The publisher and the authors make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of fitness for a particular purpose. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. Readers should consult with a specialist where appropriate. The fact that an organization or Website is referred to in this work as a citation and/or a potential source of further information does not mean that the author or the publisher endorses the information the organization or Website may provide or recommendations it may make. Further, readers should be aware that Internet Websites listed in this work may have changed or disappeared between when this work was written and when it is read. No warranty may be created or extended by any promotional statements for this work. Neither the publisher nor the author shall be liable for any damages arising herefrom.

Dedication

From D.M.S.

For my wife, Laurie, with abiding love and great appreciation for her support during the preparation of this work.

From M.C.S.

For my parents, Randall and Lelah Cole, who have always encouraged me to "do it myself," and my husband, Eric Smith, and our children, Kalmia and Ross, who have patiently awaited completion of this manuscript.

Contents

Preface to the First Edition

The writing of this book was undertaken in recognition of the need for a comprehensive veterinary text addressing health and disease issues of goats raised under varying conditions around the world. The authors' primary experiences are with intensively managed dairy and fiber goats in temperate zones. However, because most of the world's goats live in tropical and subtropical regions, serious effort has been made to fully cover disease entities and production constraints in those areas. Much of the material presented on tropical diseases is derived from the published literature. The authors invite readers whose personal and clinical experience with these diseases in goats varies from our presentation to share their knowledge with us for the purpose of improving later editions.

We intend this book for veterinary practitioners dealing with diagnosis and treatment of individual goats as well as for those striving to improve the health and productivity of commercial herds and flocks throughout the world. Veterinarians involved in formulation of animal health policy, regulatory medicine, and livestock development should also find this information valuable.

We expect this book to be useful also for academic clinicians, researchers, and veterinary students with a special interest in goats. Others who might find this book a useful reference are animal scientists, extension agents, herd managers, and hobbyists.

David M. Sherman
Mary C. Smith

Preface to the Second Edition

The first edition of Goat Medicine was well received and we are pleased to have the opportunity to produce a second edition. Since the first edition appeared in 1994, the global landscape for veterinary medicine has changed dramatically. In 1996, bovine spongiform encephalopathy was recognized to be a zoonotic disease, causing variant Creutzfeldt-Jakob disease (vCJD) in humans. In 1999, West Nile virus infection reached the United States and in a short time was endemic throughout the country. In 2001, there was a major outbreak of foot and mouth disease in northern Europe, with devastating effects in the United Kingdom. That same year, the specter of bioterrorism emerged with the use of anthrax as a weapon against citizens in the United States.

These events underscored the continued importance of infectious diseases in what has become an intimately interconnected, global society. These events also emphasized the need for veterinary practitioners everywhere to have knowledge of and be able to recognize diseases which traditionally have been considered exotic to their own countries. International issues influencing contemporary veterinary medicine are discussed further in David Sherman's other textbook "Tending Animals in the Global Village", also available from Wiley-Blackwell.

Global infectious disease trends also have affected goat medicine. In 2005, the first case of bovine spongiform encephalopathy was confirmed in a goat in France. Peste des petits ruminants, a serious viral disease of goats and sheep, has extended its range from Africa through the Middle East and well into Asia, causing widespread hardship for subsistence farmers and herders who depend on goats for their livelihoods. Repeated outbreaks of Rift Valley fever in Kenya have also taken a toll on goat populations and the people who rely on them. As such, the second edition of Goat Medicine continues to maintain a global perspective and provide information on goat diseases as they occur throughout the world.

Another significant development since the publication of the first edition has been the advent of the Internet and the increased availability of information on all subjects, including the diseases of goats. Some of this information is very good and some is not so good. As in the first edition, we have strived to provide the most accurate information available on the diseases of goats, their diagnosis, treatment, and control. We have avoided whenever possible extrapolating information from other species and we continue to strive, as in the first edition, to provide definitive information that is specific to goats and supported by citations from the world's veterinary literature as well as our own expanded experience in dealing with goat diseases in various locations around the world.

As with the first edition, we intend this book primarily for veterinary practitioners but believe that academic clinicians, veterinary students, regulatory veterinarians, researchers working with goats, animal scientists, extension agents, livestock development workers, and goat owners will also find it useful.

David M. Sherman, Kabul, Afghanistan
Mary C. Smith, Ithaca, New York

Acknowledgments

xiv   **Acknowledgments**

Onderstepoort, South Africa and Dr. Ray M. Kaplan from the College of Veterinary Medicine of the University of Georgia, Athens, Georgia were also very gracious about answering specific questions.

The many members of the American Association of Small Ruminant Practitioners were instrumental in the creation of this text because of the questions asked and answers provided through the association's on-line discussion list. Likewise, many goat owners and their animals contributed to my education and photo collection. I would also like to thank Susanne K. Whitaker and Michael A. Friedman of the Flower-Sprecher Veterinary Library, New York State College of Veterinary Medicine, Ithaca, New York for assistance in obtaining reference material. Finally, my husband Eric Smith deserves the greatest thanks for encouraging the writing of this manuscript and tolerating the time and attention that it has required of me.

Goat Medicine

Second Edition

Fundamentals of Goat Practice

OVERVIEW

Distribution of Goats

According to the Food and Agriculture Organization (FAO) of the United Nations, in 2006 there were an estimated 837.2 million goats in the world, approximately 64.2% of which were in Asia, 28.8% in Africa, 4.3% in South and Central America, 2.2% in Europe, 0.3% in North America, and 0.1% in Oceania. Approximately 4.2% of the world's goats are found in developed countries and 95.8% in developing countries (FAO 2007). Goats are highly adaptable to a broad range of climatic and geographic conditions and are more widely distributed than any other mammalian livestock. Goats are managed under every imaginable production system, including feral, transhumant, nomadic, extensive, intensive, and total confinement systems.

Use of Goats

Goats are exploited for diverse purposes, including meat production, cashmere and mohair fiber production, milk and cheese production, and skins for leather making. Specialty uses include brush and weed control, pack and draft use, animal experimentation (particu-

larly as models of ruminant digestion and human heart disease and as transgenic animals), commercial antibody production, and companionship. Goat horn and bone are sometimes used for ornamental purposes and musical instruments, while goat skins are used for drum making.

Meat production is the major use of goats on a worldwide basis, particularly in Asia, Africa, the Middle East, and Latin America, and world goat meat production more than doubled between 1980 and 2000 (Morand-Fehr et al. 2004). In 2006, the seven leading goat meat producing nations in descending order were China, India, Pakistan, Sudan, Nigeria, Bangladesh, and Iran (FAO 2007a). A myriad of local and regional breeds exists around the world that are used mainly for meat. In recent years, more attention has been paid to selective breeding in goats for meat production, leading to the development of two highly efficient, purpose-bred meat goat breeds. These are the South African Boer goat (Mahan 2000) and the Kiko goat of New Zealand (Batten 1988), both of which have gained popularity in the United States, particularly in the southeast where commercial goat meat production has been expanding.

The major milking breeds of goats originated primarily in Europe. These breeds include the Saanen, Toggenburg, Anglo-Nubian, and Alpine breeds. The more recently developed La Mancha breed originated in the United States. The Jamnapari and Beetal breeds of India are also important dairy breeds that are well adapted to and becoming more widely distributed in the humid tropics. The use of goat milk to manufacture cheese is an important industry in France, Spain, and other European countries.

Angora goats, the source of mohair fiber, have traditionally been concentrated in a number of distinct areas, notably Turkey, where they originated, South Africa, Texas, Argentina, and some central Asian republics formerly in the USSR. Cashmere or Pashmina goats, which produce cashmere fiber, are found primarily in the mountainous regions of Central Asia, including parts of Tibet, China, Mongolia, Iran, Afghanistan, Kazakstan, Kyrgyzstan, and Tajikistan. Skins are usually a byproduct of goat slaughter for meat, but skins of certain goat breeds such as the Red Sokoto of Niger are prized for high-quality leather goods such as kidskin gloves and purses. Details of the various goat industries are beyond the scope of this veterinary text. The interested reader is referred to other sources (Gall 1981; Coop 1982; DeVendra and Burns 1983; Dubeuf et al. 2004; Morand-Fehr et al. 2004).

Current Interest in Goats

Worldwide interest in goats has continued to increase dramatically during the last decade. There is greater understanding of the importance of goats in agricultural systems in low-income countries. A number of humanitarian organizations, such as Heifer International and FARM-Africa, have recognized the value of using goats as a tool in rural development programs to improve the social and economic conditions of subsistence farmers and the rural poor. Methodologies for improved goat production in the tropics in support of rural development have been published (Peacock 1996).

There is also increased demand for goat products in developed countries, especially goat cheese, cashmere goods, and even goat meat. Demand for goat meat in the United States has exceeded domestic supply in recent years. In 2004, the United States imported 2,400 metric tons of goat meat, mostly from Australia (Ward 2006).

This expanding interest in goats has increased the demand for goat-related veterinary services in the areas of clinical medicine, research, and extension. In response to this need, interested veterinarians must familiarize themselves with goats as a species distinct from sheep and cattle, recognizing their often characteristic behavior, physiology, and response to disease.

Fortunately, a number of resources have become available to provide information in these areas. The International Goat Association (www.iga-goatworld. org/) sponsors a quadrennial international conference on goats and regularly publishes the peer-reviewed, international research journal, *Small Ruminant Research*, which reports research findings on all aspects of goat production including health, nutrition, genetics, physiology, and husbandry from all over the world. The American Sheep Industry Association regularly produces a similar, multidisciplinary research publication, *Sheep and Goat Research Journal*, which focuses specifically on small ruminant production in North America and is available on the Internet (http://www.sheepusa.org/).

The American Association of Small Ruminant Practitioners (AASRP) is an excellent resource for veterinary practitioners in North America. This member organization produces a regular newsletter, *Wool and Wattles*, full of current, relevant information on regulatory and clinical issues as well as an e-mail discussion forum for AASRP members. The AASRP Website (www.aasrp.org/) provides links to other useful resources for goat health and production. Another useful Web-based resource for veterinarians is Consultant, which generates differential diagnoses based on clinical signs entered by the user on a species basis, with goats recognized as a distinct species. It is available on the Internet at http://www.vet.cornell.edu/consultant/consult.asp. Finally, many state extension agencies now have much more information available on goat husbandry and production than they had in the past, and much of it accessible on the Internet.

Distinguishing Goats from Sheep

Source of Confusion

For those whose experience with sheep and goats is limited to the common European wool breeds of sheep and the European dairy breeds of goats, the notion that individuals of the two species could be confused may seem ridiculous. However, in tropical and subtropical regions, various breeds of hair sheep are common. These breeds are often maintained in mixed flocks with local breeds of goats, and may not be readily differentiated. The following information can help in distinguishing the two species.

Genetic Distinctions

Goats have 60 chromosomes and sheep have 54. Though very uncommon, fertile goat-sheep hybrids have been reported. These hybrids have 57 chromosomes. The phenomenon is discussed in Chapter 13.

Behavioral Distinctions

A major difference between sheep and goats is feeding behavior. Sheep are grazing animals, consis-

tently feeding at ground level, while the goat is more of a browsing animal, readily feeding on shrubs, bushes, and trees. While both species are social, individual goats are less anxious than sheep when separated from the group. Goats are less tolerant of rain and more readily seek shelter in wet weather.

The males of both species will fight, buck goats by rearing up on their hind feet and coming down forcefully to butt heads, while rams back up and then charge forward to butt heads. The anatomic structure of the horns, frontal sinuses, and neck muscles of each species is appropriate to its method of fighting, minimizing the risk of injury to combatants (Reed and Schaffer 1972). When young bucks and rams are maintained together, the rams become dominant because they preemptively strike bucks in the abdomen while the male goats are still in the act of rearing up.

Whereas lambs are almost constantly at the side of ewes in early life, goats practice "lying out" or "planting" behavior with kids left in "camps" for a good part of the day while does feed.

Anatomic Distinctions

When wool is not obvious in sheep, other anatomic differences may be observed. Most goat breeds have an erect tail, while the tail of sheep always hangs down. The sheep has an upper lip divided by a distinct philtrum and the goat does not. Male goats, and to a lesser extent female goats, have beards, which are lacking in sheep. Goats do not have infraorbital, interdigital, or inguinal glands, while sheep do. Goats have sebaceous glands beneath the tailhead that sheep lack.

GOAT BEHAVIOR

General Characteristics

Goats exhibit some very distinct behavior patterns (Hafez 1975; Kilgour and Dalton 1984). Many aspects of goat behavior are conditioned by the circumstances in which the animals are kept. Many natural behavior patterns observed in free-ranging feral goats may be altered or not expressed at all under different degrees of confinement. Nevertheless, some behavior patterns are widely characteristic.

Goats tend to flock together in extended family groups. They have a strong hierarchical structure in the flock or herd. Both males and females will establish social dominance in their respective groups through head to head fighting. Goats use their horns to advantage when fighting to establish their social dominance. Therefore, all goats in a group should be either horned or hornless to avoid excessive bullying by horned goats.

When goats are accustomed to human contact, they will approach strangers rather than flee. When threatened or upset, they will turn and face an intruder and make a characteristic sneezing noise. In keeping with their browsing behavior, goats orally investigate everything in their environment. This includes veterinary equipment, paperwork, clothing, and jewelry brought within their reach. When drawing blood samples or writing health papers, it is essential to keep the paperwork in a safe place or it will be eaten or destroyed. Goats will chew on pen partitions and other structures made of wood, and a large group of goats can actually devour pen walls over a period of months. They will also eat the paint off walls, so lead paint should be avoided.

Goats are very agile and are excellent climbers. They are occasionally found in barn rafters, in trees, or on the hood of the veterinarian's vehicle, if allowed access. Providing a rock pile in paddocks or pastures can foster recreation and will help to control hoof overgrowth. Goats will stand on their hind legs and lean against fences, causing considerable damage over time. Broken limbs may occur if legs are caught in the openings of chain link fences. The goats' agility combined with their curiosity can be fatal if their heads get caught and they are strangled in fences, gates, doors, windows, or other structures. Backward curving horns contribute to this problem.

Goats are notorious for successfully undoing simple gate closures and latches. This is a common occurrence in accidental grain overload cases, so goat keepers must ensure that gates are securely fastened. Goats can easily jump fences designed for sheep and also will dig under fences that do not closely skirt the ground. Goat fencing should never have interior sloping support posts because goats will use them to climb out of the enclosure. Goats ignore barbed wire and therefore it should not be used because it can inflict serious damage. Thus, electric fencing has become popular for goat operations because the animals quickly learn to respect it.

Ingestive and Eliminative Behavior

A key to the adaptability of goats worldwide is their efficient browsing ability. This same efficiency, however, has given the goat notoriety as an important cause of desertification in some regions of the world. The reputation is not always deserved because overgrazing by numerous livestock species may be at fault, but only the goats are left surviving when vegetation is almost gone (Dunbar 1984). Goats may climb into trees to reach food when it is scarce. If permitted, they can girdle the bark from trees, thus killing them. Goats are used to clear brush to reclaim pasture land for sheep and cattle. When run simultaneously with sheep and cattle, they may improve pasture quality for these other species by contributing manure for fertilization, removing toxic plants such as oak to which they are more resistant than the other ruminant species, and

eliminating brush to allow more sunlight for improved grass growth (Ward 2006).

Owners feeding goats in confinement often complain that the animals waste a good deal of hay, particularly leaving behind the nutritious leafy parts of good legume hay. This tendency can be countered to some extent by feeder designs that inhibit the goat from pulling hay out of the feeder and dropping it on the floor. Goats are also finicky about contaminated feed and water supplies and may refuse water containing fecal pellets or hay and grain in wet troughs that smell moldy.

In free-ranging feral and Angora goats, approximately 30% of the day is spent in feeding, usually divided into sunrise, midday, and sunset periods. One-third of this is grazing time, two-thirds browsing. About half the day is spent resting, 10% ruminating, and 12% traveling (Askins and Turner 1972; Kilgour and Ross 1980). In contrast, intensively managed Saanen milking goats eat for 20% of the day, ruminate 25%, travel 20%, sleep 11%, rest recumbent 14%, and rest standing approximately 8% of each day. They defecate on average 11.2 times and urinate 8.3 times daily (Pu, personal communication 1990).

Goats raise their tails to defecate and normally produce pelleted feces. Female goats squat to urinate. During the non-breeding season, males urinate on the ground with little or no extension of the penis beyond the prepuce. However, during the breeding season, the pattern of urination is markedly different and associated with sexual behavior as discussed below. Goats cannot be prompted easily to urinate by holding off their nares, as is done with sheep. This makes simple collection of a urine specimen problematic.

Sexual Behavior

In tropical and subtropical regions, estrus generally occurs year-round while in temperate regions goats are seasonally polyestrus, with breeding season triggered by decreasing day length. Breed factors may also play a role in this pattern because relocation of some indigenous breeds to new climatic zones does not result in a change of estrus pattern. Specific information on the frequency, signs, and patterns of estrus are provided in Chapter 13. Male sexual behavior reflects the pattern seen in does. Libido and sperm quality may be depressed during anestrous seasons. However, if females are brought into estrus by hormonal manipulation, bucks quickly respond out of season.

The obnoxious behavior and strong odor of bucks during breeding season are notorious. At least two factors contribute to buck odor. First, the aroused buck repeatedly urinates on himself, soaking his head, neck, and forequarters. He will sometimes take his erect penis into his mouth. Afterwards, the buck may yawn and demonstrate the flehmen reaction, curling his upper lip. Second, the buck possesses sebaceous scent glands on his head, caudomedial to the base of the horn, which during active rutting produce an odiferous compound identified as 6-trans nonenal (Smith et al. 1984). This compound may also be released from the sebaceous gland under the tail. It acts as a potent pheromone and the odor alone can induce estrus in the doe.

Bucks show active fighting behavior at the beginning of and during the breeding season to establish dominance. Veterinarians and owners should exercise caution when working around sexually active bucks. A full grown buck striking from the standing position can produce serious or fatal injury. For this reason, bucks of different sizes in confinement operations should be segregated so that smaller, younger bucks are not injured or killed. Do not turn your back to an unrestrained buck!

During courtship, the buck will sniff the urine of does and follow with the flehmen response. To display to does, a buck holds his head erect and high or he lowers his extended head and neck to the ground. He may also kick out at the doe with an extended forelimb, but rarely actually strike her. Courtship is accompanied by much frenzied vocalizing and flicking the tongue in and out. Sexually active bucks commonly lose weight during the breeding season.

Maternal Behavior

Free-ranging goats separate from the herd and hide to kid. Confined goats may attempt to conceal themselves. As parturition approaches, does become restless and paw at the ground, making rudimentary efforts to "nest build." Details of parturition and the recognition of dystocia are discussed in Chapter 13. Following parturition, the doe actively licks the kids, and this is considered to be critical to successful bonding. If does are frightened or disturbed at this point, or if licking is delayed longer than one hour, bonding may be impaired and kids may be abandoned or mothered less effectively.

Kids are precocial, standing and seeking the hairless udder shortly after birth. In free-ranging herds, there is a "lying-out" period of several days to several weeks when does may leave kids in sheltered areas for periods of two to eight hours while they feed. Does must be familiar with the geography to return successfully to their kids. Therefore, it is not advisable to move does to new grazing areas immediately before kidding. Does will respond to alarm calls from their distant kids and return to defend them if bonding is strong. Kids gradually begin to follow their dams, learning to browse and graze. The infrequent nursing pattern of young kids makes the goat adaptable to the twice-a-day feeding regimens that are often practiced under

intensive management. If given boxes to hide in, kids raised in confinement will use them for the first week, coming out only to suckle the dam.

HANDLING GOATS

Group Considerations

Goats are highly adaptable and trainable animals. Feral goats captured in Australia and New Zealand may become used to handling in confinement within weeks, although if frightened suddenly they can clear sheep fences with ease. Dairy goats are readily trained into milking routines involving parlors and machine milking. Although Angora kids may scream the first time they are sheared, they get used to the procedure.

Goats used to human contact can be mustered by calling. Moving less tame goats on open range is similar to moving sheep. Dogs can be used, but they must be well trained. The flight distance of feral goats is eight to ten meters. Goats are more likely to turn and fight than sheep if provoked by a dog. Animals that break away from the group should be left to follow along rather than chased. The presence of sheep with the goats can actually facilitate flocking and driving, although on hills, goats tend to move upward and sheep downward. When collected in yards, anxious goats may pile up in a corner and some may suffocate, so they should be divided into small groups. When possible goats should be allowed to spend 24 hours in a handling facility before they are worked so they are more comfortable with their surroundings. Horned goats may be very wary of entering narrow races and gates. When working horned goats in close quarters, the danger of face and eye injuries to handlers is high, and protective eye wear should be used.

Individual Restraint

Tame goats will stop when caught by the gastrocnemius tendon. However, if a frightened or wary goat is actively fleeing or struggling, capture by the limb can lead to serious dislocations of joints or fractures of long bones, particularly in young animals. It is preferable to catch animals by hooking an arm around the neck or torso or by grabbing the collar, horns, beard, or, less desirably, the ears.

Goats used to human contact can be trained to lead. Goats that pull strongly against neck chains will commonly cough and, rarely, cause trauma to the trachea. Goats used to handling are usually easily restrained for examination, administration of medication, or routine sample collection. Such goats can be haltered or lead shanks can be tied to neck straps and then secured. Uncooperative goats can be straddled over the withers by a handler with the goat's hind end backed into a corner and the head held firmly by the handler (Figure 1.1). If a goat is horned, the horns should be held when restraining goats in close quarters to avoid injury to the handler. Bearded goats can be led by the beard and non-bearded goats by the ears, though some owners may object to the latter practice. For smaller, uncooperative goats, flipping the animal into lateral recumbency and then placing the handler's knee on the goat's neck may provide effective restraint.

Goats do not become passive when tipped up on the rump in the manner used for sheep, so this method of restraint is less useful; this is a problem regarding shearing. A modification of the technique to avoid struggling is to first tip up the goat, and then allow the head to fall backward between the handler's thighs so that the goat's back is resting on the handler's shins. This redistributes the goat's weight from the bony rump to the back, making it more comfortable for the goat. Tipping up the goat is useful for examining the prepuce and penis of male goats suspected of urolithiasis. In this case, the weight of the goat's upper body needs to be shifted forward to facilitate extension of the penis. Foot trimming is most easily carried out by raising the distal limbs of the standing goat.

Administering Medications

Oral Medications

Mass medication of feed and water is no more reliable in goats than in other species, because sick animals are likely to have reduced feed and possibly water intake. In addition, goats, being fastidious about water supplies, may detect a change in the odor or flavor of the water and refuse to drink it.

When drenching individual goats, the head should be held horizontally and not tilted up, reducing the chances of aspiration pneumonia. The drenching gun should be inserted at the commissure of the lips and the nostrils held off while the medication is quickly dispensed. To successfully administer boluses with a balling gun, the gun must be carefully worked over the base of the tongue before dispensing the bolus or the pill will be chewed and spit out. Put the gun into the mouth at the commissure of the lips to facilitate this process. Do not force the gun into the pharynx or traumatic injury can occur. Balling and drenching guns should be examined before use to ensure that they do not have sharp defects that could injure the goats. Passing a stomach tube in goats via the mouth is not particularly difficult if proper restraint and a suitable speculum are available. Commercially available sheep speculums work well with goats, as does a block of wood with a circular hole cut through it. Small diameter, well lubricated tubes can be passed through the nose to the stomach.

FIG. 1–1a   FIG. 1–1b

Figure 1.1. Useful restraint methods for intravenous blood sampling or medicine administration via the jugular vein of a goat. Backing the goat into a corner, as shown, improves control. In Figure. 1.1a, the goat is restrained so that an assistant, kneeling in front of the goat, can easily take the sample or give the medicine. In Figure. 1.1b, the goat is positioned with the head tucked under the handler's arm so that sampling or medicine administration can be accomplished by the handler alone. (Illustrations by Mr. Nadir Kohzad.)

Injections

Mass medication or vaccination using a common needle has long been practiced by some farmers and veterinarians. In the case of goats, as with other species, it is time to rethink this practice, particularly in light of the growing importance of caprine arthritis encephalitis virus (CAEV) in goats. This retrovirus may be transmissible by blood-contaminated needles. Certainly, in herds where the virus is known to exist, or attempts are under way to control it, it would be counterproductive and negligent to use common needles. Additional discussion of this important caprine disease is found in Chapters 4 and 5.

Another reason to use individual needles in conjunction with other good hygienic practices during vaccination is the tendency for goats to develop large swellings and even abscesses at injection sites after vaccination with clostridial, chlamydial, and paratuberculosis vaccines. If the veterinarian's technique is exemplary, he or she is unlikely to be held accountable for any problems that develop later.

If skins are marketed from a goat herd, the veterinarian should avoid injections of any kind in regions of the body that become part of the marketed skin, because defects can occur secondary to injection site reactions and devalue the skin. Therefore, the back and upper flanks should be avoided even though they are often convenient.

Intramuscular injections can cause difficulties in goats. The preferred site is in the neck, in a triangular region bounded by the vertebral column ventrally, the nuchal ligament dorsally, and the shoulder caudally. The triceps can also be used. If skin quality is not a consideration, the longissimus muscles over the back in the lumbar region may also be used. In all cases, the volume of drug administered in one site should not be greater than 5 ml. Needles should be 2 to 3 cm long and no larger than 18-gauge unless the medication is highly viscous. Shorter needles should be used for young kids.

The thigh muscles should be avoided as a site of intramuscular injection in adults and especially young

goats. The muscle mass is small compared to other ruminants, and sciatic nerve damage is not uncommon. Owners should be counseled against using this site. Even when the nerve is not damaged, marked lameness can occur when irritating drugs such as oxytetracycline are given in the leg. Permanent muscle damage can also occur that devalues the carcasses of meat goats.

Subcutaneous injections are commonly given in the neck in the same region described for intramuscular injections, or on the chest wall about 5 cm behind the point of the elbow. Injections ahead of the shoulder should be avoided in show goats, because local reactions near the superficial cervical (prescapular) lymph node may be confused with caseous lymphadenitis. Needles should be 18- to 20-gauge. The risk of accidental intramuscular injection may be increased if long needles are used.

Intravenous drugs are given via the jugular vein generally using 2 to 3 cm long needles of 18- or 20-gauge. Blood samples can be taken from the jugular vein using an 18-gauge needle. Intradermal injections are given using 26-gauge, 1-cm long tuberculin needles. Intraperitoneal injections are rarely used except to treat neonates for hypoglycemia with glucose solutions or navel infections with aqueous based antibiotics. With the kid held hanging by the front legs, an 18- or 20-gauge needle is inserted perpendicular to the skin about 1 cm to the left of the navel no deeper than 1 cm.

When intramammary infusions are given, the teat should first be cleaned and swabbed with alcohol. As in cattle, single use teat cannulae should be used for each infusion with the cannula inserted into the teat only enough to gain entry into the teat cistern. For very small teat openings, sterile tomcat catheters can be used to infuse the teat.

CLINICAL EXAMINATION OF GOATS

A complete clinical examination consists of three major elements: history taking, physical examination, and inspection of the environment. Many diseases seen in individual goats are likely to represent potential herd problems; therefore, prompt diagnosis of clinical cases is essential so that, in addition to therapy, appropriate preventive measures can be introduced into the overall management program. In many caprine diseases, subclinical cases often exist in addition to the obvious clinical ones, and additional diagnostic testing may be required to identify them. The existence of subclinical infections and carrier states is a troublesome one for veterinarians performing prepurchase health examinations or writing health certificates for exportation or interstate travel. A list of such caprine diseases that the veterinarian must be aware of is given in Table 1.1.

History Taking

Very few diseases or health-related problems are randomly distributed in a flock or herd of goats; rather, they are concentrated in specific groups, usually by sex, function, production status, or age. Always establish early on what age, sex, breed, or group of goats is dying, showing signs of illness, aborting, or showing decreased productivity. If it is a mixed farm operation, the number of other types of livestock and their degree of contact with goats should be ascertained.

Detailed history should include a determination of the total flock or herd population and estimation of its breakdown by sex, age, breed, and pregnancy status. Having determined the total animal population, the population at risk, and the number of animals affected and dying, it is possible to determine rates of disease occurrence and case fatality rates. By counting cases,

Table 1.1. Goat diseases characterized by chronic infection or a carrier state.

Viral/prion	Rickettsial	Bacterial	Protozoal	Unknown
Caprine arthritis encephalitis	Chlamydiosis	Caseous lymphadenitis	Toxoplasmosis	Udder warts in white goats
Foot and mouth disease	Coxiellosis (Q fever)	Paratuberculosis

the investigator is also in a better position to determine the actual significance of a problem as compared to the farmer's perception of it. In some cases, the loss of a few animals may be insignificant compared to a more serious unrecognized problem such as endoparasitism or ectoparasitism.

Such an epidemiologically based history should aim to identify not only specific problems but also specific risk factors that appear to be associated with mortality, morbidity, or suboptimal performance. For example, when a primary complaint of kids developing diarrhea after weaning suggests coccidiosis, additional questions concerning the segregation of kids from adults, the manner that kids are fed, the design of feeders, the frequency and manner of barn cleaning, and details on the use of coccidiostats are necessary. In such cases, modification of management practices may halt the spread of disease.

Temporal relationships are important to note. Some diseases may occur seasonally, in association with abrupt weather changes, or in relation to specific events such as breeding, pregnancy, shearing, parturition, and lactation. For example, an unexpected cold snap or heavy rain right after shearing of Angora goats can increase pneumonia, abortion, and death rates, particularly if adequate shelter and supplemental feed have not been provided.

Localization of death or disease to specific areas on the premises is helpful. For example, if losses are seen only in certain areas of the farm, specific pastures, or particular barns, then suspicion of poisoning is increased.

Other important aspects of the history include questions pertaining to the actual ration being fed and its consumption, methods of feeding, changes in feeding, access to grazing, and water supply type and water availability.

If management interventions or preventive health procedures have been undertaken recently, they should be identified. Shearing, drenching, dehorning, spraying or dipping, castration, or vaccination can be associated with increases in morbidity and mortality. When range animals are mobbed for such procedures, sudden close confinement, temporary feed deprivation, and abrupt weather changes can predispose to outbreaks of conditions such as abortion, coccidiosis, salmonellosis, hypocalcemia, or starvation as a result of mismothering. When drugs or vaccines are used, the products and dosages, number of treatments, and method of administration should be determined, particularly because many goat farmers traditionally obtain their drugs and biologicals from nonveterinary sources.

If animals have been transported recently, dates, origins, means of transportation, and quarantine times should be determined. Information should also be col-lected on visits to shows or fairs and on the origin of purchased animals, be it other farms, stockyards, or specialized goat sales. If animals have come from out of state, the relevant health certificates should be examined and the disease situation in the state of origin reviewed.

Finally, the reliability of information obtained should be checked with the actual goat keepers if the owner is not involved with day-to-day management decisions. If the veterinarian has prior knowledge of the local disease patterns in goats, such knowledge should not be used to make hasty and possibly incorrect judgments.

Special Considerations for Range and Pastured Goats

Extensively managed animals may not be closely observed, and histories can be sketchy. With large flocks, it should be determined if the animals are managed as a single flock or in smaller, self-contained units. The seasonal pattern of grazing and the length of grazing periods should be noted. Pasture composition, seasonal stocking rates per acre, the degree of pasture subdivision, and length of resting periods between grazing should be established. Note if supplemental feeding is practiced and the types of feed used. This may be important in terms of meeting specific nutritional needs, and, in the case of silage, may be associated with diseases such as listeriosis or rumen acidosis. Inquiries should also be made about whether crops are fed or grazed, the type and stage of growth, and whether there is a recent history of fertilizer or herbicide application. Knowledge of local trace element deficiencies or excesses may be helpful.

The type of grazing, whether set stocked or rotational, may be relevant to some disease outbreaks, particularly to gastrointestinal helminthiasis. The presence of other livestock species and feral, predatory, or scavenging animals or birds should be established if relevant to the problem under investigation.

Special Considerations for Intensively Managed Goats

A complete history can usually be obtained from the owner or herdsman of intensively managed goats. The patterns of disease are also likely to be different, with pneumonia and enteric diseases of young goats assuming much greater significance than the foot rot, helminthiasis, predation, or toxic plant problems more often seen under grazing systems. Feed composition and intake are more regulated but the veterinarian must inquire about episodes of sudden changes, excesses, or deprivations in the feed and water supplies.

Under close quarters, the movement, mixing, or introduction of new animals is more likely to cause an outbreak of disease. Kidding is often assisted in inten-

sively managed operations, and artificial kid rearing methods are commonly used. These procedures should be carefully reviewed when morbidity and mortality are concentrated in young kids. Weather, per se, should not adversely affect intensively managed animals. However, extremes in temperature may tax the ventilatory capacity of confinement buildings and extremely cold weather may freeze water supplies or incapacitate mechanized feeding equipment. Answers to questions about changes in dairy herd milking procedures or personnel may help to explain mastitis problems.

Special Considerations for Hobby Farms

Because hobbyists often have little previous agricultural or livestock experience, it might be helpful to practitioners to gauge the owners' knowledge and attitudes regarding basic animal husbandry before history taking. Some fundamental misunderstandings about the care and management of goats may be revealed, such as non-recognition of basic ruminant physiology and the need for roughage in the diet. In other situations, owners may know about basic husbandry and disease problems, but may have seemingly unorthodox ideas about management and treatment. A good deal of tact may be required to obtain a useful history and prescribe appropriate therapy while not offending the hobbyist's sensibilities.

In addition, hobby farmers often perceive goats more as companion animals than as livestock production units. While they may seek the expertise of a livestock clinician, they often expect the "bedside manner" of the companion animal practitioner. Therefore, the veterinarian who appears insensitive to the client's emotions or indifferent to pain of the goat or who emphasizes only the economic value of the animal may not be called to the farm again.

Special Considerations for Organic Goat Production

Consumer interest in organically produced food has grown considerably over the past twenty years or so and producers have responded by producing and marketing an expanding variety of foodstuffs certified as organic. Increasingly, this includes foods of animal origin. Goat owners may choose to raise their goats under organic conditions. Veterinary practitioners with such clients need to be aware of and familiar with the constraints on conventional therapy that are associated with organic livestock production, which is now strictly regulated by law (Karreman 2006).

In the United States, the Organic Food Production Act (OFPA) was signed into law in 1990, creating the framework for regulation and certification of organically produced foods of plant and animal origin. The OFPA created the National Organic Standards Board (NOSB) which reviews materials for consideration as acceptable for use in organic food production, including veterinary inputs used to maintain animal health. As a general rule, all natural materials are allowed for use in organic agriculture, unless specifically prohibited, while all synthetic materials are prohibited unless specifically permitted, following a successful petition process to the NOSB. The specific regulations of the National Organic Program are found in the United States Code of Federal Regulations at 7 CFR 205. These regulations became effective in 2002.

Vaccination is promoted as an organic livestock health care practice under 7 CFR 205, but the use of antibiotics and most anthelmintics is prohibited. Veterinarians must approach therapeutic interventions in organically raised animals differently than in conventionally raised animals, relying heavily on so-called natural treatments, including botanicals, acupuncture, homeopathy, etc. The standards of livestock health care practice which must be observed under the OFPA are given in 7 CFR 205.238. Veterinarians should be aware, however, that 7 CFR 205.238 considers the welfare of organically raised livestock by stipulating that an organic livestock producer may "not withhold medical treatment from a sick animal in an effort to preserve its organic status. All appropriate medications must be used to restore an animal to health when methods acceptable to organic production fail. Livestock treated with a prohibited substance must be clearly identified and shall not be sold, labeled, or represented as organically produced." The synthetic substances allowed for use in organic livestock production are found in 7 CFR 205.603. The full text of the regulations can be found at www.ams.usda.gov/nop/NOP/standards/FullRegTextOnly.html.

In Europe, organic production is regulated throughout the European Union (EU). EU regulation number 1804/99, which became effective in 2000, sets forth the rules for organic livestock production including animal health and veterinary interventions. All EU member states at a minimum comply with these rules, but some individual countries have included additional rules of their own. Specifications of the European and U.S. regulations have been compared (Nardone et al. 2004).

Special Considerations for Transgenic Goats

Production of transgenic animals using microinjection or nuclear transfer and the propagation of desirable animals using cloning are no longer just scientific research endeavors. They have become established production systems for the propagation and management of transgenic goats. It behooves veterinarians with active goat practice to be familiar with the basic techniques and health issues associated with transgenic goat production.

Transgenic technology began in 1980 when the first transgenic mouse was developed (Gordon et al. 1980).

The first transgenic goat was developed in 1989, producing rhtPA (recombinant human tissue plasminogen activator) in the milk (Ebert et al. 1991) as a potential human therapeutic agent. Since then, the field has markedly expanded with transgenic animals becoming commonplace within many programs and facilities.

The applications for transgenic animals are considerable and include not only the investigation of gene function but also the development of animal models, increased disease resistance through either transgene insertion or knock-out techniques, and production of recombinant, biopharmaceutical proteins in a number of biological fluids such as milk, blood, urine, and semen (Nieman and Kues 2003). In fact, distribution of the first transgenically derived human therapeutic recombinant protein from goat milk (ATryn®) was approved by the European Agency for the Evaluation of Medicinal Products in 2006 and by the Food and Drug Administration in the United States in 2009.

The two main techniques employed for making transgenic animals are microinjection and nuclear transfer (cloning). While microinjection was the first technology to be used in making large transgenic animals (Hammer et al. 1985), and specifically the goat (Gavin 1996), the process is inefficient with only a small percentage of the resulting animals being transgenic. Large animal nuclear transfer (Campbell et al. 1996; Wilmut et al. 1997) was developed later and provides for a near 100% transgenic rate when compared to microinjection. The cloning of the first transgenic goat soon followed (Baguisi et al. 1999; Keefer et al. 2001). There are other techniques for producing transgenic animals such as retroviral gene transfer and artificial chromosome insertion. However, these techniques have not been used yet in goats and are not mentioned further.

Most transgenic goats are maintained in USDA-APHIS-AC Licensed Research Facilities. Under the auspices of the Animal Welfare Act (AWA), these licensed facilities must maintain strict adherence to rules and regulations specifically governing animal care, health, and welfare (housing, lighting, feeding, veterinary care, and environmental enrichment at a minimum). Depending upon the type of research and the funding source, the National Institutes of Health (NIH) may also be involved through their Office of Laboratory Animal Welfare (OLAW) as government funding brings along its own slightly different set of rules and regulations for animals used in a research setting. A growing number of institutions are also striving for accreditation by the Association for the Assessment and Accreditation of Laboratory Animal Care, International (AAALAC-Int.), considered by many to set the gold standard for animal care in licensed research programs and facilities. Lastly, depending upon the intended use of any tissues/fluids from the transgenic animal, the FDA may also have regulatory oversight and impose its own set of rules and regulations.

The use of microinjection to produce a transgenic animal involves microinjection of the transgene into the pronucleus of a fertilized, one-cell embryo and then the transfer of surviving embryos to a surrogate mother. One of the first areas for possible concern, and for which observation and monitoring are appropriate, is the physical/mechanical effects on the nucleus/gene due to the actual microinjection process at the one-cell stage. If any negative impacts occur or gene functions are altered or impaired, one may see outcomes ranging from decreased pregnancy rates from transferred embryos to increased pregnancy loss, late term abortions, or possible physiological abnormalities at birth with clinical sequelae. However, years of experience now indicate that these phenomena, while possible, occurs at a very low incidence.

Regardless of the technique used to produce a transgenic goat, another possible concern involves endogenous gene function and potential transgene insertional site effects. The gene of interest inserts randomly into the genome following transgene introduction. Hence, there is a chance that an endogenous gene could be negatively impacted, leading to potential adverse physiological effects and a transgenic goat presenting with clinical signs of abnormal physiology or health. Therefore, appropriate post-parturitional monitoring of animal health is warranted for any transgenic founder animal.

Introduction of a transgene produces a goat that is hemizygous for that given transgene. Subsequent breeding within a lineage may be aimed at achieving a homozygous state for the transgene. Possible concerns may arise through this approach. First, inbreeding of related goats is the primary route to achieving a homozygous animal. Therefore, inbreeding coefficients need to be considered and animals need to be monitored for ill effects from this relatedness and for possible impacts on overall health and ability to thrive. Second, achieving a homozygous state may bring to light an insertional gene effect since both copies of an endogenous gene may now be affected thereby causing physiological or clinical issues that were not seen in the hemizygous state. Again, appropriate monitoring of animal health is warranted for the first homozygous animals produced. Lastly, the potential exists that breeding for the production of a transgenic homozygous animal will reveal a lethal outcome. A lethality issue may be suspected when: breedings of two hemizygous animals produce no detectable pregnancies; pregnancies do not hold to term with either resorptions or abortions; or, offspring succumb soon after birth. Thus, production of a homozygous transgenic animal may not always be possible and close animal

health monitoring is warranted when homozygosity is pursued.

One additional set of concerns related to transgene effects is the possibility of systemic circulation of the recombinant protein being expressed and the potential health impacts arising from expression of pharmacologically active molecules. Depending on the tissue or fluid where the recombinant protein may be directed for expression (e.g., milk, blood, urine, semen, etc.), one must be vigilant for systemic effects as the protein usually will be found systemically due to leaky vasculature and normal lymphatic drainage. Therefore, the biological nature and function of the recombinant protein being introduced must be known so that any effects which may be exerted can be anticipated and recognized. Consideration must also be given to potential adverse health impacts if this is a new gene and novel protein not normally physiologically found in the genome or animal. Lastly, the quantity of the recombinant protein that is expressed and then found systemically in the transgenic animal must be considered. Even if the target protein is endogenous to the animal, it may be found at significantly higher levels than normal and may cause physiological effects that alter normal homeostasis.

As with any traditional goat agricultural production operation for meat, milk, or fiber, optimizing health and product output starts with a sound nutritional program. Relative to transgenic production, nutritional programs should consider the nature of the recombinant protein to be produced. Specifically, if the recombinant protein is novel to the physiological output of the goat's normal cellular machinery, or if quantities are above what is normally produced *in vivo*, then one may need to augment the diet. This modified or fortified diet may need to contain increased levels of vitamins, minerals, or specific amino acids. One should understand the normal cellular machinery and biochemical pathways involved in protein production to know if or what supplementation may be appropriate or necessary.

With the development of cloning technology, nuclear transfer has become the preferred method for producing transgenic goats and has greatly improved the overall efficiency of the process. However, the use of nuclear transfer has added some additional health concerns in a small percentage of animals.

Nuclear transfer starts by removing the maternal DNA from an unfertilized oocyte through enucleation. A full complement of genetic material is subsequently replaced by addition of a somatic cell (e.g. fetal or adult skin fibroblast cell) through a process termed reconstruction. Thereafter, *in vitro* techniques are used to fuse the oocyte and somatic cell and activate the couplet to begin dividing. Following a brief *in vitro* culture period, these newly developed cloned embryos are then transferred to recipient goats using traditional embryo transfer techniques.

With nuclear transfer, a decreased *in utero* fetal survival rate can be seen very early in pregnancy and has been well documented in many species (Campbell et al. 1996; Wilmut et al. 1997; Baguisi et al. 1999). This inability to thrive may be associated with inappropriate or inadequate reprogramming (Dean et al. 2001) of the nuclear/genetic material of the donor cell line or karyoplast and has been postulated to be at the level of the DNA (e.g., methylation pattern). An altered inheritance of cellular mitochondria (Wells 2005) has also been shown to occur in cloned embryos, adding to the possible causes for some of the abnormalities in homeostasis. Both of these phenomena may be directly linked to the small percentage of physiological problems seen *in utero* for some cloned animals such as abnormal placentation and/or organogenesis (Farin et al. 2006; Loi et al. 2006; Fletcher et al. 2007). Abnormal placentation can also lead to abnormal uterine fluid homeostasis and fluid retention in does carrying cloned embryos, which may warrant close clinical monitoring or intervention where appropriate. Other possible outcomes of abnormal placentation include: a tendency toward decreased pregnancy rates for animals receiving cloned embryos, an increased *in utero* loss rate through resorption, or an increased level of abortions if there is late term fetal loss.

The potential abnormal physiology with or without clinical presentations may continue after birth and into the neonatal and early prepuberal stages (Hill et al. 1999). Documented abnormalities in a few large animal species have been shown at the level of the renal, cardiac, respiratory, hepatic, hematopoietic, and immune systems. However, if the small percentage of animals, including goats, that present with these abnormal physiological entities can be clinically supported over time, as the animals grow, many of these abnormalities resolve and they can lead normal and healthy lives (Chavatte-Palmer et al. 2002).

The vast majority of transgenic and cloned animals are normal and healthy (Walsh et al. 2003; Enright et al. 2002; Tayfur Tecirlioglu et al. 2006) and subsequent generations of animals produced from first generation clones have not shown any of the health related issues seen in a small percentage of original clones (Wells 2005). In fact, passage through the germ line has been reported to reverse any abnormal patterns detected at the DNA level in first generation clones (Wells 2005).

PHYSICAL EXAMINATION

Inspection from a Distance

It is often useful diagnostically to observe a group of goats from a distance prior to disturbing them for "hands-on" examination. This is especially true at the

time of the initial visit to identify the existence of common problems in the herd or flock. The animals should be observed at rest, while eating or drinking, and during spontaneous and forced movement. General impressions of body condition, mental attitude, and social hierarchy may be acquired and abnormal behaviors characteristic of certain diseases may be noted. Estimated prevalence of common disease problems such as kid pneumonia, diarrhea, and pinkeye can be roughly assessed, respectively, by counting coughers, stained hindquarters, and runny eyes. Other specific observations that might suggest commonly seen disease problems in goats are briefly discussed below. This is for illustration and is not meant to be comprehensive.

