proper condition, and this, combined with other factors, led to disappointing results.

Meanwhile, Robinson, with the help of assistants, had maintained a strenuous program of meridian observations. This culminated in 1859 in the publication of *Places of 5,345 Stars Observed from 1828 to 1854 at the Armagh Observatory* printed at government expense. For this work, Robinson was awarded the Royal Medal of the Royal Society in 1862.

One early investigation pursued by Robinson was the determination of the exact longitude of the Armagh Observatory. In 1838 he organized a comparison of the longitude of the Greenwich, Dunsink, and Armagh observatories by transporting 15 chronometers between the 3 locations. The following year, he compared the longitudes of Armagh and Dunsink by firing rockets from the summit of an intervening mountain to synchronize observations at the two observatories.

In 1845, the meridian program at Armagh was threatened by a proposal to build a railway link between Armagh and a neighboring town. As the railway line would pass within 160 yards of the transit instrument; Robinson was concerned that vibration would interfere with the accuracy of the observations. Robinson strenuously opposed the proposal, and the railway was prohibited from approaching within 700 yards of the observatory. Robinson was one of the first of observatory directors to have to deal with this sort of problem, and his expertise was later called upon in similar situations.

Regular weather observations were part of the observing routine at Armagh Observatory from its foundation, and the erection of a wind gauge was proposed in 1839. Robinson reviewed previous designs and, acting on an idea suggested to him many years earlier by Richard Lovell Edgeworth, he constructed a horizontal windmill with four hemispherical cups, and described it to the British Association in 1846. He continued to refine his anemometer, and an improved version was described to the Royal Irish Academy in 1855.

In his later years at Armagh, Robinson had to cope with declining financial resources as a result of the disestablishment of the Church of Ireland and the reduction in rents from lands owned by the observatory. This situation reinforced his conservative political views and led to his vigorous opposition to Irish political reform.

Robinson was an eloquent and forceful speaker and soon came to prominence as a public man of science. He regularly attended meetings of the British Association for the Advancement of Science and played a central role in bringing the association to Dublin in 1835. He served as president of the Royal Irish Academy from 1851 to 1856 and played an important part in securing new premises for the Academy in 1851. Robinson was elected a fellow of the Royal Society in 1856 and awarded honorary degrees by the Universities of Dublin, Oxford, and Cambridge. The 24-km-diameter lunar crater at 59°.0 N and 45°.9 W is named in his honor.

Robinson married twice. His first wife was Eliza Isabelle Rambaut of an Irish Huguenot family, and they had three children. Eliza died in 1839. In 1843 he married Lucy, youngest child of Richard Edgeworth and half-sister of Maria, the novelist. Robinson's daughter by his first marriage, Mary Susanna, married the Irish mathematical physicist **George Stokes**, with whom Robinson corresponded regularly on scientific matters.

Roche, Édouard Albert

Born **Montpellier, Hérault, France, 17 October 1820**
Died **Montpellier, Hérault, France, 18 April 1883**

Édouard Roche is remembered for the study of equipotential surfaces, called Roche lobes, and calculation of the distance from a planet at which satellites will be torn into rings, called the Roche limit.

Roche continued a tradition in his family, whereupon several members became professors at the University of Montpellier. There, he earned his *docteur ès sciences* degree in 1844 but spent the next 3 years at the Observatoire de Paris, working under **Dominique Arago**. While at Paris, Roche was introduced to **Urbain Le Verrier** and **Augustin Cauchy**.

In 1849, Roche accepted the position of *chargé de cours* at Montpellier and in 1852 was appointed professor of pure mathematics. The relative isolation of Montpellier likely helped foster the emergence of Roche's original ideas. He was elected a corresponding member of the Académie des sciences in 1873, but was later denied full membership in the organization. Roche's life was afflicted by poor health; he was forced to take a leave of absence in 1881 and succumbed to a lung inflammation.

Roche devoted himself to topics that lay generally outside of mainstream astronomical research in his time. He studied the equilibrium figure of a rotating fluid body that was subjected to an external gravitational force caused by another body. This condition is extremely important for determining the equipotential surfaces around a pair of point masses like a binary star. Where one (or both) of the components assumes a tear-drop shape, the space(s) so filled is called the Roche lobe. Related to this investigation was Roche's calculation of the minimum distance at which a satellite (of equal density) may revolve above its parent planet. The boundary, inside of which the tidal forces are strong enough to disrupt the satellite into smaller pieces, is called the Roche limit. This condition plays a crucial role in the formation of planetary-ring systems.

Roche likewise explained the streamlined shapes of cometary envelopes, under the assumption of a repulsive force originating in the Sun that diminished with the square of its heliocentric distance. His theoretical explanation was offered decades before such radiation pressure was discovered in the form of the "solar wind." In turn, Roche presented a thorough analysis of the "nebular hypothesis" of **Immanuel Kant** and **Pierre de Laplace**. His investigation brought a decided coherence to the notion before it was challenged by rival cosmogonic theories. Roche's treatment of the internal density distribution of the Earth, with appropriate modifications, is still of value today.

Zdeněk Kopal (1989, p. 2) has written that Roche's principal accomplishments "were too far ahead of their time to be appreciated fully."