Individual goats that appear listless, separate themselves from the herd, or are not actively feeding when others are should be noted and later caught for careful examination as should animals in very poor body condition. Reluctance to feed may be due to a wide range of systemic diseases or localized conditions such as dental or pharyngeal problems, or the result of inadequate bunk space or bullying by dominant does.

Latent signs of respiratory disease or anemia associated with parasitism can be brought out by forced movement of a flock. Anemia is manifested by rapid fatigue, increased heart and respiratory rates, and sometimes collapse. Increased respiratory rate, dyspnea, and coughing indicate respiratory problems.

Signs of skin irritation or pruritus manifested as hair loss, fleece biting, or rubbing against fences or other solid objects usually suggest ectoparasitism, though scrapie, pseudorabies, and migrating *Parelaphostrongylus tenuis* are other possibilities. Goats scratching at their ears with their hind limbs or shaking their heads vigorously probably have ear mites.

Goats observed resting or walking on their knees often have chronic CAEV infection or sore feet. Any animals with abnormalities of gait or lameness after forced exercise should be carefully examined for evidence of arthritis, fractures, laminitis, and lesions of foot rot or foot scald.

A variety of clinical signs may be observed in goats with neurologic disease. Among the more common are ataxia, posterior paresis, circling, depression, head pressing, unilateral facial paralysis, and blindness. Details on carrying out a neurologic examination and differential diagnosis for signs of neurologic disease are provided in Chapter 5.

Straining while attempting to urinate, particularly in bucks and wethers, should suggest the possibility of urolithiasis or posthitis.

Cutaneous swellings or discharges may be observed. Draining abscesses associated with lymph nodes are highly suggestive of caseous lymphadenitis in the flock or herd. A high rate of subcutaneous swellings is often associated with injection site reactions in goats in response to certain adjuvanted vaccines or bacterins or when aseptic injection techniques are not followed.

When kids are left with does, careful observation of suckling behavior can indicate kids that are not successfully nursing. Their does should be examined particularly for signs of mastitis or other udder problems.

Direct Physical Examination of Individual Goats

A topographical approach to physical examination is presented here. Because of the small size of goats, rectal palpation is limited to insertion of a finger into the rectum to assess the pelvic structures and to determine the presence and character of feces. When economics permit, physical examination findings should be supplemented through use of appropriate imaging techniques, diagnostic procedures, and laboratory tests. When numerous individuals in a herd or flock show signs of disease, field necropsy examination may be the most effective way to establish or confirm a diagnosis.

General Inspection

Body condition, mental attitude, and the status of the superficial lymph nodes should be noted. The temperature, pulse, and respiration should be recorded. Fleece in Angora goats makes visual assessment of body condition difficult. Digital palpation of the ribs, spinous and transverse processes of the vertebrae, and the loin muscle may be necessary to evaluate condition. A word of caution about condition scoring in goats: scoring systems derived for sheep are not directly applicable to goats because goats as a species tend to deposit stored fat intra-abdominally rather than subcutaneously. Scoring systems for dairy goats combine palpation of the sternal and lumbar regions and are discussed in Chapter 19. In general, any palpable back fat in a dairy goat would classify her as obese. A scoring system applied to the Small East African goat in Zimbabwe showed a good correlation between a backbone condition score and changes in bodyweight (bw), with a 1-point change in condition score representing an average change of 12% in bw (Honhold et al. 1989).

Normally goats have an alert, attentive, and inquisitive mental attitude. A depressed attitude is characterized by dullness, separation from the flock, and indifference to handling. Depression is present in a wide variety of septic and toxemic conditions but is a particularly prominent sign in pregnancy toxemia and listeriosis. An anxious or apprehensive state is often associated with urethral obstruction in males, sudden

blindness as may occur in polioencephalomalacia, or with persistent irritations such as flies and nasal myiasis. An attitude of extreme excitation is most often associated with neurological diseases such as tetanus and meningitis that may be accompanied by muscular rigidity, or encephalitic conditions such as pseudorabies and rabies.

Digital palpation of all superficial lymph nodes should always be a part of the physical exam because of the clinical importance of caseous lymphadenitis in goats. The mandibular, parotid, retropharyngeal, superficial cervical (prescapular), subiliac (prefemoral), and superficial inguinal (supramammary) lymph nodes should be inspected. Normal sized nodes may not be palpable in some of these locations but affected nodes should be readily evident. Any other swellings on the body surface should be noted. Temperature, pulse, and respiration should be measured when the animal is calm because the activity of catching the animal for examination may elevate all three parameters. When taking the goat's rectal temperature, an accumulation of brown, waxy material may be noted near the anus. This is the normal secretion of the sebaceous gland located below the base of the tail (Figure 1.2).

The normal body temperature of goats is usually reported in the range of 38.6° to 40°C (101.5° to 104°F). However, the body temperature of a normal Angora goat with a full fleece on a hot, humid day can reach 40.3°C (104.5°F) or higher, and goats of lighter bodyweight are more likely to have higher temperatures when exposed to sun than bigger goats (McGregor 1985). To accurately assess the febrile state of the patient, it is useful to record body temperatures in apparently normal herd mates.

The pulse can be measured by stethoscope over the heart or by digital palpation of the femoral artery. Normal pulse rate ranges from 70 to 90 beats per minute (bpm) in resting adults, but can be double that in young, active kids. Fetal heart rates up to 180 bpm have been recorded by ultrasound. It may be useful to assess respiratory rate both at rest and after exercise. Any abnormalities of respiration should also be noted, including flaring of nostrils, extension of head and neck, grunting, abdominal press, and so forth. Normal resting respiratory rate is 10 to 30 per minute in adults and 20 to 40 in kids.

Neonates should be inspected particularly for congenital defects. More commonly observed problems include brachygnathia, cleft palate, hydrocephalus, atresia ani, or rectovaginal fistula, and abnormalities of the genitalia associated with the intersex condition as discussed in Chapter 13. A list of congenital and inherited diseases is provided in Table 1.2. Not all of these, of course, will be evident at birth. Up-to-date information on inherited conditions of goats as well as
Figure 1.2. Typical waxy secretion found at the base of the tail of goats which is produced by the sebaceous glands in that area. This secretion should not be confused with diarrhea, vaginal discharge, or lochia. (Reproduced by permission of Dr. C.S.F. Williams.)

other species is available through the Online Mendelian Inheritance in Animals (OMIA) database at http://omia.angis.org.au/.

Goat stature is quite diverse. Many small breeds of goats such as the Pygmy or West African Dwarf goat are in fact achondroplastic dwarfs. They appear disproportionate with short legs and normal size torsos. This may draw visual attention to the degree of abdominal distension present, which though quite pronounced, is usually normal. Dwarfism because of pituitary hypoplasia is also seen in goats. These small goats are proportionate in appearance; the Sudan goat is an example (Ricordeau 1981).

Examination of the Integument

In goats the character of the skin and haircoat is a good indicator of general health. A rough, dry, unglossy coat; excessive dander or flakiness; and failure to shed

Table 1.2. Congenital and inherited abnormalities in goats.

Known inherited conditions	Known acquired conditions	Conditions of unclear status
Afibrinogenemia in Saanen goats	Anthrogryposis and hydranencephaly caused by Akabane virus	Absence of hair
Beta mannosidosis in Nubian goats	Border disease	Atresia ani
Bipartite scrotum in Angora goats	Congenital copper deficiency	Atresia coli
Brachygnathia superior or inferior	Cyclopia due to *Veratrum californicum*	Cleft palate
Cryptorchidism in Angora goats	Freemartins	Congenital goiter of Boer goats
Excessive facial hair in Angora goats		Double or fused teats
Gynecomastia		Entropion
Hereditary goiter in Dutch goats		Hydrops
Inherited abortion in South African Angora goats		Patellar luxation
Intersexes associated with polled condition		Precocious milking
Myotonia congenita		Progressive paresis of Angora goats
N-acetylglucosamine 6-sulphatase deficiency in Nubian goats (mucopolysaccharidosis IIID)		Rectovaginal fistula
Recessive atrichosis		Skeletal malformations
Robertsonian translocation		Spastic paresis
Short tendons in Australian Angora goats		Sticky kid syndrome of Golden Guernsey goats
Sperm granulomas		Umbilical hernia
Supernumerary teats		
Testicular hypoplasia		

out in the spring are all suggestive of poor nutritional status, parasitism, or other chronic diseases. The hair or fleece should be parted and the skin examined for lice, ticks, fleas (in the tropics), nodules, swellings, crusts, eczema, necrosis, neoplasia, photosensitization, and sunburn and focal or regional alopecia. The differential diagnoses for these findings are discussed in Chapter 2.

Because many goats are used primarily for cashmere or mohair production, the veterinarian should know something about the nature of goat hair used in textiles. Detailed information on the subject is given in Chapter 2.

Examination of the Head

Many conditions can cause general asymmetry or focal swellings around the head and these abnormalities should be noted. The differential diagnoses for such swellings are discussed in Chapter 3.

Membranes

Inspection of the conjunctivae and mucous membranes of the mouth may reveal paleness due to anemia, icterus resulting from hemolysis or hepatic dysfunction, or hyperemia and congestion associated with acute febrile or toxemic states.

Oral Cavity

Evidence of brachygnathism, cleft palate, mucosal lesions, dental abnormalities, or dysphagia such as drooling, salivation, dropping food from the mouth, or accumulating food in the buccal space should be noted. The differential diagnoses for these signs are given in Chapter 10. Necrotic odors of the breath may occur. They may reflect necrotic stomatitis, alveolar periostitis, pharyngitis, or even pneumonia.

Thorough examination of the oral cavity requires good restraint, a speculum, a towel, and a penlight. All oral structures should be examined and the molar arcades digitally palpated for missing teeth from outside the mouth. If more direct examination of the teeth is required, extreme caution should be taken because the molars may have sharp, jagged edges and exert powerful grinding motion. Tranquilization is indicated, because fingers can be badly injured. Wearing gloves during oral examination is a wise precautionary measure, particularly if the goat shows neurologic signs.

Eyes

Facial hair covering the eyes is a heritable trait in Angora goats. Affected goats tend to do poorly on

range because their ability to selectively browse is impaired. The body condition of such individuals should be noted as well as their prevalence in the flock. Blindness is initially assessed by testing the menace response, but facial nerve paralysis can render a sighted animal unable to blink. Intact pupillary light responses in a blind goat suggest a cerebrocortical lesion. Lacrimation and hyperemia of the conjunctiva, cloudiness of the cornea, and hypopyon in the anterior chamber should be noted if present. The differential diagnoses for these various findings are given in Chapter 6.

Nares

Both nostrils should be evaluated for symmetry of air flow. If nasal discharge is observed, determine if it is unilateral or bilateral and note its character. Collapse of a nostril may result from facial nerve paralysis. Crusting of the nares occurs when the sick animal does not clean the nostrils or it may be a sign of specific disease problems. The differential diagnoses for nasal discharge and crusting of the nares are given in Chapter 9.

Ears

Ear mites, if suspected, can be identified by collecting debris from the ear canal on a cotton swab and smearing it on a slide for examination.

Goats are often identified by tattoos inside the ear; tattoo numbers may have to be checked against health papers at shows and sales. It may be necessary to clean the inside of the ear with soap and water and use a powerful light source to backlight the tattoo to make it readable. Metal and plastic ear tags commonly tear out of goats' ears and their use should be avoided, especially in pet and show animals.

Ear tips may be lost on young goats due to prolonged exposure to freezing temperatures. Goats of the La Mancha breed lack a well-developed external ear. Only a vestigial pinna is present and is referred to as an elf (up to 5 cm, with some cartilage) or gopher (up to 2.5 cm, with little or no cartilage) ear. These animals are usually tattooed on the underside of the tail.

Horns

Goats may be horned or polled. Horn buds may be present at birth or become palpable within several days of birth. Generally, horned kids have two irregular whorls of hair over the location of the horn buds whereas hornless kids have a smooth poll with a single central symmetrical whorl of hair. It is important to establish and record which offspring are naturally polled because homozygous polled goats have a high incidence of infertility. The relationship of the polled trait and the intersex condition is discussed in detail in Chapter 13. Deformed horns, or scurs, are often seen on older goats as a result of incomplete removal of germinal horn tissue at the time of disbudding. Techniques for, and problems with, disbudding and dehorning are discussed in Chapter 18. The glands partially responsible for the characteristic odor of buck goats in the breeding season are located in skin folds just caudomedial to the horn buds.

Examination of the Neck

Traumatic injuries to the pharynx from balling guns and drenching equipment occur in goats. The throat should be palpated for swelling, heat, and pain associated with cellulitis from traumatic injury. A number of normal and abnormal structures and swellings in the neck must be differentiated on physical examination, including goiters, thymus, branchial cleft cysts, wattles, and abscesses. Their differentiation is discussed in Chapter 3. Thorough examination of the neck should include palpation of the jugular furrows for evidence of phlebitis, palpation of the esophagus for evidence of obstruction, and auscultation of the trachea. Prominent distension of the jugular vein, though possibly suggestive of congestive heart failure, is most commonly due to overly tight collars or neck chains in goats. This should be brought to the owner's attention if found.

Examination of the Chest

The extent and severity of respiratory disease is often difficult to assess in goats. To improve the chances of accurate diagnosis and prognosis, careful attention should be given to auscultation. When possible, the animal should be moved to quiet surroundings. The fleece in Angora goats should be parted to place the stethoscope in contact with the skin. The trachea and the lungs should be auscated to identify the presence of referred sounds. Eliciting a cough by compression of the pharynx may clear the trachea or reveal the presence of bronchial exudate. Care should be taken to listen with a stethoscope placed well forward under the elbow and in front of the shoulder, otherwise cranial ventral pneumonias, which are common, may be overlooked. The intensity of identifiable sounds can be augmented by forced activity of the animal before auscultation or by placing a plastic bag or exam glove over the nares to increase the depth of respiration by rebreathing of carbon dioxide. Radiographic examination is indicated when questions about the severity of lung disease persist.

Normally the heart can be heard about evenly on both the right and left sides of the chest at the fourth or fifth rib space. Mediastinal abscesses may displace the heart, resulting in a shift in intensity of cardiac sounds. Muffling of the heart sounds because of pericarditis is uncommon in goats. Murmurs are rarely heard and are discussed in Chapter 8.

Examination of the Abdomen

The abdominal contour should be inspected to assess conditions such as bloat, advanced pregnancy in females, and ruptured bladder in wethers and intact males. Characteristic contours and their clinical significance are discussed in Chapter 10. Ballotment may help to detect abdominal fluid accumulations, pregnancy, or rumen impaction. Auscultation of the rumen in the left paralumbar fossa is essential. Normal rumen contractions occur at a rate of one to two per minute. Observation of cud chewing suggests normal rumen activity.

Examination of the Limbs

Locomotor problems are common in goats. Lameness and abnormalities of gait may result from neurological disease, conformational defects, muscular dysfunction, skeletal trauma, infectious and noninfectious arthritides, and diseases of the foot. Localization of the problem by careful physical examination is the first step in making an accurate diagnosis. Differential diagnoses of locomotor problems are discussed in detail in Chapter 4.

Overgrown hooves must be pared with shears or a hoof knife to adequately assess the health of the foot. Hyperemia and swellings at or above the coronary band should be noted. They may represent either local infections or systemic disease.

All joints should be carefully palpated. Distensions of the joint capsule, heat, pain, swelling or fibrosis of periarticular structures, limitations on the range of joint motion, and enlargement of bursae should all be noted. The degree of joint enlargement may not necessarily correlate with the severity of lameness.

The vertebral column and the long bones of the legs should be palpated for evidence of fractures in acutely lame or recumbent animals. A major goal of physical examination in recumbent goats is to differentiate musculoskeletal, metabolic, toxemic, and neurologic causes of recumbency. The differential diagnoses for recumbency are discussed in Chapter 4.

Examination of the Reproductive System

Mammary Gland

Careful examination of the udder is always warranted. Visual inspection may reveal weakness of the suspensory apparatus, slack halves, abnormal swellings, and discolorations of the skin. Digital palpation of the gland will identify udder edema, active inflammation, fibrosis, scarring, or abscesses in the parenchyma or teats. In gangrenous mastitis the udder skin may be blue-black and cold and in time the gland may slough if the animal survives. Patency of the teats should be assessed in lactating animals. Supernumer-

ary teats may be present. Their identification and removal are discussed in Chapter 14.

The milk of lactating does should be observed on a black plate or strip cup to assess color, consistency, and the presence of clots or flakes. Bovine screening tests for subclinical mastitis such as the California Mastitis Test must be used cautiously in goats because normal goat milk tends to have higher cell counts. The somatic cell count issue and interpretation of test results are discussed in Chapter 14.

Vulva

Swelling and hyperemia of the vulva may be signs of heat or impending parturition, but may also be seen in herpes vulvovaginitis in conjunction with vesicles or scabs. Any vulvar discharges should be noted. As females come out of heat, the vulvar discharge, initially serous and mucoid, may become white and tenacious. This is often misinterpreted as a purulent discharge by the inexperienced observer. Often, there is a sanguinous discharge after termination of a pseudopregnancy. Speculum examination of the vaginal canal and cervix should be carried out when there is doubt about the source and nature of the discharge. Occasionally, otherwise normal does may have ectopic mammary tissue present at the vulva which may swell during lactation.

Does may show vaginal eversion or frank prolapse in advanced pregnancy or immediately post partum. After uncomplicated births, normal lochia may be discharged for a period of one to three weeks. It is reddish brown in color and odorless. Placentas are usually passed within four hours of parturition and are frequently eaten.

It is important to carefully examine the external genitalia of young does, particularly when there is a complaint of infertility, because of the high incidence of intersexes among polled goats. Malformations of the genitalia range from the clinically subtle, such as a slightly enlarged clitoris, to the overt, such as male phenotypes in genetically female individuals. Accurate record keeping may help to identify homozygous-polled individuals.

Scrotum

The scrotum and its contents should be palpated. Normally there is bilateral symmetry of all structures. A bipartite or split scrotum is a common congenital condition that some breeders consider a fault. The differential diagnoses for abnormalities of the scrotum, testes, and spermatic cord structures are given in Chapter 13. Semen samples can be collected for evaluation by electroejaculation or by use of an artificial vagina. These procedures are described in Chapter 13. Gynecomastia occurs in male goats and it is not

extraordinary to detect distended teats anterior to the scrotum during physical examination, as discussed in Chapter 13.

Penis and Prepuce

Examining the penis of male goats, especially wethers, can be difficult and is not ordinarily attempted unless there is a history of urinary or breeding problems. Details on special examination and catheterization of the penis are given in Chapter 12.

The preputial opening should be routinely examined, particularly in wethers, for the presence of ulcerative posthitis. The preputial orifice may become occluded in this condition. Crystals or drops of blood may be noted at the orifice in cases of obstructive urolithiasis.

Examination of the Environment

An examination of the environment where goats are raised should include a detailed review of all feeds used, the feeding facilities, water sources and water delivery systems; the yards, pastures, range, or buildings where the animals are kept; and any mechanical or manual equipment used as part of the routine farm procedures. Too often, farmers attempt to make do with equipment and buildings that are inadequate for an expanding operation. Because of prolificacy, goat herds tend to expand faster than owners anticipate. Inadequate feeder space for does, a smell of ammonia in the air due to poor ventilation and/or soaked bedding, and overcrowded kid pens are three examples of common faults found on environmental inspection. Besides visual inspection of equipment, farmers could be asked to demonstrate how common procedures are carried out to detect if they are using inappropriate techniques.

Equipment used for treatment should be examined for its potential to cause injury. Poorly maintained syringes with either contaminated or overly long, large-gauge needles can result in injection abscesses or systemic infections. Drug and vaccine stocks should be examined to determine if they are appropriate, clean, unexpired, and maintained at proper temperatures. Storage facilities for these items should be properly secured. If the farmer blends his own feed or components, the techniques and constituents used should be examined, particularly when toxicities are suspected. Accidental inclusion of agricultural or other farm chemicals is not uncommon. Milking machines used for goats should also be examined to determine their efficiency and the milking procedures studied if it appears that mastitis is a significant problem. Finally, the facilities available and routinely used to dispose of any dead animals should be particularly noted to see that they are consistent with any legal requirements and do not serve as environmental contaminants or as a source of infection for the remainder of the flock or herd.

In recent years, in association with the expansion of international trade in livestock and livestock products and increasing concerns about bioterrorism, there has been a growing emphasis on food safety and biosecurity, with recognition that food safety encompasses all aspects of food production, from the farm to the table. As such, quality management assurance programs have grown in popularity as have procedures to ensure biosecurity to limit the introduction and spread of disease on and between farms. Environmental inspections should include an assessment of biosecurity and aspects of management and sanitation that can affect food quality.

Special Considerations for Range and Pasture Operations

The quality and quantity of pasture and the availability of supplementary or conserved feed should be assessed. This may require a specialized knowledge of pasture species, weeds, or other potentially toxic plants. A list of plants known to be poisonous to goats is provided in Chapter 19. If possible, animals should be observed while feeding. The source of water available both year-round and seasonally, its quality, and its quantity, should also be inspected. Feed and water samples should, if necessary, be collected for laboratory examinations.

On range or pasture, goats may congregate in certain shaded or sheltered areas, particularly during periods of high or low temperatures or precipitation, and after shearing. Provision of adequate shelter should be documented. Heat stress can be reduced by ensuring the animals have adequate shade and water when the livestock weather safety index is in the danger or emergency zone. Cold stress is particularly likely in recently shorn animals, and temporary shelter and extra feed are necessary for these animals. If shelter areas are limited or overused, buildup of infectious agents can occur, leading to increases in enteric and other diseases, especially in kids. This is aggravated by poor drainage under feeders and water troughs.

Fencing for these types of operations should also be inspected, particularly regarding its effectiveness in keeping goats in and keeping predators out.

Special Considerations for Confinement Operations

In semiconfinement operations adult animals and sometimes young stock are grazed on pasture during the warmer months but confined during the winter and early spring. As herds expand, there is a tendency for small pastures to be overused, with poor nutrition and increased parasitism as the result. Stocking rates should be noted and deworming history verified.

In confinement systems, the type of buildings used for housing should be evaluated for the following: available area (square feet or square meters) per adult breeding animal, type of flooring and bedding, degree of insulation, presence of supplemental heating if any, adequacy of natural or mechanical ventilation systems, source and availability of water, and the amount of trough or bunk space per goat. Requirements for goats are given in Chapter 9. The distribution of animals within buildings should be noted. Ideally, a separate kidding facility should exist and be hygienically maintained. Artificially reared kids should be in a separate facility from adult stock, and bucks should be housed separately from milking does. Methods and times of feeding for all groups within the herd should be noted. If other species of livestock are present, consideration should be given to them as possible sources of disease for goats.

Unfortunately, many confinement goat operations have both rodent and associated feline populations. Cats are a recognized source of *Toxoplasma gondii*, a major cause of abortion in goats. Farmers should be encouraged to seek alternate means of rodent control.

Special Consideration for Hobby Farms

The principles and procedures of environmental examination already described also apply to the hobby farm. Special considerations that occur are usually the result of inexperience on the part of the hobbyist. Medications, insecticides, and grain supplies may be inadequately secured, allowing access of inquisitive goats with resultant overdoses, poisonings, and/or grain overload. In the barn, overcrowding with inadequate feeder space is often observed along with fecal contamination of feed and water supplies.

In winter, lack of adequate ventilation in closed, overcrowded barns leads to outbreaks of pneumonia. Some owners consistently shut all windows and doors, believing that animals must stay warm in winter. These individuals need to be counseled on the beneficial effects of continuous air exchange on respiratory health. Pasture problems often involve disappearance of animals or predation due to inadequate fencing, bloat due to inadequate adaption to pasture, or parasitism due to placement of young stock on contaminated, overcrowded plots. The veterinarian should examine all elements of the ration being fed on the hobby farm to ensure that the hobbyist understands basic ruminant nutrition.

Field Necropsies and Slaughterhouse Checks

The economic value of most individual goats in commercial herds and flocks is such that most owners can be persuaded to have a necropsy undertaken of an ill or obviously moribund animal. This is an extremely useful adjunct to clinical examination, because nec-

ropsy can confirm the suspected diagnosis or suggest new avenues of investigation. All necropsies should be carried out following a systematic procedure with special regard to the likelihood of any zoonotic infections being transmitted and the safe and legal disposal of carcasses.

Necropsy of all or a random sample of young animals born dead or dying in the first two to three weeks of life is an extremely valuable service that veterinarians can provide to their clients. Categorization of deaths into preparturient, parturient, and postparturient causes can be done with a minimum of laboratory diagnostic techniques and immediately direct the owner to possible ways of reducing these losses.

Whenever possible, goats slaughtered for meat or culled from the herd or flock should be examined post mortem by a veterinarian as an inexpensive and worthwhile means of disease surveillance. Such inspections can provide information on the efficacy of parasite control measures; the presence of subclinical pneumonia; and the occurrence of injection site abscesses, visceral caseous lymphadenitis, and hydatid disease. Opportunities to perform routine slaughter checks on goats at an abattoir are uncommon in the United States because the goat meat industry is decentralized, though this may change as demand for goat meat continues to increase.

Skin

NORMAL ANATOMY AND PHYSIOLOGY OF THE SKIN AND HAIR

The structure and function of the skin have been reviewed elsewhere (Scott 1988) and will not be discussed in detail here.

Skin

The epidermis can be divided histologically into four layers: stratum corneum, stratum granulosum, stratum spinosum, and stratum basale (Sar and Calhoun 1956). Goat skin is thickest on the forehead and dorsal aspect of the body. As in other species, the major histocompatibility system is involved in allograft rejection if skin grafting is attempted (van Dam et al. 1978).

Specialized Skin Structures

Wattles are specialized skin appendages sometimes found in the cervical region of goats. They contain a central cartilaginous core, smooth muscle, connective tissue, nerves, and blood vessels (Sar and Calhoun 1956). Wattles have no known function. Subcutaneous

cysts associated with the base of the wattle are discussed in Chapter 3. The presence of wattles is determined by an autosomal dominant gene with complete penetrance but variable expression regarding location (neck, ear, face), size, and number (Lush 1926; Ricordeau 1981). In a study of Saanen goats in France, does with wattles were approximately 13% more prolific than does without wattles (Ricordeau 1967).

The skin caudomedial to the horns of buck goats contains branched sebaceous glands that produce lipids and chemicals that contribute to the buck odor (Van Lancker et al. 2005). The glands are also present but much smaller in female and castrated male goats (Bal and Ghoshal 1976). These glands and descenting procedures that destroy them are discussed in Chapter 18.

Hair and Shedding

Hair growth in goats resembles that in other land mammals (Shelton 1981; Scott 1988). Hair follicles are initiated prenatally by invagination of the epidermis into the dermis. Sweat and sebaceous glands and the arrector pili muscle develop in association with the follicle. The histologic anatomy of these structures has been reviewed by Scott (1988). The hair is produced by rapidly dividing cells in the bulb at the base of the follicle. During the active phase of the growth cycle (anagen), growth from the bulb is continuous. Anagen is followed by the resting phase (telogen) and then by molting. When growth resumes, the new fiber produced by the follicle helps to push out the old fiber. In goats not specifically selected for fiber production, fibers form brush ends and growth stops at about the time of the autumn equinox, and the follicles remain dormant until late spring (Ryder 1978).

Hair follicles in goats are grouped in bundles or clusters. Within each bundle are primary follicles (often a central and two laterals) and a variable number of secondary follicles. The primary follicles produce long, coarse guard hairs, while secondary follicles produce undercoat or down. In the Angora, secondary follicles have been modified to produce mohair. Goats adapted to tropical regions have little undercoat, while secondary fibers contribute to cold resistance in goats in cold climates.

The inheritance of coat color involves numerous genes. One possible interpretation of color in American goats has been proposed by Mitchell (1989). Several other papers have attempted to summarize various aspects of color inheritance in goats (Ricordeau 1981; Adalsteinsson et al. 1994).

FIBER PRODUCTION

Certain breeds of goats are kept specifically for fiber production. Anything that adversely affects the quality and quantity of fiber harvested, including skin dis-

Figure 2.1. Angora goats, the source of mohair. (Courtesy Dr. M.C. Smith.)

eases, can have severe economic consequences. Branding paint also damages the fleece, and thus range animals should be paint branded only on the ears or horns.

Mohair

Mohair is the fleece of the Angora goat (Figure 2.1). The Angora evolved in Asia Minor many centuries ago, possibly a descendant of the wild goat of Persia. Mohair probably developed by elongation of the woolly undercoat of the primitive goat. Although the sultans of Turkey attempted to prevent exportation, populations of Angora goats reached South Africa and the United States in the mid-1880s. Currently, important production centers for mohair include South Africa, Texas, Turkey, Argentina, New Zealand, and Australia (Dubeuf et al. 2004).

Factors Affecting Mohair Quality

Mohair mainly consists of nonmedullated fibers that lack crimp. They arise mostly from secondary follicles and grow continuously, albeit at a lower rate in winter. These fibers are strong, elastic, and composed of keratin. Flat scales that hardly overlap give the fibers smoothness and luster (Margolena 1974). Different countries have different standards for fiber diameter, but the range is typically 24 to 46 microns. The fleece is typically harvested in two clips per year.

KEMP. At birth, goat fleece contains approximately 44% kemp, or medullated fibers from primary follicles, but this proportion drops to 7% by three months of age due to shedding of the kemp (Dreyer and Marincowitz 1967). Later in life, some primary follicles may produce fibers with discontinuous or no medullation. Kemp and colored fibers are generally undesirable fleece contaminants due to uneven dyeing. It has been proposed that shearing shortly before the spring and autumn equi-

noxes decreases the proportion of medullated fibers in the clip, because natural shedding of these fibers will have recently occurred (Litherland et al. 2000).

PERINATAL NUTRITION. In the developing fetus, a central and two (or more) lateral primary follicles are in place by ninety days of gestation (Wentzel and Vosloos 1974). The development of secondary hair follicles occurs later and is affected by nutrition during the fourth month of gestation through the first month after birth. Poor nutrition during these critical times probably will compromise the Angora goat's ability to produce mohair later in life (Eppleston and Moore 1990).

AGE AND NUTRITION. Hair follicle density in the skin determines fiber density in the fleece and is under both genetic and nutritional control. Fiber diameter increases with age and bodyweight. Kids produce mohair with a fiber diameter of 28 microns or less at the first shearing, whereas the diameter of the fibers from adult goats varies from 36 to 46 microns. The mohair mass produced peaks at three to four years of age, but because the finer fibers are more valuable, the economic value of the fleece peaks somewhat sooner (van der Westhuysen et al. 1988).

Under nutrition results in reduced body growth and production of mohair as well as a reduction in fiber diameter (Russel 1992). Thus, finer, lighter fleece is produced during periods of drought or overstocking. A slightly coarser fleece may result from overfeeding, although published documentation of this is scarce. In one study in which Angoras were fed individually to maintain different bodyweights, fiber diameter increased 0.4 microns for each kilogram increase in bodyweight (McGregor 1986). Nutrition of Angora goats is discussed more in Chapter 19.

STRESS MEDULLATION. A reversible change from normal to medullated fibers occurs in a stress syndrome that seems to be comparable to wool break in sheep. Reported causes of stress-induced medullation include lactation for twins, transport, and hard work by bucks. The time period when the stress occurred can be demonstrated by immersing a full-length staple of fleece in kerosene in a black container. Kemp fibers and bands of medullation in mohair will show as white streaks due to air-filled cores. Normal mohair is almost invisible in kerosene (Ensor 1987).

Other possible causes of medullation have been reviewed (Lupton et al. 1991). Dietary protein and energy levels do not seem to be important in individually housed animals, but heredity may contribute. Selection should be based on objective evaluation of whole fleeces, not just mid-side samples, of Angora goats older than one year of age.

Freeze Loss

Whenever Angoras are shorn, even during summer months, they are vulnerable to exposure to wind, rain, and temperature changes. Angoras have minimal body fat and a small body size, with relatively greater surface area, as compared to sheep. Mortality can be very high in freshly shorn goats, especially if they have not had time to return to full feed before inclement weather arrives. Methods of limiting freeze loss include sheltering the animals for four to six weeks after shearing, shearing with a comb that leaves a longer stubble, and leaving a narrow strip of unshorn hair ("cape") along the backbone (Shelton 1981; Bretzlaff 1990).

Feeding of alkali-ionophore-treated grains (to avoid rumen acidosis, see Chapter 19) is helpful when shorn animals are exposed to severe weather. Individual recumbent animals may respond to intravenous or intraperitoneal glucose (van der Westhuysen et al. 1988).

Cashmere

Cashmere is a fine, soft fiber used to produce fashion-wear. It comes from the downy undercoat of certain goats (Figure 2.2). Originally, cashmere was combed from Pashmina goats in Central Asia (Mason 1984). Goat down (unmedullated, from secondary follicles) with a mean fiber diameter of 19 microns or less can be produced by many breeds. By comparison, the mean diameter of the guard hair outer coat is typically 60 to 90 microns. Latitude, and therefore photoperiod, appear to be more important than altitude as a factor influencing down production. Evidence of this is that most Australian cashmere production occurs near sea level (Couchman 1987). In spring-born kids, maximum secondary follicle development (as determined by skin biopsy or fiber measurements) is achieved by 20 weeks of age, permitting selection at that time (Henderson and Sabine 1991).

Figure 2.2. **Cashmere goats from Mongolia. (Courtesy Dr. M.C. Smith.)**

Cashmere goats have a three-phase annual cycle of fiber growth that is influenced by photoperiod, probably via melatonin (Klören and Norton 1995), and nutrition. The period of fiber growth typically coincides with summer in wethers and maiden does but is often delayed until autumn and early winter in lactating does (McDonald 1985). Next, fiber regression occurs and the root bulb of the fiber forms an enlarged brush end, which holds the fiber in the follicle. Finally, there is a follicle resting phase when no down is grown and improved nutrition has no direct effect on cashmere production. The fiber is shed (or the entire fleece may be cast simultaneously) when the fibers are lost from the secondary follicles. The fleece may be harvested by shearing just before it would be shed naturally, usually at the end of the winter. Freeze losses of shorn goats may occur. It may be several months before normal seasonal growth resumes (Betteridge et al. 1988). Chemical defleecing with mimosine has been investigated as a means of leaving the protective guard hairs on the goat (Luo et al. 2000).

Raw, or greasy, cashmere contains both guard hairs and down. Dehairing machinery removes the long guard hairs that remain after hand removal of most of the coarse hairs. Major suppliers of the raw fiber are China, Mongolia, Afghanistan, and Iran. The maximum guard hair content after dehairing is 0.5% for knitting and 3% for the weaving trade. Imported cashmere is sometimes contaminated with anthrax (*Bacillus anthracis*) spores (Hunter et al. 1989).

As with mohair, the finest cashmere fibers are produced under conditions of nutritional stress. In an Australian study, however, feeding enough energy to maintain or slightly increase body condition during summer and autumn maximized cashmere production. Fiber diameter of the total fleece averaged 1 micron larger for goats fed energy at 1.25 maintenance (M) compared with 0.8 M (McGregor 1988).

Cashgora

Cashgora is a coarse cashmere with more luster, mostly harvested from the progeny produced by crossing Angoras with feral goats in Australia and New Zealand. The current fiber diameter is 20 to 23 microns. Some breeders are attempting to stabilize the fleece type.

Pygora

Pygoras are a newly developed breed resulting from the crossing of purebred pygmy goats and purebred Angoras. Two such "first generation crossbreds" are mated to produce the actual pygora. Currently registration requirements include fleece evaluation. The soft undercoat resembles cashmere, comes in a variety of colors, and is often plucked or combed for sale to handspinners in the United States (Hicks 1988).

PRODUCTION OF SKINS

The annual worldwide production of goat skins was estimated at 200 million in 1983. Of these, 95% were produced in developing countries (Robinet 1984). The estimate for 1995 was 295 million pieces, with India, China, and Pakistan remaining important producers of goat leather products (Naidu 2000). The quality of the skins produced is influenced by breed, nutritional status of the goat, disease conditions affecting the skin, and traumatic injuries (e.g., from injections, thorns, and dog bites). Angora skins are considered to be unsuitable for leather production because of insufficient connective tissue (van der Westhuysen et al. 1988). Local drought conditions result in particularly weak skins. Mange, grubs, tick infestations, capripox and contagious ecthyma infections, and dermatophilosis decrease the value of goat skins. When the goat has been slaughtered, additional losses occur during flaying, drying, and storage. Humid weather predisposes to rotting while extremely arid conditions make cracking of the skins more likely.

Goat skins are used in local villages for water containers, tents, mats, and leather. Others are exported as cured skins, simple tanned skins, drum heads, or leather. Uses include footwear, garments, bookbinding, and luggage. The demand is expected to remain steady. Production could be most easily increased by limiting wastage (Holst 1987).

DIAGNOSIS OF SKIN DISEASE

The ideal approach to the diagnosis of skin disease is a logical progression from history, to an overall clinical examination of the goat, to a detailed examination of the skin, and finally to confirmatory testing or diagnosis by response to therapy. The experienced clinician often performs these steps subconsciously and in an abbreviated fashion. For instance, if contagious ecthyma has been diagnosed on the farm in past years and now three otherwise sleek and healthy kids have proliferative scabs restricted to the lips and muzzle, the prior probability that these kids also have contagious ecthyma is so high that no additional testing is justified. On the other hand, when the skin disease is unusual, chronic, or refractory to initial therapy, the entire sequence should be followed for best results.

History

Historical information to gather includes details on feeding and management, health history of the affected animals, date when signs were first noticed, and any apparent spread to others in the herd. It is also important to determine if there has been any contact, however brief, with goats or other ruminants from other farms, and what treatments have already been applied with what results (Jackson 1986).

Clinical Signs of Skin Disease

A reasonably short differential diagnosis list can usually be generated if close attention is paid to primary lesions (those directly reflecting the underlying disease). Primary lesions include papules, vesicles, pustules, and nodules. Secondary lesions such as scales, crusts, and alopecia are often the result of self-trauma or superimposed bacterial infections. Secondary lesions are less helpful for making a diagnosis, but may suggest the need for symptomatic therapy. Subcutaneous lesions are discussed in Chapter 3.

Papules

A papule (pimple) is a circumscribed solid mass less than 1 cm in diameter that is usually elevated and erythematous. Follicular papules suggest bacterial, fungal, or parasitic infection whereas papules without a hair follicle at the center are typical of allergy and ectoparasites. A large flat-topped lesion, usually arising from confluent papules, is termed a plaque.

Vesicles and Pustules

A vesicle is a papule-shaped fluctuant elevation containing serum. Vesicles are transient and suggest autoimmune, irritant, or viral etiologies. A pustule is a pus-filled vesicle and indicates infection if follicular in orientation but may be autoimmune (pemphigus) if non-follicular. Demodicosis is a common pustular disease in goats. Pox lesions (contagious ecthyma, capripox) follow a typical progression from papule, to vesicle, to pustule, to a crust or proliferative lesion.

Hyperkeratosis

Hyperkeratosis is an increased thickness of the stratum corneum. The term is often used in place of the more precise term orthokeratotic (anuclear) hyperkeratosis. Parakeratotic hyperkeratosis (often called parakeratosis) differs in that nuclei remain in the keratinized layer of the skin. Both of these conditions are common and nondiagnostic histologic findings in chronic skin diseases of many sorts. Diffuse parakeratosis suggests ectoparasitisms, seborrhea, zinc responsive disease, dermatophytosis, and dermatophilosis (Scott 1988). During physical examination, hyperkeratosis is used to refer to accumulations of adherent keratinized material.

Scales and Crusts

Scales (squames, flakes) are loose fragments of stratum corneum. Admixture with sebaceous and apocrine secretion makes the scales yellowish, greasy, and adherent. Crusts are solid adherent combinations of materials such as serum, blood, pus, keratin, microorganisms, and medications. They indicate that exuda-tion has occurred and thus have multiple causes. Close examination (crust biopsy), however, may reveal diagnostic clues such as dermatophyte hyphae, *Dermatophilus*, or many acantholytic keratinocytes (pemphigus complex). Crusts are said to be pallisading when layers of keratin and exudate alternate, as is common in dermatophilosis and dermatophytosis. Bacterial colonies are to be expected in all crusts, whatever the cause, and have no diagnostic significance.

Alopecia

Spontaneous hair loss occasionally occurs in Angoras and more often in crossbreds, mainly at the end of winter. Shearing at an inappropriate time is thought to increase the risk of hair loss. Nutritional deficiencies or imbalances (such as high calcium with low zinc) have also been incriminated (van der Westhuysen et al. 1988). There are anecdotal reports that hair loss and scaling along the dorsal spine of adult goats resolve when an organic zinc supplement is added to the concentrate portion of the ration. Periorbital alopecia (with mild scaling) is often prominent in vitamin E or selenium responsive dermatosis and alopecic exfoliative dermatitis. There are also anecdotal reports of almost complete hair loss (early shedding) in dairy does that have been subjected to photoperiod manipulation for out-of-season breeding. Partial alopecia (hypotrichosis) is a nonspecific secondary lesion. Alopecia can be induced by self excoriation when pruritus is present or can be the result of grooming by pen mates (Figure 2.3).

Pruritus

Pruritus, or the semblance of itching, frequently leads to excoriations and other secondary lesions. If pruritus is severe, special consideration is given to the

Figure 2.3. Alopecia on the side of a wether caused by grooming by its pen mate, a white-tail deer. (Courtesy Dr. M.C. Smith.)

possibility of sarcoptic or chorioptic mange. Other conditions that may be pruritic include lice, fleas, hypersensitivity to other insects such as *Culicoides*, zinc deficiency, pemphigus, and photosensitization. Occasionally, bacterial or fungal dermatitis is mildly pruritic. If vertically oriented linear excoriations develop, migration of *Parelaphostrongylus tenuis* through the spinal cord or dorsal nerve roots should be considered. Acute pruritus in a goat that dies very soon after clinical signs are noted is suggestive of pseudorabies (Baker et al. 1982). Extreme pruritus but with a longer clinical course has been reported in a single goat with confirmed rabies (Tarlatzis 1954). Pruritus was reported as a clinical sign in 11 of 20 goats in Great Britain with scrapie (Wooldridge and Wood 1991) and in more than 80% of 500 goats developing scrapie in Italy after infection via a contaminated contagious agalactia vaccine (Capucchio et al. 2001).

Erythema

Erythema, or reddening of the skin, occurs in many acute disease conditions and is thus not diagnostic. It is an early sign in photosensitization. When a chronic disease condition also has crusting and alopecia, response to therapy may be difficult to judge. Subsidence of a previously prominent erythema suggests improvement, even before hair regrowth is noted.

Pigmentary Changes

Few skin diseases in goats are associated with pigmentary changes. Decoloration of hair might occur with copper deficiency because a copper-containing enzyme is necessary for melanin production. Affected Toggenburg goats and repigmentation with copper supplementation have been reported (Lazarro 2007). Light-skinned Saanen goats normally develop large irregular areas of black pigmentation when exposed to sunlight. The color fades with confinement away from the sun.

Absence of Skin

Cutaneous asthenia, a congenital skin defect seen in sheep where the skin is abnormally fragile and easily torn, has apparently not been reported in goats. There is an anecdotal report of epitheliogenesis imperfecta, where a portion of the epidermis is absent, in a pygmy goat (Konnersman 2005b).

Body Localization as an Aid to Diagnosis

The entire body surface should be examined. The distribution of skin lesions over the body helps to arrive at a diagnosis. Listed here are some diseases found initially or most severely on the extremities of goats. These diseases are characteristically but not invariably found in the specified locations. Lesions present only on the ventrum may result from contact dermatitis or parasite invasion. Lesions present only on nonpigmented skin may be caused by photosensitization or sunburn.

Lips, Face, and Neck

- Contagious ecthyma
- Capripox
- Peste des petits ruminants
- Bluetongue
- Staphylococcal folliculitis
- Dermatophilosis
- Dermatophytosis
- Sarcoptic mange
- Zinc deficiency
- Pemphigus foliaceus
- Protothecosis

Ears

- Dermatophilosis
- Dermatophytosis
- Sarcoptic mange
- Ear mites
- Photodermatitis
- Squamous cell carcinoma
- Frostbite
- Pemphigus foliaceus

Feet

- Contagious ecthyma
- Foot and mouth disease
- Staphylococcal folliculitis
- *Dichelobacter* infection (foot rot)
- Dermatophilosis
- Sarcoptic mange
- Chorioptic mange
- *Pelodera* dermatitis
- *Besnoitia* dermatitis
- Zinc deficiency
- Contact dermatitis
- Pemphigus foliaceus

Udder

- Contagious ecthyma
- Staphylococcal folliculitis
- Zinc deficiency
- Hyperpigmentation from exposure to sun
- Neoplasia

Perineum

- Contagious ecthyma
- Caprine herpesvirus
- Staphylococcal dermatitis
- Ticks
- Neoplasia
- Ectopic mammary gland

Clinical Laboratory Examination

Simple observation allows identification of most of the clinical signs of skin disease, and thus many conditions can be diagnosed with reasonable certainty with just the findings of a physical examination. However, the repertoire of injured skin is limited, and the same sign (such as a pustule or crust) may occur in a variety of conditions of different etiologies.

Skin Scrapings

When searching for surface-dwelling ectoparasites such as lice and nits or chorioptic mange mites, a flea comb can be used to harvest scales and crusts or hair from extensive portions of the body. The collected sample is then placed in a petri dish or ziplock plastic bag for transport to good light or even a dissecting scope. After initial visual examination, the sample next undergoes a fecal flotation procedure. Mites and eggs come to the surface with centrifugation and can thus be concentrated and separated from the debris that would otherwise obscure their presence.

Repeated, deep scrapings using a scalpel blade dipped in mineral oil are usually necessary to identify sarcoptic mange mites or their eggs. A few drops of 20% potassium hydroxide solution are added to the sample, a coverslip is applied, and clearing of debris allowed to proceed for 15 to 30 minutes before microscopic examination. Larger samples may be processed by boiling 10 minutes in 10% potassium hydroxide solution, centrifuging, and performing a sugar flotation on the sediment.

Direct microscopic examination of hair and keratin is useful for demonstrating the presence of dermatophytes. Ectothrix infections of hair shafts often can be seen if the specimen is placed in mineral oil. Clearing in potassium hydroxide solution, as for mite identification, is another option.

Bacterial Examination

Skin lesions in goats are almost invariably heavily contaminated by bacteria, including *Staphylococcus aureus*. A culture is most meaningful, then, if material is aspirated from an intact pustule, nodule, or abscess. A punch biopsy obtained after careful disinfection of the skin surface is suitable for culture if intact pus-containing structures are absent. Routine inoculation onto a blood agar plate (aerobic) and into thioglycolate broth (anaerobic) is recommended. More immediate guidance can be derived by making a direct smear of an aspirate or deep aspect of a biopsy specimen and staining with new methylene blue, Gram's, or Diff Quik® (Harleco, Gibbstown, NJ) stain. Such a preparation should reveal bacteria within neutrophils and macrophages if they are pathogenic, rather than contaminant bacteria that will be extracellular and clumped in colonies. Gram-positive branching filaments are typical of dermatophilosis.

Fungal Culture

When ringworm is suspected, hairs should be plucked from the periphery of an active lesion after swabbing the area gently with 70% alcohol solution to discourage the growth of bacteria and saprophytic fungal contaminants. Sabouraud's dextrose agar (Sab Duet®, Bacti Labs, Mountain View, CA) is routinely used. Most strains of *Trichophyton verrucosum* require thiamine for growth; this can be supplied by adding 1 to 2 ml of injectable B-complex vitamins to the culture plate, but products containing alcohol should be avoided. The cultures are incubated at 86°F (30°C) with a pan of water in the incubator to maintain adequate humidity. Cultures should be checked every day for thirty days. Standard texts should be consulted for identification of fungal isolates (Scott 1988).

Biopsy for Histology

A biopsy should be performed if a skin disease appears to be unusual or severe and especially if there has been no response after three weeks of initial therapy.

Several areas are selected as having typical or primary lesions and marked by drawing a circle with a felt-tipped pen. The skin is prepared by clipping hair and injecting lidocaine subcutaneously at each chosen location. The skin must never be scrubbed. In very small kids, dilution of the lidocaine to 1% or 0.5% may be advisable. A 6-mm punch (Baker/Cummins, Miami, FL) is used to cut out a full thickness skin sample, which should be blotted flat, dermis side down, onto a small piece of a tongue depressor. The skin specimen quickly adheres to the wood; it can then be dropped upside down into a vial of 10% buffered formalin, where the wood will keep it suspended in the preservative. The skin defect is closed with absorbable suture. Consideration should be given to the tetanus vaccination status of the animal and tetanus antitoxin or toxoid given if indicated.

The testing laboratory should be consulted if electron microscopic examination is required (as for pox). Glutaraldehyde is usually the preferred fixative.

Immunofluorescence Testing

An autoimmune skin disorder (pemphigus foliaceus) may be suspected from clinical signs or after routine histologic examination of a skin biopsy specimen. If confirmation with direct immunofluorescence testing is desired, a new skin sample (with intact vesicles and pustules) should be procured and fixed with Michel's fixative, which is best obtained from the laboratory that will perform the testing. Glucocorticoids should not be administered for at least three weeks

before testing to avoid false negative results (Scott 1988). Diffuse intercellular deposition of immunoglobulin is found in caprine pemphigus.

ETIOLOGIC DIAGNOSES

Readers who desire a more exhaustive reference list for any of the conditions described below should consult D.W. Scott's Large Animal Dermatology textbook (1988). Several review papers also discuss dermatologic diseases of goats (Smith 1981, 1983; Mullowney and Baldwin 1984; Scott et al. 1984a, 1984b; Manning et al. 1985; Jackson 1986) and many are illustrated in a recent text (Scott 2007).

VIRAL DISEASES

Contagious ecthyma and capripox viruses cause prominent skin lesions in goats. Virus infections involving other body systems also may have cutaneous manifestations. Warts (cutaneous papillomas) in goats have not been proven to be of viral origin and are discussed under neoplastic conditions.

Contagious Ecthyma

Contagious ecthyma is a contagious, zoonotic disease of goats and sheep (and camelids) that has several alternative names, including orf, soremouth, scabby mouth, and contagious pustular dermatitis. It has worldwide distribution.

Etiology and Epidemiology

The cause is an epitheliotropic parapoxvirus that enters the goat through skin abrasions (Mayr and Büttner 1990). The virus replicates in proliferating keratinocytes in the damaged epidermis (McKeever et al. 1988) and then causes a primary viremia to lymph nodes, bone marrow, and liver. In some cases, the virus then becomes generalized, with a second viremic phase, and spreads to the head, extremities, udder, genitals, lungs, and liver (Mayr and Büttner 1990). The morbidity in young kids often approaches 100%, while mortality from starvation and secondary infections may be as high as 20% (Van Tonder 1975) but is usually much lower.

Scabs that fall to the ground during resolution of lesions have long been incriminated as the source of infection to other animals months or even years later (McKeever and Reid 1986), and this is indeed possible if the environment remains dry. More recently, persistently infected carrier sheep, some of which are asymptomatic, have been demonstrated to be an important source of contagion (Lewis 1996). Presumably carrier goats also occur, and infection can be activated by stress (Mayr and Büttner 1990).

Clinical Signs

The incubation period is three to eight days (Mayr and Büttner 1990). Papules progress rapidly to vesicles, pustules, and scabs. Crusty, proliferative lesions typically form on the lips but can also affect the face, ears, coronary band, scrotum, teats, or vulva. In one outbreak, where exposure presumably occurred in contaminated pens at a show, lesions occurred on the neck, chest, and flanks of seven goats rather than on the lips or teats (Coates and Hoff 1990). In another case report, lesions were most common on haired skin of adult goats and the first crusty scabs noticed were on the caudal aspect of the hind legs (Moriello and Cooley 2001). The scabs frequently harbor secondary bacteria (such as staphylococci) or even screwworm maggots (Boughton and Hardy 1934). Sometimes large masses of granulation tissue develop under the scabs. Lesions regress in three or four weeks.

Most adult goats with lesions on the lips (Figure 2.4) continue to eat and milk well. Occasional goats, especially young kids exposed to other diseases or management deficiencies, will develop generalized lesions or severe secondary bacterial infections. Lesions on the teats of milking animals may compromise the health of the sphincter and predispose to bacterial mastitis. Associated pain may cause the doe to reject nursing efforts by its kid.

Severe generalized and persistent proliferative lesions have been seen in Boer goats and their crosses in the United States (Figure 2.5). Draining lymph nodes are markedly enlarged in these animals, and thymic atrophy is often present. Preliminary research has not proven whether this variation represents a viral strain difference or a difference in immune

response of the affected Boer goats (de la Concha-Bermejillo et al. 2003; Guo et al. 2003). Close examination of many sheep and goats with a more typical presentation of contagious ecthyma often reveals a mild lymphadenopathy.

Diagnosis

Diagnosis is usually based on clinical signs alone, although electron microscopy or immunologic techniques to demonstrate antigen in scabs or serology could be used for confirmation or to rule out capripox infection (Robinson and Balassu 1981). In lambs experiencing contagious ecthyma, serum antibodies often do not appear until after reexposure (Mayr and Büttner 1990). Similarly, rural physicians usually make the diagnosis in their human patients on clinical signs alone, but urban dermatologists lacking experience with the disease may insist on biopsy for histologic or electron microscopic examination (Gill et al. 1990; Green et al. 2006). Skin biopsies of ruminants reveal ballooning degeneration of keratinocytes and eosinophilic cytoplasmic inclusions (Robinson and Balassu 1981; Scott 2007), although the inclusions are not always detectable (Housawi et al. 1993). The crusts consist of multiple layers of necrotic cellular debris and neutrophils. Histopathology helps to distinguish contagious ecthyma from the convalescent stages of peste des petits ruminants.

Therapy

The possible beneficial effects of treatment must be weighed against the danger of zoonotic infection (Figure 2.6). Any person handling an affected goat should wear gloves. Numerous products have been used topically, with anecdotal reports of faster healing.
However, these products have been used with minimal consideration of meat and milk residues. These include kerosene mixed with lard, penetrating oil spray (WD-40®), and bismuth subsalicylate (Pepto-Bismol®). Systemic antibiotics are indicated if secondary bacterial infections are severe. An udder salve is indicated to keep scabs on the teats pliable. If painful, proliferative lesions within a kid's mouth cause feeding to decrease, the kid could be anesthetized and subjected to debridement (electrocautery after spray cryotherapy). This approach has been used in lambs with good results (Meynink et al. 1987).

Vaccination

Commercially available vaccines often are unattenuated live virus preparations (basically ground-up scabs) or are tissue culture strains, although the level of protection afforded by the latter appears to vary with the strain (Pye 1990). An autogenous vaccine can be made by crushing, in saline, a few grams of scabs between two spoons or with a mortar and pestle. The suspension is filtered through cheesecloth and a few drops of antibiotic solution such as penicillin/streptomycin are added to control bacteria (Bath et al. 2005). The skin in a hairless, protected area is lightly scarified and the virus suspension is rubbed in. Sites for vaccination include the inside of the ear pinna, the underside of the tail, or the axilla. Avoid the medial aspect of the thigh, because the infection can be spread to the lips by chewing and to the udder and teats by direct contact (Lewis 1996). Scabs appearing at the vaccination site in one to three days indicate a "take." Monitoring this reaction as evidence of continued vaccine viability permits owners to economize by freezing leftover vaccine for later use. If some animals

in the herd develop vaccination scabs but others do not, a pre-existing immunity is probably responsible for absence of a take.

Where a newer, parenteral vaccine is available, subcutaneous vaccination with a live cell culture vaccine avoids postvaccinal disease or excretion of the virus. Use of this vaccine every six to twelve months has been recommended in noninfected herds, and in the face of an outbreak (Mayr and Büttner 1990).

In countries where capripox virus exists, vaccinating goats for capripox sometimes provides solid immunity against contagious ecthyma, whereas vaccination or natural infection with the contagious ecthyma virus provides no protection against capripox (Sharma and Bhatia 1958).

There are several controversies associated with vaccination. The first is whether to recommend vaccination in a herd that is not endemically infected. The vaccine, because it is unattenuated, will introduce the disease to such a herd. In herds in which buying or showing of goats occurs regularly, vaccination prevents the occurrence of an outbreak during the show season or in milking animals. It is important to vaccinate at least six weeks before the show season so that vaccine scabs will be gone before the first show. (Presumably this procedure would increase the prevalence of subclinical carriers at shows and thereby increase the risk to unvaccinated animals in attendance.) When soremouth has appeared on the premises, it may be desirable to vaccinate all as yet unaffected goats to limit the duration of the outbreak. A program of vaccination for all young kids often in conjunction with annual revaccination of late pregnant adults is then established. Disinfection of the pens after all lesions have cleared is recommended if the owner chooses not to follow a routine vaccination program. Suitable disinfectants include 5% creolin solution, formalin, detergents, and commercially available virucidal disinfectants (Mayr and Büttner 1990).

The occurrence of colostral immunity in vaccinated animals is disputed (Robinson and Balassu 1981). French enterprises that assemble kids from many sources, however, have found it advisable to pay a premium for kids from vaccinated dams. This is because vaccination of the dam seems to be more effective than vaccination of kids at birth in preventing adverse effects of the disease on the quality of kid skins (Faure 1988). In an experimental study in Mexico, kids born to dams vaccinated (virulent vaccine) in late pregnancy were challenged by skin scarification with virulent virus. Kids younger than forty-five days old resisted challenge, whereas kids older than forty-five days developed characteristic lesions (Perez 1989).

Work with sheep has suggested that vaccinating at the time of drying off is preferable to vaccinating later in pregnancy when lambs are to be raised by the ewes.

Lymphocytes migrating to the udder at the end of lactation produce antibodies in the milk that may protect the lips and mouth of nursing lambs (Le Jan et al. 1978).

Capripox

The malignant pox diseases of sheep, goats, and cattle are not host-specific, although they show host preferences. Strains can be distinguished by restriction endonucleases but not by several serologic tests (Black 1986). Currently all strains are included in the Capripox genus of poxvirus.

Etiology and Pathogenesis

Capripoxviruses are distinct from parapoxviruses. They are acid-labile and sensitive to lipid solvents. Malignant sheep and goat pox infections occur in the Middle East, Far East, and Africa (Davies 1981). A benign form of goat pox has been reported from California (Renshaw and Dodd 1978) and Scandinavia (Bakos and Brag 1957) but the agents involved were not confirmed to be capripox viruses (Committee on Foreign Animal Diseases 1998). Skin lesions and scabs are major sources of virus. The virus resists desiccation and may survive in scabs for at least three months. Transmission is often through skin abrasions or by inhalation, with an incubation period of three to eight days. Viremia occurs, and the virus is carried to other sites in the skin, regional nodes, spleen, kidney, and lungs. The virus is excreted from skin lesions and in nasal exudates and milk. Night herding (congregating herds at night for protection) and stabling favor spread of the disease. Wild ungulates are not thought to serve as reservoirs.

Clinical Signs

The severity of signs varies with the strain of capripox. Young animals are most severely affected. Early signs include rhinitis, conjunctivitis, and pyrexia 104° to 107.6°F (40° to 42°C). The animals stand with arched back and are anorectic. Cutaneous lesions (reddish macules and papules, 0.5 to 1.5 cm diameter, Figure 2.7) and lesions on the external nares and lips and within the mouth appear one or two days later. Skin lesions persist for four to six weeks. In some outbreaks, vesicular lesions of the skin coalesce. Oral lesions on the tongue and gums tend to ulcerate. Regional lymph nodes may be enlarged up to eight times their normal size (Committee on Foreign Animal Diseases 1998). Animals that die frequently have lesions in the lungs and alimentary tract.

The hair is erect over skin lesions, the skin is thickened, and crusts of exuded serum form on the surface. Healing may leave an ulcer and then a permanent scar after the full skin thickness sloughs. Damage to hides causes important economic losses.
Figure 2.7. Early macules of capripox infection on the skin of an experimentally infected sheep. (Courtesy National Veterinary Services Laboratories, Ames, Iowa.)

When the disease first enters a susceptible flock, morbidity may be more than 75%, and 50% of affected animals die. Mortality may increase to 100% in kids or when superimposed on other virus infections such as peste des petits ruminants. The morbidity rate is lower in endemic flocks. Some animals convert serologically without development of clinical signs. European breeds are generally more severely affected than native breeds (Karim 1983; Kitching 1986).

There is also a nodular form ("stonepox") in sheep and goats that resembles lumpy skin disease of cattle (also caused by a capripox) (Patnaik 1986). Vesicles and pustules are absent and there is no cross-immunity with more typical strains of goat pox or with contagious ecthyma. The virus is present in blood and skin throughout the course of the disease, which is often fatal (Haddow and Idnani 1948).

In the benign goat pox form, vesicles and pustules develop from papules on the lips and udder (and sometimes on the perineum and inside of the thigh). Pock lesions heal in five to eight weeks, leaving behind permanent scars.

Goat pox, like contagious ecthyma, has been considered to be a zoonotic disease (Bakos and Brag 1957; Sawhney et al. 1972), but more recent authors dispute this (Committee on Foreign Animal Diseases 1998).

Diagnosis

Capripox is most likely to be confused with contagious ecthyma because lesions may be limited to the lips, oral mucous membranes, or udder. Electron microscopy (Hajer et al. 1988) and serologic tests (such as immunodiffusion and serum neutralization) readily differentiate capripox from the parapoxvirus of contagious ecthyma. Histopathology reveals large eosinophilic intracytoplasmic inclusions, vasculitis, thrombosis, and necrosis (Davies 1981).

Control

Import restrictions covering animals and animal products from endemic areas are required to avoid introduction of this disease to non-infected regions. Quarantine and slaughter of diseased and contact animals would be recommended if introduction occurred. A carrier state has not been documented to occur.

Prophylactic vaccination reduces morbidity in endemic (often nomadic pastoral) regions. Most trials have shown excellent cross-protection with various strains of sheep and goat pox (Davies 1981). Live, attenuated vaccines (using a mild strain) are preferred but difficult to distribute (Kitching 1986). An experimental subunit vaccine reduced the severity of signs without risking introduction of the disease (Carn et al. 1994). A recombinant capripoxvirus vaccine has been produced that protects goats against peste des petits ruminants as well as against capripox (Romero et al. 1995). Use of autogenous vaccines may increase the incidence of disease (Das et al. 1978). Contagious ecthyma vaccines do not protect against goat pox.

Miscellaneous Virus Infections

As already discussed under the heading of pruritus, goats with rabies or pseudorabies may show skin lesions that result from severe pruritus. These conditions are discussed in Chapter 5. Scrapie in goats (also discussed under neurologic diseases in Chapter 5) may be pruritic, as demonstrated by biting and rubbing at the legs, flanks, lumbar region, and neck, and by alopecia in these areas (usually without scab formation). The clinical course of scrapie may last three to four months (Hadlow 1961; Brotherston et al. 1968; Harcourt and Anderson 1974).

Peste des Petits Ruminants

Peste des petits ruminants (PPR) is a morbillivirus infection that causes serious losses in sheep and goats throughout its range (Committee on Foreign Animal Diseases 1998). The major clinical signs of stomatitis, enteritis, and pneumonia are described in the appropriate chapters. During early stages of the disease, the lips are edematous and brown scabs cover eroded and ulcerated epithelium. Goats that survive the acute phase of the disease may develop labial scabs that persist up to fourteen days; histologically, acanthosis and hyperkeratosis are evident. Necrotic epithelium is infiltrated with degenerating neutrophils. There is no papilliform proliferation or ballooning degeneration typical of contagious ecthyma, although lesions are grossly similar (Whitney et al. 1967; Abraham et al. 2005). Syncytial multinucleated giant cells and

eosinophilic cytoplasmic inclusions may be seen in the epithelium (Çam et al. 2005). Goats that are vaccinated with inactivated vaccine (Nduaka and Ihemelandu 1975) or that are re-exposed to PPR after recovery from the virus also develop labial scabs that heal in about ten days (Ihemelandu et al. 1985). In these animals, histology reveals proliferation of macrophages and lymphocytes, suggesting an immune response.

Bluetongue

Bluetongue is a disease of sheep and cattle caused by an orbivirus that has at least twenty-four serotypes and is spread by *Culicoides* insects. Signs in sheep include fever, stomatitis, coronitis, and birth of lambs with congenital brain anomalies. Goats are susceptible to bluetongue in that viremia and fever occur and antibodies develop (Luedke and Anakwenze 1972; Backx et al. 2007), but overt clinical signs are rarely seen or described in goats in the United States. During an outbreak in cattle in Israel, two Saanen goats were found with swollen lips and marked salivation (Komarov and Goldsmit 1951). During the recent outbreak of bluetongue in northwestern Europe, a small number of goats developed edema of the lips and head, small scabs on the nose and lips suggestive of mild contagious ecthyma, and erythema of the udder skin (Dercksen et al. 2007). Goats may serve as a natural reservoir for the bluetongue virus (Erasmus 1975). Virus isolation and serology help to distinguish bluetongue from foot and mouth disease, rinderpest, and peste des petits ruminants. Bluetongue is discussed in detail in Chapter 10.

Caprine Herpesvirus

Experimental inoculation of kids with a herpesvirus isolate has produced vesicles, ulcers, and crusts on the muzzle and feet (Waldvogel et al. 1981). Ulcers also occurred in the mouth, esophagus, rumen, and intestines. In one naturally occurring outbreak, numerous foci of necrosis and hemorrhage were found in the skin of a single kid (Mettler et al. 1979). Any histologic finding of acidophilic intranuclear inclusion bodies in epithelial cells suggests the possibility of herpesvirus infection. The disease is discussed in Chapters 12 and 13.

Foot and Mouth Disease (FMD)

The picornavirus that causes FMD is a very important and exceedingly contagious disease of cattle in South America, Europe, Africa, and Asia, but is currently absent from the United States, Canada, and Australia. Signs in cattle include fever, stomatitis with vesicles and bullae, anorexia, agalactia, and a very prolonged convalescence. The disease in sheep and goats is usually mild, and only important in that these animals and meat from them may transmit the disease to cattle. However, during outbreaks of foot and mouth disease, other (often idiopathic) oral lesions can cause great concern to regulatory authorities, at least in sheep (Watson 2004). Lameness is often the most pronounced clinical sign in goats; vesicles or bleeding ulcers may be found in the interdigital space or at the coronary band (McVicar and Sutmoller 1968; Mishra and Ghei 1983). Goats are routinely vaccinated in endemic regions. The disease is discussed in detail in Chapter 4.

Vesicular Stomatitis

Vesicular stomatitis is a rhabdovirus disease primarily affecting horses, cattle, and swine, and limited to the Western Hemisphere. Typical signs in these species are oral vesicles and ulcers, salivation, coronitis, and teat lesions. Regulatory officials should be notified so that the disease may be differentiated from foot and mouth disease. The epidemiology is poorly understood, but may include insect vectors such as sand flies (*Lutzomyia*) and black flies (*Simulidae*) (Committee on Foreign Animal Diseases 1998). Goats are considered to be resistant, but according to unpublished reports, vesicular stomatitis in goats has been accompanied by vesicles at the commissures of the lips, which must be differentiated from early lesions of contagious ecthyma.

BACTERIAL DISEASES

Secondary bacteria, especially staphylococci, commonly invade almost any skin lesion on a goat. Thus, other etiologies should be ruled out before assuming that bacteria isolated from the surface of a lesion are causative. Other organisms, such as *Corynebacterium pseudotuberculosis* and *Dermatophilus congolensis*, are usually significant if present. Foot rot, an interdigital dermatitis caused by *Dichelobacter* and *Fusobacterium* spp., is discussed in Chapter 4.

Staphylococcal Dermatitis

Staphylococcal skin infections are common in goats and may be primary or secondary. The bacteria are also normal skin flora. In one Spanish study, 346 strains of staphylococci were isolated from axillary skin or udder of 133 healthy goats, and 21% of these isolates were coagulase-positive (*S. aureus* and *S. hyicus*) (Valle et al. 1991).

Etiology

Impetigo is a superficial pustular dermatitis that does not involve hair follicles. Staphylococcal folliculitis is an infection and inflammation of hair follicles (Scott 1988). The species involved often has not been reported. Staphylococcal species isolated from goats with skin disease include *S. intermedius*, *S. aureus*, *S. chromogenes*, and *S. hyicus* (Scott 1988; Andrews and

Lamport 1997; Mahanta et al. 1997). Species identification is not a good predictor of antibiotic sensitivity (Biberstein et al. 1984).

Clinical Signs and Diagnosis

The primary lesion is a nonfollicular or follicular papule that develops into a pustule. Lesions may enlarge or coalesce, discharge purulent or serosanguinous exudate, and become encrusted (furunculosis, Scott 2007). Alopecia and scaling are prominent in the chronic or healing stage. Multiple small pustules of impetigo frequently appear on the teats and udder (Figure 14.3) or perineum and underside of the tail. Because these pustules may be preceded by vesicles and followed by scabs, they may be confused with lesions of contagious ecthyma (Smith 1981). Direct smears show degenerate neutrophils with phagocytosed cocci (Scott 2007). When lesions remain localized they are relatively benign and self-limiting, except that lesions on the teats predispose to staphylococcal mastitis. Fly bites on the udder (fly worry) are said to resemble a staphylococcal infection but to be more pruritic (Matthews 1999).

In some goats, the infection becomes general, involving the skin of the abdomen, inner thighs, and even the neck and back. Other distributions are possible, especially if the staphylococci are secondary to another condition, such as chorioptic mange. Periocular alopecia and crusts comprise yet another possible manifestation (Scott 1988). Confusion with mycotic infections or nutritional deficiencies is possible.

A presumptive diagnosis is often based on inspection alone. Gram stains and cultures document the presence of staphylococci, while evaluation of skin biopsy specimens should help to rule out other diseases that might have been primary and still require therapy.

Treatment and Prevention

Localized lesions on the udder may be washed with an iodophor or chlorhexidine shampoo, dried, and then coated with an antiseptic or antibiotic ointment. Affected does should be milked last. Single service paper towels and attention to hand washing by the milker decrease the risk of spread to other does. Rubber gloves protect against transmission of infection to humans. Similar treatment of lesions around the tail is possible, but these seem to be less important and frequently heal spontaneously.

If a generalized infection is suspected, culture of the organism and determination of antibiotic sensitivity are recommended. Systemic antibiotic treatment (one to two weeks of therapy) may start with penicillin, pending results of sensitivity testing. As the concern over methicillin-resistant staphylococci increases in both veterinary and human medicine, it is very important for the practitioner to remember that many of the antibiotics used to control these infections in other species are forbidden by law in all sheep and goats in the United States, because of their status as food animals. Thus, no matter what the laboratory reports for a sensitivity pattern, chloramphenicol, fluoroquinolones such as enrofloxacin, and glycopeptides such as vancomycin are absolutely forbidden in all goats.

Autogenous bacterins may be tried for control of chronic or epizootic infections (Scott et al. 1984a), but bacterins have not received scientific evaluation in caprine dermatology.

Dermatophilosis

Dermatophilosis, also known as streptothricosis, is a common skin infection in goats worldwide. Cattle, sheep, horses, various wildlife species, and humans are also affected (Stewart 1972; Hyslop 1980).

Etiology

Dermatophilus congolensis is a Gram-positive, pleomorphic, facultative anaerobic actinomycete. It produces motile zoospores which invade the skin.

Pathogenesis

Dermatophilus congolensis may survive in soil or in dust on an animal's hair coat during dry weather. It is introduced into the epidermis following injuries of any sort, including those caused by tick bites and thorny vegetation. Its life cycle is activated by moisture (Bida and Dennis 1976). Outbreaks often occur during periods of heavy rain or high humidity (Mémery and Thiéry 1960; Yeruham et al. 2003).

Clinical Signs

Several localizations of the disease have been reported. Ears are commonly involved, especially in young kids (Larsen 1987). Tiny wart-like scabs first appear on the inner hairless surface of the ear pinna. They are easily rubbed off, exposing dry, circular, light-colored areas beneath. Raised scabs with matted hairs form on the external portions of the ears and are more tightly attached (Figure 2.8). The lesions are nonpruritic and benign and last two to three months in kids if not treated (Munro 1978).

Other affected areas of the body include the nose, muzzle, feet, scrotum, and underside of the tail (Mémery 1960; Yeruham et al. 2003; Loria et al. 2005; Scott 2007). These areas of skin frequently are exposed to moisture or mild abrasion from vegetation. Thick proliferative crusts may be mistaken for lesions of contagious ecthyma (sore mouth) (Tiddy and Hemi 1986). In fact, the simultaneous presence of both diseases has been reported in splenectomized kids (Munz 1969, 1976) and in Yaez goats, a cross between domestic goats and wild ibex (Yeruham et al. 1991). The dry

Figure 2.8. Dry scabs typical of dermatophilosis on the external surface and margin of the ear. (Courtesy Dr. M.C. Smith.)

crusts, scaling, and alopecia of healing or chronic lesions resemble ringworm. Secondary bacterial infections (e.g., staphylococci, corynebacteria, *Fusobacterium necrophorum*) are to be expected and may lead to pruritus or pain. Sometimes the entire dorsum of the goat is involved with lesions clinically resembling rain scald in horses; continuous exposure to wet weather presumably is an important etiologic factor (Bida and Dennis 1976; Scott et al. 1984a). Damage to hides can be extensive. Suppurative lymphadenitis has been reported in Beetal goats from which *D. congolensis* was demonstrated by smear and culture (Singh and Murty 1978).

Diagnosis

The diagnosis can be confirmed in several ways. When lesions are moist, an impression smear of the underside of a scab reveals Gram-positive branching filaments either unsegmented or in railroad track arrangements of two to eight parallel rows of cocci (Scott 2007). Giemsa or Diff Quik® stain may also be

used. The organisms in smears also fluoresce under ultraviolet light after staining with acridine orange (Mathieson 1991). Fluorescent antibody techniques have been used for rapid identification of the organism in smears of exudate (Pier et al. 1964). In dry lesions, skin biopsy is necessary to demonstrate the organism. In addition to superficial exudate, there is hyperkeratosis and infiltration of the epidermis and hair follicles with neutrophils. Bacterial filaments in the biopsy sample are periodic acid Schiff (PAS) positive (Loria et al. 2005).

Culture of the organism by a diagnostic laboratory will also confirm the diagnosis, but this is best done under microaerophilic conditions with increased carbon dioxide (Scott 1988). Scabs are ground up in saline and cultured at once and also after twenty-four hours at room temperature. A medium that selects for Gram-positive organisms (such as colistin-nalidixic acid medium) is helpful. Tiny gray adherent colonies composed of branched mycelia may be visible after forty-eight hours and should then be subcultured; it is common for the original plate to be rapidly overgrown by contaminants.

Several serologic tests have been used to identify antibodies against *D. congolensis*. The purpose was to potentially monitor the prevalence of exposed animals. The tests have included passive hemagglutination (which showed 23% of slaughtered goats in a Nigerian study to be seropositive) (Oyejide et al. 1984) and radial immunodiffusion (Makinde 1980).

Therapy and Prevention

Penicillin-streptomycin was commonly recommended for dermatophilosis in individual animals in the past, but this product is no longer available in the United States. Tetracycline is also effective. Where feasible, shelter from the rain and bathing (iodophors, 2% to 5% lime sulfur) and grooming to remove crusts should be recommended. Improved nutrition and control of external parasites (especially ticks) are also desirable for treatment and prevention. Cleansing thick crusts with hydrogen peroxide will help to control secondary anaerobic infections. Brushes should be disinfected before being used on other animals. Goat handlers should also be warned that people are occasionally infected with this organism. Carrier animals appear to be the reservoir for the agent, but the organism can also survive for many months in the environment. Vaccination against dermatophilosis has not been successful (Bida and Dennis 1976), and recovery does not appear to provide immunity.

Corynebacterium pseudotuberculosis

Corynebacterium pseudotuberculosis is usually associated with lymph node enlargement (caseous lymphadenitis) and is discussed in detail in Chapter 3. However,

small nodules and draining tracts in the skin sometimes occur in goats (Scott 2007) and may be a source of infection to others. Diagnosis is made by culture and by skin biopsy, which reveals a tuberculoid granulomatous reaction (Scott 1988). Affected animals should be isolated or culled.

Actinobacillosis, Actinomycosis, and Protothecosis

Actinobacillosis, a suppurative to granulomatous disease of sheep caused by *Actinobacillus lignieresii*, has not been well documented in goats. Diagnosis is based on demonstration of cheese-like granules less than 1 mm in diameter in pus or by aerobic or anaerobic culture of the organism. In direct smears, club-like bodies radiate from the center of the granules and crushing reveals small Gram-negative bacilli. Rinsing and culturing the granules, rather than simply swabbing a fistulous tract, is recommended to avoid overgrowth with secondary bacteria (Scott 1988). Treatment, at least for sheep, typically involves sodium iodide (20 mg/kg of sodium iodide as a 10% solution intravenously or subcutaneously) weekly for four to five weeks and streptomycin (20 mg/kg/day) for five to seven days.

A case of pyogranulomatous dermatitis has been reported on the udder of an aged dairy goat. A diagnosis of *Actinomyces* sp. was based on the appearance of the organism in Gram stained smears and the presence of sulfur granules. Raised knot-like lesions were yellowish brown or reddish black and abscesses extended into the parenchyma of the udder. Udder amputation was the proposed therapy but the goat died first (Hotter and Buchner 1995).

A single case of pyogranulomatous dermatitis around the nares caused by a *Prototheca* sp. has been reported from a mature goat in Brazil (Macedo et al. 2008). Ulcerated nodules contributed to inspiratory dyspnea and weight loss. Oval to spherical, nonbudded, walled sporangia typical of this algal-like organism that lacks chlorophyll were demonstrated in histologic section. Treatment was not attempted, but various antifungal agents are used to treat human and canine cutaneous protothecosis.

FUNGAL DISEASES

Ringworm and other fungal infections usually occur when nutrition or environmental conditions are inadequate. Crusting, alopecic skin disease should not be assumed to be of fungal origin without laboratory confirmation.

Ringworm

Etiology

A variety of dermatophytes have been cultured from ringworm in goats. These include *Microsporum* *canis* and *M. gypseum*, *Trichophyton mentagrophytes*, *T. schoenleinii* and *T. verrucosum*, and *Epidermophyton floccosum* (Philpot et al. 1984; Scott 1988).

Clinical Signs and Diagnosis

Lesions in goats consist of alopecia, scaling, erythema, and crusts. They typically involve the face, external ears, neck, or limbs, and may be annular in shape (Scott 2007). Pruritus is not usual, but has been reported (Chineme et al. 1981). Microscopic examination of hairs and keratin from the periphery of an active lesion (as described above) may reveal ectothrix invasion of hair shafts. Species identification requires culture and examination of both colony and microscopic morphology.

Treatment and Prevention

Young animals (Pandey and Mahin 1980) or those living in a dark, damp, dirty environment, or those with debilitating nutritional or infectious diseases are most at risk for developing ringworm. Management changes, then, may be required to control an outbreak in goats. Most cases of dermatophytosis in large animals regress spontaneously in one to four months. Thus, although oral griseofulvin has been reported to be effective in treating ringworm in goats at 25 mg/kg/day for three weeks (Chineme et al. 1981), this expensive therapy is usually not justified (Scott 1988).

Topical treatment does reduce contamination of the environment and the risk of spread to other animals or man. People handling infected goats should take precautions to avoid contracting the infection themselves. Lime sulfur (2% to 5%), iodophors, and 0.5% sodium hypochlorite as total body sprays daily for five days and then weekly are recommended for ringworm (Scott 1988). Captan (3%) is effective (Scott 1988), but not approved in the United States for food-producing animals. Topical thiabendazole paste or iodine ointments or products for athlete's foot (tinea pedis) can be used on small lesions. All in-contact animals should also be treated, and the environment disinfected with sodium hypochlorite if possible. Pens that have previously housed young cattle with ringworm should be thoroughly disinfected before goats are introduced.

Yeast Infections

Budding yeasts are occasionally present in large numbers in samples taken from goats with alopecia, scaling, and crusting (Scott 1988). In most instances they probably represent secondary opportunists (Reuter et al. 1987). A *Malassezia* (*Pityrosporum*) species was suspected in milking goats with annular lesion on the teats and udder, based on PAS-positive organisms seen in the epidermis (Bliss 1984). A *Malassezia* species,

possibly *M. pachydermatis*, was isolated from an adult goat with chronic greasy, seborrheic lesions over the trunk but sparing the extremities (Pin 2004). The animal responded rapidly to weekly chlorhexidine-containing shampoo and topical enilconazole. In a third reported case, *Malassezia slooffiae* in hyphal and yeast forms was identified in the skin of an adult Pygmy goat with a one-month history of weight loss and extensive alopecia and crusting of the body and limbs (Uzal et al. 2007). Goats with yeast infections should be evaluated for chronic wasting diseases, with special attention given to possible nutritional deficiencies (e.g., protein, trace minerals).

Miscellaneous Fungal Infections

Peyronellaea glomerata, ordinarily a saprophyte on decaying vegetation, has been isolated from hyperkeratotic ear lesions on goats (Dawson and Lepper 1970). Brown septate hyphae were abundant in the stratum corneum in skin biopsies.

Several fungal species can produce mycetomas (granulomatous subcutaneous lesions with draining sinuses and granular fungal elements) in goats (Gumaa et al. 1978; Gumaa and Abu-Samra 1981). Proliferation of the periosteum of underlying bone may be marked.

Cryptococcus neoformans, a rare cause of pneumonia and mastitis in goats, has also caused ulcerated granulomas in the skin of the head of one goat and in the nasal passage of another goat in Australia (Chapman et al. 1990). The diagnosis was made by demonstrating the oval or budding encapsulated organisms in smears, histopathology samples, or culture.

PARASITIC DISEASES

Many external parasites, including lice, ticks, and mange mites, infest goats. Each is discussed separately, but there is an extensive overlap in the realm of therapy. For the convenience of the reader, some of the chemicals effective against external parasites are listed in Table 2.1 (Scott 1988; Bowman 2003).

Lice

All species of goat lice complete their life cycle on the host and are quite host-specific. Eggs (nits) are attached to hairs and hatch in five to eighteen days. The nymphal stages look like tiny adults; young lice mature fourteen to twenty-one days after hatching. *Bovicola* (*Damalinia*) *ovis*, the sheep louse, can become established on goats, and thus goats may be a source for reinfesting sheep during louse control programs (Hallam, 1985).

Clinical Signs and Diagnosis

Bloodsucking lice (order Anoplura) have relatively narrow heads with piercing mouth parts. Two species

Table 2.1. Some chemicals used for control of external parasites of goats.

Chemical	Concentration and form
Amitraz (L)	0.025%–0.05% spray
Coumaphos (L)	0.25% spray, 0.5% dust
Crotoxyphos (L)	0.25%–1% spray, 2% dust
Dichlorvos (L)	0.5%–1% spray
Eprinomectin (L)	0.5–1 mg/kg pour-on
Fenvalerate	0.05% dip
Fipronil	0.29% spray (not labeled for food animals)
Ivermectin	20–40 mg/100 kg subcutaneous injection
Lime sulfur (L)	2%–5% dip
Lindane	0.06% spray, 0.03% dip
Malathion	0.5% spray, 5% dust
Methoxychlor	0.5%–1% spray/dip, 5% dust
Permethrin (L)	0.05% spray, 0.5% spot treatment
Phosmet	0.15%–0.25% spray/dip
Trichlorfon	0.2% spray/dip

Note that many of these products are not licensed for goats in most countries. Chemicals designated by (L) are generally appropriate for dairy animals. Product labels should be read for instructions and safety precautions.

have been reported from goats in the United States: *Linognathus stenopsis* (females 2.75 mm long, males 2.2 mm) and *Linognathus africanus* (distinguished by bulging posterolateral margins of the head; females 2.15 mm, males 1.65 mm). They are bluish-gray and infest both Angoras and the other breeds of goats (Price and Graham 1997). Blood loss and secondary bacterial skin infections may occur in addition to pruritus. Heavy infestations may kill kids.

Biting lice (order Mallophaga) have broader chewing mouth parts. They are pale, small (1 to 2 mm) and more difficult to see. They provoke rubbing and scratching and can also bite through the hairs, resulting in alopecia and moderate to severe damage to Angora fleeces, depending on the louse numbers. The yellowish, hairy *Bovicola* (*Damalinia*) (*Holakartikos*) *crassipes* and the red louse *Bovicola* (*Damalinia*) *limbatus* are common on Angora goats, while *Bovicola* (*Damalinia*) *caprae* is the slightly smaller biting louse usually found on meat or dairy goats in the United States. The same goat can be infested with more than one louse species at a time (Sebei et al. 2004). Certain goats appear to have a natural resistance to biting lice, as documented during efforts to cause experimental infestations (Merrall and Brassington 1988).

Diagnosis is by physical examination and demonstration of lice or nits directly or on material collected by plucking or combing. A flea comb works well to

harvest material that can be placed in a ziplock bag for later examination with a dissecting microscope or hand lens. In one study, biting lice were concentrated in the withers area (where the goat had more difficulty grooming itself) while sucking lice were more prevalent over the brisket and shoulders (Merrall and Brassington 1988). Because lice are sensitive to elevated temperatures, their location on the body may vary with air temperature and exposure to sunlight. Populations are generally higher in winter than summer.

Therapy

Numerous insecticides are effective against goat lice (Moore et al. 1959; Bowman 2003), but nits are not killed. Resistance also may develop, and has been documented for permethrins (Levot 2000) but in some instances may be the result of product failure to reach the lice (Bates et al. 2000). Label directions should be followed to avoid contamination of milk and meat. Because nits are not killed by the initial therapy, treatment should be repeated at ten- to fourteen-day intervals if possible to remove young lice before they mature. Treating before kidding helps to prevent the normally rapid transfer of lice to newborn kids. In goat breeds that are shorn, and even in dairy breeds, the best results are obtained by treatment after removal of the fleece and attached nits.

Products used include crotoxyphos (1% in water spray or 3% dust), coumaphos (0.25% in water spray or 0.5% dust), dichlorvos, and fenvalerate. Pour-ons are more convenient than sprays or dips, and dusts are preferred to dips in cold weather. Coumaphos (Konar and Ivie 1988) and fenvalerate pour-ons may cause milk contamination. Newer permethrins appear to be both safe and effective, with no milk or meat withdrawal requirements. In India, flumethrin pour-on at 1 mg/kg provided complete louse control on goats for more than six weeks (Garg et al. 1998). Eprinomectin as a pour-on would be safe for lactating goats but is not approved in the United States. Ivermectin, also unapproved, at 20 mg/100 kg subcutaneously, is efficacious against sucking but not biting lice; it should not be used in lactating dairy goats and this dose is likely to select for resistant gastrointestinal parasites (see Chapter 10). For pets and young kids, rotenone, flea powders labeled for cats, and even flea collars may be more convenient that commercial livestock preparations. Note that extralabel use of pesticides is not sanctioned in the United States and agricultural products containing rotenone are being withdrawn from the market.

Insect hormones have been used experimentally to control lice (Price and Graham 1997). Three spray treatments of 0.1% synthetic juvenile hormone at two-week intervals controlled biting lice for four months (Chamberlain and Hopkins 1971).

Fleas

Dog and cat fleas (*Ctenocephalides* spp.) sometimes infest goats in tropical regions (Obasaju and Otesile 1980, Opasina 1983) and in the United States (Konnersman 2005b). In Greece, human fleas (*Pulex irritans*) cause long-term infestations of dairy goats (Christodoulopoulos and Theodoropoulos 2003; Christodoulopoulos et al. 2006). The wingless, laterally compressed, 2- to 4-mm-long adult insects suck blood and cause local irritation. Fleas frequently leave their hosts. Eggs are laid on the goat or on the ground. Clinical signs include restlessness, rubbing and chewing, excoriations, alopecia, nonfollicular papules, and crusts. The fleas are easiest to find when the goat is restrained on its back. Anemia and weight loss may occur in young or debilitated animals (Fagbemi 1982). Peripheral eosinophilia and infiltration of the skin by eosinophils suggest that an allergy to flea saliva may be involved in severe cases (Yeruham et al. 1997). Treatments suggested for lice are also appropriate for fleas, but the environment and all mammalian hosts must be treated.

Keds

Melophagus ovinus is a wingless blood-sucking fly (six legs) that infests both sheep and goats. The parasite is 6 to 7 mm long and easily seen, resembling a tick. The entire life cycle is completed on the host in five weeks or longer. The parasite causes skin irritation and blood loss, but damage to hides may have greater economic significance. Shearing removes many keds. The insecticides used for louse control are also effective against keds.

Biting Flies, Gnats, and Mosquitoes

Black flies (Simuliidae) may attack goats in swarms in the spring in areas of running water. Insecticides work poorly for repelling these pests, and stabling during the day may provide the most relief (Gnad and Mock 2001). Stable flies (*Stomoxys calcitrans*) and horse flies and deer flies (Tabanidae) also inflict painful bites. Residual topical permethrin products will provide some relief. *Culicoides* gnats are additional bloodsucking pests that swarm in the afternoon and evening. They are reported to cause significant skin lesions on small ruminants (Gnad and Mock 2001) but these lesions are not well described. Individual animals may become hypersensitized to the saliva of the gnats. *Culicoides* gnats are important vectors for bluetongue virus and bunyaviruses. Mosquitoes take blood meals from goats, as from other mammals. Control efforts are usually directed at eliminating stagnant water.

The diagnosis of insect hypersensitivity is usually presumptive in an animal that develops seasonal pruritus and self-excoriation (Figure 2.9). If insect

Figure 2.9. Apparent recurrent insect hypersensitivity in a buck that showed severe pruritus and self-excoriation in the early spring in New York. (Courtesy Dr. M.C. Smith.)

repellants and stabling do not control the signs, injectable dexamethasone can be used in nonpregnant goats.

Cutaneous Myiasis

The New World screwworms *Cochliomyia* (previously *Callitroga*) *hominivorax* in North, Central, and South America are the maggots of flies that must deposit their eggs in wounds or at body orifices rather than in dead carcasses. The species was eradicated from the United States in 1966 by the use of sterile males. The parasite is reportable in the United States and briefly entered Texas from Mexico in 1982; it also arrived on assorted imported animals and people in later years (Alexander 2006). One case involved a larva found on an Angora goat in Texas in 1998, following a hurricane (AVMA 1999). Shearing, dehorning, castration, and ear marking wounds and tick bites are common targets, as are the mouth and navel of newborns. As a complication to the presence of maggots in foul-smelling, pruritic lesions, toxemia or septicemia may kill the goat. Wounds should be debrided and treated with a topical insecticide such as malathion or coumaphos in ointment form. Fly repellents prevent repeat attacks, and antibiotics are indicated if the animal is systemically ill. Injectable avermectins have prevented establishment of screwworm larvae in wounds of calves (Alexander 2006). Dicyclanil, an insect growth regulator, shows promise for long-term prophylaxis of this and other forms of myiasis (Sotiraki et al. 2005).

Chrysomya bezziana is known as the Old World screwworm fly and has been documented to cause myiasis in goats on the Arabian peninsula (Spradbery et al. 1992; Abo-Shehada 2005). Although this fly has not yet been transferred to the Western Hemisphere,

modern transportation certainly makes translocation possible.