Roeslin, Helisaeus

Born **Plieningen, (Baden-Württemberg, Germany), 17 January 1545**
Died **probably Haguenau, (Bas-Rhin, France), 14 August 1616**

Helisaeus Roeslin was one of the first to recognize that comets are astronomical bodies rather than atmospheric bodies and, with **Nicholas Bär** (Raimarus Ursus) and **Tycho Brahe**, formulated a geo-heliocentric model of the planets. Roeslin studied astronomy and medicine at the University of Tübingen from 1561. Samuel Eisenmenger (Siderokrates) became his teacher in astronomy, astrology, and alchemy. Roeslin finished his studies in 1569 with the degree of a doctor of medicine. He joined Eisenmenger in the employ of the Markgraf von Baden. Influenced by Eisenmenger, Roeslin devoted himself to the spiritualistic theory of Kaspar von Schwenkfeld, but showed religious tolerance during his whole life. In 1569 he became physician in Pforzheim, married, and became an employee of the Pfalzgraf von Pfalz Veldenz. There Roeslin became a well-known doctor. From 1582 onward he was physician in the city of Haguenau.

Roeslin's astronomical interests rose with two events, the supernova of 1572 (SN B Cas) and the great comet of 1577. He developed a theory of the comet that placed it first in the Earth's atmosphere. Later he withdrew this idea and agreed with the theory of **Christoph Rothmann** and Brahe, in which comets belong to the sphere of the planets. In his publication in 1597 he explained the nature of comets as heavenly bodies in the sphere of the planets. Roeslin claimed that comets are not atmospheric phenomena and that this is in clear contradiction to **Aristotle**'s ideas. With the observation of comets there is no way to maintain the idea of the unchangeable heavenly regions and their perfection and divinity. The tail of a comet he explained as light focused by the comet itself.

Therefore, for Roeslin, comets are "secondary stars," which have not been created during the "first 6 days of the world," but were "born" later. Also, they are not permanent bodies and after some time of visibility they disappear again. Moreover, comets move in circular orbits around the Sun, but not only in the zodiacal belt. With this work, Roeslin gained major significance in the history of cometary science. He is one of the first astronomers who spoke clearly of regular orbits of comets. Roeslin's opinion was contrary to the widely held views of Rothmann, Brahe, and **Johannes Kepler**. His works from 1597 and 1609 are quite significant, because the theory of comets as heavenly bodies was written in German for the first time, and he also clearly pointed out the contradiction to the physics of Aristotle.

Among Brahe, Bär, and others, Roeslin developed the idea of a geo-heliocentric system (*De opere Die creationis*, 1597), which only differs from the others in details. Roeslin still considered the planets to be fixed on spheres with no space in between. The example of Roeslin shows how widespread the theory of geo-heliocentricity was at that time. Roeslin and Kepler had several public debates, but Kepler did not succeed in convincing Roeslin of the heliocentric system. They reconstructed different birth dates of Jesus Christ (Roeslin 1.25 years BCE, Kepler 5 years BCE), and in astrology Kepler could not follow Roeslin's ideas and conclusions concerning comets and planetary motion.

Under the pen name "Lambert Floridus Plieninger," Roeslin published a paper concerning the calendar reform of Pope Gregory XIII. Like many other authors of his time (*e. g.*, **Wilhem IV** and **Michael Mäestlin**), Roeslin carried on the controversy against the new calendar, mainly for theological reasons, and claimed the pope wished to use the calendar to regain power over the Protestant church.

Roger of Hereford

Flourished **England, 1176–1178**

Roger of Hereford was an astronomer working in the region of Hereford in the late 12th century. His alternative names perhaps reflect an English name "Young," "Lénfant," or "Childe."

Roger adapted the astronomical tables of Toledo for the meridian of Hereford in 1178, using as his basis the version composed for the meridian of Marseilles by **Raymond of Marseilles**. Two years earlier (1176) he wrote a work on the ecclesiastical *computus* (for calculating the church calendar), in which he compared unfavorably the traditional Latin learning on the *computus* with the new learning from Hebrew and Arabic sources.

Other writings attributed to Roger are several works concerning astrology, which may all derive from a *Liber de quattuor partibus iudiciorum astronomie*; this draws on the corresponding work of Raymond of Marseilles, as well as on translations of Arabic astrological texts made by **John of Seville** and Hermann of Carinthia. Roger may too have written on alchemy, if the *De rebus metallicis* once existing in Peterhouse, Cambridge, is authentic.

Roger was held in high esteem by contemporary English scholars, which is indicated by the fact that Alfred of Shareshill dedicated his translation of the Aristotelian text on botany, *De vegetabilibus*, to him. To Roger may be attributed the invention of a new way of calculating horoscopes mathematically. He did much to further the study of the mathematical sciences in England, and provides a link between the pioneers in this study, **Petrus Alfonsi** and **Adelard of Bath**, and **Robert Grosseteste**, who joined the bishop's household in Hereford while Roger was still active there.

Rohault, Jacques

Born **Amiens, (Somme), France, 1620**
Died **Paris, France, 1665**

Jacques Rohault was a self-taught mathematician and experimentalist, and a popularizer of natural philosophy. He was the son of Ambroise Rohault and Antoinette de Ponthieu. In the mid-1650s, he began a series of extremely popular lectures on natural philosophy. These lectures popularized **René Descartes**'s natural philosophy, but laid great emphasis on experiment and observation, and omitted the metaphysical foundations that Descartes had gone to great trouble to provide. Rohault became the leading defender of Cartesianism in France, and his *Traité de physique* (Treatise on physics) (1671) became the leading textbook of the age. It offered a probabilistic reading of natural philosophy, but avoided any detailed mathematics, and completely ignored **Johannes Kepler**'s work. It presented natural philosophy as an observational discipline rather than a mathematical one. Nevertheless, the *Traité* was exceptional in the scope and clarity of its treatment. As far as cosmology is concerned, the keystone of Cartesian cosmology is the vortex theory, which explains the formation of stars and planets, and the stability of planetary orbits, in terms of the rotation of matter around central points, and Rohault offered a detailed defense of this theory, which was extended to gravity, magnetism, and other phenomena.