Wohlfahrtia magnifica is an important cause of primary myiasis in Asia (Iran to Mongolia) and the Mediterranean area. Infestation of goats increases with age, and the body regions most commonly struck are the genitalia and the extremities (Ruiz-Martinez et al. 1991). Clinical signs include inflammation, pruritus, apathy, and weight loss (Ruiz-Martinez et al. 1987).

A variety of blowfly larvae (calliphorine myiasis) can be found in the same wounds that attract screwworms and are differentiated by close examination of larval anatomy. Bacterial activity (fleece rot, fecal contamination of skin, urine scald) also can make intact skin attractive to these flies. Foul-smelling ulcers are filled with maggots. Cleansing of the wound with a mild solution of pine oil is helpful, because most of the maggots will come out of their holes and drop to the ground. Insecticides, fly repellents, and antibiotics are applied as for screwworms.

Warbles

Przhevalskiana (*Hypoderma*) *silenus* is a warble fly that naturally infests goats in Mediterranean countries and Asia. *Hypoderma aeratum* is reported to parasitize goats in Cyprus, Crete, and Turkey, while *H. crossi* infests goats in the dry, hilly regions of India (Soulsby 1982). Recent authors have suggested that these are all one species (Otranto and Traversa, 2004). *Hypoderma bovis* and *H. lineatum* (warble flies of cattle) have not been documented to infest goats (Colwell and Otranto 2006).

Pathogenesis and Clinical Signs

Adult *P. silenus* flies lay eggs on the hairs of the legs and chest in spring. It is believed that the larvae migrate by a direct subcutaneous route to the back rather than passing through the esophagus or spinal cord (Otranto and Puccini 2000). First-stage larvae appear under the cutaneous trunci muscle, which becomes necrotic and infiltrated by neutrophils. The larvae penetrate the overlying muscle and skin and molt into the second instar. Larval debris and cellular infiltrates accumulate, and a wall of granulation tissue forms around each larva (Cheema 1977), which is typically 10 to 12 mm long. Third-stage larvae drop to the ground to pupate. As many as 150 larvae have been found in a single goat (Prein 1938). In a slaughterhouse survey in Turkey, 53% of 1,049 goats examined were infested with *P. silenus*. Larval numbers ranged from one to fifty-two per infested animal with an average of seven (Göksu 1976). Sometimes the hide has the appearance of a sieve. The holes in the hides cause tremendous losses in the fine leather industry in Iran, where 93% of goats in a slaughterhouse study were infested (Rahbari and Ghasemi 1997).

Therapy

Ivermectin, at dosages of 5 to 20 mg/100 kg, has been effective in killing all instars of the warbles (Tassi et al. 1987; Yadav et al. 2006). Even microdoses of ivermectin (0.5 mg/100 kg as injectable, 1 mg/100 kg as pour-on) are highly efficacious and result in minimal milk contamination (Giangaspero et al. 2003). Modern systemic insecticides are often not available in countries where this parasite abounds. Shepherds have been taught to remove warbles during the winter months.

Ticks

Ticks are important ectoparasites throughout the world.

Etiology

A discussion of the life cycles and identification of the many species reported to infest goats is beyond the scope of this book; readers should refer to standard parasitology texts (Soulsby 1982). Some important species are listed in Table 2.2 and species occurring in the United States have been reviewed by Gnad and Mock (2001). Soft ticks belong to the family Argasidae and feed repeatedly on their hosts. Hard ticks, family Ixodidae, have a shield on the dorsal surface and feed only once during each stage. Larval ticks have six legs, while nymphal and adult ticks have eight legs. Ticks are referred to as one-host, two-host, or three-host, according to whether they drop off the host to molt between larval and nymph stages and between nymphal and adult stages. Ticks are not especially host-specific (Scott 1988).

Clinical Signs and Diagnosis

The attachment site varies with the tick species (Baker and Ducasse 1968), and may show papules, pustules, or wheals initially, with crusts and ulcers forming secondarily. Demonstration of the tick will make the diagnosis, but skin biopsy to demonstrate embedded tick mouth parts may be necessary in persistent, nodular lesions. Secondary bacterial infections and myiasis are possible. Ticks such as *Amblyomma hebraeum* and *Rhipicephalus glabroscutatum* attach to feet, especially between the claws, and may predispose to foot abscesses (MacIvor and Horak 1987). Damage to hides is important. Other important consequences are blood loss and the transmission of very serious diseases such as anaplasmosis, babesiosis, heartwater, theileriasis, and tick-borne fever. Tick paralysis may also occur. Pituitary abscess has been associated with attachment of ticks beneath backswept horns of Boer goats in South Africa (Bath et al. 2005). These conditions are discussed elsewhere in this book.

Therapy

Simple extraction of the tick is recommended when ticks and goats are few. A device with a slit that is

Table 2.2. Some ticks of importance to goats.

Tick	Distribution	Importance
Argasidae: soft ticks		
Otobius megnini	North and South America, southern Africa, India	Causes irritation and blood loss in ears
Ornithodorus spp.	United States, Asia	Transmits Q fever, *Theileria,* and *Anaplasma*
Ixodidae: hard ticks		
Ixodes ricinus	Europe	Transmits tick-borne fever, louping ill, tick paralysis
Ixodes pilosus	South Africa	Does not cause paralysis
Ixodes rubicundus	South Africa	Tick paralysis
Boophilus decoloratus	Ethiopia	Transmits *Borrelia, Theileria*
Boophilus microplus	Tropics	Tropical cattle tick
Rhipicephalus appendiculatus	Africa	Attaches in ears and beneath tail; transmits Nairobi sheep disease
Rhipicephalus bursa	Africa and southern Europe	Transmits *Theileria ovis, Babesia ovis*
Rhipicephalus haemaphysaloides	India	Transmits tick-borne fever
Haemaphysalis punctata	Europe, North Africa	Transmits *Babesia motasi, Theileria*
Amblyomma hebraeum	Africa	Transmits heartwater
Amblyomma variegatum	Africa and Caribbean	Transmits heartwater
Amblyomma cajennense	North and South America	Tick paralysis (Brazil)
Dermacentor spp.	Worldwide	Sometimes causes tick paralysis

placed around the mouthparts and then rotated works better than tweezers and direct traction for manual removal (Zenner et al. 2006). A large variety of sprays, dips, and pour-ons (see Table 2.1) will reduce the population of ticks and provide temporary protection. The use of insecticides can be reduced by local spraying or hand-dressing of the body area (ear canal, perineum) where ticks are located (Baker and Ducasse 1968). Systemic ivermectin may also prevent complete engorgement (Wall and Shearer 2001). Residues in meat, milk, and the environment are a concern, as is the possible development of resistance of ticks to insecticides (Stampa 1964) and of gastrointestinal strongyles to ivermectin.

Control

Total eradication of a tick species is usually very difficult. A reduction in tick numbers is achieved by several applications of insecticide at two- to three-week intervals. Two- and three-host ticks require treatments throughout the tick season, while one-host ticks are more likely to be on the host and therefore killed with one or two treatments. Amitraz has been used as a pasture spray to decrease tick burdens (Harrison and Palmer 1981). In certain circumstances, burning the pasture or cultivating the land may aid in tick control.

Sarcoptic Mange

The mite that causes sarcoptic mange (scabies) in goats has been referred to as either *Sarcoptes rupicaprae* or a goat-specific strain of *Sarcoptes scabiei*. It tunnels through the epidermis and feeds on tissue fluids (Scott 1988). Experimental infection of desert sheep with a goat strain of *Sarcoptes scabiei* has been documented (Ibrahim and Abu-Samra 1987) and probably occurs naturally when the two species are raised together. Molecular analyses suggest that all sarcoptic mites belong to a single, heterogeneous species (Zahler et al. 1999). Human infection can occur from handling affected goats (Menzano et al. 2007).

Clinical Signs

The condition is reported to begin with the appearance of small pruritic nodules, especially on the head, several weeks after contact with another infested goat or chamois (Menzano et al. 2007). The skin disease seems to be self-limiting in some goats, while others develop extensive severe dermatitis around the eyes and ears and on the neck and thorax, inner thighs, udder, and scrotum. Hyperkeratosis and alopecia are accompanied by self-excoriation and restlessness. The thickened skin is wrinkled and fissured (Abu-Samra et al. 1981; Kambarage 1992) and may harbor a secondary bacterial infection. Severely affected goats lose weight and have prominent peripheral lymph nodes. Some deaths occur (Zamri-Saad et al. 1990; Menzano et al. 2007). The value of the hide is markedly decreased.

Diagnosis

Confirmation of the diagnosis usually requires deep scrapings at the margin of lesions; the mites are identified by the presence of long unjointed pedicels on the pretarsi. Even if no mites are seen in multiple scrapings, a biopsy report of eosinophilic dermatitis and tunnels should indicate a presumptive diagnosis of sarcoptic mange (Deorani and Chaudhuri 1965; Scott 1988). In some chronic cases, diagnosis is made by response to therapy. Local regulations may require reporting a positive diagnosis to government authorities.

Therapy

Treatment of lactating animals can be accomplished with repeated (perhaps five to ten) applications of lime sulfur solution every five to seven days. Two treatments of 0.05% amitraz seven to ten days apart are recommended for controlling scabies in dairy cattle in the United States, and should thus be safe for dairy goats. In nonlactating animals, many different parasiticides have been applied with some success, but relapses are common when treatment is discontinued (Jackson et al. 1983). Sprays often fail to adequately penetrate the long and thick hair coat of unshorn animals. Some animals may need antibiotics for secondary bacterial infections.

More recently, ivermectin (subcutaneously) has simplified treatment, especially because the inconvenience and stress of bathing a disgruntled goat in cold weather are avoided. A cleansing shampoo is recommended to remove crusts, even if ivermectin is given. However, excellent response, including disappearance of the crusts, was achieved in Saudi Arabia when goats were treated with ivermectin (1 ml of a 1% solution per adult of unspecified weight) twice, one week apart. Live mites were recovered from treated animals for at least two weeks, but all goats yielded negative skin scrapings three weeks after the second treatment (Wasfi and Hashim 1986). In another instance, three doses two weeks apart of subcutaneous ivermectin at 0.2 or 0.4 mg/kg were effective (Zamri-Saad et al. 1990). Three treatments fourteen days apart with topical moxidectin at 0.5 mg/kg were successful in clearing a severely infected Italian goat herd of the parasite; a higher dose, more appropriate for goats, might have been more rapidly effective (Menzano et al. 2007). For the lactating animal, a single topical application of eprinomectin (Eprinex® pour-on, Merial) at 1 mg/kg (twice the cattle dose) might be preferable, because milk residues remain below the limit established for dairy cows (Dupuy et al. 2001).

Chorioptic Mange

Some authors believe that the chorioptic mange mite of goats belongs to the species *Chorioptes bovis*, while others consider it to be host-specific and designate it as *C. caprae* (Scott 1988).

Epidemiology

The mite lives on the surface of the skin and feeds on epidermal debris. It may exist on nonclinical carrier goats and can also survive in the environment for as long as ten weeks (Liebisch et al. 1985). This accounts for sudden occurrence of mange lesions in closed herds. Mite populations are affected by the environment, with the highest mite numbers and most severe clinical signs in cold weather. In a New Zealand study of feral goats, the prevalence of chorioptic mites was 100% in the winter, although marked lesions were found on the legs of only five of 368 goats overall (Heath et al. 1983).

Clinical Signs and Diagnosis

The lesions (nonfollicular papules, crusts, alopecia, erythema, and ulceration) are most commonly or initially found on the lower limbs, with occasional spread to udder, scrotum, and perineal region (Scott 2007). Pruritus, as demonstrated by stamping or chewing at the limb lesions, may be obvious, or the alopecia and crusts may appear benign (Figure 2.10). Only rarely is the dermatitis caused by *Chorioptes* generalized (Dorny et al. 1994).

Diagnostic samples can be obtained with a flea comb or by skin scrapings; adding rotenone to the mineral oil used for collecting scrapings will prevent the escape of the mites on the way to the microscope (Scott 1988). The mites have short pedicels on their pretarsi. Zinc deficiency and bacterial skin infections are important differential diagnoses that may be present concurrently with mange.

Therapy

Treatment of chorioptic mange is sometimes very easy, but hypersensitivity of certain goats to the mites can lead to treatment failure and frustration. All in-contact goats should be treated simultaneously to eliminate the carrier state and the premises disinfected. Lime sulfur (four weekly, total body sprays or dips in 2% solution) is safe for lactating dairy goats. Crotoxyphos (0.25%), coumaphos (0.25%), trichlorfon (0.2%), amitraz (0.05%), and lindane (0.03%) must be applied at least twice at ten- to fourteen-day intervals. In one study, a single dip with fenvalerate (0.05%) killed all mites on Angora goats (Wright et al. 1988). Injectable ivermectin can be expected to kill many but not all of the mites, because of their superficial location. Topical application of ivermectin (0.5 mg/kg applied once to

Figure 2.10. Mild crusting and scaling on the pastern of a goat with chorioptic mange. (Courtesy Dr. M.C. Smith.)

healthy skin) has been shown to be effective against *C. bovis* on cattle (Barth and Preston 1988). Fipronil (Frontline® Spray, Merial) has also been advocated for goats (Konnersman 2005b). National regulations concerning milk and meat residues should be respected. Using shampoo to remove crusts and shearing of mohair will improve efficacy of externally applied acaricides. Systemic antibiotics for secondary bacterial infections and judicious use of glucocorticosteroids in apparently allergic goats are indicated in select cases.

Psoroptic Mange

The classification of mites of the genus *Psoroptes* is currently unsettled (Scott 1988; Zahler et al. 1998; Bates 1999). The proposed role of ear mites in the transmission of mycoplasma infections is discussed in Chapter 9.

Etiology and Epidemiology

The most commonly reported ear mite of goats is the cosmopolitan *Psoroptes cuniculi*. Prevalence in necropsy studies appears to be high (twenty-one of twenty-four and eight of eighteen) (Williams and Williams 1978; Cook 1981). The mite can be found in the external ear canal of kids as young as ten days old, with most kids infested by the third week (Williams and Williams 1978). In feral goats in New Zealand, the

infestation was often unilateral and was more common in winter and in older goats (Heath et al. 1983). When it causes body mange (in parts of the world where sheep are affected with psoroptic mange), the parasite is sometimes referred to as *P. caprae*. The mite has long, segmented pedicels and is often visible to the naked eye. It does not burrow but feeds on tissue fluids. Prolonged survival times (as long as twelve weeks) in the environment have been reported (Liebisch et al. 1985).

Clinical Signs and Diagnosis

Clinical signs of ear mite infestation include head shaking (Dorny et al. 1994) and scratching, sometimes with alopecia of the part of the ear repeatedly brushed by a hind foot. Occasional goats have flaky or scabby lesions or laminated crusts on the external ear or even on the poll, back, and pasterns (Littlejohn 1968; Munro and Munro 1980; Heath et al. 1983; Lofstedt et al. 1994), but most have no externally visible lesions. Otoscopic examination (tranquilization advised for adult goats) easily demonstrates the presence of the mite. A plug of yellowish wax is commonly found in the ear canal (Munro and Munro 1980; Cook 1981; Heath et al. 1983), and extracting some of this material with a cotton swab for examination is an alternative means of diagnosis. Palpation of the base of the external ear may elicit a crackling sound associated with exudate in the canal (Nooruddin and Mondal 1996). Rarely, otitis externa progresses to otitis media and interna with head tilt.

Body mange caused by *Psoroptes* resembles sarcoptic mange but is accompanied by less scab formation (Wasfi and Hashim 1986). Before sheep scab due to *Psoroptes ovis* was eradicated from Texas, Angora goats were noted to have a much more severe form of *Psoroptes cuniculi* infestation than was seen on dairy goats, as evidenced by serious damage to skin and hair (Graham and Hourrigan 1977). Skin scrapings should be collected from the margin of lesions. If the scrapings are collected into a ziplock bag or petri dish, the sample can be warmed to stimulate movement of the mites during later close examination. Reporting to regulatory authorities may be required.

Therapy

Treatment of ear mange is often foregone or limited to removal of any bells from goats showing clinical evidence of pruritus (to avoid continual disturbance of the owner). External lesions may be swabbed with an acaricide. Canine ear mite preparations may be used on goats with mites confined to the ear canal, but removal of crusts and debris is necessary and recurrence is likely (Munro and Munro 1980). The life cycle probably takes about three weeks, and several weekly treatments are advised (Littlejohn 1968). In nonlactat-

ing pet goats, two treatments with injectable or oral ivermectin one to two weeks apart (20 mg/100 kg) is a rational therapy (Lofstedt et al. 1994). Instillation of several drops of an ivermectin solution into each ear canal is also effective (Konnersman 2005b).

Body mange can be treated with routine acaricides (including amitraz; Harrison and Palmer 1981) as dips or sprays. Ivermectin (two injections one week apart) also has been found effective in treating psoroptic mange in goats (Wasfi and Hashim 1986).

Raillietia

A separate genus of ear mites of goats is *Raillietia* (Cook 1981; Lavoipierre and Larsen 1981). The feral goats that harbored only these mites showed no evidence of associated clinical disease, although ear irritation might be expected to occur. *Raillietia* mites tend to be larger than *Psoroptes*, and their longer legs originate from the anterior half of the body. The possible involvement of ear mites in transmission of mycoplasma infections is discussed in Chapter 9.

Demodectic Mange (Demodicosis)

Demodex caprae is a cigar-shaped mite that commonly inhabits the hair follicles and sebaceous glands of goats. It has a worldwide distribution. As in other hosts, demodectic mites have been found in the eyelids of goats with no visible lesions anywhere on the body (Himonas et al. 1975).

Epidemiology

Confinement housing and crowding seem to favor development of demodectic mange. The mites appear to survive only a few hours away from the goats, but infection via contact with contaminated feeders might occur. In fact, natural spread from one adult goat to another has not been documented. The appearance of nodules in certain goats in a herd but not in others may reflect the immune competency of the animal (Das and Misra 1972). This could be related to genetic factors, nutrition (e.g., selenium or protein deficiency), or stress (e.g., high production). It seems likely that goats are first infested as young kids but that lesions do not become detectable until many months later (Williams and Williams 1982).

Clinical Signs and Diagnosis

Portions of the body exposed to friction, such as the face, neck, shoulders, and sides, are commonly involved, whereas the ventral abdomen and udder remain free of nodules. Where animals with skin lesions have been followed, it has been observed that nodules are first detectable at ten to fifteen months of age (Euzeby et al. 1976). Initially the lesions are very small and only located by careful palpation (Smith 1961). However, defects may be readily detectable in
Figure 2.11. Cigar-shaped demodectic mange mites in a smear of exudate expressed from a skin nodule. (Courtesy Dr. M.C. Smith.)

hides at this stage or even earlier (Röhrer 1935). By eighteen to twenty months of age the nodules have enlarged to lentil or pea size, but because they remain painless they may not be noticed unless the goat is clipped (as for a show). Occasional animals demonstrate mild pruritus (Durant 1944), but this is a relatively rare finding.

Each nodule corresponds to a distended pilosebaceous follicle. Firm digital pressure will force out a ribbon of yellowish white paste from a central pore. Microscopic examination of this caseous material reveals numerous eggs, larvae, and mature mites (Figure 2.11). The diagnosis is thereby confirmed. The disease process peaks at about three years of age. Nodules may reach a diameter of 0.5 to 1.25 cm. At this time, the severely affected goat may be apathetic and unthrifty, and may lose weight or milk poorly. It is not clear if these signs are because of mange infestation or underlying (nutritional) problems. The nodules become smaller, firmer, and less numerous in older animals.

Therapy

Various treatments have been proposed. When only a few nodules are present, squeezing or incising each one to permit removal of its contents will result in a cure of the hair follicle thus treated. Iodine or other disinfectant is applied when the nodule is expressed to kill residual mites. Some goats carry several hundred discrete lesions. Others have a generalized dermatitis rather than the typical nodule form of the disease. For them, topical or systemic organophosphates, amitraz (0.025%), or weekly ivermectin or eprinomectin may be effective (Thompson and Mackenzie 1982; Strabel et al. 2003). Because the lesions resolve over weeks or months, documentation of a treatment effect is difficult. Nodules may remain long after the mites have died. In one instance, nodules reappeared after amitraz

(twelve topical treatments) was discontinued (Brügger and Braun 2000). Because secondary bacterial infections are generally absent in undisturbed lesions, antibiotic therapy is not indicated.

Treatment is normally only undertaken in show animals, except when nutritional deficiencies exist. It has been suggested that severely affected animals should not be used for breeding because of a possible hereditary susceptibility to the disease (Scott 1988).

Free-living Mites

Trombiculid mite adults and nymphs are free-living. The larvae (chiggers, harvest mites) are reddish and six-legged. They attack the pasterns, muzzle, and ventrum of animals pastured in infested fields and woods or when contaminated forage is fed to housed animals. Clinical signs of irritation and pruritus, papules, edema, exudation, and ulceration may be expected. Skin scrapings to identify the larvae permit differentiation from other conditions such as chorioptic mange, staphylococcal dermatitis, and zinc deficiency. Mites may be absent in chronic cases. The condition is well reported in sheep (Wall and Shearer 2001) and is occasionally recognized in goats (Nooruddin et al. 1987). An insecticide dip or spray might give eventual relief.

Exposure to biting grain or forage mites such as *Tyroglyphidae* spp. may occasionally cause dermatitis in goats (Matthews 1999). Likewise, a pruritic goat housed with poultry, especially in late summer, might be being attacked at night by poultry mites (*Dermanyssus gallinae*) (Matthews 1999).

Rhabditic Dermatitis and Strongyloidiasis

Strongyloides papillosus larvae penetrate unbroken skin, enter capillaries, and travel in the blood to the lungs. Here they exit into air passages and travel up the trachea and down the gastrointestinal tract to the intestines. There are no histologic changes in the skin on first exposure, but pustular dermatitis is created as host resistance develops via repeated exposures. This is characterized by edema, inflammatory infiltration (neutrophils, eosinophils, lymphocytes, and giant cells), and destruction of the larvae. This condition is best described in sheep (Turner et al. 1960). Affected goats are reported to stamp, dance, and nibble at their feet, especially after a rain (Baxendell 1988). Warm, moist habitats for the larvae should be eliminated and the animal treated with an anthelminthic such as fenbendazole, levamisole, or ivermectin.

Pelodera (*Rhabditis*) *strongyloides* is a free-living soil nematode that can invade portions of skin in contact with moist ground and decaying organic matter (Scott 1988). Although not reported in goats, it could presumably cause pruritic dermatitis in goats housed under unsanitary conditions. Diagnosis is by scraping or skin

biopsy and control by sanitation, including removal of dirty bedding. The hookworm (*Bunostomum*) is another nematode that could conceivably produce dermatitis while penetrating the skin. Additional conditions to be considered in the differential diagnosis include contact dermatitis, mange, and trombiculidiasis (chiggers).

Parelaphostrongylosis and Elaphostrongylosis

Parelaphostrongylus tenuis, the meningeal worm of the white-tail deer, commonly causes neurologic disease in goats in North America. Some paretic and nonparetic goats with *P. tenuis* infection have developed linear, vertically oriented skin lesions on the neck, shoulder, thorax, or flank (Smith 1981; Scott 1988, 2007). Owners report that the goat has excoriated these areas by biting or rubbing, as if responding to intense pruritus. Lesions are usually unilateral and alopecic, crusted, or scarred (Figure 2.12). One lesion may heal and another appear closer to the goat's head. One possible explanation is that migrating parasite larvae irritate dorsal nerve roots supplying individual dermatomes. The diagnosis of *P. tenuis*-induced dermatosis should be entertained when goats with linear pruritic lesions have been exposed to pastures frequented by deer. Neurologic deficits suggesting spinal cord damage and eosinophilia or increased protein in the cerebrospinal fluid lend additional support to the diagnosis. Treatment and control of this parasite are discussed in Chapter 5.

Goats in Norway have been affected with a very similar neurologic disease, in which the migrating parasite is *Elaphostrongylus rangiferi* and the natural host is the reindeer. In one herd pruritus was noted to

Figure 2.12. Vertically-oriented alopecic lesion on the side of a cashmere goat that had been pastured with white-tail deer, suggesting irritation of a dorsal nerve root by *P. tenuis*. (Courtesy Dr. M.C. Smith.)

precede the neurologic signs (Handeland and Sparboe 1991). When goat kids were experimentally infected with *E. rangiferi*, pruritus was common from four to ten weeks after infection (Handeland and Skorping 1993). The muscle worm of deer, *Elaphostrongylus cervi*, has been associated with neurologic disease of goats in Europe, but pruritic skin lesions have not been reported.

A differential diagnosis for this syndrome might be psychogenic self-mutilation (Yeruham and Hadani 2003). Examination of biopsy samples reveals only the skin damage induced by chewing or scratching. However, unless the spinal cord is also examined it will not be possible to rule out irritation to a nerve root supplying the affected skin.

Filarid Dermatitis

Several filarid worms are known to cause dermatitis in small ruminants. Insect vectors, especially flies, deposit larvae in skin wounds. Papular, alopecic, or crusty lesions develop, and are accompanied by pruritus. In Malaysia, a crusty dermatitis of the feet of goats has been ascribed to *Stephanofilaria kaeli* (Fadzil et al. 1973). In India, *Stephanofilaria assamensis* has been recovered from skin sores on goats (Patnaik and Roy 1968). Skin scrapings, and smears of blood oozing from the skin after the scrapings have been made, reveal adult parasites and microfilaria. Biopsy samples may be fixed in formalin or macerated and examined with a dissecting scope. Eosinophils predominate in the inflammatory reaction to the parasites. Trichlorfon has been efficacious for treating affected goats.

Elaeophora schneideri (a subclinical intra-arterial parasite of mule deer and black-tailed deer in the mountains of the western United States) occasionally infests sheep and elk. Transmission is by horseflies. Adult worms block arteries of the head, and microfilaria lodge in skin capillaries. Erythema, alopecia, ulcers, and crusts appear on the face and poll, and sometimes the abdomen and feet of sheep. Blindness, neurologic signs, and keratoconjunctivitis also may occur. The absence of documented caprine cases may reflect how rarely goats are grazed above 2,000 meters in the mountain ranges. However, the parasite has been reported in the southeastern United States, Texas, and the Pacific coast states, and goats are listed as occasionally infected (Haigh and Hudson 1993).

Besnoitiosis

In Africa and the Middle East, protozoal parasites of the genus *Besnoitia* cause a widespread dermatitis and alopecia in wild and domestic goats. Some workers believe that the organism infecting goats, termed *Besnoitia caprae*, is distinct from that infecting cattle, *B. besnoiti* (Njenga et al. 1995). Lesions may be especially severe on the scrotum and lower limbs. The skin is

thickened to corrugated (hyperkeratosis), sometimes with hyperpigmentation and exudation (Oryan and Sadeghi 1997). Diagnosis is by demonstration in skin biopsy specimens of cysts (oval or spherical, average size 175 × 290 microns) containing bradyzoites and surrounded by a collagen capsule (Bwangamoi 1967; Cheema and Toofanian 1979). There is also a correlation with the presence of *Besnoitia* cysts in the scleral conjunctiva (Bwangamoi et al. 1989). No specific treatment is available. Control measures for goats have not been described but might include the use of a bovine tissue culture vaccine (Radostits et al. 2007) and avoiding feed contamination with cat feces. Biting flies possibly transmit the parasite.

NUTRITIONAL DISEASES

A goat subject to deficiencies in dietary energy or protein can be expected to have a dry, sparse hair coat and dry, thin, scaly skin. These changes are nonspecific because they occur with many chronic, wasting diseases. Copper deficiency, which is discussed in Chapter 19, has been associated with depigmentation of the hair coat (Lazzaro 2007). Certain trace mineral or vitamin deficiencies cause changes in the skin that have been described in more detail. Alopecia, possibly related to liver damage, has been produced by experimental feeding of *Aristolochia bracteata* in goats in Sudan (Barakat et al. 1983).

Zinc Deficiency and Zinc Responsive Dermatosis

It has been suggested that a practical level of dietary zinc in production diets is 45 to 75 ppm (McDowell et al. 1991). The National Research Council (2007) now admits that a previous recommendation of 10 ppm did not allow for poor absorbability, which can be estimated to be as low as 15%.

Etiology

Calcium excesses in the diet may contribute to a relative zinc deficiency. This might explain zinc-responsive dermatitis in nonlactating does or male goats receiving dairy rations or alfalfa. Zinc deficiency was recognized in two aged nonlactating does after their diet was switched to an alfalfa gruel to compensate for tooth loss (Singer et al. 2000). Other minerals which influence zinc absorption are selenium, copper, and cadmium (National Research Council 2007). Zinc is not stored in the body in an available form, so a daily dietary source is needed.

Some animals appear to have inadequate absorptive abilities (possibly genetically determined, Krametter-Froetscher et al. 2005), because dermatosis persists in the face of normal dietary concentrations of zinc and interfering minerals.

Second-generation goats on an experimental nickel-deficient diet developed zinc deficiency and associated parakeratotic skin changes (Anke et al. 1977). This is unlikely to occur with ordinary diets.

Clinical Signs

Clinical signs observed in goats with zinc deficiency include hyperemia and pruritus (inconstant) of the skin; alopecia; thick fissured crusts on the back legs, escutcheon, face, and ears; and dandruff-like scales over the rest of the body (Neathery et al. 1973; Nelson et al. 1984; Scott 1988; Krametter-Froetscher et al. 2005). Crusts commonly encircle the nares, eyes, and mouth. The hair of zinc-deficient goats has been described as greasy and matted (Groppel and Hennig 1971). Fiber break with loss of mohair can have serious economic consequences in Angoras (Schulze and Üstdal 1975). Weight loss may occur; clinical aspects of zinc deficiency unrelated to the skin are discussed further in Chapter 19.

Diagnosis and Treatment

Skin biopsies are important for demonstration of hyperkeratosis and parakeratosis and for ruling out other conditions with similar signs (e.g., mange, dermatophilosis). The diagnosis of zinc deficiency by laboratory tests is difficult. It appears that some goats may have a zinc responsive dermatitis, although plasma, liver, and even dietary zinc levels appear to be within normal ranges (Reuter et al. 1987). Serum levels less than 0.8 ppm might be associated with skin lesions. Lower serum zinc concentrations (0.54 ppm) have been recorded in goats from Florida herds with a history of seasonal dermatosis when compared with serum levels in other herds without such history (0.83 ppm) (McDowell et al. 1991). An Austrian report gives the normal caprine serum zinc range as 0.57 to 0.63 ppm (Krametter-Froetscher et al. 2005).

In many instances, the diagnosis is achieved by response to treatment. A rather arbitrary dose of 1 gram zinc sulfate orally per day has been used with good success; if marked improvement has not occurred after two weeks of therapy, other diagnoses should be pursued more vigorously. There is a published report of a single goat with skin lesions of lateral truncal alopecia and scaling improving in seven to ten days with institution of 14 grams zinc sulfate orally per day for six weeks. Signs reappeared two to three weeks after cessation of therapy (McDowell et al. 1991). In the Austrian report, two adult goats with onset of clinical signs during pregnancy responded to 1 gram zinc sulfate per day, whereas the response to 50 to 200 mg zinc oxide per day was less complete (Krametter-Froetscher et al. 2005). The efficacy of dietary zinc methionine for alleviating signs in goats has not been documented. A mineral supplement that includes zinc should be offered routinely, with additional zinc for animals with a suspected hereditary basis for the

dermatosis. A slow-release bolus containing zinc, cobalt, and selenium is available in the United Kingdom (Matthews 1999). Dietary excesses of calcium should be corrected.

Iodine Deficiency

Diseases of the thyroid gland are discussed in detail in Chapter 3, and the role of iodine in caprine nutrition is discussed in Chapter 19.

Etiology

Certain soils (such as that found in much of the northern United States and the Himalayas) are deficient in iodine. Goitrogens (such as members of the Cruciferae family, see Chapter 3) may interfere with uptake of iodine by the thyroid gland. Additionally, inherited abnormalities of thyroid function have been recognized in inbred Dutch goats.

Clinical Signs

Adult goats with goiter caused by iodine deficiency generally show no skin changes (Kalkus 1920; Dutt and Kehar 1959). Likewise, clinical signs of hair loss or skin abnormalities were absent in one outbreak of goiter and cretinism in Angora kids ascribed to consumption of goitrogens during pregnancy (Bath et al. 1979). In iodine deficiency severe enough to cause stillbirth, however, newborn kids sometimes had a normal hair coat but often were hairless or covered with very fine hair (Kalkus 1920). Skin lesions have been reported in experimental hypothyroidism produced by administration of thiourea to kids. A rough hair coat and subcutaneous edema were noted clinically. Histologic changes included hyperkeratosis and plugging of hair follicles (Sreekumaran and Rajan 1977). Kids with hereditary goiters were similar to thiourea-treated animals in that they were sluggish and grew poorly. Again, the hair coat was sparse and the skin thick and scaly (Rijnberk 1977). It appears that goats with goiter may or may not have accompanying skin lesions, but that iodine deficiency should not be suspected as the cause of skin disease in the absence of goiters.

Treatment and Prevention

Iodine deficiency can usually be prevented by supplying an iodized salt or salt and mineral product (as the only source of supplemental salt). Excessive feeding of goitrogens should be avoided. Weekly application of an iodine-containing solution (such as 1 ml of tincture of iodine) to the skin will also meet the needs of the animal (Kalkus 1920).

Vitamin A Deficiency

Vitamin A is necessary for normal function of epithelial tissues, including the skin. Neurologic manifestations of deficiency are discussed in Chapter 5 and ocular manifestations in Chapter 6.

Etiology

Because beta-carotene, which is abundant in green-leaved plants, is converted into vitamin A after ingestion, deficiencies are unlikely when goats are fed good pasture or green hay. Grains (except yellow corn and green peas), roots (except carrots and sweet potatoes), and old or weathered hays are low in carotene. Cases of vitamin A deficiency in goats are most likely to occur in semi-arid environments (during the dry season or periods of drought) or when the diet consists of poor, old hay and grain other than corn. Experimental aflatoxicosis in goats has caused a gradual decrease in serum vitamin A levels (Maryamma and Sivadas 1973).

Colostrum is rich in vitamin A and usually supplies the needs of the kid until forage consumption begins. Colostrum-deprived kids can be expected to be deficient in vitamin A.

Clinical Signs and Diagnosis

Clinical signs relative to the skin include a rough, dry hair coat, patchy alopecia, and a generally unhealthy appearance (Majumdar and Gupta 1960; Caldas 1961; Dutt and Majumdar 1969). Hyperkeratosis (identified histologically) (Scott 1988) and plasma vitamin A levels less than 13 µg/dl, at least in sheep (Ghanem and Farid 1982), support the diagnosis, as do low levels of vitamin A in the liver (except for precolostral neonates).

Treatment and Prevention

Dietary supplementation, as discussed in the nutrition chapter, is preferable to injectable vitamin A. An excellent source is leafy alfalfa or alfalfa meal. Intramuscular or subcutaneous injection of vitamin A (3,000 to 6,000 IU/kg every two months) is appropriate for individual unthrifty goats or when daily oral supplementation is not possible. A single oral dose of 600,000 IU has proven effective in lambs for thirty-four weeks, and it is recommended that this be given two months after the start of the dry season (Ghanem and Farid 1982).

Massive overdose of vitamin A, as has been achieved in experimental feeding trials, results in a moderate hyperplasia of the dermis and seborrhea of the ventral abdominal and inguinal skin (Frier et al. 1974).

Vitamin E and Selenium Responsive Dermatosis

A nonpruritic dermatosis characterized by a dry, thin hair coat, general seborrhea and scales, and periorbital alopecia has been observed in kids and adult goats (Smith 1981).

In some instances, dietary selenium deficiency has been documented, and the response to injectable vitamin E/selenium has been dramatic. In other goats, diagnosis was based on negative skin scrapings and response to both injectable E/selenium and oral vitamin E (400 IU) given with vegetable oil daily for one month. Dietary supplementation with black oil sunflower seeds or wheat germ oil might be helpful because of vitamin E and fat content (Konnersman 2005b). Controlled therapeutic trials have not been conducted, and criteria for positively diagnosing the condition have not been established.

Zinc deficiency is an important differential. Skin biopsy results of goats with vitamin E and selenium responsive dermatosis have revealed orthokeratotic hyperkeratosis, whereas zinc responsive disease is characterized by parakeratotic hyperkeratosis (Scott 1988).

Selenium Toxicity

Hair loss in goats consuming *Astragalus* spp., especially involving the beard and flank region, has been linked to possible selenium excess (Reko 1928). This seems plausible because selenium toxicity from a variety of selenium-concentrating plants or from contaminated water causes loss of mane and tail hairs in horses. In another herd outbreak ascribed to consumption of a seleniferous (500 ppm) *Astragalus* spp., the only reported skin change in goats that died was a rough hair coat (Hosseinion et al. 1972). Selenium may substitute for sulfur in sulfur-containing amino acids in the hair and hoof (Scott 1988). This leads to alopecia and lameness, with cracks and deformities developing in horns and hooves (Gupta et al. 1982), as discussed in Chapter 4.

Sulfur Deficiency

A recently recognized condition of severe fleece eating in cashmere-producing goats and of sheep in one valley (Haizi area) in China has been ascribed to sulfur deficiency, possibly compounded by calcium and copper deficiency. Affected goats repeatedly bite bits of fleece off themselves or other animals in the flock, concentrating on the fiber over the hips, abdomen, and shoulder. Some animals are left with almost naked skin and may die of exposure. Skin is keratinized and hair follicles are reduced in size and number. Signs are alleviated by moving to another valley or by the arrival of lush spring grass. The sulfur content of the fiber in affected animals was low (2.4%) compared with a normal content of 4%. Medicated pellets containing aluminum sulfate prevented or treated the skin condition, although muscle atrophy and kidney lesions were not reversed (Youde 2001, 2002; Youde and Huaitao 2001).

Rule-outs for such a herd problem include external parasites, lack of dietary fiber, boredom, and accidental deposition of concentrates into the fleece during distribution of feed.

ENVIRONMENTAL INSULTS

The skin may be damaged by excessive exposure to light, cold, or irritants such as urine. Bites by poisonous snakes and spiders undoubtedly affect goats occasionally but are poorly documented.

Sunburn

Exposure to sunlight is associated with the development of skin tumors in white goats, as discussed below. Light-skinned animals exposed to bright sunlight (ultraviolet light, 290 to 320 nm) (Scott 1988) after a winter stabling period are also susceptible to sunburn, especially of the muzzle, perineum, and teats. Signs include erythema, edema, vesicles, ulceration, and crusts (Scott 2007). Prevention involves gradually increasing times of exposure to sunlight and applying sunblocking ointments or iodine teat dips after milking. Treatment is by temporary removal from the sun and use of soothing burn ointments. Contamination of milk should be avoided.

Photosensitization

In photosensitization, superficial layers of lightly pigmented skin are sensitized to ultraviolet light (320 to 400 nm) of wavelengths longer than those causing simple sunburn.

Etiology

There are several mechanisms by which a photodynamic agent may reach the skin and cause dermatitis if exposed to light (Galitzer and Oehme 1978). Certain toxins are ingested preformed, and are said to cause primary photosensitization. Examples include phenothiazine, fagopyrin (from buckwheat, *Fagopyrum esculentum*), hypericin (Bale 1978) (from *Hypericum* spp.) and furocoumarins (from *Ammi majus* and *Thamnosma texana*) (Ivie 1978; Scott 1988, 2007). Secondary, or hepatogenous, photosensitization occurs when the normal end product of chlorophyll degradation in the rumen, phylloerythrin, accumulates because of faulty liver excretion. Any severe liver disease could conceivably lead to photosensitization in goats consuming chlorophyll and exposed to sunlight, but toxic plants are most frequently incriminated. These include *Lantana* (Pass 1986), *Agave lecheguilla* (Mathews 1938; Burrows and Stair 1990), *Nolina texana* (Mathews 1940), *Panicum coloratum* (Muchiri et al. 1980), *Tribulus terrestris* possibly in association with the saprophytic fungus *Pithomyces chartarum* (Glastonbury and Boal 1985; Jacob and Peet 1987), and *Panicum coloratum* (Muchiri et al. 1980). Additional hepatotoxic plants are listed in

Chapter 11. An inherited congenital porphyria has been reported in other species, but apparently not in goats.

Clinical Signs

The clinical signs in goats with photosensitization vary, depending on the protection afforded the skin by long hair or pigmentation and whether liver disease is present. The head, udder, and vulva of white breeds exposed to sunlight initially develop erythema, edema, and intense pruritus. Photophobia is observed and the goats seek shade. Acutely there may be dyspnea or dysphagia. Eventually necrosis and sloughing of lips or teats may occur. Pigmented skin is unaffected. The entire dorsum may be involved in recently shorn animals. Liver function tests help to differentiate primary from secondary photosensitization.

Exudation of yellow, serous fluid from the skin surface and intense icterus of the entire carcass are reported in goats with hepatogenous photosensitization from *Tribulus terrestris*. This condition is called geeldikkop, which means "yellow thick head." Similar lesions have been produced experimentally by oral dosing of goats with sporidesmin. Feral and Angora cross goats were more resistant than Saanens, which in turn required two to four times as much sporidesmin as sheep to produce comparable liver lesions and clinical signs (Smith and Embling 1991).

Therapy and Prevention

Affected goats should be removed from the sun, and additional ingestion of hepatotoxic plants or toxins avoided. This may require moving or supplementing range animals. Laxatives might be helpful if ingestion has occurred recently, and antihistamines and antibiotics are given if much skin is destroyed. Affected skin is sprayed with methylene blue and fly repellents if housing is not possible. Selection for skin pigmentation will decrease the prevalence of photosensitization, but losses resulting from liver disease will continue unabated unless exposure to hepatotoxins is prevented.

Kaalsiekte

The South African bitterkarroo bush *Chrysocoma ciliata* (*C. tenuifolia*) produces skin disease in young kids and lambs if their dams consume large quantities of the plant pre partum. The toxin is excreted in milk, causing hair shedding and diarrhea (Steyn 1934). Kids develop pruritus when exposed to sunlight and lick off large patches of hair. Sequelae include death from exposure, a crusty dermatitis from sunburn, and abomasal hairballs. Supportive treatment (protection from sunburn and wind, laxatives to remove hairballs) should continue until hair returns. Keeping the does and ewes off the infested veld from one month before until one month after parturition will prevent the condition (Kellerman et al. 2005).

Frostbite

Special attention should be given to drying of the ears when kids are born in cold environments. Otherwise it is common for the ear tips to develop frostbite. If the initial edematous stage is not treated, the affected skin becomes necrotic and eventually sloughs. The ear tips are rounded and alopecic and the remaining pinna is of variable length. The feet of neonates and teats and scrotum of adults are also at risk of frostbite under extreme environmental conditions.

Ensuring that the extremities remain dry is important for prevention of such injuries. Immediate first aid involves rapid thawing in warm water 106° to 111°F (41°C to 44°C) (Scott 1988) or with a hair dryer. Beef calf producers report that freezing of the ear tips can be prevented by using stockinette or duct tape to keep the ears closely apposed to the warmer head during the first days.

Ergotism

Ergot toxicity (a mycotoxicosis caused by alkaloids produced by *Claviceps purpurea*) causes sloughing of the extremities in cattle, similar to frostbite, and is potentiated by exposure to cold. There is a single report of lameness and gangrenous necrosis with sloughing just above the coronary band in goat kids grazing on fescue parasitized by the fungus (Hibbs and Wolf 1982).

Urine Scald

During the breeding season bucks urinate on their face, beard, and front legs whenever sexually aroused. Although this habit heightens the doe-attracting aroma of the breeding male, it can lead to dermatitis in the areas that are continuously wet with urine. Clipping of long hair allows for faster drying of the skin. Skin lesions can be washed with a mild soap or vinegar solution (5 ml in 500 ml water, Konnersman 2005a) and then liberally coated with petroleum jelly, zinc oxide, or other water repellent ointment daily, until the end of the breeding season.

Similar skin care year-round may be required for intersexes or males after urethrostomy or bladder marsupialization if the perineum or inside of the thighs becomes wet during urination. Males on a high protein diet may develop posthitis and moist infections of the skin of the prepuce. In addition to general wound care, the ration should be corrected, as described in Chapters 12 and 19.

Other Contact Dermatitis Conditions

Caustic agents that cause stomatitis (see Chapter 10) may be expected to cause dermatitis as well, if applied

to the external skin. There are various anecdotal reports of occasional skin irritation and hair loss following topical application of numerous parasiticides. If this occurs, the animal should be washed with warm water and a mild detergent to remove residual product.

Dehorning Paste

An alkaline paste is sometimes used by producers to disbud young kids. The paste eats through and destroys the skin from which horns would grow. Clipping hair and applying a ring of petroleum jelly may help contain the paste to the horn bud. Rubbing against other animals and pawing with a hind foot in response to local pain spread the paste and cause skin necrosis elsewhere on the body of the disbudded kid or other pen mates. Paste dehorning should be discouraged.

Milk

Some kids develop alopecia or even raw skin lesions (due to rubbing) on the lips and face where contact with milk or milk replacer has occurred. The condition has been termed "labial dermatitis" and can be prevented by washing or wiping the kid's face after each feeding (King 1984).

Decubital Sores

Emaciated or recumbent animals commonly develop full thickness skin necrosis over bony prominences such as elbows, hocks, and sternum. Deep, clean, dry bedding and frequent turning of the animal help prevent such lesions. Even with daily cleansing and drying of the sores, healing occurs very slowly, and only if underlying debilitating conditions are corrected. Sternal abscesses are discussed in Chapter 3.

Plant Awn Migration

The barbed seeds of numerous plants, especially grass awns, can penetrate the skin and migrate in the subcutaneous or deeper tissues. Nodules, abscesses, or draining tracts may develop (Scott 2007). An extensive discussion of potentially damaging plants in southern Africa (Kellerman et al. 2005) does not mention goats, but there is no reason to believe that they would not be affected.

NEOPLASIA

The most common skin tumors of the goat are cutaneous papilloma (warts), squamous cell carcinoma, and melanoma. Hemangioma, hemangiosarcoma, histiocytoma, mast cell tumor, and cutaneous lymphosarcoma have also been reported (Bastianello 1983; Manning et al. 1985; Roth and Perdrizet 1985; Allison and Fritz 2001; Bildfell et al. 2002; Konnersman 2005b). Ectopic mammary gland, which could be mistaken for a neoplastic condition, is discussed in Chapter 3.

Papilloma

Common warts probably occur much more frequently in goats than the caprine literature suggests. This is because those on the head or neck are benign and often self-limiting. If noticed at all, they are recognized as warts and because of a favorable prognosis, biopsy or treatment is not attempted. Favorable response to autogenous vaccine, after surgical removal of the largest warts, has been reported in a study with no untreated controls (Rajguru et al. 1988). The involvement of multiple animals in one closely confined herd has been taken as evidence for an infectious origin (Davis and Kemper 1936), although a wart virus has not been demonstrated in caprine papillomas.

Udder Warts

Warts on the udder have a different clinical course and are apparently limited to white goats (Saanens or Angoras) that have lactated at least once (Moulton 1954; Ficken et al. 1983; Theilen et al. 1985). The papillomas involve the white skin of both udder and teats and are typically multiple (Figure 14.5). They may either be flaky or form elongated cutaneous horns. Some transform into squamous cell carcinomas with wide base and ulcerated surface. The carcinomas may rarely metastasize to the supramammary lymph node. Additional discussion of these tumors is included in Chapter 14.

Carcinomas

Carcinomas of the skin also occur on other regions of the goat and without a preceding papilloma lesion. Again, white breeds in sunny climates are at risk. Angoras and Boer goats frequently develop carcinomas of the perineum (vulva and anus) (Thomas 1929; Curasson 1933; Hofmeyr et al. 1965; Yeruham et al. 1993). Ears, horn stumps, and muzzle (van der Heide 1963) may also be involved. The tumor may be sessile or pedunculated and becomes ulcerated as it enlarges. Detection often follows development of a foul-smelling exudate (Ramadan 1975). Possible origins for these tumors include squamous cells, basal cells, and sebaceous glands. Early surgical treatment is curative; otherwise affected animals should be culled. An affected ear can be easily amputated using local anesthesia and a Burdizzo emasculatome, placed on an angle to give a more cosmetically acceptable pointed shape to the remaining ear cartilage. Myiasis hastens the death of animals left untreated.

Melanomas

Melanomas appear to involve the same skin areas as the carcinomas, especially the vulva, perineum, and ear (Venkatesan et al. 1979; Bastianello 1983; Ramadan 1988). Indeed, it is sometimes unclear whether a given

tumor is a pigmented basal cell carcinoma or a melanoma (Jackson 1936). In other instances, both clinical course (metastases to internal organs) and histologic findings are consistent with malignant melanoma (Sockett et al. 1984). The prognosis is poor, as metastases commonly occur to local nodes, liver, and lung. A breed predilection was demonstrated in the Sudan in a review of sixty-two affected goats; the gray or brown "American" goats originally imported from Syria were more commonly affected than the more numerous all black native Nubian goats (Ramadan 1988). The Angora goat has been proposed as a model for human melanomas, because both tumors and benign melanocytic lesions can be induced by exposure to sunlight (Green et al. 1996).

INHERITED OR CONGENITAL CONDITIONS

A possibly inherited absence of hair at birth has been reported in a buck kid and his sire (breed unspecified) (Kislovsky 1937). The sire developed a nearly normal fleece as it grew older, but the kid died young. Neither histology nor additional matings were performed.

"Sticky kid syndrome" is a congenital disease reported in purebred Golden Guernsey goats, and may be inherited as a recessive character. At birth the kids have a sticky and matted coat that does not dry normally. The coat remains harsh and sticky in older goats (Jackson 1986).

Kids, unlike lambs, do not appear to develop congenital changes in the hair coat when exposed in utero to border disease virus (Orr and Barlow 1978).

Wattle cysts, which are located subcutaneously in the cervical region, are discussed in Chapter 3.

MISCELLANEOUS CONDITIONS

Dermatologists in referral hospitals see a disproportionate number of goats with "uncommon" skin diseases that have not responded to empirical treatments, including antibiotics, parasiticides, and manipulations of the diet. Extensive diagnostic work-up has characterized and identified the cause of some of these conditions, but others remain perplexing. In particular, crusting lesions of Nubian goats, especially involving the ears and face, have frequently defied attempts to identify an etiology or an effective treatment.

Pemphigus

Pemphigus foliaceus is an autoimmune disease in which the affected individual (man, dog, cat, horse, or goat) develops auto-antibodies against the glycocalyx of keratinocytes. Reports of the condition in goats are few (Jackson et al. 1984; Scott et al. 1984; Valdez et al. 1995; Pappalardo et al. 2002). There is no evidence that the condition is hereditary.

Clinical Signs and Diagnosis

Clinical findings include vesicles or blisters, pustules, crusts, alopecia, and sometimes pruritus. The lesions may be generalized over the entire body or may be concentrated in or begin in a more restricted location, such as the perineal region, ventral abdomen, and groin (Jackson et al. 1984). Diagnosis requires full-thickness skin biopsies of lesions containing intact vesicles or pustules. Routine histology (formalin fixation) reveals intraepidermal acantholysis with formation of clefts, vesicles, or pustules. Cells of the stratum granulosum may be seen attached to the overlying stratum corneum (Scott 1988). These granular "cling-ons" may also be found in direct smears of intact vesicles, along with nondegenerate neutrophils and/or eosinophils (Scott 2007). Direct immunofluorescence testing (tissue in Michel's fixative; no glucocorticoids administered in the past three weeks) reveals intercellular deposition of immunoglobulin. Serologic testing (indirect immunofluorescence) is unreliable for the diagnosis of caprine pemphigus (Scott et al. 1987).

Treatment

Treatment of pemphigus may be attempted with high doses of systemic glucocorticoids (1 mg/kg prednisone or prednisolone IM twice daily for seven to ten days, then alternate morning therapy at reduced dosage). A long-acting corticosteroid injection (dexamethasone-21-isonicotinate 0.04 mg/kg IM) once every two months suppressed clinical signs in one goat (Pappalardo et al. 2002) but the potential risks are greater. Oral prednisolone is not used because of very low bioavailability in ruminants (Koritz 1982). In young or nonresponsive goats, chrysotherapy with aurothioglucose (1 mg/kg weekly until response is observed, then monthly) may be tried. This drug has been discontinued in the United States. Although adverse reactions to gold have not been reported in goats, hemograms and urinalyses should be monitored. Gold treatment was successful in one reported case (Scott et al. 1984) and unsuccessful in another (Valdez et al. 1995).

Alopecic Exfoliative Dermatitis, Psoriasiform Dermatitis

A nonpruritic, seborrheic skin condition affecting pygmy goats of all ages has been described in England. Hair loss, scaling, and crusting occur around the eyes, lips, chin, ears, ventrum, and perineum. Histology reveals a psoriasiform dermatitis, and the condition responds to steroids but recurs when treatment is stopped (Jefferies et al. 1987, 1991). There is orthokeratotic and parakeratotic hyperkeratosis (Scott 2007). A very similar condition has been studied in pygmy goats in the Netherlands (Kuiper 1989). The condition was not contagious and did not respond to administra-

tion of corticosteroids, zinc, vitamin A, or selenium. A hereditary basis was suspected.

Lichenoid Dermatitis

This idiopathic condition was reported in a two-year-old Boer buck in Israel (Yeruham et al. 2002). Pruritic flat-topped angular scaly papules were present in the skin over the entire surface of the goat. The lesions were 10 to 20 mm in diameter but coalesced into plaques on the head. Some lesions were fissured. Histologic findings included orthokeratotic hyperkeratosis, epidermal hyperplasia, and microabscesses. Poxviruses, dermatophytes, and granulomatous and neoplastic conditions were ruled out by histopathology. A photograph of a similar case from Belgium, which resolved spontaneously after several months, has been published by Scott (2007).

Allergy or Hypersensitivity

Occasionally a pruritic, alopecic to crusty condition is seen on the dorsal midline of pastured goats in spring and summer. No external parasites are found on the animal, and practitioners have implicated a hypersensitivity to the saliva of *Culicoides* spp. midges (Scott 2007). Stabling at dusk and dawn may limit exposure to the insects and a brief course of systemic corticosteroids may alleviate the pruritus.

Other cases of poorly explained pruritic skin disease have been observed and defied diagnostic efforts to determine the etiology. In one such instance, orthokeratotic hyperkeratosis and perivascular infiltration with eosinophils in a five-year-old wether with crusting on the back and neck suggested allergy, as did response to dexamethasone therapy, but skin testing and manipulation of diet and environment were unsuccessful (Humann-Ziehank et al. 2001).

Subcutaneous Swellings

Whether the owners in a locality refer to them as lumps, bumps, bunches, or something else, swellings beneath the skin on a short-haired goat are likely to attract attention and require diagnosis, if not a treatment. The diagnosis depends on both the physical characteristics of the lump and its exact anatomic location. Aspiration, along with culture or cytologic examination dictated by the nature of the aspirate, can usually provide a definitive diagnosis. However, after the practitioner gains experience with goats, aspiration is only occasionally required. Herd history, signalment of the animal, and physical examination findings give reasonable certainty in the diagnosis of numerous benign conditions. Aspiration, then, is limited to confirmation of diagnoses that might require some other action, often surgery, or that carry a grave prognosis.

SWELLINGS WITH UNRESTRICTED DISTRIBUTION

Certain conditions can cause local swelling over almost any part of the goat's body. They will be considered before conditions with a more regional distribution. Masses limited to the dermis or epidermis, joint distension, and changes involving the mammary gland and scrotum are discussed in other chapters.

Hematoma and Seroma

A fresh hematoma is easily diagnosed by aspiration of nonodorous, sterile, red fluid. A yellow sterile fluid containing few erythrocytes is present in a seroma or organized hematoma. Diagnostic aspiration, however, is not without risk. Even with very careful attention to skin preparation, the needle is likely to carry a few bacteria into the accumulated fluid. Unless the hole in the skin is offset from the point where the needle enters, a small tract will permit leakage of fluid and retrograde entry of more bacteria. It is hard to imagine better growing conditions for a bacterial culture than in whole blood or serum at body temperature.

The practitioner might choose to drain a fluctuating lump, whether it be hematoma, seroma, or abscess. This procedure should be delayed a week or more if a hematoma is suspected to avoid renewed bleeding when the pressure of containment is relieved. If the swelling is not over a large blood vessel and antibiotic residues in milk or meat are of no concern, then small

fluid pockets may be drained through a needle and subsequently injected with penicillin or other antibiotic. A pressure bandage may prevent recurrence. Larger pockets must be opened widely and packed with gauze soaked in an antiseptic or provided with indwelling drains if proper healing is to occur. Seromas on the poll of breeding bucks, resulting from regular head bashing with other males, are best left totally alone.

Cellulitis and Abscess

Cellulitis is an acute, diffuse, edematous, suppurative inflammation of deep subcutaneous tissues or muscle. The swelling may be painful and accompanied by fever. The cause is often foreign body penetration or injection of irritant drugs. Aspiration for cytology and culture and sensitivity testing is warranted if the goat is systemically ill.

If encapsulation and abscess formation occur, signs of local inflammation (pain, heat) decrease (Figure 3.1). Given time, many abscesses "ripen" or develop a soft spot in the capsule where rupture is likely to occur. This helps to distinguish an abscess from a hematoma. The hematoma is initially fluctuant but later develops a firm capsule as the blood organizes and resorption begins. Abscesses usually heal rapidly when drainage is supplied. Lancing an abscess at its softest spot reduces both pain and hemorrhage associated with the

Figure 3.1. Large, thin-walled abscess in the upper neck of a one-month-old kid from which a *Streptococcus* sp. was cultured. (Courtesy of Dr. M.C. Smith.)

surgical procedure. Another, more ventral location may be more appropriate for incision, however, to allow better drainage. Caseous lymphadenitis should be ruled out (by culture or with less certainty by absence of lymph node involvement in any animal in the herd) before the animal with a draining abscess is returned to the herd.

Emphysema

When crepitation is palpable in subcutaneous or deeper tissues, it is important to determine the origin of the air or other gas that is present. Air may be escaping from the respiratory tract (tracheal laceration, severe pulmonary emphysema) or it may be entering through sucking skin wounds (Tanwar et al. 1983). Attention to the primary problem should stop the inflow of air, and resorption will occur gradually over days or weeks.

A crepitant, painful swelling caused by infection of wounds with gas-forming clostridia such as *Clostridium chauvoei* may lead to death of the animal (van Tonder 1975). The condition can be diagnosed by cytologic examination of aspirates, anaerobic culture, or immunofluorescence testing. Aggressive treatment with systemic and intralesional penicillin is successful in early stages. Gangrenous tissues slough later if the animal survives. In regions where clostridial infections are common, multivalent clostridial vaccines (*C. chauvoei, C. septicum, C. novyi*) provide inexpensive protection.

Edema

Pitting edema without crepitation may occur in wounds infected with *Clostridium septicum* (malignant edema) or *C. novyi* (swelled head in bucks). Other causes include trauma without tissue infection, frostbite, hypoproteinemia (parasitism, kidney disease, paratuberculosis), and congestive heart failure. Udder edema is discussed in Chapter 14.

LYMPH NODE ENLARGEMENT

Although enlargement of one or more lymph nodes in a goat typifies caseous lymphadenitis, other etiologies may be involved. In particular, other bacterial infections may cause hyperplasia or abscessation of the regional node (Gezon et al. 1991). Lymph node enlargement is common in animals with joint infection, including caprine arthritis encephalitis virus infection. Skin diseases such as sarcoptic mange and contagious ecthyma are often accompanied by enlarged nodes. Finally, lymphosarcoma occasionally causes enlargement of external lymph nodes.

Caseous Lymphadenitis

Caseous lymphadenitis is a chronic contagious disease that mainly affects sheep and goats (Brown and Olander 1987; Williamson 2001) and is increas-

ingly recognized in camelids (Anderson et al. 2004). The condition occurs worldwide and is well known in many regions of North and South America, Australia, New Zealand, Europe, and South Africa.

Etiology

Corynebacterium pseudotuberculosis (previously known as *C. ovis*) is the causative agent of caseous lymphadenitis. Its cultural characteristics are described under diagnosis. Horses are occasionally infected with the organism and may develop ulcerative lymphangitis or chronic abscess, but a different biotype from the one infecting sheep and goats is apparently involved (Aleman et al. 1996). Experimental intradermal inoculation of goats with strains of equine origin has caused abscesses at the injection site and in draining nodes but not in visceral locations (Brown et al. 1985). Most equine strains reduce nitrate to nitrite, whereas small ruminant strains do not.

Pathogenesis

The organism enters the goat's body through wounds or small breaks in the skin or mucous membranes and eventually becomes localized in a regional lymph node. Experimentally, tiny abscesses are detectable in lymph nodes by eight days after intradermal inoculation (Kuria et al. 2001). Cell wall lipid permits the organism to resist digestion by cellular enzymes, and *C. pseudotuberculosis* can survive as a facultative intracellular parasite, even in activated macrophages (Holstad et al. 1989). Sphingomyelin-specific phospholipase D exotoxin produced by the organism is largely responsible for its spread.

The incubation period until abscesses are noted in superficial lymph nodes is typically two to six months or longer (Ashfaq and Campbell 1980). These abscesses may rupture and drain spontaneously. The environment and curious herdmates thereby become contaminated, but the initially infected goat's abscess heals. It is common for one or more additional lymph nodes, following the lymphatic drainage pattern, to develop abscesses several months later. Experimental intradermic inoculation with small numbers of bacteria has demonstrated that spontaneous cures, without abscess rupture but accompanied by development of antitoxin titers, can occur (Langenegger and Langenegger 1988).

Internal (visceral) abscesses, especially in the lungs, may develop if the organism reaches the thoracic lymph duct or if it is inhaled. The association of internal abscesses with respiratory disease and wasting disease is discussed in other chapters. Other adverse economic effects of the infection in a herd include decreased market value of stock for sale and of hides from slaughtered goats. Milk production may be decreased.

Clinical Signs

The goat without internal abscesses typically shows no clinical signs other than enlargement and abscessation of one or more peripheral lymph nodes (Figure 3.2). Many of the external lymph nodes that may be involved in caseous lymphadenitis are pictured in Figure 3.3. Exactly which nodes are infected depends on the location of the wound that allowed entry of the organism into the body. Thus, most dairy goats (75% to 87%) with external abscesses have lesions on the head and neck (Ashfaq and Campbell 1979a, 1979b; Holstad 1986b; Schreuder et al. 1986) (parotid,

Figure 3.2. Abscessation of a parotid lymph node due to caseous lymphadenitis. (Courtesy of Dr. M.C. Smith.)
Figure 3.3. Location of common swellings caused by caseous lymphadenitis and caprine arthritis encephalitis. An abscess in the location of external lymph nodes (stippled) suggests caseous lymphadenitis. Enlargement of atlantal or supraspinous bursae (cross-hatched) may occur with CAE.

Figure 3.4. Abscessation of a popliteal lymph node. (Courtesy of Dr. M.C. Smith.)

mandibular, and superficial cervical "prescapular" nodes), presumably because injuries from thorns, splinters from wooden feeders, combat wounds, and scratching at lice most commonly occur here. Contact of these skin lesions with milking stands, feeders, or scratching posts contaminated by draining abscesses of other goats leads to infected nodes about the head and neck. By contrast, a popliteal lymph node (Figure 3.4) would only become enlarged if infection occurred in the distal hind limb. Mammary lymph node involvement can result from infection of skin lesions on the udder or from mastitis. Slaughterhouse studies typically show the highest prevalence in the prescapular node, among the nodes routinely inspected (Ghanbarpour and Khaleghiyan et al. 2005).

Diagnosis

Diagnosis of the condition is based on the presence of a firm to slightly fluctuant subcutaneous swelling in the anatomic location of a lymph node (Burrell 1981). In a herd with a history of caseous lymphadenitis, the clinical findings alone are considered presumptive evidence. When a herd history is lacking (no previous veterinary evaluation, assembled herd, individual pur-

chased animal), then laboratory assistance may be indicated for confirming the diagnosis. A sample for culture is obtained by inserting a sterile needle through shaved, disinfected skin into the mass. If aspiration yields nothing, the needle is withdrawn and saline is flushed through the needle to obtain material for a stained smear or culture. Even when the point of skin penetration is intentionally offset from the point where the needle passes through the wall of the abscess, some pus can leak back and serve as a focus of infection to others in the herd. Thus, if pus is present, the lump and the goat should be handled as if caseous lymphadenitis were present (see below) until culture results become available. Cultures of pus from draining caseous lymphadenitis lesions are frequently overgrown by nonpathogenic organisms or secondary invaders such as *Proteus* species. However, other bacterial infections such as anaerobic *Staphylococcus aureus* (Alhendi et al. 1993) and *Arcanobacterium pyogenes* and neoplasia, including lymphosarcoma, must be ruled out if *C. pseudotuberculosis* is not isolated. The other conditions causing subcutaneous swellings, as discussed in this chapter and reviewed elsewhere (Williams 1980; Fubini and Campbell 1983), also should be considered in the differential diagnosis.

The pus in an abscessed node in a goat may be creamy white, yellowish, or greenish; it is typically odorless and is more pasty (less inspissated) than in sheep. A lamellar "onion ring" configuration as seen in sheep with this disease is rarely present in goats (Batey et al. 1986).

The organism (a facultative anaerobe) grows readily but slowly on blood agar (Brown and Olander 1987). The colonies are very tiny or invisible after twenty-four hours (Lindsay and Lloyd 1981), and a longer incubation period is recommended before declaring that no growth has occurred. The colonies are still tiny and button-shaped after forty-eight hours, but are surrounded by a narrow zone of hemolysis. The colonies can be easily moved around on the surface of the agar plate and splatter when placed in a flame, because of high content of lipid. The organism is catalase-positive whereas *Arcanobacterium pyogenes*, which also produces tiny colonies, is catalase-negative (Quinn et al. 2002). Gram-stained smears show Gram-positive or Gram-variable small coccoid rods. A longer rod form is sometimes seen in smears of pus.

Serologic tests such as the bacterial agglutination test and synergistic hemolysis-inhibition (SHI) test (Zaki 1968; Brown et al. 1985,1986b; Holstad 1986a) are valuable in identifying goats with early or internal forms of caseous lymphadenitis. The SHI test is commercially available in the United States, through the University of California, Davis, and several other laboratories, and has a sensitivity of 98% in goats (Brown and Olander 1987). However, in the same study popu-

lation, 28% of goats with no demonstrable abscess were also SHI positive, indicating a lack of specificity.

Laboratory personnel report that a titer of 1:256 or greater correlates well with internal abscesses, but that occasionally an animal with a walled-off abscess tests negative. Experimental infections have not been detectable serologically until at least fifteen days after infection (Kuria et al. 2001), so purchased animals should be retested at the end of their quarantine period. Colostrally derived antibodies may cause false positive test results in kids under six months of age (Williamson 2001). Also, most tests have not been specific enough for current infection to justify their use in culling programs (Ellis et al. 1990). A decreasing titer on a retest taken two to four months after the first sample suggests that an active infection is not present. An ELISA test to detect antibodies against exotoxin and used for disease eradication in the Netherlands (Dercksen et al. 1996) has recently been improved to increase sensitivity to 94%, specificity of 98% (Dercksen et al. 2000).

Because the organism is a facultative intracellular pathogen, cell mediated immunity is involved in the immune response. Preliminary work with a commercially available bovine interferon gamma ELISA (Bovigam, Pfizer Animal Health) for cell mediated immunity to *C. pseudotuberculosis* has suggested that it is sensitive to prior infection and is unaffected by vaccination (Menzies et al. 2004). Caprine interferon gamma cross-reacts in the assay. This test may be useful to detect carriers in vaccinated herds, although it may not reflect the extent of the infection.

The increases in total serum proteins and gamma globulin that are reported for goats with caseous lymphadenitis (Desiderio et al. 1979) are also nonspecific. An intradermal allergic test using a water-soluble protein "lymphadenin" has been used to differentiate goats with abscesses from uninfected goats (Langenegger et al. 1986). Injections were made in the shoulder region and the maximum increase in skin-fold thickness occurred after forty-eight hours.

Surgical Treatment

Treatment of individual animals involves either draining or surgically removing the abscessed nodes. Ripened abscesses can be incised generously at a ventral point and the cavity flushed with dilute disinfectant. Because the infection is potentially zoonotic, people performing this procedure should wear gloves. The pus should be collected and burned and the goat should be kept strictly isolated until the lesion is completely covered by healthy skin, typically twenty to thirty days later (Ashfaq and Campbell 1980). Allowing an abscess to rupture in the main goat pen or returning the animal to the herd where herd mates will lick the wound will only serve to contaminate the environment and spread the infection. Stanchions, milking stands, and keyhole feeders in particular will become contaminated. The advantages of surgical removal of the encapsulated abscess are that the treated animal does not need to be quarantined afterward and spread to other nodes is less likely to occur, but veterinary expertise is required and there are dangers associated with anesthesia and dissection near large blood vessels and cranial nerves. Extirpation of abscessed parotid nodes is particularly dangerous, and treatment of a retropharyngeal abscess requires marsupialization.

An alternative but controversial treatment for carefully chosen abscesses is to inject them with 10% formalin at the point where the ripening abscess has become fixed to the overlying skin. A 16-gauge needle is used and approximately 20 ml of formalin is repeatedly injected into and withdrawn from the abscess until the cloudiness of the formalin/pus mixture in the syringe is no longer increasing; larger abscesses require a larger initial volume of formalin. This causes sloughing of the node within a few weeks but raises specters of meat or milk contamination or carcinogenesis in the minds of many veterinarians. Formalin is rapidly converted to formic acid, and formate is an intermediate in normal metabolism in the body. If the abscess is not fixed to the skin, formalin leaking out of the injected abscess will damage surrounding tissues as well as cause pain to the animal.

Antibiotic Therapy

In the past, long-term treatment with antibiotics or isoniazide of abscesses inaccessible to surgical management has not been rewarding. Antibiotic sensitivity testing is of little benefit, because most antibiotics do not penetrate into the abscessed lymph node and the organism itself may be intracellular. Administration of penicillin or tetracycline for a few days after spontaneous rupture or lancing of an abscess is suggested to prevent dissemination of the organism to other lymph nodes, but the value of this treatment has not yet been determined in controlled clinical trials.

Success in treating foal pneumonia caused by *Rhodococcus equi* with a combination of erythromycin and rifampin led to renewed interest in medical treatment of valuable sheep and goats. Pharmacokinetic data derived from other species suggest that an oral dose of 10 to 20 mg/kg rifampin s.i.d. might be appropriate (Sweeney et al. 1988; Frank 1990; Jernigan et al. 1991). A possible erythromycin dosage is 4 mg/kg administered intramuscularly or subcutaneously. Because erythromycin is highly irritating, a rifampin/penicillin combination might be preferable. Treatment should be continued for four to six weeks. Reports of the efficacy of rifampin in goats with caseous lymphadenitis are not yet available. One report of rifamyin at 10 mg/kg IM b.i.d. for ten days combined with long-acting oxytetracycline at 20 mg/kg IM every third day gave a

promising reduction in the size of affected lymph nodes, though the animals were only followed for one month (Senturk and Temizel 2006). There is no information available for estimation of meat or milk withdrawals to avoid antibiotic residues after the use of rifampin.

More recently, azithromycin has become popular for treatment of rhodococcal pneumonia in foals because of good intracellular penetration and long half-life (Chaffin et al. 2008), and the pharmacokinetics of this antibiotic in goats have been studied (Carceles et al. 2005). Again, to date there is no information on efficacy, dose, or withdrawal times if azithromycin is used in goats with caseous lymphadenitis.

Herd Eradication and Control Programs

Eradication of caseous lymphadenitis from a herd is difficult. The owner must be willing to cull goats and sheep with multiple abscesses and forgo purchase of animals from infected herds. Introduction of the disease into the United Kingdom by imported goats has underscored the risks associated with an open herd status (Gilmour 1990; Lindsay and Lloyd 1991). Ideally, a negative serologic test should be required before purchase, even from a herd believed to be free of the disease. Newly acquired animals, including camelids, should be examined for lymph node enlargement at least monthly for one year or more after arrival. An eradication program based on culling of serologically positive animals was successful in fifty-three herds (approximately 13,000 adult goats) in the Netherlands (Dercksen et al. 1996).

Valuable infected animals may be kept isolated; their kids should be removed at birth and fed heat-treated or bovine colostrum to avoid transmission of the disease as the newborn searches for the udder. Commercial pasteurization is known to kill *C. pseudotuberculosis* in milk (Baird et al. 2005). Division of an enzootically infected herd into infected and apparently uninfected groups has also been proposed as a means of limiting spread (Mullowney and Baldwin 1984). The housing facilities should be free of nails, wire, and other objects that might induce breaks in the skin. Control of external parasites is very important because pruritic goats will rub themselves on nails and posts. Needles, tattooers, and surgical instruments should be sterilized between animals. Shearing equipment that has been used on another farm should likewise be disinfected.

All wounds should be treated promptly with a disinfectant, and the umbilical cords of kids should be dipped in iodine at birth. In infected herds of Angora or Cashmere goats, animals should not be dipped for control of external parasites during the two weeks immediately after shearing; topical pour-on insecti-

cides can be substituted. Animals with chronic respiratory disease or wasting should be culled, or at least isolated from the herd. Natural transmission from lung lesions via discharge of pus into airways has been demonstrated in sheep (Ellis et al. 1987).

An environment contaminated with pus may be the source of new infections for weeks or months. Recovery of the organism from wood surfaces, straw, hay, and soil has been demonstrated by various researchers (Augustine and Renshaw 1986; Brown and Olander 1987). Thus, the isolation facilities used to contain a goat after rupture or lancing of an abscess should have a concrete floor. The bedding should be burned and the pen thoroughly cleaned (pressure washed) and disinfected between animals. In a successful herd eradication program in Norway, housing areas used by infected animals were left vacant for three months after disinfection and the upper 10 cm of soil in the paddocks was removed to decrease the risk of soil-borne infection (Nord et al. 1998).

Vaccination

Numerous studies using mice have evaluated immune responses to the organism. Cell-mediated immunity has been demonstrated to restrict bacterial proliferation. Neutralization of exotoxin (phospholipase D) produced by the organism is believed to limit spread from the primary site of infection.

The value of vaccination as an aid in controlling the disease in ruminants has been frequently questioned. A decrease in the prevalence of abscesses in the herd has often been noted where autogenous bacterins have been used, but concerned owners have simultaneously culled known infected goats and generally improved hygienic measures. As a note of caution, if not properly prepared and tested, an autogenous vaccine against this organism may contain enough free toxin to kill the vaccinated goat. The SHI test does not distinguish between naturally infected and vaccinated goats unless serial tests are compared, so test and cull is difficult to use once a vaccination program has been implemented. Likewise, vaccinated goats test falsely positive in an ELISA for antibodies against exotoxin and cell wall antigens (Sting et al. 1998).

A commercial vaccine (Glanvac®, Commonwealth Serum Labs, Melbourne, Australia) developed in Australia has been evaluated in goats (Anderson and Nairn 1984a, 1984b; Brown et al. 1986a). This product is a formalinized exotoxin with incomplete Freund's adjuvant. In one study, challenge by swabbing a live culture onto abraded skin revealed that either one or two doses of vaccine gave good protection; three of twenty vaccinated goats developed abscesses, as compared to ten of ten control goats (Anderson and Nairn 1984a). Colostrally derived immunity protected young kids against challenge (Anderson and Nairn 1984b). In

enzootically infected herds, serologic titers in kids disappear by three to four months of age, only to reappear after exposure to the organism. Vaccination should probably be performed before four months of age (Holstad 1986c), but colostrally derived antibody may interfere when vaccination is begun before three months (Paton et al. 1991).

A different commercial vaccine (Case-Bac® and Caseous-DT®, Colorado Serum Co., Denver, CO) is available in the United States. This bacterin-toxoid preparation is only labeled for sheep, where its efficacy has been documented (Piontkowski and Shivvers 1998), but it has been used on goats. There are numerous anecdotal reports of adverse reactions including severe milk drop, lameness, anorexia, fever and depression for one to two days after vaccination in adult dairy goats in infected herds, but many owners and practitioners report that vaccination of young stock beginning at two or three months of age has been helpful in reducing disease prevalence. Vaccination should probably be continued for many years, because of the possibility that one or more members of the original herd remain carriers and shedders of the organism.

Field evaluation of crude filtrated *C. pseudotuberculosis* toxoid combined with whole killed cells has been disappointing in goats (Holstad 1989), whereas another experimental whole cell vaccine gave a nonstatistically significant trend for fewer cases in the vaccinated goats in a field trial in Canada (Menzies et al. 1991). A formalin-inactivated whole cell vaccine with aluminum gel phosphate adjuvant gave partial protection (estimated at 77%) in a field trial under extensive conditions in Brazil (Ribeiro et al. 1988). Whole cell preparations of the organism adjuvanted with mycobacterial components have been evaluated (Brogden et al. 1990). A modified live intradermal vaccine has been developed by EMBRAPA in the State of Bahia, Brazil.

Zoonotic Potential

Human lymphadenitis caused by *Corynebacterium pseudtotuberculosis* has been reported, especially from Australia (Peel et al., 1996; Mills et al. 1997). The course was often protracted and diagnosis delayed until a culture was performed. Recovery usually required surgical removal of the affected lymph node, with supplemental antibiotics. Owners, slaughterhouse workers, and veterinarians should handle infected animals and abscesses with caution.

Melioidosis

In tropical areas such as Southeast Asia, Malaysia, the Netherland Antilles, and parts of Australia, a zoonotic disease caused by *Burkholderia (Pseudomonas) pseudomallei* is seen in goats and must be differentiated from caseous lymphadenitis. The disease seen in humans has been reviewed recently (Cheng and Currie 2005).

Etiology

Burkholderia (Pseudomonas) pseudomallei is a Gram-negative bacillus with polar flagella that may show bipolar staining. It closely resembles *P. aeruginosa*. The organism may be cultured on sheep blood agar or MacConkey agar (up to four days at 37°C). Some strains are hemolytic.

Epidemiology and Pathogenesis

The organism resides in soil and contaminated water. Survival in soil for up to thirty months has been reported (Thomas and Forbes-Faulkner 1981). Infected animals, including rodents, pass the organism in feces. Spread from animal to animal by biting insects also occurs. Vertical transmission is possible, as natural and experimental infection of pregnant goats has led to infection of aborted and live born kids (Retnasabapathy 1966; Thomas et al. 1988a).

Clinical Signs

Initial bacteremia is followed by formation of abscesses and granulomas in superficial lymph nodes, lung, and other internal organs. Prescapular lymph nodes are commonly involved and contain grayish yellow, creamy pus (Sutmöller et al. 1957). Chronic mastitis (van der Lugt and Henton 1995), weight loss, polyarthritis, and meningoencephalitis are also reported.

Diagnosis and Control

The indirect hemagglutination test (positive at 1/40 or higher) is considered most suitable for screening, because it has a sensitivity of 98%. The 100% specific complement fixation test (positive at 1/8 or higher) is used for confirmation (Thomas et al. 1988b). Sensitivity of the complement fixation test is lowered (82%) in chronic infections. The final diagnosis is made by culture. Older lesions in goats are sometimes sterile (Thomas et al. 1988b).

Antibiotic treatment is ineffective. Infected goats are to be eliminated and the herd monitored by serologic testing (Baxendell 1984).

Other Infectious Agents

Goats with arthritis because of a variety of causes may have enlargement of the associated lymph node. Regional lymph node enlargement is a constant finding with caprine arthritis encephalitis virus infection (Robinson and Ellis 1986), which is a common cause of lameness and enlarged joints in dairy goats in North America, Europe, and Australia. The reader should refer to Chapter 4 for an in-depth discussion.

Dermatophilus congolensis, a Gram-positive organism that forms branching filaments in pus, has been

isolated from abscessed superficial lymph nodes of Beetal goats. Other breeds housed with infected goats were not involved (Singh and Murty 1978). This organism more typically causes a superficial dermatitis. Goats with contagious ecthyma (soremouth) virus infection may have noticeable enlargement of lymph nodes draining the head. Mange can also cause marked lymph node enlargement. See Chapter 2 for discussion of skin diseases.

In regions where trypanosomiasis is endemic, *Trypanosoma brucei*, and to a lesser extent, *T. congolense* and *T. vivax*, cause a marked lymphadenopathy in goats. *Theileria* is another blood-borne parasite that causes enlargement of lymph nodes. These diseases are discussed in Chapter 7.

Infectious agents causing mastitis (including tuberculosis) may cause enlargement of the supramammary lymph nodes and are discussed in detail in Chapter 14.

Lymphosarcoma

Lymphosarcoma in goats is a neoplastic disease of unknown etiology. It has many similarities to sporadic or juvenile bovine lymphosarcoma. Neither the bovine leukemia virus nor antibodies against that virus associated with adult bovine lymphosarcoma have been found in goats with naturally occurring lymphosarcoma, although one experimentally produced goat case has been reported (Olson et al. 1981).

Lymphadenopathy of superficial nodes is not a consistent finding; only three of ten goats in one report were thus affected (Craig et al. 1986). In these animals, a lymph node aspirate yielding many lymphoblasts might confirm the diagnosis (Duncan and Prasse 1986). However, as least in cattle, fine needle aspirates have relatively low sensitivity for diagnosis of lymphosarcoma (Washburn et al. 2007).

Goats affected with lymphosarcoma are generally older than two years of age. They may have a variety of clinical signs, including high fever, emaciation, diarrhea, or dyspnea. The organs most frequently involved are liver, spleen, lungs, and lymph nodes, although the reproductive tract has also been involved (DiGrassie et al. 1997). Rapid deterioration occurs when clinical signs are noted, with death or euthanasia supervening in one week to two months in most cases. This is in contrast to the long and usually benign course of external caseous lymphadenitis.

Prominent Lymph Nodes of Normal Size

A distinction must be made between increased size and increased ease of palpation of lymph nodes. Animals that are emaciated because of malnutrition, parasitism, or chronic infectious diseases have very prominent nodes because subcutaneous fat is absent.

SWELLINGS INVOLVING THE HEAD

A number of specific conditions are limited to the head or neck. These are discussed below and some of them can be located with the aid of Figure 3.5.

Retention of a Cud in the Cheek

Contented goats frequently have a bulge in the cheek region during rumination. The swelling disappears as soon as mastication is complete or the goat is startled. If such a swelling persists and is found on careful digital examination to consist of a cud rather than a thickening of the cheek (abscess), neurologic dysfunction, a tooth problem, or some other condition interfering with mastication or swallowing should be suspected.

Tooth Problems

Absent, irregular, or abscessed teeth may lead to improper chewing and accumulation of feedstuffs or cuds between the dental arcade and the cheek. These problems are discussed below and in Chapter 10.

Facial Nerve Paralysis

Cud retention may indicate facial nerve paralysis, and thus should prompt a thorough neurological examination (see Chapter 5). Deviation of the philtrum, drooling, inability to blink, and drooping of the pinna may also be present. Conditions to be considered in differential diagnosis include traumatic injury to the facial nerve, otitis media, listeriosis, and other lesions involving the brain stem. Of these, listeriosis
Figure 3.5. Swellings involving the head or neck: (1) cheek abscess or cud retention, (2) salivary mucocele, (3) tooth root abscess, (4) bottle jaw, (5) thyroid gland, (6) thymus gland, (7) wattle cyst.

should receive special consideration, because the disease is most apt to be successfully treated if clinical signs are limited to peripheral nerve dysfunction.

Salivary Mucocele

Painless swellings on the side of the face sometimes are cystic structures filled with saliva.

Anatomy and physiology

The parotid salivary glands of the goat are roughly rectangular and extend from the ear to the bifurcation of the jugular vein. Each parotid duct runs subcutaneously across the lateral surface of the masseter muscle near its ventral border. It empties into the mouth via the parotid papilla, which is opposite the upper fourth premolar or first molar (Habel 1975). The mandibular salivary glands are triangular in shape. They lie deep to the parotid gland and caudal to the mandibular lymph node, along the medial side of the angle of the mandible. The mandibular ducts, which are less accessible to injury than the parotid ducts, go to the medial side of each sublingual caruncle. The monostomatic ducts of the sublingual glands open on the lateral side of each sublingual caruncle. Sialography can be performed (Tadjalli et al. 2002). In addition to these major paired glands, there are diffuse layers of salivary gland tissue in the walls of the mouth and pharynx.

The salivary glands of ruminants secrete continuously. The saliva is slightly alkaline, because of its high concentration of bicarbonate. The physiologic function of saliva is discussed in Chapter 10.

Etiology

Blockage or rupture of a duct can lead to formation of a salivary mucocele. Forceful restraint of the head of young kids against a metal brace during disbudding has led to mucocele formation. It is also important to avoid damaging the glands or the parotid ducts in surgical operations involving the head and neck, in particular drainage or extirpation of abscessed lymph nodes.

Painless fluid-filled cysts have been reported on the side of the face or in the submandibular region of young Nubian goats. These cysts were found to be lined by pseudostratified columnar epithelium containing goblet cells. Parotid salivary gland duct epithelium appears similar, and thus these cysts were presumed to be developmental anomalies (Brown et al. 1989). Figure 3.6 shows a one-month-old Nubian kid that had fluid-filled cysts bilaterally at birth. These cysts, which appeared to be outpocketings of a salivary duct, were removed surgically and the ducts ligated.

Clinical Signs and Diagnosis

Aspiration of the soft, fluctuant, nonpainful swelling should yield a clear, watery or slightly blood-tinged

Figure 3.6. Congenital salivary gland duct cyst in a Nubian kid. (Courtesy of Dr. R.P. Hackett.)

mucoid fluid that is colorless and odorless. The pH level is higher than that of blood. Confusion with a tapeworm cyst over the mandible, as discussed below, might be possible (Ghosh et al. 2005).

Treatment

Salivary cysts can be excised, as long as the caudal portion is ligated to occlude the parotid salivary gland duct. Excision of the gland itself is not required (Brown et al. 1989). Such swellings should not be lanced, because a chronic fistula and continuous loss of saliva may result. The discharge is not only aesthetically displeasing; the loss of bicarbonate, which approaches 30 to 50 grams per day in experimentally cannulated sheep, can lead to life-threatening acidosis.

Abscess

Subcutaneous abscesses on the head, as elsewhere on the body, may involve a variety of organisms, including *Corynebacterium pseudotuberculosis*, *Arcanobacterium pyogenes*, *Escherichia coli*, and staphylococcal and streptococcal species (Ashfaq and Campbell 1979b). *Nocardia* has also been isolated from chronic subcutaneous abscesses on the face and elsewhere on the body (Jackson 1986). An anaerobic staphylococcus has been associated with a herd outbreak of subcutaneous abscesses involving the head in goats in the Sudan (El Sanousi et al. 1989).

From Biting Cheek

When an abscess is located in the cheek, exactly where upper and lower molar teeth meet, the possibility of a self-inflicted injury with contamination by bacteria in the oral cavity must be considered. Filing of exceptionally sharp points on the teeth may be justified to avoid recurrence. Manual restraint of a

goat's head in such a way that skin of the cheek is forced between the molar arcades (as when teaching a kid to drink from a bucket) and tight halters should be avoided.

From Other Wounds

Wounds in the skin or oral mucosa may result from puncture by thorny vegetation or from grass awns. Bite wounds by predators or more dominant goats also offer a portal of entry for pyogenic organisms. In general, identifying the exact microorganism involved is not important, other than for ruling out caseous lymphadenitis. Draining and then flushing the abscess with dilute iodine usually provide adequate therapy. Systemic penicillin is given if the goat is systemically affected or the lesion is especially large.

Actinobacillosis is somewhat different in that *Actinobacillus lignieresii* causes multiple chronic, firm, nodular lesions, often with draining tracts in sheep. The lesions are located in soft tissues of the head or in the regional lymph nodes. The presence of small (less than 1 mm in diameter) granules in the pus is quite suggestive of actinobacillosis but unfortunately they are not often seen. Confirmation requires culture of the organism. Sulfonamides, streptomycin (not available in the United States), and sodium iodide have been recommended for treatment; penicillin is not effective. The occurrence of actinobacillosis in goats has not been documented. The condition is commonly seen in sheep flocks free of *C. pseudotuberculosis* and can be mistaken for caseous lymphadenitis, resulting in unnecessary culling if cultures are not performed.

From Dehorning

Dehorning represents a special wound that may become infected and eventually develop into an abscess beneath the eschar from heat cautery or the bandage or scab from surgical horn removal. This condition is discussed below under sinusitis.

Tooth Root Abscess

As a sequel to periodontal disease (perhaps from feeding coarse hay or hay containing grasses with barbed awns), foreign material gets between the tooth and gum and an abscess may form around the root of a molar tooth. In the authors' experience this occurs most often in the lower jaw and is accompanied by decreased hay consumption and difficulty cudding. The infection progresses until bony distortion of the ventral ramus is noted (Figure 3.7). The swelling is easily detected by comparing the thickness of the mandibles while palpating with the thumb and forefinger of each hand. This ventral swelling may break and drain pus. An oral exam (with xylazine tranquilization) should be conducted to identify obviously broken or loose teeth that need to be extracted. More typically,

Figure 3.7. Tooth root abscess involving the mandible. (Courtesy of Dr. M.C. Smith.)

the tooth involved can only be identified with an oblique radiograph of the jaw. Some of these goats respond to repeated iodine flushing of the draining tract and three to four weeks of penicillin or florfenicol or some other antibiotic selected on the basis of culture and sensitivity. A pelleted hay product encourages feed consumption during the initial stages of therapy because extensive chewing is not required.

Although surgical extraction of the involved tooth has not been reported in the caprine literature, experience with other species suggests that this might be the preferred treatment if accomplished without fracture of the mandible. Oral extraction would be very difficult (if the tooth is not loose) because of poor exposure, and consideration should be given to osteotomy of the lateral mandibular plate, as is described for llamas and small exotic ruminants (Turner and McIlwraith 1989; Wiggs and Lobprise 1994; Niehaus and Anderson 2007). After the tooth is repelled into the mouth, a pack of dental acrylic will exclude food particles from the surgery site.

Actinomycosis

Lumpy jaw (*Actinomyces bovis*) apparently is very rare in goats (Baby et al. 2000; Seifi et al. 2003). Involvement of bone and presence of sulfur granules raises the suspicion of this infection. Treatment is as for actinobacillosis, with five to seven days of streptomycin if available (10 mg/kg twice or three times daily) combined with oral iodides as a possible protocol. Daily subcutaneous injections of oxytetracycline at 20 mg/kg can be substituted. Important conditions to consider in differential diagnosis are tooth root abscess,

osteodystrophia fibrosa, and invasion of the jaw bones by lymphosarcoma (de Silva et al. 1985; Craig et al. 1986; Guedes et al. 1998; Rozear et al. 1998).

Osteodystrophia Fibrosa

A marked bilateral enlargement of the mandible has been reported in young (and occasionally adult) goats consuming mostly concentrate and thus having excessive phosphorus relative to calcium in the diet. The mandibles are soft (readily penetrated by a needle) and the cheek teeth are rotated so that the crowns are directed toward the tongue (Andrews et al. 1983). Demineralization is evident on radiographs (Singh 1995). In advanced cases, it may be impossible to open the mouth. Spontaneous fractures may occur. Feeding a good hay (such as alfalfa, which is high in calcium) and restricting the grain should prevent this condition, which is discussed in more detail in Chapter 4.

A similar mandibular (and maxillary) osteodystrophia fibrosa has been observed in four goats on a long-term (472 days) feeding trial with *Leucaena leucocephala*. The calcium to phosphorus ratio was more than 6:1. The kidney, thyroid, and parathyroid were histologically normal, and occurrence of the condition was not explained (Yates et al. 1987). Chronic renal disease might result in similar bone lesions.

Bottle Jaw

The presence of fluctuant pitting edema in the intermandibular space of goats that are not obviously in heart failure should arouse the suspicion of endoparasitism (see Chapter 10). The edema results from hypoproteinemia, which follows blood and plasma loss caused by nematode infestations of the gastrointestinal tract and liver failure in fluke infestation. Paratuberculosis also can cause severe enough hypoproteinemia to manifest as bottle jaw, as can renal disease. These conditions are discussed in Chapters 10, 11, and 12.

Swelled Head of Bucks

Fighting bucks may develop severe edematous infections of the head in regions where *Clostridium novyi* is prevalent. Other clostridia including *C. chauvoei*, *C. sordelli*, and *C. septicum* may be involved. The swelling begins near the horns and eyes but may extend down the face, neck, and chest. Tissues are full of yellow fluid and clostridia may be demonstrated on smear or anaerobic culture. Lymph nodes are swollen. The animal is lethargic and febrile. Death usually occurs within one to two days unless the swellings are opened surgically to allow oxygenation and massive doses of antibiotics (penicillin) are given. Photosensitization (see Chapter 2) might appear similar but does not spare the ears and is less rapidly fatal (King 1984). Bucks with a simple seroma on the poll from fighting will not be systemically ill.

Deformation of the Cranium

An abnormal profile of the cranial bones suggests hydrocephalus in the neonate and sinusitis or parasitic cyst in the older goat.

Hydrocephalus

Occasionally kids are born with an obvious doming of the skull and congenital hydrocephalus. This is usually sporadic, with no known predisposing cause, although some kids congenitally infected with Akabane virus (see Chapters 4 and 13) have hydrocephalus. The hereditary lysosomal storage disease of Nubians, beta mannosidosis, is also accompanied by deformation of the cranium, and is discussed in Chapter 5. Kids with hydrocephalus should be euthanatized if neurologic abnormalities are severe enough to interfere with nursing or locomotion.

Sinusitis

Except in neonatal kids, surgical dehorning invariably opens the frontal sinuses, into which hay and other foreign matter may easily fall. If a scab closes the opening before any infection present is eliminated, it is possible for an abscess to develop that may eventually lead to softening and distortion of overlying bone. A history of open dehorning within the last six months would be suggestive. Careful percussion may demonstrate a relative dullness over the affected sinus. Radiographic evaluation is recommended if there is any doubt that the swelling is over the frontal sinus rather than the cranial cavity or tooth roots. Drainage should be established and the sinus flushed daily, after removal of any foreign material or necrotic bone.

Enzootic intranasal tumor and lymphosarcoma, as discussed in Chapter 9, can invade the sinuses and cause bony distortion of the face. Digital pressure on softened bone causes expulsion of a seromucous exudate from the nostrils when an enzootic intranasal tumor is present (De las Heras et al. 1991). Decreased airflow is detectable through the nostril on the affected side. A dorsoventral radiograph reveals the space occupying nature of the tumor.

Coenurus Cerebralis (Gid)

Coenurus cerebralis is the larval form of the canine tapeworm *Taenia multiceps*. It can form cysts in the parenchyma of the brain or on its surface in sheep and goats. Blindness or various other neurologic signs occur, depending on the exact location of the cyst. The overlying skull may bulge and soften or even perforate. Where this sign is relied on for diagnosis it is reported to be common (Sharma and Tyagi 1975), although many affected animals show no outward changes in the skull. Insertion of an 18-gauge needle through the softened bone yields clear fluid under pressure, and

sometimes the cyst can be extracted from the cranium by aspiration through a tube inserted via this needle. At least one goat has been cured by injecting Lugol's solution into the cyst. A more detailed discussion of this parasite is supplied in Chapters 5 and 6. The parasite may no longer be present in the United States.

SWELLINGS INVOLVING THE NECK AND CHEST

Caseous lymphadenitis, as already discussed, should always be considered when swellings are present in the region of cervical or prescapular lymph nodes. Many other conditions of varied etiology cause diffuse or localized swellings on the neck or chest.

Abscesses Other Than Caseous Lymphadenitis

Abscesses that do not respond to simple drainage should be reassessed (including radiographic examination) for possible presence of a foreign body such as a needle, plant fragment, or piece of necrotic bone. Abscesses in the neck and near the left elbow have been reported in goats that ingested sewing needles (Sharma and Ranka 1978; Tanwar and Saxena 1984).

Mycetomas, as discussed in Chapter 2, are chronic, subcutaneous, fungal-induced swellings, often with underlying periosteal reaction.

Tissue Necrosis ("Sterile Abscesses") Caused by Injections

A number of vaccines, including multivalent clostridial (Green et al. 1987), paratuberculosis (Holstad 1986d), caseous lymphadenitis, and foot and mouth disease vaccines, cause large, roughly spherical, firm, persistent swellings (granulomas). This occurs in most of the animals vaccinated and does not require contaminated vaccine or dirty needles to occur. A provisional diagnosis is based on the presence of such a tissue reaction in a site known to have been used previously for vaccination. No treatment is required in commercial animals unless local infection occurs. These swellings are of more concern in pets and show goats, where surgical extirpation of the lump may be requested by the owner. It is important to inject these animals in a cosmetically acceptable location, such as behind the shoulder or elbow, because a reaction can be expected from many adjuvanted, effective vaccines. In general, injections should not be given subcutaneously in the neck of a show animal. It is difficult for veterinarians writing health certificates to feel confident that goats with a nodular swelling in this region are free of caseous lymphadenitis.

Administering vaccines and antibiotics deep into musculature is not a satisfactory method of avoiding problems. The result, an often severe necrosis of muscle, is more difficult to observe but clearly painful to the goat. Tender, firm swellings, lameness, or reluc-

tance to rise are common. When a site in the hind limb is used, sciatic nerve paralysis is also common, especially in young or emaciated animals with limited muscle volume. In addition, if the animal is to be used for meat, the muscle necrosis, which outlasts tissue residues by weeks or months, results in carcass damage that requires trimming or that escapes the notice of the meat inspector but is obvious and unappealing to the consumer.

Certain solutions are so irritating to tissue that they should not be administered subcutaneously or intramuscularly to goats. Some proprietary calcium preparations with phosphorus and dextrose included are noted for causing sloughing of tissue at the injection site. Failed attempts at intravenous injection may cause large swellings over the jugular vein where irritating drugs were mistakenly deposited in a perivascular location.

In animals kept for antibody production, it is normal to find numerous firm subcutaneous nodules where the adjuvanted antigen has been injected.

Wattle Cyst and Thyroglossal Duct Cyst

Wattles are reportedly caused by a dominant autosomal gene with complete penetrance but variable expression regarding the shape and location of the wattles (Ricordeau 1981). Occasionally, cysts occur unilaterally or bilaterally at the base of the wattle or at the site of previous wattle amputation. These cysts are certainly not rare but rarely are of enough concern to be reported in the literature. They are variously referred to as branchial cleft cysts (Williams 1980), dermoid cysts (Gamlem and Crawford 1977), or wattle cysts (Fubini and Campbell 1983). Wattle cysts are usually present at birth, although they may enlarge with time and become more noticeable later. They contain a thick or thin clear liquid and refill or become abscessed after aspiration. They can be excised intact under local anesthesia if care is taken to avoid the underlying jugular vein; excision may be necessary in show goats because of possible confusion with caseous lymphadenitis. Breed predilections reported in the literature may be biased by the prevalence of given breeds or family lines in certain regions.

Wattle cysts should be differentiated from thyroglossal duct cysts that are located on the midline, below the hyoid apparatus (Al-Ani and Vestweber 1986; Nair and Bandopadhyay 1990; Al-Ani et al. 1998). Thyroglossal cysts sometimes become quite large over time and can be removed surgically with due care.

Thyroid Gland and Goiter

Anatomy and Physiology

The thyroid of the goat is bilobed and located slightly behind the larynx. Right and left lobes, which

lie lateral to the trachea, are joined by a thin isthmus that passes across the ventral aspect of the trachea (Reineke and Turner 1941). In young animals, the lobes of the thyroid gland are often embedded in thymic tissue. The isthmus becomes more fibrous (less glandular) and more caudally located with advancing age (Roy et al. 1975).

The thyroid gland forms several hormones by iodinating organic compounds that contain the amino acid tyrosine. Thyroxine (T_4) and 3,5,3-triiodothyronine (T_3), when formed, are stored in colloid within the acini of the thyroid gland until needed. The thyroid gland and its hormones control the metabolic rate of an animal by regulating cellular oxidation (Wilson 1975). Selenium is required for hepatic conversion of T_4 to T_3 (Köhrle 2000).

Goiter is an enlargement of the thyroid gland. In ruminants, goiter usually suggests attempted compensation for a hypothyroid state. Normally, low thyroxine and triiodothyronine output stimulates increased thyrotropin (thyroid-stimulating hormone) output, which leads to increased iodine uptake from the blood and hyperplasia of the gland. The enlarged gland may be able to compensate by increased iodine trapping.

Normal Thyroid Function Tests

Natural hypothyroid states other than goiters have not been reported in goats. If testing is done, it should be remembered that, at least in dogs, corticosteroid therapy and the terminal stages of nonthyroidal illnesses can both depress plasma T_4, possibly because of interference with T_4 binding by plasma proteins.

The thyroid function of goats has been investigated by researchers wishing to use the species as a model for the physiology of larger ruminants. For instance, uptake of radioiodine (^{131}I) has been studied in goats (Flamboe and Reineke 1959; Davis et al. 1966; Ragan et al. 1966). Thyroidectomy, as discussed below, has also been performed to study normal thyroid function.

Thyroid hormone level determinations are more accessible to practitioners, although caprine normals are not well established. Repeated serum thyroxine level determinations in twenty female and forty male goats of dairy breeds, from two weeks to six years of age, yielded a mean of 6.53 ± 0.03 (SE) µg/dl of thyroxine. The range was 2 to 17 µg/dl (Anderson and Harness 1975). Thyroid function tests were also performed on up to fifty-five pygmy goats from a laboratory colony (Castro et al. 1975). No sex differences were noted. Mean values recorded included: protein bound (organic) iodine, 8.1 ± 1.2 (SD) µg/dl; T_4, 7.2 ± 1.1 µg/dl; and cholesterol, 90 ± 29.7 mg/dl. Because values were within normal human ranges, the authors concluded that there was no evidence of thyroid malfunction.

As part of a study to establish normals for ten species, thyroid hormones were assayed in duplicate from ten goats (Reap et al. 1978). Average values (± standard deviation) and ranges were: T_4, 3.45 ± 0.47 (3 to 4.23) µg/dl and T_3, 145.9 ± 29.32 (88 to 190) ng/dl. The average thyroxine value for four young and four adult goats (breed not specified) was 4.25 µg/dl in another study (Kallfelz and Erali 1973). Thyroxine levels in Angoras in South Africa were found to fluctuate with no obvious seasonal pattern (Wentzel et al. 1979). In one study of dairy goats, the plasma thyroxine level decreased by approximately 30% during the first week of lactation, relative to the prepartum period (Emre and Garmo 1985).

The author has evaluated thyroid-stimulating hormone response in three normal adult dairy goats (M.C. Smith, unpublished data). Serum thyroxine concentrations approximately doubled four hours after intravenous injection of 5 IU of thyrotropin. A similar response was seen in 25 juvenile goats after receiving intravenous thyrotropin releasing factor at 1 µg/kg; T_3 increased a mean of 318% at one hour and T_4 increased a mean of 174% (97% to 227%) at four hours after stimulation (Reinemeyer et al. 1991). Baseline values in this study were 30 to 90 ng/dl T_3 and 3.1 to 6.1 µg/dl T_4.

Experimental Hypothyroidism

Thyroidectomy has been performed in the goat. Ectopic thyroid tissue can be destroyed by ^{131}I administration where surgical removal of the visible thyroid glands is not sufficient (Ekman 1965). Parathyroid function is maintained because a pair of external parathyroids is located separately from the thyroid glands, embedded in thymic tissue.

When adult goats underwent thyroidectomy, the major clinical sign was body weight gain. Does that received ^{131}I during pregnancy produced stillborn kids with no detectable thyroid glands. These does had reduced milk production. Goats that underwent thyroidectomy developed marked thickening and softening of the skin with local hair loss and they shivered intensely when exposed to cold (Andersson et al. 1967).

When young kids underwent thyroidectomy, growth stopped within one to two months, kids became lethargic, and the head developed a dish-faced appearance (Reineke and Turner 1941). Growth recommenced if iodinated proteins were fed.

Goats with hypothyroidism have also been created experimentally by daily oral feeding of thiourea (Sreekumaran and Rajan 1978) and by injection of methyl thiouracil or thiourea (Gupta et al. 1990). When young kids were thus treated, weight loss and myxedema (edema and gelatinous infiltration of subcutaneous tissue) developed (Sreekumaran and Rajan

1977). Skin changes in these kids are discussed in Chapter 2. When eight-month-old male goats were made hypothyroid with thiourea, plasma testosterone levels decreased to less than 12% of pretreatment levels (Gupta et al. 1991). Long-term feeding of *Brachiaria mutica* grass with high but sublethal nitrate concentration has resulted in abnormally small and firm thyroid glands and mild proliferation of the acinar epithelium (Prasad 1983).

Naturally Occurring Dietary Goiter

Enlargement of the thyroid gland is usually a nutritional disease.

ETIOLOGY.   There are two major mechanisms by which diet can cause development of goiters in goats: iodine deficiency and feeding of goitrogens. In addition, experimental cobalt deficiency (and thus vitamin B_{12} deficiency) has produced elevated thyroxine levels accompanied by marked hypertrophy and hyperplasia of the thyroid gland (Mgongo 1981); however, in a later study thyroid function was not markedly impaired by cobalt deficiency (Mburu et al. 1994).

IODINE DEFICIENCY GOITER.   "Endemic" goiter in goats has generally been recognized in the past in the same regions where human goiter occurred. Soils are deficient in iodine or do not release it readily to plants and drinking water. Iodine-deficient regions include the Great Lakes, Great Plains, Rocky Mountains, and Pacific Coast regions of the United States (Lall 1952); Switzerland; parts of Great Britain (Wilson 1975); and the Himalayas (Raina and Pachauri 1984). The availability of iodized salt has decreased the prevalence of this type of goiter in both the United States and Western Europe. Goiter remains common in the Himalayas, where supplementation is not as available (Singh et al. 2002).

Breeds of goats vary in sensitivity to iodine deficiency. The Boer goat, a rapidly growing meat breed from South Africa, seems to be especially susceptible. It is possible that selection for resistance to iodine deficiency would be selection for slow growth rate (van Jaarsveld et al. 1971). In the Himalayas, where caprine goiter was extensively studied, indigenous strains were apparently more resistant to iodine deficiency than were goats (Barbari or Alpine) purchased from outside regions (Rajkumar 1970). The Angora goat is apparently very susceptible to iodine deficiency (Kalkus 1920).

GOITROGENS.   Goitrogens are compounds that interfere with the uptake of dietary iodine or with its metabolism in the formation of thyroxine (Bath et al. 1979; Cheeke 1998). Thiocyanate is a goitrogen present in many species of brassicas, members of the Brassicaceae (Cruciferae) family. Increasing dietary iodine will overcome the inhibitory effects of thiocyanate on selective concentration of iodine by the thyroid. Goitrin (thio-oxazolidone) is a thiouracil-type goitrogen found in the seeds of rape, kale, and other *Brassica* spp. that blocks hormone synthesis; its action cannot be overcome by feeding additional iodine.

Thiourea is similar and also interferes with organic binding of iodine; it has been used to produce experimental hypothyroidism (Wilson 1975). Mimosine in *Leucaena leucocephala* is broken down metabolically to a goitrogen in ruminants (Hegarty et al. 1976; Prasad 1989) but this chemical can be detoxified by natural populations of rumen bacteria (Hammond 1995). See further discussion in Chapter 10. African pearl millet (*Pennisetum typhoides*) is goitrogenic for goats, although the toxin has not been identified (Abdel Gadir and Adam 1999).

CLINICAL SIGNS AND LABORATORY FINDINGS.   The normal thyroid gland is 0.20% of body weight (Kaneko 1997). In goitrous regions, unsupplemented adults have marked enlargement of the thyroid, which is sometimes the size of an orange (Kalkus 1920). The goats otherwise look healthy. Reproductive performance may be decreased (Kategile et al. 1978). Humoral and cell-mediated immune responses may be decreased (Singh et al. 2006).

Affected kids have thyroid enlargement at birth (Figures 3.8 and 3.9), and enlargement of the kid's pituitary gland has also been described (Ozmen and Haligur 2005). They may be stillborn or are very weak and die within a few hours. Increased blood flow to the thyroid may cause a palpable thrill. Most of these kids are hairless or covered with very fine hair, while some have a normal hair coat (Kalkus 1920; Love 1942; Paliwal and Sharma 1979). It has suggested that multiple fetuses in a litter are more apt to be affected with dietary goiter than a single fetus (Ozmen and Haligur 2005).

In one outbreak in South African Angoras, believed to be caused by thiocyanate from heavily fertilized alfalfa pastures, kids were viable but abnormal from birth (Bath et al. 1979). They were short, blocky, obese, and inactive. The skull was broadened laterally and prognathia inferior was present in all cases. Goiters were easily palpated bilaterally. Mean thyroxine level for four goitrous goats was 3.1 µg/dl, whereas the mean of four normal goats was 5.9 µg/dl. Plasma cholesterol was five times higher (10.9 mmol/l versus 1.8 mmol/l) in goitrous than control goats. In another case report, does were fed on cabbages and the kids appeared normal except for goiters measuring as large as 7 cm by 4.5 cm (Lombard and Raby 1965). The largest goiters were associated with severe dyspnea and death, whereas less markedly affected kids grew poorly.

A study from an iodine deficient area of India evaluated 252 congenitally goitrous kids born to 574 does with goiter. Clinical signs included thyroid gland hypertrophy and palpable thrill, enlarged joints,

Figure 3.8. Congenital iodine deficiency goiter in a still-born kid. (Courtesy of Dr. M.C. Smith.)
Figure 3.9. Goiters exposed in twin stillborn kids by reflecting the skin. (Courtesy of Dr. M.C. Smith.)

muscle contracture, an arched back and waddling gait, partial to complete alopecia, weakness, and lethargy. Hydrocephalus and prognathism were less common. Serum cholesterol was increased while T_3 and T_4 were decreased. The incidence of stillbirth in this study was 18% (Sing et al. 2003).

DIAGNOSIS. Major differentials for a diagnosis of goiter include encapsulated abscesses and wattle cysts, which are unlikely to be bilateral and in the exact location of the thyroid. Thymic enlargement is more difficult to distinguish because the thyroid glands are normally embedded in the thymus. The kid with an enlarged thymus grows rapidly, has a healthy hair coat, and is active. As long as trace mineralized salt is available and no known goitrogens are being fed, the continued good health of the growing kid remains the ultimate diagnostic test to rule out goiter. Biopsy is not necessary, although normal thyroids contain acini lined by low cuboidal epithelium and filled with colloid, as opposed to the tall columnar epithelium, papillary infolding, and minimal colloid of goitrous glands (Love 1942; Roy et al. 1964). A hyperplastic goiter is transformed into a colloid goiter when the diet is improved or the lower iodine needs of an older animal are met, resulting in a gland that is still enlarged but has much colloid in the acini. Iodine content of the goitrous thyroid gland is reduced. Subclinical goiter is diagnosed when the glands appear to be normal size but are histologically hyperplastic.

TREATMENT AND PREVENTION. The actual dietary iodine requirement for goats, as discussed in Chapter 19, is 0.8 mg/kg dry matter for lactating females and 0.5 mg/kg for the rest of the herd. Cruciferous plants increase the ration iodine requirement to approximately 2 mg/kg.

Iodine deficiency goiter is treated or prevented by supplying iodine to the goat, especially the pregnant doe. This can easily be done with iodized salt, assuming that no iodine-free salt source is available for the goats to satisfy their salt requirements. In a report from India, biochemical and hormonal values normalized in goitrous kids when colloidal iodine (I_2) was given orally at 0.1 mg/kg bodyweight for 100 days (Singh et al. 2003). Synthetic sodium thyroxine (0.2 mg/day orally to goats weighing 16 to 20 kg) also corrected many clinical signs of deficiency (Singh et al. 2006) but should not be necessary once the diet is corrected.

In the classic experiments of Kalkus (1920), oral daily potassium iodide (2 grains, 130 mg) or weekly application of 1 ml of tincture of iodine to the back throughout gestation were both successful in preventing goiter. Iodine treatment during the preceding pregnancy sometimes was enough to permit production of another normal kid. Adult goats with iodine deficiency goiter showed a decrease in thyroid size after treatment (Kalkus 1920; Welch 1928).

Congenital goiter caused by goitrogens is best avoided by not feeding the incriminated forages (especially brassicas) during pregnancy. Supplemental iodine can also be fed to the does (Heras et al. 1984).

Hereditary Goiter

Congenital goiter occurred spontaneously in an inbred strain of Dutch goats (mixed Saanen and dwarf goats). The trait was maintained and studied extensively as a model for thyroid defects in humans.

PATHOGENESIS. The condition was inherited as an autosomal recessive trait (Kok et al. 1987). Thyroglobulin, the normal precursor of the thyroid hormones T_3 and T_4, was not produced in the goat that was homozygous for this trait. As a consequence, the normal feedback mechanisms were impaired and continuous thyrotropin secretion led to development of a goiter. The responsible mutation in the thyroglobulin gene has been characterized (Rivolta and Targovnik 2006).

CLINICAL AND LABORATORY FINDINGS. Normal thyroids (both together) in this breed weighed 1 to 4 g, and goiters weighed 15 to 300 g. Plasma T_3 levels (9 to 36 ng/dl) and T_4 levels (less than 0.4 µg/dl) were substantially lower than normal goat T_3 (124 to 151 ng/dl) and T_4 (5.9 to 10.2 µg/dl) levels (de Vijlder et al. 1978). Histologically, the goitrous thyroid had hypertrophic and hyperplastic epithelium consistent with prolonged thyrotropin stimulation. Colloid was almost absent.

In addition to having enlargement of the thyroids, goitrous kids were sluggish and grew poorly. The hair coat was rough and sparse. If thyroxine replacement was not provided, the hair coat eventually disappeared almost completely and the skin became thick and scaly (Rijnberk 1977). Euthyroidism could be achieved with these goats using iodide supplementation (1 mg I⁻ per day orally). Other proteins were iodinated and then converted to T_3 and T_4 even though thyroglobulin still was not synthesized (van Voorthuizen et al. 1978).

CONGENITAL GOITERS IN OTHER BREEDS. Congenital goiters of possibly hereditary etiology have also been found in Boer goats (van Jaarsveld 1971). Except for the enlargement of the thyroid glands (average 37 g compared with the normal average 2 g), the kids appeared normal. Histologically, there was hypertrophy of the thyroid epithelium with absence of colloid. Normal iodoproteins were present, but the thyroglobulin polymers tended to dissociate into subunits. Congenital goiters (average 43 g compared with a normal average of 9 g) have also been suspected to be hereditary in Shami dairy goats (Al-Ani et al. 1998). An autosomal recessive hereditary goiter in goats in Inner Mongolia was controlled by removing known carriers and identifying other carriers in the herd using a goat-homologous assay for thyrotropin (Mei and Chang 1996).

Thymus

Young kids, especially if well fed, sometimes develop bilaterally symmetric swellings in the upper neck in the region of the thyroid gland (Figure 3.10). The swellings may first become noticeable as early as
Figure 3.10. Enlarged thymus in the upper neck of a rapidly growing Nubian cross kid. (Courtesy of Dr. M.C. Smith.)

two weeks of age and regress spontaneously, often at about four months of age (Pritchard 1987) or somewhat later (Bertone and Smith 1985). The kid is otherwise healthy, with a good hair coat, and therefore is unlikely to be affected with severe iodine deficiency or goiter. Another subcutaneous swelling occurs at the thoracic inlet. Aspiration of either the cranial or caudal cervical masses, while not indicated, yields thymic tissue. The origin of the excessive thymic tissue might be remnants from embryologic development or accessory thymus; in any case, the glandular tissue involutes naturally and no treatment is needed. Owners should be warned of the potential for iodine toxicity if unnecessary supplements, such as kelp, are fed when no thyroid deficiency exists.

Tumors of the thymus occur in adult goats, and their presence as a space-occupying lesion or incidental finding in the thorax is discussed in Chapter 9. Less commonly, remnants of the cervical portion of the thymus become neoplastic. Diagnosis is by examination of a biopsy or aspirate, and treatment by surgical excision.

Thymic tissue may also be embedded within the thyroid gland of goats of any age (Roy et al. 1976), often in association with parathyroid tissue, but no clinical relevance has been reported for this histologic finding.

Phlebitis

Because the jugular veins are commonly used for venipuncture and administration of various medications, iatrogenic phlebitis may be expected to occur occasionally. Hematomas typically resolve quickly without treatment, whereas perivascular deposition of irritating drugs can lead to cellulitis or even abscessation. Conservative therapy, including application of hot compresses, is preferable to lancing a swelling so close to the jugular vein.

Atlantal Bursitis

Atlantal bursitis is a fairly specific but uncommon sign of caprine arthritis encephalitis virus infection. A fluctuant swelling is located underneath and extends on both sides of the ligamentum nuchae (Figure 3.11). The bursa often contains mineralized material, which can be demonstrated with a radiograph (Garry and Rings 1985). Histology shows hyperplasia of synovial cells and mononuclear cell infiltration (Gonzalez et al. 1987). An abscess can develop if aspiration is attempted. The supraspinous bursa may be similarly involved, as may be other bursae over the carpus, olecranon, or tuber ischii. Usually at least some degree of lameness is present by the time the atlantal bursa becomes noticeably distended.

Sternal Abscesses and Hygromas

Sternal abscesses were detected in seventy-two goats in a large antibody-producing herd over a sixteen-year period (Gezon et al. 1991). These abscesses were 3 to 15 cm in diameter and usually involved skin and subcutaneous tissues, but rarely invaded muscle or bone. Two of the goats, however, had osteomyelitis of the sternum. Bruises and abrasions of an area com-

Figure 3.11. Distension of the atlantal bursa in a goat with clinical CAE arthritis. (Courtesy of Dr. M.C. Smith.)

monly exposed to manure were proposed as an explanation of the occurrence of the abscesses. Antibiotic therapy had little effect on the condition. The authors did not adequately report culture results, and thus no conclusions can be drawn from this study concerning bacteria present in unbroken sternal abscesses.

Sternal abscesses are, in the authors' experience, most common in goats afflicted with severe lameness, such as from arthritis associated with caprine arthritis encephalitis virus infection. Two hypotheses come to mind to explain this association. First, the lame goat spends more time in sternal recumbency and therefore may develop a hygroma or decubital sore. Second, the caprine arthritis encephalitis virus-induced arthritis might involve joints between sternebrae, with secondary bacterial infection. Successful treatment of these abscesses often requires surgical debridement. Radiographic evaluation for osteomyelitis or enlargement (and probable infection) of lymph nodes within the thoracic cavity are helpful in offering a prognosis and determining the extent of surgical debridement required. Goats that are markedly lame and emaciated or have extension of infection into the thorax will probably benefit little from treatment of a sternal abscess.

Warbles

Larvae of *Przhevalskiana silenus*, a warble fly that migrates to the back region of goats in Mediterranean countries and Asia, are accompanied by localized inflammatory reaction and granulation tissue in the subcutaneous tissue. This parasite is discussed in Chapter 2. Although cattle warble fly larvae (*Hypoderma* spp.) could potentially invade goats, natural occurrence has not been documented and experimental infections with *Hypoderma lineatum* larvae did not progress to the development of subcutaneous warbles (Colwell and Otranto 2006).

Tapeworm Cysts

The intermediate form of the dog tapeworm *Taenia multiceps* (previously called *Multiceps multiceps* or *M. gaigeri*) forms cysts within the central nervous system (CNS) of sheep and goats, but also outside the CNS of goats, especially in muscle and subcutaneously (Verster 1969). Scolices are arranged in clusters and there are no internal or external daughter cysts. These cysts have been reported as the cause of large (approximately 15 cm in diameter) subcutaneous swellings distributed over the limbs and body of goats in the Sudan (Ramadan et al. 1973; Hago and Abu-Samra 1980) and India (Shastri et al. 1985). The cysts are fluctuating, cool, and covered with hairless skin. Depending on the cyst location, there may be interference with locomotion, feeding, or function of internal organs. Head shaking is commonly observed when cysts are near the base of the ear.

Several methods of treatment have been successful, including excision of the cyst, lancing the cyst and packing the cavity with gauze soaked in iodine, or aspirating all the fluid and infusing 0.5 to 1 ml of Lugol's iodine into the collapsed cyst (Nooruddin et al. 1996). When a herd outbreak occurs, as in a reported case involving forty-seven of 169 Black Bengal goats, emphasis should obviously be put on treating dogs for tapeworms and destroying the carcasses of dead goats to prevent consumption by the dogs or wild canids (Patro et al. 1997).

SWELLINGS INVOLVING THE ABDOMEN AND ESCUTCHEON

Alteration in the abdominal silhouette is discussed in detail in Chapter 10.

Umbilical Hernia

Umbilical hernia caused by the incomplete closure of the umbilical ring (in the absence of omphalitis) is rare in goats. A genetic predisposition has not been identified in this species (Hámori 1983). Nevertheless, prudence dictates that males that will be used extensively for breeding should be free of all recognizable congenital defects.

Goats with a swelling originating from the umbilical region should be examined by palpation while standing, and if necessary, in lateral recumbency. If the swelling is easily reduced with no tenderness or thickened stalk, then it is likely that it is a hernia unaccompanied by an abscess. In young female goats, wrapping the abdomen for two to four weeks with adhesive elastic tape may permit closure of the hernia ring to occur. If the defect is large, an internal abscess is suspected, or the patient is male, surgical repair is the preferred therapy. The goat is placed in dorsal recumbency and standard techniques appropriate for herniorrhaphy in calves are employed. Prosthetic mesh may be required to close large defects in the body wall (Fubini and Campbell 1983).

An alternative nonsurgical repair has been described using an elastrator castration band. The animal is lightly sedated and placed in dorsal recumbency. With all of the contents of the hernia sac replaced into the abdomen, two metal pins such as diaper pins are inserted through the skin on each side of the sac, so that they will sit close to the abdominal wall. An elastrator band is then placed around the hernial sac, between the pins and the body wall, where it causes sloughing of the skin and healing of the defect within two weeks (Navarre and Pugh 2002). Tetanus prophylaxis is imperative.

Umbilical Abscess

If palpation of an umbilical swelling reveals warmth, tenderness, or just an irreducible fluctuance, diagnos-tic aspiration is indicated. Omphalitis may result in abscessation of remnants of umbilical arteries, the umbilical vein, or the urachus. Ultrasonography may be useful for evaluation of the extent of internal involvement of an umbilical abscess. External abscesses are drained and systemic antibiotics are administered for one week or longer. If evidence of infection or concurrent hernia persists, surgical debridement and herniorrhaphy are recommended.

Abdominal or Flank Hernia

The abdominal wall of a goat is relatively thin. Muscle tearing and separation often occur from blunt trauma during fighting, shearing, or crowding through narrow doorways. Diagnosis of a unilateral flank hernia is usually obvious, although it is important to determine if a pregnant uterus is trapped in a subcutaneous location. When the hernia or stretching of the body wall is bilateral (as from doorways) it should be distinguished from pregnancy, hydrometra, obesity, or ascites by careful physical examination.

Small hernias may be surgically repaired, while hernias large enough to impede parturition are usually an indication for culling in a commercial herd. Tranquilization with xylazine and local anesthesia using a ring block of lidocaine (not to exceed 10 mg/kg) has been used for repair of abdominal hernias in goats (Al-Sobayil and Ahmed 2007). Either absorbable or nonabsorbable suture is satisfactory, with nonabsorbable (the authors used silk) favored in older animals or those with more longstanding hernias.

Ventral Hernia

Occasionally, trauma or extreme abdominal distention leads to rupture of the ventral abdominal muscles caudal to the umbilicus, as described in sheep (Arthur et al. 1989). This results in edematous swelling of the abdominal wall and dropping of the udder. Successful surgical repair has been reported in a goat (Misk et al. 1986). The late pregnant uterus can become trapped in the hernia in a subcutaneous location, making vaginal delivery difficult (Horenstein and Elias 1987). Successful surgical correction of such a "metrocele" at four months gestation has been reported (Radhakrishnan et al. 1993).

Ventral Edema of Angoras

Angora goats in South Africa, the United States, New Zealand, and England have developed severe edematous swelling ("swelling disease" or "water belly") of the ventral abdomen and chest and sometimes the limbs and submandibular region after shearing or other stress (Mitchell et al. 1983; Byrne 1994a, 1994b; Thompson 1994). As many as 15% of the herd may be affected. The swelling consists of clear, copious, nonclotting fluid and disappears spontaneously in a

few days. Possible etiologies discussed in the literature include hypoproteinemia and change in capillary permeability, stress (via increased aldosterone secretion and sodium retention), and vitamin E deficiency. Research attempting to recreate the condition with parasitic infections or modify it with increased dietary protein has been inconclusive, but in general the smaller goats with lower plasma total protein concentrations are at higher risk (Snyman and Snyman 2005).

Hypoalbuminemia due to parasitism or paratuberculosis and edema caused by congestive heart failure must be ruled out in individual animals that do not recover rapidly. If sudden deaths occur in the herd, vitamin E status should be investigated (Byrne 1994a). Otherwise, no treatment is indicated except provision of feed and shelter for newly shorn animals.

Urethral Rupture

Bucks and wethers with urolithiasis may develop a ventral swelling (water belly) if the urethra ruptures and urine leaks into subcutaneous tissues. The swelling is edematous and cool; aspiration yields a watery fluid that may have an ammoniacal odor when heated. The fluid can be reabsorbed if the obstruction to normal urine flow is relieved. Localized skin sloughing may occur. Urolithiasis and its treatment are discussed in detail in Chapter 12.

Gangrenous Mastitis

The skin of the ventral abdomen anterior to the udder may become swollen and edematous because of vascular thrombosis in goats with gangrenous mastitis. Initially the swelling is cool; necrosis and sloughing may eventually occur. Gangrenous mastitis is discussed in Chapter 14.

Ectopic Mammary Gland

The embryonic mammary line of mammals extends from the pectoral region to the vulva. Although female goats usually develop only two functional glands in an inguinal location, milk-secreting tissue is occasionally located bilaterally in the lips of the vulva (Lesbouyries and Drieux 1945; Kulkarni and Marudwar 1972; Ramadan and El Hassan 1975; Smith 1986). As parturition approaches, the vulva enlarges, as does the udder. This vulvar swelling is firm and lobular (Figure 3.12), is separated from the skin, and does not subside promptly after parturition as physiologic edema would. Instead, the vulva remains distended for as long as three months, but eventually subsides as the glandular tissue becomes atrophied from the back-pressure of entrapped milk. The condition is merely a curiosity but can be confirmed by aspiration of a whitish fluid containing fat globules. The bilaterally symmetrical nature of the swelling also helps to dif-
Fig. 3.12. Ectopic mammary gland distending the vulva of a mature Saanen doe one day after parturition. The doe also has a retained placenta. (Courtesy of Dr. M.C. Smith.)

ferentiate ectopic mammary gland from an adenocarcinoma or other neoplasm (see Chapter 2).

Mammary gland development in the buck (gynecomastia) is discussed in Chapter 13.

Musculoskeletal System

Maintenance of musculoskeletal health is critical to the general well being of goats. Under extensive management systems, normal ambulation is essential for efficient and adequate food gathering and flight from predators. Agility and limb strength are especially important in hilly, rocky environments and during periods of food scarcity when goats will actually climb into trees to obtain feed. Successful breeding performance for male goats depends on sturdy, pain-free hind limbs for efficient mounting of does. For milking does, incorrect hind limb conformation and overgrown hooves can adversely affect udder health, and skeletal conformation is considered an important trait in linear appraisal systems for evaluating dairy goats.

This chapter presents clinically important background information relating to the musculoskeletal system, the differential diagnosis of musculoskeletal diseases on the basis of presenting sign, and detailed discussion of the primary diseases affecting the muscles, bones, and joints of goats. The reader is referred to Chapter 19 for additional background information on requirements and use of specific nutrients affecting bone and muscle health.

BACKGROUND INFORMATION OF CLINICAL IMPORTANCE

Anatomy and Physiology

A detailed review of the musculoskeletal anatomy of the goat is beyond the scope of this text and the information is available from other sources (Chatelain 1987; Constantinescu 2001; Popesko 2008). A representation of the caprine skeleton is given in Figure 4.1 and topographic muscular anatomy of the goat in Figure 4.2.
Figure 4.1. Normal Skeletal Variations

Goats commonly have numerical variation in vertebrae. The normal vertebral formula is seven cervical, thirteen thoracic, six lumbar, five sacral, and seven to twelve coccygeal vertebrae. One survey of 185 goats revealed that 24% had numerical variation of vertebrae or the presence of structurally transitional vertebrae (Simoens et al. 1983). Common variations include twelve thoracic, five lumbar, and four or six sacral vertebrae. These variations are rarely, if ever, associated with clinical disease.

An extra sesamoid bone is infrequently found at the lateral head of the gastrocnemius muscle (Rajtova 1974). Floating ribs, with no connection to the costal arch, also occur infrequently (Hentschke 1980).

Bone Growth

There are several reports on epiphyseal closure times in growing goats (Dhingra and Tyagi 1970; Rajtova 1974; Ho 1975; Dhingra et al. 1978). The findings are widely disparate for numerous epiphyses; the reasons for these disparities are unclear. In the most recent study in Korean native goats, the distal humeral

epiphysis fused at eight to twelve months; proximal radial epiphysis and distal tibial epiphysis fused at one year; and proximal and distal epiphyses of ulna and femur, proximal epiphyses of humerus and tibia, and distal epiphysis of radius fused at one year or later (Choi et al. 2006). Sexual dimorphism occurs in caprine bone growth. Males have longer and wider bones and later closure of epiphyses than females (Rajtova 1974).

The Parathyroid Glands

The parathyroid glands play an important role in the development and maintenance of normal bone through the action of parathyroid hormone on calcium and phosphorus metabolism (Hove 1981; Care and Hove 1982). Histologic evaluation of the glands can be a valuable aid in the diagnosis of metabolic bone disease. These glands may be difficult to locate in the goat because of small size and variable relationship to other tissues. There are usually two pairs, though accessory parathyroid tissue can occur.

The anterior pair are usually located deep in the anterior portion of the neck at the bifurcation of the

common carotid artery. In the young goat, thymus is present at this site and the parathyroid gland may be recognized as a small reddish brown mass about 5 mm in diameter at the cranial pole of the thymus. Thymic tissue is atrophied in older goats, and the external parathyroid gland may be found caudal to the bifurcation of the common carotid artery. The posterior pair are usually located within the paired thyroid glands, most often in the middle portion on the medial aspect of the thyroid. The parathyroid tissue may be isolated in a distinct connective tissue capsule or mingled with thyroid tissue.

Conformation

There is increasing application of linear appraisal systems to generate sire summary information for the genetic improvement of dairy goats in breeding programs. The linear appraisal system is modeled after that used in dairy cattle and attempts to define a structural conformation consistent with functional durability as well as reproductive and productive efficiency. Type traits related to conformation that are included in linear appraisals are stature, rump angle, rump width, and rear legs (Wiggans and Hubbard 2001).

Skeletal conformation is also a significant component of dairy goat judging. Feet and legs are distinct structural categories subject to scoring. Recognized defects that reduce an animal's score include excessive spreading of the toes, shallow heels, turning out of the front feet or legs, rolled or turned-over claws, weak pasterns, winged-out shoulders or elbows, bowed or crooked forelimbs, straight stifles, rear limbs too

close together (impinging on udder), turned-in hocks, and enlarged joints (Considine and Trimberger 1978). The selection and judging of meat goats also includes skeletal and conformational criteria (Martinez et al. 1991).

Clinical Pathology

The most commonly used clinical chemical parameters for assessment of bone in health and disease are serum alkaline phosphatase (AP), calcium, and inorganic phosphorus. Variations in these parameters associated with different metabolic and nutritional bone diseases of goats are summarized in Table 4.1. Serum vitamin D and magnesium levels are less frequently evaluated. For evidence of muscle damage, serum activities of creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase are most commonly measured. Reported values for these parameters in goats are given in Table 4.2. As discussed later, variation may occur with regard to age, breed, sex, and stage of production or pregnancy status.

Alkaline Phosphatase

In goats, as in other species, serum AP is higher in young animals compared with adults due to AP activity associated with the increased osteoblast function of growing bone (Castro et al. 1977; Sugano et al. 1980; Bogin et al. 1981). In healthy adults, most of the serum AP present is derived from liver, particularly bile duct epithelium. Tissue enzyme profiles in goats demonstrate that AP activity is fifty to one hundred times greater in kidney than in liver (Kramer and Carthew 1985). However, in renal disease, AP from tubular epithelium is released into the urine rather than the blood. There are now immunoassays available for measurement of bone-specific alkaline phosphatase that were developed for use in humans, validated in sheep, and successfully applied to goats (Liesgang et al. 2006).

There is considerable variation in serum AP activity between individual goats even within the same age group, resulting in a very wide range of reported normal values. In any individual healthy goat, however, serum AP levels usually remain constant (Kramer and Carthew 1985). More recently, measuring bone-specific alkaline phosphatase in Saanen does, it was shown that serum concentrations dropped progressively through pregnancy and reached their lowest point in the week following parturition. This reflects remodeling and calcium release from bone in response to skeletal demands of the fetus and early lactation (Liesegang et al. 2006, 2007). There is evidence that high and low AP enzyme levels in goats are heritable with the high level being genetically dominant (Lode 1970). Therefore, detection of a single high serum AP value in an individual goat may be difficult to interpret clinically. Increases in serum AP on serial samples within the same goat are a more reliable indication of bone or liver disease.

Calcium

The reported range of normal serum calcium in goats is fairly narrow. Nevertheless, within that range, significant differences have been noted with regard to age, breed, pregnancy status, and lactation status. Young goats tend to have higher serum calcium than mature goats (Bogin et al. 1981; Ridoux et al. 1981). In a French study, Saanen goats had higher mean serum calcium levels than Alpine goats (Ridoux et al. 1981). Mean serum calcium was significantly higher in black

Table 4.1. Clinical pathological changes associated with metabolic bone and muscle diseases in goats.

Disease	Serum alkaline phosphatase	Serum calcium	Serum phosphorus	Other changes
Rickets	Increased	Decreased	Decreased	Decreased serum vitamin D levels may also occur
Epiphysitis	Normal	Normal	Normal	Excessive calcium in ration likely
Fibrous osteodystrophy	Increased	Normal or decreased	Normal or increased	Excessive phosphorus in ration likely
Chronic fluorosis	Normal or increased	Normal or decreased	Normal or increased	Increased fluoride levels in bone
Enzootic calcinosis	Increased	Increased	Increased	Calcification of soft tissues
Hypervitaminosis D	Highly variable	Increased	Increased	Increased serum vitamin D_3 levels

Table 4.2. Some normal values for bone- and muscle-related enzymes and electrolytes in goat serum.

Parameter	Unit	Goat description	Mean	± SD	Range	Reference

M = male; F = female; SD = standard deviation

Bengal goats during pregnancy than during lactation. Levels were higher in early pregnancy than in late pregnancy but higher in late lactation than in early lactation (Uddin and Ahmed 1984).

Phosphorus

The range of inorganic phosphorus concentrations found in the serum of normal goats is often wider than calcium. Serum phosphorus levels are significantly higher in young animals than in mature animals (Boss and Wanner 1977; Bogin et al. 1981; Ridoux et al. 1981). The calcium-to-phosphorus ratio also is altered with age, reported as 1.1 in goats three to four months of age and 1.37 in goats two to five years of age (Bogin et al. 1981).

Breed differences have also been noted between Saanens and Alpines, with a lower mean serum phosphorus in the Saanen breed. Serum phosphorus concentration may be significantly higher during pregnancy than during lactation, but does not vary during different stages of pregnancy or lactation in contrast to calcium (Uddin and Ahmed 1984).

Magnesium

Serum magnesium levels have received less scrutiny in the goat than in other species. No variations of serum magnesium levels were noted as a function of age in goats three to four months of age compared with goats two to five years of age (Bogin et al. 1981). Similarly, no differences were noted in Saanen kids whose magnesium levels were measured every twenty days up to eight months of age. The mean serum magnesium ranged from 2.23 to 2.49 mg/dl (Boss and Wanner 1977).

Vitamin D

There is little published information on normal caprine serum or plasma levels of vitamin D and its metabolites in health or disease. Studies of vitamin D metabolism suggest that the conversion of vitamin D_3 to 25-(OH)D_3 is limited in goats compared with other farm animal species (Hines et al. 1986).

One comparative study of sheep, camels, and Sinai desert goats kept in direct sunlight in summer showed the goats to have lower mean plasma levels of 25-(OH)D_3 than either of the other species; 23.9 ± 5.7 ng/ml versus 40.7 ± 9.1 ng/ml for sheep and 443 ± 96 ng/ml for camels (Shany et al. 1978). Studies on the effects of pregnancy and lactation on bone metabolism in goats indicate that serum 1,25 dihydroxy Vitamin D levels peak in the first week of lactation under the influence of parathyroid hormone to stimulate active calcium transport in the intestine to help restore the serum calcium pool in the face of lactational demand (Liesegang et al. 2006). Serum vitamin D levels return to prepartum levels by one month post partum.

Creatine Kinase

Enzyme activity of creatine kinase (CK) in tissues other than cardiac and skeletal muscle is minimal in the goat, making CK the most reliable indicator of muscle damage (Kramer and Carthew 1985). Age differences have been observed in serum CK levels, with young, growing goats having higher concentrations than older goats (Sugano et al. 1980). Enzyme activity within muscle itself also decreases with age (Braun et al. 1987). No significant differences were observed in serum CK levels of adult female goats measured two weeks prepartum, three weeks post partum, and two months into lactation (Garnier et al. 1984).

The reported range of normal serum CK in goats is fairly narrow, yet the potential for elevation is enormous in the face of widespread muscle necrosis. Mild, nonpathologic increases in serum CK may be noted due to low level muscle damage after transport, fighting, poor venipuncture technique, or intramuscular injections, while in acute nutritional muscular dystrophy, serum CK levels may easily increase a hundredfold or more.

Aspartate Aminotransferase

Aspartate aminotransferase (AST) is found in muscle and is increased in the blood when myodystrophy occurs. It is less specific for muscle damage than CK, however, because it also occurs in high concentration in the livers of goats (Kramer and Carthew 1985). When evaluated alone, AST cannot be used to discriminate between muscle and liver disease.

Lactate Dehydrogenase

Serum lactate dehydrogenase (LDH) is a collection of LDH isoenzymes derived from a variety of tissues including liver and muscle. It is also present in high concentration in red blood cells, so hemolysis during handling of blood samples can artificially elevate serum LDH. It is not as reliable an indicator of muscle damage as is CK. Evaluation of isoenzymes of LDH would enhance the specificity for muscle, liver, and other tissue forms but this analysis is not routinely performed. The relative proportions of LDH isoenzymes in the serum of normal goats are LDH-1, 29% to 51%; LDH-2, 0% to 5%; LDH-3, 24% to 40%; LDH-4, 0% to 6%; and LDH-5, 14% to 36% (Brooks et al. 1984). Proportional increases in serum levels of LDH-3, LDH-4, and especially LDH-5 are indicative of skeletal muscle damage. An increase in LDH-5 was also noted in normal, healthy goat kids between birth and three weeks of age (Sobiech et al. 2005).

There is conflicting data on whether significant differences in serum LDH levels occur in relation to age (Castro et al. 1977; Bogin et al. 1981; Varshney et al. 1982). In adult females, the range of serum LDH levels

may be higher during lactation than during pregnancy (Garnier et al. 1984). Females have significantly higher serum LDH levels than males (Castro et al. 1977). Normal serum LDH levels are generally lower in goats than in cattle or sheep. The LDH activity in muscle itself is significantly decreased in adult goats compared with kids (Braun et al. 1987).

Diagnostic Procedures

Imaging Techniques

Plain radiography can be extremely helpful in the diagnosis of skeletal disorders. The convenient size and relative cooperativeness of goats makes radiography a realistic option in caprine medicine. When necessary, goats can be sedated with xylazine or other sedatives to facilitate radiographic procedures. If sedated goats are made recumbent for radiographic procedures, care must be taken to avoid bloat and/or regurgitation. When possible, the animal should be fasted for twelve hours before sedation, the head placed lower than the body to facilitate drainage of ingesta out the mouth, and the left side should be dorsal to facilitate access to the rumen in case of bloat. Procedures for sedation are discussed in Chapter 17.

Reports of special radiographic procedures related to the caprine locomotor system are limited. Angiography of the caprine digit has been described (Burns and Cornell 1981). Bone scans using nuclear scintigraphy can help to identify localized areas of inflammation in the skeleton. Radiopharmaceuticals, however, are not approved for use in animals intended for the human food supply, so application may be limited to pet goats. The procedure has been done in goats using intravenous injection of 99m-technetium pyrophosphate followed by scanning three hours later with a rectilinear scanner (Milhaud et al. 1980). Good definition of ribs, joints, kidneys, and cervical vertebrae was achieved, while excessive accumulation of technetium in the urinary bladder interfered with visualization of the bony pelvis. Scintigraphy has been used in goats to quantitate the severity of joint inflammation in caprine arthritis encephalitis and has been found to correlate well with histopathological grading (Papageorges et al. 1991). Radiolabelled ^{99m}Tc-ciprofloxacin scintigraphy was also applied in the work-up of a case of acute hind limb paresis in a three-week-old goat that demonstrated suppurative vertebral osteomyelitis and diskospondylitis at necropsy (Alexander et al. 2005).

Electromyography

Normal electromyographic (EMG) responses of calves, sheep, and goats have been compared. Average action potentials of the superficial digital flexor muscle were 8.1 ms in the goat, 8.2 ms in the sheep, and 10.5 ms in the calf. The average peak potentials were 6.3 ms in the goat, 5.7 ms in the sheep, and 4.8 ms in the calf. Average amplitudes of the potentials were 322 uV in the goat, 253 uV in the sheep, and 337 uV in the calf. The proportion of biphasic and triphasic potentials was 93% in the goat, 92% in the sheep, and 85% in the calf (Mielke et al. 1981).

The EMG response can be used in the diagnosis of goats with myotonia congenita. Other applications of the EMG reported in goats include the diagnosis of ruminal adhesions to the abdominal wall (Cheong et al. 1987) and the identification of skeletal muscle denervation in swayback (Wouda et al. 1986).

Arthrocentesis and Synovial Fluid Analysis

Arthrocentesis and synovial fluid analysis can aid in the differential diagnosis of arthropathy. Strict asepsis should be observed during arthrocentesis. A 1.5-inch (3.8 cm) 18- or 20-gauge needle can be used to obtain fluid. Sedation facilitates the procedure.

The carpal joints are most often enlarged in goats with joint problems. The radiocarpal joint is distinct, while the midcarpal and carpometacarpal joints communicate. Access to these joints is improved when the carpus is flexed to a 90-degree angle. The extensor carpi radialis tendon running centrally over the anterior aspect of the carpus should be identified as a landmark. This may be complicated by the common occurrence of thick skin, callus, or hygroma on the carpi of goats. The radiocarpal joint is entered just lateral to the lateral edge of the extensor carpi radialis tendon, while the more distal midcarpal joint is entered medial to the medial edge of this tendon. The carpometacarpal joint is not accessible directly (Sack and Cottrell 1984).

The shoulder joint is approached laterally. The acromion and the notch in the proximal border of the greater tubercle of the humerus are used as landmarks. The needle is inserted into the joint distal to the midpoint between the two landmarks with the tip of the needle directed medial to the greater tubercle (Sack and Cottrell 1984).

The elbow joint is approached from the lateral aspect. The two landmarks are the lateral epicondylar crest of the humerus and the cranial border of the olecranon that together form an angle that points distally. The needle is inserted into the angle and directed mediodistally and slightly cranially into the olecranon fossa (Sack and Cottrell 1984). For aspiration of joint fluid from the stifle, the joint can be approached from the proximo-lateral side between the patella and the lateral patellar trochlea (Rørvik 1995). Approaches to other joints have not been described specifically in goats, but techniques described in cattle are generally suitable (Greenough et al. 1981).

Normal caprine synovial fluid should be clear and colorless to slightly yellow, free of particulate debris, and should not clot. Mean total protein has been reported as 1.84 ± 0.22 g/dl (Nayak and Bhowmik 1990). Total cell counts should be less than $500/mm^3$ (Crawford and Adams 1981). Monocytes and lymphocytes should predominate in normal synovial fluid and neutrophils should not exceed 10% of the total cell count. Abnormalities in synovial fluid reported in various caprine diseases are discussed throughout the chapter.

Muscle and Bone Biopsy

No special concerns have been identified for performance of muscle or bone biopsies in goats. The rib is commonly used for biopsy in the diagnosis of metabolic and nutritional bone disease. The costochondral junction is especially useful when rickets is suspected.

Regional Anesthesia

Intravenous regional anesthesia can be used successfully in goats to perform minor or major surgical operations on the distal forelimbs or hind limbs, including amputations (Babalola and Oke 1983). This procedure is described in Chapter 17.

Foot Trimming

Therapeutic and prophylactic foot trimming are important procedures in goats. Aggressive paring of the foot promotes healing in cases of foot rot, foot abscesses, and puncture wounds by allowing aeration and drainage of affected tissues. Corrective trimming also promotes normal comfort and conformation in cases of chronic laminitis.

Prophylactic trimming is required to maintain normal hoof structure and provide a strong base for support of the limbs. Overgrowth of the feet is particularly a problem in intensively managed goats, where normal wearing of the hoof associated with exercise is limited (Figure 4.3). Overgrown feet cause abnormal gait and undue stress on joints, tendons, and ligaments. Goats in confinement should have their feet trimmed a minimum of twice a year.

Pointed hoof shears or a hoof knife is appropriate equipment. Unlike sheep, goats resist being tipped on their rumps for foot trimming. The feet are simply lifted for trimming with the animal in a standing position. Large bucks and squirmy kids are often easier to trim if restrained in lateral recumbency by a knee placed on the neck. The basic steps of foot trimming are illustrated in Figure 4.4. They include removal of hoof wall that has overgrown the sole, shortening of the toe, and leveling of the sole and heel.

In the properly trimmed foot, the coronary band should be parallel to the weight bearing surfaces of the claws. Excessive shortening of the toe by trimming will

Figure 4.3. Severely neglected, overgrown foot of a goat. Such excessive growth is caused by continuous confinement and lack of exercise. (Reproduced by permission of Dr. C.S.F. Williams.)

cause the animal to "break forward" at the fetlock, while inadequate trimming of the toe causes the animal to rock backwards on the foot, reducing contact between the anterior sole and the ground, thus causing undue stretching of the flexor tendons.

DIAGNOSIS OF MUSCULOSKELETAL DISEASE BY PRESENTING SIGNS

This section is a guide to the differential diagnosis of musculoskeletal problems and attempts to include all possible diagnoses independent of geographic occurrence or relative incidence. Such information is included in subsequent discussions of the specific diseases later in the chapter or elsewhere in the text.

Abnormally Appearing or Sore Feet

Infectious causes of abnormally appearing or sore feet include foot scald, foot rot, foot abscess, foot and mouth disease, bluetongue, and dermatophilosis. In foot and mouth disease and bluetongue, which are most often subclinical in goats, oral lesions may be seen in conjunction with hoof lesions. Dermatophilosis, or mycotic dermatitis, can affect the feet and distal limbs as well as other areas of skin. This is also true of mange mite infestations, particularly chorioptic mange.

Metabolic and nutritional causes include zinc deficiency and laminitis. In zinc deficiency, hoof lesions are seen along with dermatitis. Acute and chronic forms of laminitis occur. In acute laminitis feet are predominantly sore and hot, while in chronic laminitis they are malformed and overgrown.

Chronic selenosis is the only reported toxic cause of abnormally appearing feet. Traumatic causes include overgrown hooves secondary to inadequate trimming, foreign bodies such as stones or wood chips lodged

between the claws, bruising of the sole, and puncture wounds of the foot, especially those that lead to foot abscesses.

Swelling Around the Joints

Swollen joints usually imply arthritis. It is important to differentiate in the goat between true arthritides and periarticular or superficial swellings. Goats maintained in confinement, particularly on hard surfaces, develop a marked thickening of the skin, particularly over the carpi, hocks, and sternum, which can make the joint itself appear swollen. Goats are also prone to carpal hygromas. These are soft, fluctuant, periarticular swellings on the anterior aspect of the carpi. However, filling of the carpal bursa is also an early sign of arthritis caused by caprine arthritis encephalitis (CAE) virus infection and this must be differentiated from an uncomplicated hygroma.

Infectious causes of arthritis include the CAE virus, various *Mycoplasma* spp., and a variety of bacterial agents. Polyarthritis in neonates or young goats is usually bacterial or mycoplasmal in origin. Chlamydial arthritis is a well known cause of arthritis in sheep, but documentation of chlamydial arthritis in goats is lacking (Nietfeld 2001) despite the fact that it is sometimes cited as a cause of arthritis in the species. Similarly, erysipelothritic polyarthritis caused by *Erysipelothrix rhusiopathiae* is a well known endemic problem in young lambs, but its suggested occurrence in goats is poorly documented.

Nutritional and metabolic causes of swollen joints include rickets and so-called nutritional arthritis or osteopetrosis. Rickets is actually an enlargement or distortion of the improperly calcified epiphyses adjacent to a seemingly swollen joint. Nutritional arthritis, secondary to excessive calcium feeding, is reported primarily in bucks of dairy breeds.

Traumatic injury to the joints is common in goats because of their propensity to fight and to climb and explore. Swellings may occur secondary to avulsions of tendons and ligaments, dislocations, and hemarthrosis. Does in advanced pregnancy sometimes develop edematous swellings around and above the coronary bands, particularly on the hind limbs. This is presumably because of circulatory compromise and usually resolves with parturition. However, it may also be associated with pregnancy toxemia, as discussed in Chapter 19.

Degenerative osteoarthritis may be seen, especially in very old goats, or in goats with poor conformational characteristics, such as excessive straight-leggedness in the hind limb.

Stiff, Painful, or Abnormal Gait

Abnormalities of gait can be caused by neurologic dysfunction or musculoskeletal diseases. The differen-

tial diagnoses for neurologic causes of gait abnormality are given in Chapter 5. While most neurologic diseases cause some degree of paresis or ataxia, tetanus is noteworthy in producing a stilted, stiff gait, which suggests musculoskeletal pain. This is also true in the case of spastic paresis, a neurogenic disease that causes intermittent stiffening of the hind limbs. Similarly, peritonitis, pleuritis, or mastitis may cause sufficient pain on motion that affected animals show a guarded, stilted gait.

Regarding primary musculoskeletal diseases, any of the causes of painful feet or swollen joints identified above can contribute to development of a stiff, abnormal, or painful gait. Additional causes of muscle origin include nutritional muscular dystrophy in its early or mild stages, parasitic myositis involving tapeworm cysts of the muscle, and myotonia congenita, in which a stiff gait is intermittent and may be preceded by a generalized muscular contraction, causing the goat to fall down as seen in so-called "fainting goats." Enzootic calcinosis caused by ingestion of *Trisetum flavescens* or yellow oat grass can cause calcification of tendons and ligaments with a resulting painful gait.

Additional causes of skeletal origin include fibrous osteodystrophy associated with excessive phosphorus in the diet, and chronic fluorosis leading to abnormal bone growth and apparent bone pain. Copper deficiency in kids causes a primarily neurologic disease known as swayback or enzootic ataxia. However, affected kids may also have bone pain associated with abnormal osteogenesis and subsequent bone fragility.

Failure to Extend a Limb or Limbs

The differential diagnosis for failure to extend a limb or limbs varies markedly with the age of the affected animal. In newborn goats, arthrogryposis or persistent flexure of joints may be caused by congenital Akabane disease, inherited beta-mannosidosis in goats of the Nubian breed, possible congenital lupinosis, or contracted tendons associated with positional constraints *in utero* during fetal growth. An inherited tendon shortening also occurs in Australian Angora goats. In older kids, enzootic ataxia sometimes is accompanied by flexor contracture of the forelimbs.

In mature animals, ankylosis of joints in a flexed position is a common outcome of chronic CAE virus arthritis. The carpi are most often affected. However, any traumatic or infectious cause of arthritis may result in a reduced range of motion when chronic in nature. Dislocations or luxations may also cause pain on extension of joints, with animals favoring a flexed position.

When goats are recumbent from any cause, tendon contracture occurs rapidly. Initiation of regular physical therapy to manually straighten the front limbs is advisable if goats are expected to be recumbent more than twenty-four hours.

Non-weightbearing on a Single Limb

This refers to animals that are able to extend the affected limb, but are unwilling to bear weight on it. Differential diagnoses include fractures, dislocations, severe arthritis involving a single joint, puncture wounds of the foot, severe foot rot, foot scald, or foot abscesses. Fractures may be primarily traumatic in origin or may be predisposed by increased bone fragility such as occurs in rickets, fibrous osteodystrophy, copper deficiency, and chronic fluorosis. Osteomyelitis may also predispose to fracture or cause sufficient pain to result in non-weightbearing.

Bowed Limbs

Bowing of the forelimbs is seen primarily in metabolic bone diseases. Known causes include epiphysitis, rickets, and a condition known as bowie, or bentleg, associated with phosphorus deficiency. Bowing of the hind limbs may occur in zinc-deficient goats. Poor conformation in individual goats with weak attachments of the shoulder assembly may lead to winged out elbows and the appearance of bowed limbs.

Conditions Restricted to a Forelimb

Luxation of the scapulohumeral joint may be common in goats. One veterinary referral center reported on five cases seen over a twenty-six-month period. The affected limb is carried in a semiflexed position and abducted and rotated outward, with apparent pain on attempts at extension. The condition is successfully managed by surgical intervention to stabilize the joint (Purohit et al. 1985).

Carpal hygromas are common in goats maintained on rough, hard flooring. They must be differentiated from other causes of carpal swelling as discussed above in the section on swollen joints.

Conditions Restricted to a Hind Limb

Lateral luxation of the patella occurs in goats and is believed to be congenital, associated with hypoplasia of the lateral trochlear ridge. Progressive lameness occurs and the laterally displaced patella is palpable along with crepitus. Affected goats keep the stifle and hock flexed, because extension of the limb is difficult and painful when the patella is displaced. Successful surgical correction may be accomplished via trochlear sulcoplasty and desmotomy (Baron 1987).

Rupture of the gastrocnemius muscle belly above the tendon can occur in goats as in cattle, producing a palpable swelling on the caudal aspect of the hind limb above the hock and a characteristic hind limb position where the hock remains on the ground while the animal is standing (Figure 4.5). A similar stance was reported in a goat with a ruptured calcaneal tendon secondary to dog bite (Hunt et al. 1991). This case was successfully treated by tranposition of the tendon of the peroneus longus muscle.
Figure 4.5. Typical stance of goat with ruptured gastrocnemius muscle. Note that the hock is resting on the ground while the animal is standing. (Courtesy of Educational Media, Cummings School of Veterinary Medicine at Tufts University, Mr. David Wilman, photographer.)

Spastic paresis, a progressive neurological disorder, manifests as intermittent episodes of muscular rigidity in the gastrocnemius muscle and hyperextension of one or both hind limbs. Affected goats may actually lift their hind ends off the ground during active episodes and walk only on the forelimbs if both hind limbs are affected simultaneously. The condition occurs in several breeds of cattle and is generally considered to be a genetic disorder with a complex manner of inheritance (Scarratt 2004). The condition is uncommon in goats and it is unclear if it also represents a genetic disorder in this species. In cattle, surgical treatments include tibial neurectomy or gastrocnemius tenotomy but there are no reports of treatment in goats.

Weakness and Recumbency

This clinical presentation encompasses a broad range of differential diagnoses, as weakness and recumbency can occur in a variety of neurologic and systemic diseases. Only primary muscle and skeletal problems are listed here.

Muscular diseases associated with weakness and recumbency include clostridial myositis, nutritional muscular dystrophy, ingestion of myodegenerative plants such as *Cassia roemeriana* or *Karwinskia humboldtiana*, and milk fever or hypocalcemia, a metabolic disease discussed in Chapter 19. Myotonia congenita can cause affected goats to be recumbent, but the effect lasts only approximately one minute.

Myasthenia gravis, a cause of profound muscle weakness in humans and dogs, has been reported in one veterinary text as occurring in the goat, but no primary reference is cited (Fraser 1986). A published review of this disease does not identify myasthenia gravis as a naturally occurring disease in goats (Lindstrom 1979) and a search of the literature as recently as 2007 produced no case reports in goats. However, myasthenia gravis has been produced experimentally using goats as an animal model by the induction of auto-antibodies to acetylcholine receptors. These antibodies block neuromuscular transmission (Lindstrom 1976).

Arthritis can be sufficiently painful to inhibit ambulation. Acute mycoplasma arthritis is especially associated with recumbency in goats. Severe hoof diseases, such as foot rot, chronic selenosis, and laminitis, can also keep goats recumbent.

Bone abnormalities can produce recumbency either through bone pain or secondary fracture. Metabolic bone diseases associated with recumbency include rickets and fibrous osteodystrophy. Traumatic fractures, especially those of the vertebral canal, must also be considered in goats unwilling to rise. Osteomyelitis can also predispose to fracture and recumbency, especially if involving the vertebrae.

SPECIFIC DISEASES OF THE MUSCULOSKELETAL SYSTEM

VIRAL DISEASES

Caprine Arthritis Encephalitis

First recognized in the early 1970s, caprine arthritis encephalitis (CAE) has emerged as a significant and costly disease of goats. Goats exposed to the causative lentivirus may remain subclinically infected or develop one or more of several clinical syndromes, which include arthritis, progressive paresis or other neurologic dysfunction, an induration of the udder with hypogalactia, chronic interstitial pneumonia, or progressive weight loss. Arthritis is the most common clinical presentation and is discussed here.

Etiology

The CAE virus is an enveloped, single-stranded RNA virus in the lentivirus genus of the family Retroviridae. Other lentiviruses, or slow viruses, include the maedi-visna (MV) virus of sheep, also known as the ovine progressive pneumonia or OPP virus, the equine infectious anemia virus, the bovine immunodeficiency virus, the feline immunodeficiency virus, the simian immunodeficiency virus, and types 1 and 2 of the human immunodeficiency virus (HIV) associated with acquired immunodeficiency syndrome (AIDS). Historically, CAE and MV viruses were considered to be similar but distinct viruses with strong host species predilection for goats and sheep respectively. However, recent phylogenetic studies indicate that these distinctions do not hold strongly, that genetic recombination occurs, and that there is evidence for cross species transmission. The two viruses are now classified together in the small ruminant lentivirus (SRLV) serogroup. The phylogenetic basis for this revision and its diagnostic and epidemiologic significance are discussed in more detail in the CAE-MV section of Chapter 5.

These are cell-associated viruses characterized by the presence of a magnesium-dependent, RNA-dependent DNA polymerase, or reverse transcriptase, which permits the production of proviral DNA from the viral RNA genome using the host cell machinery (Cheevers and McGuire 1988). Typical of lentiviruses in general, CAE virus infection is considered to be lifelong, and serum antibodies to the virus, if not of colostral origin, are considered synonymous with infection.

The CAE viral genome consists of three essential retroviral genes—*gag*, *pol*, and *env*—as well as the regulatory/accessory genes—*tat*, *rev*, and *vif*. The genome produces five structural proteins and four nonstructural proteins. The *env* gene encodes for the envelope glycoprotein gp135 or surface (SU) protein and the transmembrane protein. Antigenic variation in the

SU protein occurs as a result of *env* mutation and is responsible for the biological and serological variation of CAE virus isolates (Concha-Bermejillo 2003). The *pol* gene encodes for the viral enzymes reverse transcriptase, protease, endonuclease/integrase, and dUTPase involved in transcription and protein synthesis during viral replication. The molecular biology of CAE virus and other animal lentiviruses has been reviewed (Clements and Zink 1996).

The CAE virus can be identified from live animals *in vitro* by co-cultivation of concentrated leukocyte preparations derived from blood, milk, or synovial fluid with goat synovial membrane in cell culture. At necropsy, suspect tissues from joint, lung, or udder can be cultivated directly in tissue culture flasks and examined for cytopathic effect (CPE), which is manifested as development of refractile stellate cells and syncytia formation. When CPE is seen, presence of virus should be confirmed by immunolabelling or electron microscopy (OIE 2004). CAE virus is susceptible to heat, detergents, and formaldehyde.

Epidemiology

The neurologic form of CAE was the first to be described in the United States, in 1974 (Cork et al. 1974). The causative virus was first isolated from a case of arthritis in 1980 and the relationship of the two forms of the disease was recognized at that time (Crawford et al. 1980). The initial name of the disease, viral leukoencephalomyelitis of goats, was gradually replaced by the currently applied name, caprine arthritis encephalitis.

A global serologic survey reported in 1984 provided much initial information about the distribution of CAE virus in goats (Adams et al. 1984). The highest prevalence occurs in countries with long established, intensive goat dairying industries, namely Canada, France, Norway, Switzerland, and the United States. The seroprevalence exceeded 65% in all of these countries. In countries actively importing dairy goats, such as Kenya, Mexico, New Zealand, and Peru, the overall prevalence of CAE infection was often less than 10%. However, it was highest in imported dairy goats, next highest in local goats in contact with imported goats, and least prevalent or nonexistent in goats not having contact with imported goats. Indigenous African goat breeds tested in Somalia, Sudan, and South Africa were free of infection. The same pattern of prevalence in imported, contact, and indigenous goats was reported from Jamaica (Grant et al. 1988) and from Algeria (Achour et al. 1994).

In twenty-four states of the United States, 81% of 1,160 goats tested were positive for CAE virus infection (Crawford and Adams 1981) while a subsequent, larger survey in twenty-eight states reported only 31% of individual goats positive but 73% of herds positive

(Cutlip et al. 1992). In Great Britain, 10.3% of herds tested and 4.3% of all goats tested were positive (Dawson and Wilesmith 1985). In New South Wales, Australia, 82% of 115 herds were infected. Among the five different dairy breeds tested, the prevalence varied from 26.8% to 43.4%, while the prevalence in Angora goats was only 4.8% (Grewal et al. 1986). In South Australia, prevalence in dairy goats tested over three years ranged from 18% to 45%, while the combined prevalence in Angora, Cashmere, crossbred, and feral goats was 0.1% (Surman et al. 1987). In most cases, Angora goats with serologic or clinical evidence of CAE infection have a history of contact with infected dairy goats. A New Zealand survey indicated a prevalence of 1.5%, with a distribution pattern associated with goats imported from Australia (MacDiarmid 1983).

Additional information continues to become available on the prevalence of CAE in different countries and regions. There are multiple reports from Europe. In Norway, fifty-one dairy goat herds distributed throughout the country were tested and 42% of animals and 86% of herds were positive (Nord et al. 1998). In Sweden, approximately 90% of the dairy goat herds, comprised mostly of the endangered native Swedish Landrace breed, were found to be infected with CAE (Lindqvist 1999). In Spain, where the disease was suspected but not yet confirmed, a survey of twenty-two dairy herds identified 77.3% of the herds and 12.1% of the individual goats tested as positive (Contreras et al. 1998). In Hungary, where 30% of goats tested were positive, the prevalence of infection was associated with purchase of breeding stock from farms that had imported purebred milking goats and an association was also made with large herd size (Kukovics et al. 2003). In a study from South Tyrol in Italy, 38% of herds and 23.6% of goats tested were positive, with goats older than twenty-six months having a significantly higher prevalence than younger goats. Goats born indoors had a significantly higher prevalence than those born outside, and dairy goats in commercial herds had a higher prevalence than dwarf goats kept as pets (Gufler et al. 2007).

In Latin America, Brazil has conducted numerous serosurveys of various size and design in different states and regions of the country. CAE is present in Brazil and, as in other places, is more common in imported or crossbred dairy goats than indigenous non-dairy breeds. One survey of dairy goat herds in Rio Grande Norte state revealed 57% of the herds with at least one positive goat (Souza e Silva et al. 2004). In Yucatan state of Mexico, seroprevalence was very low but all the animals identified as positive were exotic breed dairy goats which had been imported into the Yucatan (Torres-Acosta 2003).

From the Middle East, a Jordanian survey found that 23.2% of herds and 8.9% of goats sampled were

positive for CAE (Al-Qudah et al. 2006). In Asia, Japan was presumed to be free of CAE, but a serosurvey reported in 2006 indicated a seroprevalence of 21.9% in goats from around the country as well as clinical disease in native Japanese Shiba goats, including arthritis, mastitis, and pneumonia (Konishi et al. 2006). More recent reports from Africa are limited. South Africa is reported to be "relatively free" of CAE and maintains strict import regulations to minimize risk while Kenya is reported to have eradicated the disease (Werling and Langhans 2004).

CAE virus can be transmitted vertically and horizontally. The main route of vertical transmission is from dam to kid via ingestion of virus-contaminated colostrum and milk. The main route of horizontal transmission is by direct or close contact with infected animals. Sexual transmission, though possible, plays a limited role in the spread of CAE. Risk factors associated with the transmission of CAE have been reviewed (Rowe and East, 1997; Blacklaws et al. 2004). The strong association of CAE virus infection with intensively managed dairy goats is due largely to management practices that facilitate transmission of the virus from does to kids in the perinatal period as well as horizontally between adults (East et al. 1987, 1993; Greenwood et al. 1995).

In the perinatal period, the major mode of transmission of CAE virus to kids is by direct suckling of their own infected dam or by consuming pooled milk or colostrum from other infected does. Virus may be present in colostrum and milk as free virus or incorporated into somatic cells. Even subclinically infected does can shed virus into colostrum and milk. Because common methods of identifying infected goats, such as the agar gel immunodiffusion (AGID) test, can produce false-negative test results, all colostrum and milk derived from does in known-infected herds is potentially suspect as a source of virus unless heat-treated or pasteurized, as discussed later.

Additional potential sources for infection of kids in the perinatal period include *in utero* infection, exposure to virus in birth fluids during kidding, licking of the kid by the doe after birth, or possibly aerosol transmission between a coughing doe and her kid. Experimental evidence for the presence of CAE virus *in utero* or in saliva, birth fluids, or aerosols is limited compared to what is known about the virus in milk and colostrum. However, epidemiological observations with CAE in goats as well as experimental evidence of the transmission of the maedi-visna virus from ewes to lambs suggest that these routes of transmission are possible and that CAE control programs should take them into account in order to succeed (Rowe and East 1997; Blacklaws et al. 2004).

To date, there are still no definitively documented cases of *in utero* infection of kids with CAE, although there are several indications that this is a possible route of infection. Some cesarean-derived or vaginally delivered kids raised in isolation have seroconverted in the first few months of life (Adams et al. 1983; East et al. 1993). There is also a report of uterine lesions in a goat with the arthritic and pneumonic forms of CAE infection (Ali et al. 1987). More recently, using PCR techniques, CAE virus-infected cells were detected in the uterus and oviducts of CAE virus-infected goats (Fieni 2003).

It is now evident that horizontal transmission also plays a significant role in the spread of CAE. An early indication of this related to international trade in livestock when it was observed that local goats became infected, seroconverted, or even manifested clinical disease when imported, infected purebred dairy goats were placed in their midst in countries not previously recording the disease. Another strong indication of horizontal spread is the common finding in many studies that seroprevalence increases with age in infected herds. Some seroconversion in goats less than one year of age may result from neonatal infections with delayed humoral response. However, it is highly unlikely that the majority of adult seroconversions are due to this, as in naturally and experimentally infected kids, an antibody response is usually detectable between three and ten weeks following exposure, though delays of up to eight months and possibly longer for seroconversion have been reported (Rimstad 1993).

Additional evidence has come from studies examining the spread of infection in known infected herds, which indicates that direct contact was involved in horizontal transmission. A California study examined the prevalence of seropositive goats in herds attempting to reduce CAE infection by feeding heat-treated colostrum and milk to kids. It was demonstrated that seroconversion still occurred in some of these kids later in life, particularly when CAE-positive adults were maintained in the herd (East et al. 1987). However, when seropositive animals in a herd were physically segregated from seronegative animals that had been raised on heat-treated colostrum and pasteurized milk, rates of seroconversion were three-fold lower than when seropositive animals remained commingled with seronegative animals (Rowe et al. 1992).

There are a number of possible ways that horizontal transmission can occur when infected and noninfected dairy goats are commingled. One important route is via milk in association with milking practices. Experimental intramammary transmission of virus has been reported (East et al. 1993; Lerondelle et al. 1995). In one study, direct contact for more than twelve months between uninfected and infected goats was necessary before horizontal transmission could be demonstrated under non-dairy conditions. However, when unin-

fected does were milked with infected does, 60% became infected in less than ten months (Adams et al. 1983). Rowe and East (1997) suggest a variety of mechanisms by which horizontal transmission might be effected via milk, including shared milking machines, the impact of backflowing milk against the teat end during machine milking, milk-contaminated hands or towels, aerosolization of milk during milking with subsequent inhalation or contamination of equipment, and spilled or open containers of milk licked or consumed by goats.

In addition to milk, the lungs of infected goats may be a source of aerosolized virus because the lungs are a target organ of CAE infection. Coughing may release virus into the air to be inhaled by nearby animals in confinement housing. Other lung infections may further exacerbate this risk because bacterial or other viral pneumonias stimulate an inflammatory response that may bring additional CAE virus-laden macrophages to the lungs and increase the frequency of coughing of inflammatory debris. There is good, indirect evidence that aerosol spread of CAE infection is important. In a French study, kids raised on treated colostrum and raw colostrum were maintained in varying degrees of separation and their rates of seroconversion monitored over time. With no separation at all, 34.7% of the kids receiving treated colostrum became seropositive. When separation by a hurdle was imposed, 28.4% seroconverted. When a wall separated them in the same building, 24.1% seroconverted, and when kept in totally separate buildings, only 16.4% seroconverted (Péretz et al. 1994).

Sexual transmission is a possible but unlikely factor in the spread of CAE infection. There are no reports of infection of does by infected bucks through mating or use of artificial insemination, although in one study, does were monitored for seroconversion for eighteen months following mating with or artificial insemination from infected bucks (Adams et al. 1983). There is a report, though, of CAE virus in the seminal fluid and non-spermatic cells of two of six bucks experimentally infected with the virus (Travassos et al. 1998). Virus-infected cells have also been identified in preputial swabs of several bucks and semen from the epididymis of an infected buck (Rowe and East 1997). In sheep, maedi-visna virus was not isolated from semen of experimentally infected rams until they were also superinfected with *Brucella ovis* and developed epididymitis with leukocytospermia (Concha-Bermejillo et al. 1996).

In a similar study, maedi-visna virus was found in epididymal tissues in rams coinfected with *B. ovis* and the virus (Preziuso et al. 2003). While the use of only noninfected bucks in breeding programs would be ideal, these observations and findings suggest that CAE virus-infected bucks may be used safely for breeding if some precautions are observed. Infected bucks should not commingle with does, but rather should be hand mated to does to limit their contact time. They also should be free of any concurrent disease of the genital tract that would possibly increase the presence of virus-infected inflammatory cells in the semen.

There are no reports of CAE transmission associated with embryo transfer. Nevertheless, while embryos with the *zona pellucida* intact could not be experimentally infected with CAE virus, those with the *zona pellucida* absent could be infected (Lamara et al. 2002) and supported productive replication of the CAE virus (Al-Ahmad et al. 2006). In another study, the presence of CAE-infected cells in oviductal washing fluid collected during embryo harvest from infected does was confirmed using a nested PCR for proviral DNA (Fieni et al. 2002). Embryos are considered safe as long as they are washed according to the International Embryo Transfer Society and are derived from seronegative flocks.

Iatrogenic transfer of CAE virus is also a consideration in horizontal transmission, though actual occurrences are not well documented. Since the virus is present in peripheral blood mononuclear cells, transfer of blood between animals by multiple use of needles for injection and the use of tattooing instruments without disinfection between animals are potential means of iatrogenic infection.

Finally, a number of behavioral traits were observed in CAE virus-infected dairy goat herds which were considered to contribute, at least potentially, to the spread of infection within the herds (Greenwood et al. 1995). These included teat sucking and biting by does, eye licking in hot weather, contact of the nose and mouth with vaginal and anal areas, nasal secretions present on muzzles of goats and in feed troughs, expulsion of milk into the environment when does lay on their udders, leaking of milk from udders before milking, drinking of milk in strip cups in the milking parlor, and drinking of urine and anal intercourse by bucks. While the risk associated with these different behaviors varies markedly, taken together they underscore the vigilance necessary for implementing successful control programs in infected herds.

Pathogenesis

Lentivirus infections are "slow virus" infections and are characterized by a high prevalence of inapparent infection, a prolonged but variable prepatent period, persistence of the virus in the host, multiple organ system involvement, and a chronic disease course with recurrent episodes of acute disease, such as is seen in the arthritic form of CAE (Cheevers and McGuire 1988). The pathogenic mechanisms of animal lentiviruses have been reviewed (Clements and Zink 1996).

Persistence of the virus in the host is facilitated by the ability of the lentivirus to sequester as provirus in host cells without the necessity of frequent multiplication. The CAE virus uses the monocyte/macrophage cell line as its principal host cell type. The virus remains inactive in monocytes and replication of virus is linked with maturation of monocytes to macrophages after they leave the bone marrow or blood and localize in tissue sites. This has been referred to as a "Trojan Horse" strategy whereby virus gains access to target tissues undetected in monocytes (Peluso et al. 1985). Activation of disease is associated with activation of virus translational activity in infected cells. The mechanisms by which lentiviral replication is first restricted and then subsequently expressed are complex and not yet completely understood, but the subject has been recently reviewed (Bertoni 2007). An important factor may be availability of viral transcription factors present in mature, tissue bound macrophages, but not present in circulating monocytes.

Infection of the goat with CAE virus induces both a strong humoral and cell mediated immune response, but neither is protective. In fact, caprine arthritis encephalitis is an immunopathological disease in which lesions result from an immune reaction to viral antigens, especially surface glycoproteins. This concept is supported by numerous observations including the fact that vaccinated goats develop more severe lesions when experimentally challenged than unvaccinated goats, that persistently infected goats develop acute arthritis when experimentally challenged, that the severity of joint lesions correlates with the presence of virus and antiviral antibody in the joint, and that the lesions occurring in CAE consist mainly of lymphocytes and macrophages (Adams et al. 1985; McGuire et al. 1986).

After kids consume colostrum or milk containing CAE virus-infected macrophages, these infected cells are taken up intact from the gut and enter the reticulendothelial system to establish infection in the kid (Narayan and Cork 1985). Subsequently, infected monocytes reach target tissues such as synovium, lung interstitium, choroid plexus, and udder where the activation of virus replication in conjunction with macrophage maturation induces the lymphoproliferative lesions that characterize CAE. Lungworms may possibly predispose to the pneumonic form of CAE in infected goats by inducing monocyte migration and macrophage proliferation in parasitized lung (Ellis et al. 1988).

Maternal antibody against CAE provides no protection against infection in suckling neonates and usually disappears within sixty to eighty-five days after suckling (Adams et al. 1983). Kids infected at birth can show an active antibody response as early as three to four weeks and usually by ten weeks (Ellis et al. 1986).

When the antibody response develops, antibodies are present for life, although the serum concentration may wax and wane at different times or may be below the threshold of tests used to detect them.

Clinical Findings

In addition to subclinical infection, there are five known clinical forms of CAE in goats: arthritis, leukoencephalomyelitis, interstitial pneumonia, mastitis, and progressive weight loss. Arthritis, the most common form, is discussed here. The neurologic form is discussed in detail in Chapter 5 in association with maedi-visna. The respiratory form, a chronic progressive interstitial pneumonia of adult goats, is described in Chapter 9. It is sometimes also observed clinically in goats with the arthritic form. The udder form, an indurative viral mastitis with hypogalactia or agalactia noted at parturition in young does, is described further in Chapter 14. Progressive weight loss can occur as the sole clinical manifestation of CAE virus infection, or in conjunction with any of these other clinical forms. It is discussed in more detail in Chapter 15.

The arthritic form of CAE occurs in sexually mature goats, usually after the first year, most commonly in the second, but any time in adulthood. The onset may be insidious or acute and the clinical course varies considerably among individuals. All limb joints and the atlanto-occiptal bursa may be affected. The most common site is the carpal joint, the next most commonly involved joints are the tarsal, stifle, and fetlock joints; the atlanto-occipital bursa; and finally the coxofemoral joint. A single or multiple joints may be involved at any time in the course of disease.

Early signs of arthritis may be subtle. Joints may appear and feel normal but affected goats may have decreased ambulation and feeding activity, a reluctance or difficulty in rising, a stiff gait or abnormal posture after rising, and weight loss. Alternatively, affected goats early in the course of disease may present with an obvious, acute swelling in association with the joint but with little evidence of pain or restricted activity.

The most obvious swellings are on the anterior aspect of the carpus and are periarticular, associated with fluid accumulating in the carpal bursa. Such swellings may be up to 10 cm in diameter, and are fluctuant, cool, and not painful to the touch (Figure 4.6a). Fluid can be aspirated from these swellings for diagnostic purposes, but drainage only leads to refilling. The condition may remain at this stage of development in some animals for months or even years, or show periodic cycles of swelling, possible pain, and spontaneous improvement.

For many goats, however, the infection progresses steadily to a debilitating and painful arthritis. This is

usually accompanied by gradual weight loss and a rough hair coat. Fevers are not part of the disease process. The fluctuant swelling of the bursa gives way to a firmer swelling associated with inflammation and thickening of the joint capsule and surrounding structures, and the animal becomes increasingly reluctant to use the affected limb. Progressive mineralization of the joint capsule and soft tissues, exostoses of the bones, and collapse of the joint contribute to pain, a restricted range of motion, and finally ankylosis. When the carpus is involved, there is a marked tendency to carry the limb in a partially flexed position (Figure 4.6b). Ultimately, a permanent, severe flexion of the carpus may occur, and when both forelimbs are involved, the animal is forced to ambulate in a permanently kneeling position on the carpi (Figure 4.6c).

Involvement of the hind limbs usually results in less obvious swellings, but thickening of peri-articular structures may be palpable in the hock region. There is progressive reluctance to rise and increasing stiffness of gait. When the hips are involved the animal may develop a sufficiently painful and swaying gait to erroneously suggest neurogenic incoordination.

Clinical Pathology and Necropsy

Most diagnostic testing conducted relative to CAE is for the purpose of surveillance and implementation of control programs. As such, both clinically and subclinically infected animals must be identified. Isolation of the virus as a diagnostic tool is problematic in that virus concentrations in infected animals are low, particularly in subclinically infected animals and virus culture techniques are costly and time consuming. Since infection is lifelong and the presence of antibody signifies infection, serological methods for detection of antibody are preferable to virus isolation. The most commonly employed serological tests are the agar gel immunodiffusion test (AGID), the indirect ELISA (iELISA) and the competitive ELISA (cELISA). These are the prescribed tests for use in international trade to determine CAE infection status (OIE 2004). Additional, supplementary tests for detection of antibody are the radioimmunoprecipitation assay (RIPA), western blot (WB), and radioimmunoassay (RIA).

The AGID has been the most commonly used test for routine screening, providing good sensitivity and excellent specificity. Antigen for the prescribed AGID test is derived from whole virus that has been concentrated from culture supernatants and contains both the core antigen p28 and envelope antigen gp135. Detection of antibodies to both antigens improves the sensitivity of the test compared to using one or the other. While there is cross-reactivity of antibodies against CAE and MV viruses, the sensitivity of the AGID test is improved if the CAE virus is used to detect CAE infection in goats.

There are more than thirty publications of ELISA tests for detection of SRLV infection with considerable variation in their performance relative to the AGID and relative to each other. A summary of all these SRLV ELISA test results has been published (Andrés et al. 2005). While early iterations of ELISA did not perform as reliably as the AGID, improvements in antigen development now make ELISA tests more sensitive and specific than AGID, and ELISA has become the preferred test for many laboratories and regulatory agencies. There are two main categories of ELISA assay in use—antibody detecting iELISAs, which use either whole virus or recombinant proteins/synthetic peptides as antigens, and cELISAs, based on the use of anti-viral monoclonal antibodies. For iELISAs overall, assays using whole virus antigen tend to be more sensitive than single recombinant antigen assays. However, if both a core antigen and an envelope antigen are included in the recombinant antigen assays, sensitivities and specificities are equivalent to whole cell antigen iELISAs (Andrés et al. 2005.)

In a recent report of a competitive ELISA using a monoclonal antibody binding to CAEV gp135 or SU glycoprotein, the sensitivity and specificity were recorded as 100% and 96.4%, respectively, as compared to RIPA (Herrmann et al. 2003). In the absence of a gold standard reference test to definitively establish CAE infection, RIPA, WB, and RIA are often used as reference tests to establish the comparative performance of various serologic methods with regard to sensitivity and specificity. They can also be used directly in serosurveillance but are generally considered too cumbersome and costly for high throughput testing.

The major limitation in the use of serosurveillance for control of CAE is the fact that delayed seroconversion is known to occur in CAE infection, as discussed earlier. With delays in seroconversion of eight months or longer following infection, some infected individuals will be missed in herd-wide testing programs. One potential solution to this problem is the detection of viral antigen by use of PCR techniques. A number of PCR protocols have been reported with most studies using peripheral blood mononuclear cells (PMBC) as the target cell for CAE virus detection. However, since only approximately one in a million leukocytes contain virus, PCR assays may fail to detect virus because the virus load is below the detection limit of the assay and some investigators have employed co-cultivation of PMBC with fibroblasts to increase virus load. Overall, PCR tests have tended to be less sensitive than many ELISA techniques (Andrés et al. 2005). Nevertheless, there are reports of PCR identifying CAE virus-infected goats prior to seroconversion without co-cultivation (Reddy et al. 1993; Rimstad et al. 1993).

In addition to testing of PBMC, PCR has been applied with equivalent results to semen, milk, and

synovial fluid of goats. Currently, it is recommended that serology be combined with PCR for optimal detection of SRLV infection (Andrés et al. 2005).

Care must be taken in interpreting positive serology in the diagnosis of clinical cases of CAE. Because there are many causes of arthritis, pneumonia, and mastitis in goats, and because the majority of CAE-infected animals are subclinically infected, positive serology for CAE does not necessarily mean that the swollen joint, respiratory signs, or abnormal udder are due to CAE infection.

In the case of arthritis, arthrocentesis and examination of synovial fluid can support the diagnosis of CAE-induced arthritis. In active cases, the fluid is red to brown in color and has a low viscosity. Cell counts are elevated to the range of 1,000 to 20,000/mm^3 with mononuclear cells comprising more than 90% of the cell population. The majority are lymphocytes and the remainder are synovial cells and macrophages (Crawford and Adams 1981). Synovial biopsy can also be useful for histopathologic examination or for virus culture by explantation techniques. Examination of cells in synovial fluid using PCR techniques may also aid the diagnosis when lesions and clinical signs are consistent with CAE but serology is negative (Reddy et al. 1993).

A wide range of radiographic findings can be observed. In early cases, distension of bursae with fluid and other periarticular soft tissue swellings may be present. In advanced cases, CAE arthritis is characterized by more severe soft tissue changes including calcification of joint capsule and adjacent tendons, tendon sheaths, ligaments, and bursal contents (Figure 4.7). Early bony changes include mild periosteal reactions and periarticular osteophyte production. Later signs are more severe and include marked osteophyte production, breakdown of subchondral bone, collapse of joint spaces, and ankylosis (Crawford and Adams 1981).

At necropsy, affected goats are usually emaciated. Affected joints and adjacent bursae and tendon sheaths are usually enlarged. Foci of mineralization and/or necrosis as well as fibrous scar tissue may be visible in tendons and other periarticular structures. When the joint is opened a dramatic synovial proliferation is frequently observed. The synovial membrane appears brown and velvety and is thrown up into fingerlike projections. Cartilage surfaces can be roughened, ulcerated, or eroded depending on the severity of the case. "Rice bodies" are commonly found in the joint space, tendon sheaths, and bursae. Collapse of subchondral bone and ankylosis may also be noted (Crawford and Adams 1981).

Histologically, joint lesions are characterized by synovial hyperplasia with subsynovial mononuclear infiltrates, including lymphocytes, macrophages, and

Figure 4.7. Radiographic changes in the carpus of a goat with advanced CAE arthritis. Note mineralization of extensor tendon and other soft tissue structures. (Courtesy of Cummings School of Veterinary Medicine at Tufts University.)

plasma cells. Multinucleated cells are occasionally observed. Fibrin deposition is common on synovial surfaces. There is necrosis and mineralization of synovial, perisynovial, and tendon collagen. The lesion of mononuclear infiltration seen in the synovium may also be seen in other target tissues such as udder and lung, even when there has been no clinical involvement of these organs. Similar mononuclear infiltrative lesions have also been observed in the uterus of a CAE virus-infected goat (Ali 1987) and the kidney of another (Dawson et al. 1983). Central nervous system lesions are described in Chapter 5, lung lesions in Chapter 9, and udder lesions in Chapter 14.

Diagnosis

A presumptive diagnosis of CAE arthritis is based on a combination of a history of CAE in the herd, positive serology and/or PCR, clinical signs consistent with the disease, synovial fluid abnormalities consistent with the disease, and typical histopathology on synovial biopsy or post mortem examination. All other traumatic, metabolic, and infectious causes of arthritis

must be differentiated from CAE arthritis. Concurrent processes can occur, so cultures of synovial fluid for mycoplasma and bacteria are advised for definitive case assessment.

Treatment

There are no known treatments for any of the clinical forms of CAE. Animals with mild cases of the arthritic form of the disease can be made more comfortable by providing regular, correct hoof trimming, providing easily accessible feed and water, and by the long-term use of oral analgesics such as aspirin or phenylbutazone. Aspirin can be given at a dose of 100 mg/kg every twelve hours or phenylbutazone at a dose of 10 mg/kg once a day. Phenylbutazone must be avoided in goats producing meat or milk for human consumption. Additional nonsteroidal anti-inflammatory drugs are discussed in Chapter 17. Physical therapy could delay the progress of CAE arthritis, but there is no published evidence to support this.

Goats with advanced cases of arthritis, unable to extend the legs and forced to walk on their flexed carpi, should be euthanized. Such goats are less frequently encountered now than they were a decade ago because of increased awareness on the part of owners about CAE and more aggressive culling of advanced cases. Discovering such goats on a farm should alert the veterinarian to the need for client education concerning CAE.

Control

Attempts to prevent introduction of CAE into CAE-free countries or zones are based on import regulations that require validation of negative status in individual animals to be imported. The international standard suggested by the World Organization for Animal Health (OIE) is that animals be accompanied by an international veterinary certificate which attests that: the animals showed no clinical sign of CAE on the day of shipment, that animals over one year of age were subjected to a diagnostic test for CAE with negative results during the thirty days prior to shipment, or that CAE was neither clinically nor serologically diagnosed in the sheep and goats present in the flocks of origin during the past three years, and also that no sheep or goat from a flock of inferior health status was introduced into these flocks during that period. The prescribed serologic tests are AGID or ELISA (OIE 2007).

For countries, zones, or states where CAE is already present, testing and certification/accreditation programs may be implemented for control. Few countries, Switzerland being one (Perler 2003), have mandatory, nationwide regulatory control programs for CAE. Other countries, for example, New Zealand, France, and Sweden, have instituted voluntary testing and accreditation programs, usually in association with producer groups to encourage the establishment of CAE-negative herds and flocks (MacDiarmid 1985; Davidson 2002; Chartier 2008; de Verdier 2008). Australia has voluntary programs operating on the state and territory level (Animal Health Australia 2008). Such control programs usually involve annual or semiannual, herd-wide, serologic testing and removal of positive reactors from the herd.

At the farm level, efforts to eliminate CAE from herds known to be infected focus on three main areas: attempting to raise CAE-free kids by implementing kid-rearing techniques that reduce the risk of exposure to virus, periodic serologic testing of the herd, and culling or separating diseased and seropositive animals from healthy, seronegative animals.

RAISING CAE-FREE KIDS. Modification of kid-rearing techniques is probably the most frequently implemented aspect of herd control programs. The goal is to eliminate exposure of kids to virus and is based on the assumption that most new infections in kids develop in an infected herd as a result of ingestion of virus-contaminated milk or colostrum. More stringent programs also remove kids from dams immediately at birth on the assumption that the potential exists for kids to be exposed to virus when they are licked and cleaned by their infected dams. Washing birth fluids off the kids immediately after birth has also been recommended.

To achieve this level of control, attendants need to be present at birth so kids can be removed from their dams before they are able to stand and suckle. To improve the chance of being present at kidding, timed induction of parturition with prostaglandins can be used as discussed in Chapter 13. Once kids are removed from the doe, they should be raised in separate facilities from adult animals, especially if infected adults are maintained on the farm, and they should never again be commingled with known-infected goats.

Ideally, kids removed from the dam should be fed heat-treated goat colostrum as an appropriate, CAE virus-free source of maternal antibodies to provide passive immunity against neonatal diseases. Pasteurization of colostrum at high temperature for short periods can denature protective immunoglobulins and causes the colostrum to gel, making it impossible to feed. As an alternative, heat treatment of colostrum at 132.8°F (56°C) for sixty minutes has been demonstrated experimentally to block transmission of virus and permit absorption of immunoglobulins (Adams et al. 1983).

Automated equipment for performing this task is now available but may not be affordable for many small herds. Owners of small herds can be advised to heat colostrum to 134.6°F (57°C) for ten minutes and then transfer it to a thermos flask that has been pre-

heated with boiling water. The colostrum is then held in the closed thermos flask for sixty minutes to accomplish virus inactivation. It is essential that the temperature remain above 132.8°F (56°C) for the entire period (MacKenzie et al. 1987) and it should be verified by thermometer at the end of the holding period. Excess colostrum may be successfully frozen for later use to reduce labor expenditure.

Because heat treatment of colostrum is a laborious task, goat owners actively seek alternatives to this practice. Feeding no colostrum should be viewed as an unacceptable practice because this results in failure of passive transfer of immunity and puts kids at risk for other dangerous diseases. Feeding unpasteurized colostrum only from seronegative does is not without risk because false-negative serologic test results do occur. Administration of unpasteurized cow colostrum results in acceptable levels of circulating serum antibodies in kids, but the persistence and efficacy of such heterologous antibody in kids has not been documented. The practice is reported to be effective in raising orphan lambs. Of course, unpasteurized cow colostrum, while it does not contain CAE virus, may contain other organisms such as *Mycobacterium paratuberculosis* that are potentially infectious for goats. In addition, feeding of cow colostrum has occasionally been associated with hemolytic anemia in kids (Perrin and Polack 1988).

A number of products are being marketed as colostrum supplements for calves, lambs, or kids. Such products usually contain lyophilized colostrum or whey immunoglobulin concentrates. Many goat owners have seized upon these products as colostrum substitutes suitable for use in CAE control programs. However, it has been demonstrated that some of these products, when administered to kids as directed by the manufacturer, do not raise serum antibody levels above a level consistent with a diagnosis of failure of passive transfer of antibody (Sherman et al. 1990). Numerous anecdotal reports suggest a marked increase in the incidence of neonatal septicemia when some colostrum supplements have been used in place of colostrum (Scroggs 1989; Custer 1990).

Newer products on the market may be more reliable, but all such products should be used with caution and kids monitored for an increased occurrence of neonatal septicemia or other disease. Antibody levels in kid serum can be measured by a number of methods as discussed in the section on failure of passive transfer in Chapter 7.

After administration of heat-treated goat colostrum, kids must be raised on pasteurized goat milk, cow milk, or commercial milk replacer through weaning. Goat milk can be pasteurized by heating to 165°F (73.9°C) for fifteen seconds. The feeding of milk replacers to kids is discussed in Chapter 19.

PERIODIC SEROLOGIC TESTING. Submission of serum samples from all goats of breeding age and older for detection of antibody to CAE virus can be useful to establish the prevalence of disease, monitor progress in control programs, serve as a basis for creating infected and noninfected strings of goats in the herd, or identify animals for culling.

There is not universal agreement on the appropriate frequency of testing for herd control programs and the frequency of testing required varies between herds based on initial level of infection, size of herd, capacity to rigorously implement necessary management changes, and other epidemiological factors. It has been suggested, for example, that kids be tested monthly up to six months of age because of variability in the time of seroconversion following perinatal infection. This is not necessary if the kid-rearing interventions discussed above are assiduously practiced, but if management is lax, then such testing may be worthwhile to identify perinatally exposed kids and to underscore lapses in control practices. It should be noted that kids fed heat-treated colostrum from infected does will have false positive serologic tests for several months at least.

In general, goats should be tested at least annually, and preferably, semi-annually, because sensitivity of the serologic tests is not 100% and serum antibody levels may fluctuate in individual goats, as in late pregnancy when serum antibody levels may be reduced due to maternal transfer of antibodies from serum to colostrum. Timing a herd-wide test for the beginning of the breeding season is useful because the results can be used to advantage in making breeding, culling, and management decisions relating to CAE control well before kidding time.

CULLING OR SEPARATION. Kids raised CAE-free using the above protocols may still seroconvert after weaning as a result of horizontal transmission in herds where known-infected adults are allowed to remain and commingle in the herd (East et al. 1987). Herd owners attempting to eliminate CAE from their herds should be strongly encouraged to include aggressive culling of seropositive adults as an integral part of the control program. Otherwise, the efforts placed on rearing of CAE-free kids may, in many cases, be futile.

However, in many infected herds, particularly commercial milking herds where the need for milk and replacement does is high, there is frequently resistance to the notion of culling seropositive adults on economic grounds, even though kid rearing techniques are practiced to reduce the prevalence of CAE. In these cases, it is necessary to maintain two separate groups within the herd—a seropositive group and a seronegative group that are physically separated to the greatest extent possible. Separate buildings are ideal, but may be impractical. Solid wall separation is the next best option, but if that too is not possible, then the animals

must be physically separated by a distance of at least 2 m with a double fence or barrier that allows no direct contact between individuals in the two groups.

Separate feeding, watering, grooming, and other such equipment should be maintained for each group, but if that is not possible, the equipment should be used first on seronegative animals and always washed and disinfected after using on seropositive animals. Seronegative goats should be milked first as a string before seropositive goats and considerable care must be taken to avoid contamination of surfaces, clothing, and equipment with milk from seropositive does in milking parlors where it might make contact with seronegative does the next time they are milked.

Other practical considerations for effective control programs are to avoid bringing goats to fairs and shows if possible, or at least avoid commingling goats either at the event or during transport to and from the event. No animals should be introduced into a herd attempting to eliminate CAE unless that animal comes from a known CAE-negative herd, or the individuals test negative and can be quarantined for six months and retested before entering the herd. Ideally, only seronegative bucks should be used for natural service, but if that is not possible, then the buck should be left with the doe only long enough to breed under observation to avoid unnecessary contact. Because the virus is present in peripheral blood monocytes in infected animals, the use of separate needles and syringes for each animal during treatment and vaccination is advised because iatrogenic transmission is at least theoretically possible. Similarly, tattooing of goats may involve blood contamination of the tattooing instrument, so disinfection with phenolic or quaternary ammonium compounds between uses is advised.

If sheep are kept on the same premises with goats and CAE control efforts are undertaken, sheep should be included in the testing program and subjected to similar segregation and management interventions for control. Recent evidence indicates that cross transmission of small ruminant lentivirus between the two species occurs (Shah et al. 2004, 2004a) and may adversely affect CAE control programs (Perler 2003).

Foot and Mouth Disease

Foot and mouth disease (FMD), also known as aphthous fever, is a highly contagious viral disease of wild and domestic, cloven-hoofed animals. Although it usually produces low mortality, it does produce high morbidity and represents a disease of extreme economic importance to animal industries worldwide through loss of productivity and constraints on trade in livestock and livestock products.

In the goat, FMD most often assumes a subclinical form, though clinical cases can and do occur. The major concern with caprine FMD is that subclinically infected goats may act as a source of infection for cattle in mixed livestock systems and through movement and international trade. Knowledge of the disease in small ruminants has been reviewed (Sharma 1981; Pay 1988; Barnett and Cox 1999; Kitching and Hughes 2002).

Etiology

FMD is caused by a nonenveloped, icosahedral, single-stranded RNA virus of the genus Aphthovirus, in the family Picornaviridae. There are seven immunologically distinct virus serotypes, each with numerous strains. The seven serotypes are identified as A, O, C, Asia 1, South African Territories (SAT) 1, SAT 2, and SAT 3. The development of immunity after natural exposure or vaccination is highly type-specific, and to a varying degree, strain-specific. Constant global surveillance of outbreaks is necessary to monitor changes in virus type prevalence so that appropriate type- and strain-specific vaccine formulations can be prepared and maintained. The global challenges of maintaining appropriate and sufficient vaccine banks and reserves for FMD has recently been reviewed (Paton et al. 2005).

The virus is cultivated *in vitro* on bovine thyroid, bovine kidney, or other suitable cell lines, and produces a cytopathic effect but no inclusion bodies. It is quite resistant to freezing and desiccation, but does not survive high temperatures or extremes in pH very well. Direct sunlight kills it, but organic debris protects it from the sun. It dies off rapidly in muscle tissue of infected animals, but can persist in offal, blood, and bone marrow. High relative humidity prolongs the life of aerosolized virus. Sodium hydroxide, acetic acid, sodium carbonate, and sodium hypochlorite are the most effective disinfectants. The commercial disinfectant Virkon®S, which contains multiple ingredients, has come to be widely used as a disinfectant in FMD outbreak control.

Epidemiology

Foot and mouth disease is one of the most highly regulated livestock diseases in the world, with extensive international efforts undertaken to control the spread of the virus through restricted movement of both live animals and animal products. FMD currently is enzootic in large areas of Africa, Asia, the Middle East, Eastern Europe, and South America. Areas free of FMD include North America, Central America, and the Caribbean, as well as Australia, New Zealand, Japan, and many islands of the Pacific.

At present, serotype O is geographically the most widely distributed FMD type in the world and a serotype O PanAsia lineage virus has been responsible for many FMD outbreaks over the last two decades. This

lineage originated in India in 1990 and spread through the Middle East, Turkey, and Eastern Europe. It then moved eastward into the People's Republic of China in 1999 and then to Taiwan, South Korea, Japan, Mongolia, and far-east Russia. The virus then appeared in South Africa in late 2000 and in the United Kingdom in February 2001, where it produced a devastating outbreak of FMD. It spread from there to Ireland, France, and the Netherlands before being brought under control (Grubman and Baxt 2004). Goats are believed to have been involved in the spread of type O PanAsia, at least with regard to its introduction into Saudi Arabia when, in the 1990s, that country banned the importation of cattle from India due to concerns about rinderpest but continued to import Indian goats and sheep.

More than seventy species of wild and domesticated mammals are susceptible to FMD infection. Cattle and swine are seriously affected by FMD infection with high morbidity and overt clinical disease, but comparatively low mortality rates. In contrast, the disease in sheep and goats is less pronounced and often remains subclinical (O'Brien 1943; Nazlioglu 1972; Sharma 1981; Dutta et al. 1984). This is not always the case. In one Indian outbreak of FMD in goats due to virus type A22, morbidity was 82.5% and mortality 8.2% (Mishra and Ghei 1983).

Human infection very rarely occurs and the disease is generally not considered to be zoonotic. However, the virus can survive in the upper respiratory tract of people for twenty-four hours after exposure and be transmitted subsequently to animals. This has implications for effective disease control in the age of international jet travel.

Foot and mouth disease continues to be a threat to livestock worldwide, largely because the highly contagious virus is readily transmitted under a wide variety of conditions that are difficult to detect. Among these are: the shedding of virus by infected animals before the onset of clinical signs or during convalescence; the existence of subclinically infected, convalescent, or even vaccinated animals that can act as carriers; and the presence of virus in improperly processed products containing meat, milk, bone, blood, offal, or skin of infected animals. The potential for disease transmission via semen either during natural service or artificial insemination has not been investigated in goats, although it has been demonstrated to occur in cattle.

In enzootic regions, the primary mode of transmission is by close or direct contact between infected and susceptible animals. This can be via aerosolization of virus present in the secretions and excretions of the infected animal or by entry of virus through cuts and abrasions or mucous membranes. Wind or other mechanical vectors, including veterinarians on farm visits, can carry the infective virus long distances. Contaminated bedding, feed, and equipment can serve as a source of infection. Goats and sheep are less likely than cattle to become infected by long distance airborne virus because their lower respiratory volume makes it more difficult to take in infective doses of virus via aerosol (Kitching and Hughes 2002). Mechanical carriage of virus on humans and vehicles was considered a frequent factor in disease spread between flocks in the 2001 UK outbreak. In areas where pastoralism and communal grazing are common, as in many parts of Africa, south Asia, and the Middle East, infected small ruminants contaminate river water, ponds, pastures, shrubs, and other aspects of the environment, contributing to the dissemination and persistence of disease (Uppal 2004). In serosurveys in Morocco, transhumant and nomadic herds had a higher prevalence of FMD than stationary herds (Barnett and Cox, 1999).

It is now generally accepted that subclinically infected goats and sheep can play an important role in transmission of the disease to cattle, and small ruminants were deemed responsible for epizootics of FMD in cattle in Tunisia in 1989, Greece in 1994, Southeast Asia in 1999, and Turkey in 2001 (Kitching and Hughes 2002; Uppal 2004). In many parts of the world, sheep and goats are herded or managed together and traded in commerce together so it is often difficult to ascribe a specific role for goats in transmission or spread of FMD as distinct from sheep. However, there are also some documented situations in which goats are specifically identified as the source of new infections. A goat clandestinely brought from Turkey was deemed responsible for a type O outbreak in cattle in Bulgaria in 1991 (Kitching 1998). Goats have also been implicated in an outbreak of FMD in Kuwait with type Asia 1 when infected goats with this strain were imported from Bangladesh (Kitching and Hughes 2002). The index case for the FMD outbreak in the Netherlands in 2001 was a dairy goat/veal calf farm and the first clinical cases were seen in goats. It is believed that the infection was introduced with purchased, imported calves but because the calves on the premises were housed individually and the goats commingled freely, circulation and expression of the virus occurred first in the goats (Bouma et al. 2003).

Virus has been isolated from nasal secretions of healthy appearing goats forty-eight hours before the development of clinical FMD (Raghavan and Dutt 1974). Intranasal inoculation of goats with viruses of A, O, or C type produced a 100% infection rate, with virus present in the oropharynx for up to twenty-eight days in 87% of goats, and no cases of severe clinical disease. Lesions that did occur were mild enough to be overlooked by casual observation (McVicar and Sutmoller 1968). Animals in which virus can be

recovered from the oropharynx beyond twenty-eight days post-infection are defined as carriers. The maximum duration of the carrier state in goats is reported to be four months, as compared to nine months in sheep and up to three and a half years in cattle (Alexandersen et al. 2003).

Some ruminant animals, including some goats, may become carriers when exposed to FMD virus, even if they are immune as a result of previous vaccination or recovery from infection. The percentage of animals that become carriers is variable and the infectivity titer of virus in oropharyngeal samples is usually low. Excretion is also intermittent and the titer declines over time. Development and persistence of the carrier state may be determined both by the animal species and the strain of virus involved (Alexandersen et al. 2003). In a review of the role of small ruminants in the transmission of FMD, it was concluded that sheep and goats are most likely to be involved with the transmission of FMDV during the early stages of either clinical or subclinical FMD infection rather than when they are carriers and the period of greatest risk of transmission is up to seven days after contact with the infection (Barnett and Cox 1999).

Host species susceptibility may also vary with virus type. For example, a devastating outbreak of FMD in pigs in Taiwan in 1997 with type O virus O/Taw/97 did not cause disease in cattle and goats on the same farms with affected pigs (Yang et al. 1999). That virus strain was related to others involved in earlier porcine FMD outbreaks in the Far East. However, in 1999, FMD occurred again in Taiwan, caused by a type O strain more closely related to type O strains circulating in the Middle East and India, and in the 1999 Taiwan outbreak, goats and cattle were clinically affected (Grubman and Baxt 2004).

The frequently mild clinical manifestations of FMD in small ruminants can lead to oversight or misdiagnosis and thereby contribute to the further spread of disease. For example, serotype O was introduced into Tunisia in 1989 in infected sheep and goats imported from the Middle East. Clinical signs were mild and lameness observed in these animals was initially thought to be due to bluetongue. Eventually the disease spread to cattle, at which time it was quickly identified as FMD due to the more obvious clinical manifestations in that species. However, by then the disease had time to disseminate and spread into Algeria and Morocco (Kitching 1998). In the UK in 2001, difficulty in accurately recognizing clinical FMD in sheep contributed to the dissemination of the disease through transport of unrecognized cases. However, it also contributed to the emergency destruction of many sheep flocks deemed clinically affected that subsequently turned out to be negative when test results were completed (Kitching and Hughes 2002).

Pathogenesis

Infection is most commonly initiated by inhalation of aerosolized virus or by direct entry of virus into abraded epithelium of the mouth or feet. After inhalation, multiplication occurs initially in the pharynx and, after direct entry, in the epithelium of the mouth or feet. After three to eleven days, a subsequent viremia ensues in susceptible animals. This is the febrile stage of the disease and lasts three to four days. Virus is found in most tissues and shed in all secretions and excretions during viremia. Young kids may die of viral myocarditis at this stage. In surviving goats, virus ultimately localizes in the epithelial cells of the buccal cavity and feet, and sometimes the teats. Virus multiplication in epithelium leads to hydropic degeneration and coalescence of fluid-filled cells to form enlarging vesicles up to 3 or more cm in diameter in cattle. The overlying epithelium becomes devitalized and the mechanical trauma of eating or walking causes sloughing of the tissue, exposing raw painful ulcers underneath. This leads to the signs of stomatitis and lameness characteristic of overt clinical disease.

Large, fluid-filled vesicles, such as those seen in cattle, are rarely observed in the mouths of goats and sheep. The thinness of the lingual epithelium in small ruminants causes superficial lesions to rupture early, leaving shallow erosions which usually heal within a few days. Lesions in the mouth of large and, to a lesser extent, small ruminants are most often seen on the dental pad and the tongue but may also be seen on the lips, gums, and cheeks, and sometimes on the hard palate (Alexandersen et al. 2003).

Clinical Findings

Subclinical infection is the most common outcome in goats exposed to FMD virus. In acute cases, initial, nonspecific signs of FMD may include dullness, inappetence, restlessness, increased heart and respiratory rates, shivering, and fever. Milking goats may become agalactic. Pregnant does may abort. Mortality, when it occurs, is most likely in neonatal kids. Mortality up to 55% in young kids has been observed even when older animals show no morbidity (Hedjazi et al. 1972). In such kids, peracute death from myocarditis often occurs with no other signs.

When goats do show specific signs of FMD, they are more often affected on the feet than in the mouth. Therefore, lameness is the most suggestive sign of caprine FMD and demands careful examination of the feet, though oral lesions and signs of stomatitis can and do occur. In a severe Indian outbreak of FMD in goats, 12.5% of cases had only oral lesions, 40% only foot lesions, and 47.5% both foot and oral lesions (Mishra and Ghei 1983). Similarly, in another Indian outbreak in a herd of 385 goats, 8.3% of cases had only

oral lesions, 63.8% had only foot lesions, and 27.7% of cases had both foot and oral lesions. The overall morbidity rate was 16% and only one seven-day old kid died, for a mortality rate of 0.26%. All other affected animals recovered within a period of ten to fifteen days (Kumar et al. 2004).

Early in the course of clinical disease, vesicles may be found along the coronary band, in the interdigital space, and sometimes on the heels. Any or all of the feet may be involved. Over several days, vesicles rupture leaving behind painful ulcers. Lameness may grow more pronounced and the ulcers on the feet may become secondarily infected with bacteria. Animals may be reluctant to stand or move. Though uncommon, in extreme cases the hoof wall may separate at the coronary band and the hoof slough. Severely affected goats may succumb to starvation, dehydration, predation, septicemia, or secondary pneumonia. In uncomplicated FMD, or with supportive care, oral and foot lesions heal gradually over two to three weeks and goats return to normal, although some animals may remain thin for extended periods.

Early vesicle formation in the oral cavity can lead to signs of lip smacking and drooling. Hyperemic foci or small raised fluid-filled vesicles may occur in the mucosa of the lips, tongue, and palate, but are likely to rupture quickly due to the thin buccal epithelium in small ruminants. Rupture of oral vesicles exposes mucosal ulcers leading to mouth pain and a reluctance to eat, and produces lesions more easily confused with other, non-vesicular causes of stomatitis in small ruminants. Vesicles on the teats may also occur (Olah et al. 1976) as may vesicles on the prepuce.

Goats suspected of having FMD need to be inspected very carefully for vesicle formation. Vesicles in the mouth may be small and few in number and not lead to overt signs of stomatitis. Likewise, foot lesions may be mild, affect only one or more limbs, and produce minimal secondary signs. If actual fluid-filled vesicles are not observed, later lesions after vesicle rupture may look merely like abrasions due to trauma.

Clinical Pathology and Necropsy

A definitive diagnosis of FMD from field cases requires laboratory confirmation because the disease cannot be differentiated clinically from other vesicular diseases, including vesicular stomatitis which can occur, albeit rarely, in goats, and because in small ruminants, classical clinical signs as described in cattle may be minimal or absent. Due to the highly contagious nature of this disease and the need to initiate regulatory disease control plans in a timely fashion, laboratory diagnosis of any suspected FMD case is a matter of urgency. When FMD is suspected, regulatory authorities should be notified immediately and sample collection and shipment should be done by trained, authorized personnel according to strict standards of biosecurity with tests performed in a laboratory that meets the World Organization for Animal Health (OIE) requirements for Containment Group 4 pathogens (OIE 2007a).

The best samples to submit for laboratory diagnosis are epithelium from unruptured or freshly ruptured vesicles or vesicular fluid. If such samples are not available, which may commonly be the case in affected goats, blood and/or esophageal–pharyngeal fluid samples taken by probang cup can yield virus. Myocardium or blood can be submitted from fatal cases, but vesicles are preferred when available.

As prescribed by the World Organization for Animal Health (OIE), diagnosis of FMD is by virus isolation or the demonstration of FMD viral antigen or nucleic acid in tissue or fluid samples. Detection of virus-specific antibody can also be used for diagnosis, and antibodies to viral nonstructural proteins (NSPs) can be used to differentiate infection from vaccination. Detailed descriptions and reference sources for laboratory tests used in the diagnosis of FMD are found in the OIE Manual of Diagnostic Tests and Vaccines for Terrestrial Animals which is available in print and on the internet (OIE 2004a) and are outlined briefly here.

Virus isolation is best performed on cell culture systems using primary bovine (calf) thyroid cells or primary pig, calf, or lamb kidney cells. Other cell lines, such as BHK-21 (baby hamster kidney) and IB-RS-2 cells, may also be used but are generally less sensitive when there are low amounts of infectivity. Cytopathic effect (CPE) occurs in infected cell cultures in forty-eight hours. If none is seen, cell cultures are frozen and thawed and a new cell culture inoculated to check again for CPE.

For detection of viral antigens, an indirect sandwich ELISA technique has largely replaced complement fixation (CF) as the test of choice in recent years. The ELISA is more specific and sensitive than CF and not affected by pro- or anti-complement factors. This ELISA confirms the presence of FMD virus and the serotype. Different rows in multiwell plates are coated with rabbit antisera to each of the seven serotypes of FMD virus. Thus, the FMD viral antigens of different serotypes present are captured when sample suspensions are added to the wells. Guinea-pig antisera to each of the serotypes of FMD virus is then added to create the "sandwich" and this is followed by addition of rabbit anti-guinea-pig serum conjugated to an enzyme to reveal a color reaction that can be quantified by spectrophotometry.

Nucleic acid recognition tests, such as the reverse transcriptase-polymerase chain reaction (RT-PCR), are being used increasingly for virus detection. Agarose gel or real time RT-PCR can be used to amplify genome

fragments of FMD virus in epithelium, milk, serum, and oropharyngeal samples. Specific primers have been designed to distinguish between each of the seven serotypes, and RT combined with real-time PCR has a sensitivity comparable to that of virus isolation.

Characterization of FMD strains is very important for tracking the spatial movement of FMD infection, identifying host species adaptations for particular strains, and developing suitable and effective vaccines. The molecular epidemiology of FMD is based on the comparison of genetic differences between isolates. Dendrograms showing the genomic relationship between vaccine and field strains for all seven serotypes based on sequences derived from the 1D gene, which encodes for the VP1 viral protein, have been produced. RT-PCR amplification of FMD virus RNA, followed by nucleotide sequencing, is the current preferred option for generating the sequence data for strain comparisons.

Serological tests for FMD are conducted for four main reasons: to certify individual animals prior to import or export, confirm suspected cases of FMD, substantiate the absence of infection, and demonstrate the efficacy of vaccination. To confirm mild cases or where epithelial tissue cannot be collected, as may often occur in small ruminants, the demonstration of specific antibodies to structural proteins (SPs) of FMD virus in animals known to be unvaccinated is sufficient for a positive diagnosis. The SP tests are serotype-specific and detect antibodies elicited by vaccination and infection. The virus neutralization test, the solid-phase competition ELISA, and the liquid-phase blocking ELISA for detection of antibodies to SPs are the prescribed tests of the OIE for use in international trade of livestock.

In addition to structural proteins, FMD virus also expresses eight non-structural proteins (NSPs) during viral replication. There is no viral replication in the host when killed virus vaccines are used for FMD control. Thus, tests for antibodies to some non-structural proteins of FMD virus are useful in providing evidence of previous or current viral replication in the host, independent of vaccination status. In contrast to structural proteins, NSPs are highly conserved and therefore are not serotype specific, so the detection of these antibodies is not serotype restricted. Unfortunately, some NSPs are produced during growth of vaccine virus in tissue culture and some traces of these NSPs may contaminate the final killed vaccine product and elicit a host immune response. The NSP 3D is most commonly associated with this contamination and therefore is not a good candidate antigen for NSP antibody tests.

Currently the non-structural polyproteins 3AB and 3ABC are the preferred antigens. Tests prescribed by OIE for detection of antibodies to NSPs include indirect ELISA and the enzyme-linked immunoelectro-transfer blot assay. The use of diagnostic techniques based on detection of antibodies to NSPs to distinguish FMD virus infection from vaccination has been recently reviewed (Clavijo et al. 2004).

A full necropsy should be conducted on suspect FMD cases that have died. At the time of necropsy, careful inspection of the feet, oral cavity, pharynx, and teats is required to determine the presence of vesicles or ulcerations consistent with a diagnosis of FMD. In addition, the so-called "tiger heart" lesion may be observed, especially in kids dying peracutely. This name refers to a striped appearance of the myocardium caused by the presence of necrotic, small gray foci and irregular streaks in the heart muscle. These same lesions may occasionally occur in skeletal muscle.

Microscopically, vesicular epithelial lesions include hydropic degeneration of cells in the *stratum spinosum*, disintegration of cells, and accumulation of fluid. Where vesicles have ruptured, ulcers will be noted and may be associated with suppurative inflammation if secondary bacterial infection has occurred. The heart lesion is one of focal coagulative necrosis accompanied by lymphocytic and sometimes neutrophilic infiltrates.

Diagnosis

Definitive diagnosis is based on isolation of virus from suspected cases of FMD. Because vesicular diseases of goats are uncommon, any vesicular lesion of the mouth, muzzle, oral cavity, feet, or teats should be considered as suspect for FMD, even in FMD-free countries, and reported to appropriate authorities immediately. Because vesicles are fragile and transient in goats, advanced cases may present with ulcers, or crusts over lesions that make the diagnosis less obvious. Therefore, FMD must be considered whenever there are signs of lameness and/or stomatitis, especially when the two signs occur together.

Diseases with the potential of producing both signs together in goats include bluetongue, vesicular stomatitis, pemphigus, and contagious ecthyma. Bluetongue and vesicular stomatitis rarely produce clinical disease in goats, though in the recent outbreak of bluetongue in Europe in 2006, goats in the Netherlands showed oral lesions and udder lesions (Dercksen et al. 2007). Pemphigus is unlikely to affect more than one goat in a herd. Lesions of contagious ecthyma are found primarily on the mouth but can be found in other locations as well, including the teats and legs, although overt lameness is unlikely. Ionophore toxicity is an important differential for the myocarditis lesion of FMD that causes sudden death in kids, as discussed in Chapter 8, as is nutritional muscular dystrophy as discussed later in this chapter.

Treatment

There is no specific treatment for FMD. However, supportive care can help facilitate recovery of affected animals. Such efforts include confinement, provision of easily masticated, high-quality feed and water, and the administration of antibiotics, or application of topical antiseptics to prevent or control secondary bacterial infections of ulcerative lesions. Foot baths using 5% potassium permanganate solution have also been recommended (Kumar et al. 2004). Depending on the regulatory protocols in effect, it may be required to destroy all animals involved in an epizootic, so consideration of treatment may become moot.

Control

Considerable international effort is made to restrict the global spread of FMD. The World Organization for Animal Health, based on the input of its member nations and technical experts, has produced recommended standards for trade in livestock and livestock products aimed at effective control. These recommendations are available in print or on the Internet in the Terrestrial Animal Health Code (OIE 2007b). Countries that are FMD-free, such as the United States, do not accept imports of livestock from FMD-enzootic countries. However, the importation of certain animal products is permitted but only from approved, inspected abattoirs and/or processing plants.

When outbreaks do occur in FMD-free countries, they are eradicated by stamping out procedures and zoo-sanitary measures, with or without the addition of ring vaccination of livestock around the outbreak locale. Countries that are FMD-free but that border enzootically infected countries may practice regular, annual "frontier" vaccination of livestock along the pertinent national boundaries to create buffer zones against incursion of infection.

In enzootic countries, FMD is controlled by restriction of livestock movement, isolation or slaughter of exposed and infected animals, ring vaccination around outbreak locales, or maintenance of a systematic national vaccination program. Effective vaccination depends on ongoing surveillance to ensure that all important, locally occurring strains of FMD virus are included in multivalent vaccines (Blaha 1989). Based on geography, livestock distribution, and other factors, some countries may maintain recognized FMD-free zones within their borders even when the whole country is not considered disease free. The same principles of movement control, surveillance, and vaccination apply for the maintenance of FMD-free zones, and export of livestock and livestock products are permitted from these FMD-free zones when international surveillance and testing standards are met.

Several disease control recommendations were made by the Permanent Commission on Foot and Mouth Disease of the OIE in 1972 specifically concerning goats and sheep (Anonymous 1972). Small ruminants brought to seasonal pasture grounds should be vaccinated against FMD at least once a year. If prophylactic vaccination campaigns are carried out in cattle, then goats and sheep should be vaccinated as well. When it is necessary to undertake ring vaccination of cattle after an outbreak, goats and sheep should be included in the vaccination scheme. Finally, veterinary supervision of goats and sheep should be intensified at markets and during movement to and from pasture grounds, because transhumance, or seasonal movement of livestock to different feeding grounds, has been associated with increased spread of FMD.

Despite these recommendations, inclusion of small ruminants in vaccination efforts is not widely practiced for several reasons. First, it is not proven that prophylactic vaccination of small ruminants is essential to eradicate the disease in cattle (Barnett and Cox 1999). In addition, there is some evidence that FMD in sheep and goats may be self-limiting (Anderson et al. 1976), although this depends on the strain of virus and the susceptibility of the small ruminants involved, e.g., indigenous breeds versus exotic imports.

Perhaps the most significant resistance to mass vaccination of small ruminants is related to the cost, particularly in developing countries with large populations of sheep and goats and limited veterinary service budgets for disease control. As a result, small ruminants tend to be vaccinated, if at all, only when they are in association with large numbers of cattle or swine. When sheep and goats are included in regular vaccination campaigns in countries where FMD is endemic, they are rarely vaccinated more than once a year (Kitching and Hughes 2002). In Israel, all susceptible species, i.e., cattle, sheep and goats, are vaccinated regularly every year. In the event of an outbreak, all the animals at the outbreak site and in the surrounding area are immediately revaccinated (Leforban 2002).

Killed vaccines are currently in widest use and are usually trivalent, containing strains A, O, and C. However, many FMD vaccines are produced locally to reflect prevalent serotypes and strains and therefore vary in composition, so blanket recommendations for vaccination cannot be made. Based on local production techniques, they may also vary in immunogenicity, purity, and efficacy. Standards for FMD vaccine production are provided by the World Organization for Animal Health (OIE 2004a) and development and performance of killed FMD vaccines has been reviewed (Barteling et al. 2002).

Killed vaccines can be effective in goats when given at one-third the dose volume applied to cattle, with immunity usually lasting from five to six months

(Sharma 1981). When cattle, sheep, and goats are vaccinated with inactivated FMD vaccines, sheep, and especially goats, respond with lower mean antibody titers than cattle (Polydorou et al. 1980; Garland 1981). Optimal responses are obtained when two primary vaccinations are given about two weeks apart followed by regular boosters at six-month intervals.

The choice of adjuvant used in vaccine may have an impact on goat response to vaccination. In a study comparing oil adjuvanted and aluminum hydroxide adjuvanted FMD vaccine, the oil adjuvant elicited superior immune response, the rapidity of development of response was quicker, and the persistence of antibody at higher concentrations was greater (Patil et al. 2002). Vaccinating goats for FMD at the same time other vaccines are given does not adversely affect the host response (Gogoi et al. 2004).

Public concerns of animal welfare sparked by images of the mass destruction of livestock in the UK during the FMD outbreak of 2001 have stimulated considerable discussion among scientists and regulatory policy makers on the use of vaccination to control FMD as a way of reducing the slaughter of animals. The topic is complex and beyond the scope of this presentation. More extensive discussions of the role of vaccination in FMD control are available elsewhere (LeForban 2002; Pluimers et al. 2002; Radostits et al. 2007).

There is considerable ongoing research to develop new and more effective FMD vaccines. Objectives include identification of antigens which might confer immunity across multiple serotypes, vaccine formulations that may stimulate more rapid and stronger protective responses, and vaccines which contain antigenic markers that can be used in serologic testing to distinguish between vaccinated and naturally infected animals. Recent developments in FMD vaccine technology have been reviewed (Barnett and Carabin 2002; Grubman and Baxt 2004; Grubman 2005). There is also interest in the use of antiviral compounds such as type 1 interferon which, if administered to animals at risk in an outbreak, can block the establishment of new infections (Grubman 2005).

Akabane Disease

Akabane virus infection is a cause of congenital arthrogryposis and hydrancephaly in kids, lambs, and calves in Asia, Africa, the Middle East, and Australia.

Etiology

Akabane virus is a helical, enveloped, single-stranded RNA bunyavirus in the Simbu group of the family Bunyaviridae. The virus can be cultivated in chick embryos or Vero cell or hamster lung cell cultures, and passaged in suckling mice. It is an insect-transmitted arbovirus. The principal vector is the biting midge *Culicoides brevitarsis* but some other *Culi-coides* spp. and some species of *Aedes* and *Culex* mosquitoes are also known to carry the virus. Other arthropod-borne bunyaviruses in the Simbu group, the Aino and Peaton viruses, can also infect ruminants and cause congenital defects but there are as of yet no reports of clinical disease in goats with these two viruses. Antibodies to Tinaroo and Douglas viruses, non-pathogenic members of the Simbu group, have also been reported in goats (Cybinski 1984).

Epidemiology

The host range of Akabane virus includes goats, sheep, cattle, camels, horses, donkeys, and zebras, as well as other wild ruminants. Clinical disease has been observed only in goats, sheep, and cattle. Congenital arthrogryposis and hydrancephaly of domestic ruminants caused by the Akabane virus have been known in Australia and Japan for decades. Epizootics involving goats, cattle, and sheep have been reported from Japan (Inaba 1979) and Israel (Shimshony 1980). The virus infection is enzootic in Southeast Asia, extending northward to Japan and Korea, southward to northern and eastern Australia, and westward to the Middle East and eastern Africa. In Kenya, 50% to 90% of cattle sampled had serologic evidence of infection, while prevalence in goats and sheep was only 13% to 33% (Davies and Jessett 1985). New Zealand is free of infection (Oliver 1988). The infection is unknown in the Western Hemisphere, but in the United States another bunyavirus outside of the Simbu group, Cache Valley virus, has been associated with congenital arthrogryposis and hydrancephaly in sheep (Edwards et al. 1989). While there is serologic evidence of infection in goats, case reports in goats are rare (Edwards et al. 2003). The virus is discussed further in Chapter 13.

The geographic pattern of infection reflects closely the habitat of the arthropod vectors. In Australia, *Culicoides brevitarsis* is the only certain vector. Akabane virus has been isolated from *C. wadai* but no further studies have been carried out to confirm it as a vector (Animal Health Australia 2001). In Japan, *Culicoides oxystoma* may be the principal vector (Kurogi et al 1987), but the virus also has been isolated from the mosquitoes *Aedes vexans* and *Culex tritaeniorhynchus*. In the Middle East, the principal vector is *Culicoides imicola* (Brenner 2004). New infections with Akabane virus occur when weather conditions permit large populations of *Culicoides* to develop and expand or be carried by wind beyond their normal distribution limits (Al-Busaidy et al. 1988). Naive populations of livestock are then exposed.

Seroconversion occurs if these animals are nonpregnant, but no disease is observed (Sellers and Herniman 1981). If animals are pregnant, then abortions, stillbirths, or congenital defects are noted. Congenital

defects are most likely when dams are infected in early gestation. Malformations in goat kids are common when infection occurs between days thirty and fifty of gestation and kids are normal when infection occurs during the last one hundred days of gestation (Kurogi et al. 1977; Shimshony 1980). Epizootics tend to occur at four- to six-year intervals, presumably when immune animal populations are replaced by younger, naive populations.

Neonatal losses can be severe. In the Israeli epizootic of 1969 to 1970, 563 kids were affected, representing up to 50% of the kids born in some herds. Goats appeared more susceptible than sheep, and male, twin kids were more often affected than female, single kids (Shimshony 1980).

Pathogenesis

Infection with Akabane virus does not result in clinical disease unless animals are pregnant. Virus is introduced to susceptible hosts through insect bites. A viremia usually of a two- to four-day duration ensues; in pregnant dams, the virus enters the placenta and fetus. The primary site of viral damage in the fetus is the developing neural tube. In calves, with a bovine gestation of nine months, the outcome of fetal infection depends on the stage of fetal development, with hydrancephaly alone occurring with early infection, hydrancephaly and arthrogryposis occurring in later infection, and arthrogryoposis occurring alone in still later infection. Goats have a shorter gestation and, as mentioned above, fetal malformations develop when infection occurs between days thirty and fifty of gestation, and both hydrancephaly and arthrogryposis may be seen together in affected kids.

In hydrancephaly, occlusion of the ependymal system leads to increased cerebrospinal fluid pressure and dilatation of the ventricles, resulting in progressive degeneration and thinning of the cerebral cortex. The cerebellum and brain stem are less frequently affected. Loss of mentation, blindness, and incoordination result from this process. In arthrogryposis, there is a marked diminution or disappearance of ventral horn cells in the spinal cord that leads to a neuromyodysplasia. The failure of normal muscle development in the limbs and along the vertebral column results in muscle dystrophy, tendon contracture, and permanently flexed or extended joints. The joints themselves are normal. Infected fetuses produce antibody to the Akabane virus, and serum samples obtained before the neonate's ingestion of colostrum can be used to diagnose infection.

Clinical Findings

Infection of nonpregnant goats is subclinical. Pregnant goats may remain healthy but abort or deliver stillborn kids. Veterinarians may first encounter Akabane disease when assisting a goat in labor, because dystocias are common when arthrogryposis is present. During epizootics, cattle and sheep in the practice area may also be delivering abnormal calves and lambs. Kids with arthrogryposis are usually born alive and at term. They are unable to rise and affected joints are rigidly flexed or extended. There is severe muscle wasting; there may be scoliosis or wry neck. With hydrancephaly, the kids may be dummies. They may be able to stand and walk if arthrogryposis is not concurrent, but the gait may be uncoordinated. These kids are usually blind and unaware of their surroundings. If a nipple or teat is placed in the mouth, they may suck.

Clinical Pathology and Necropsy

Umbilical and heart blood samples or thoracic fluid from aborted fetuses, or precolostral blood samples from live kids should be tested for antibody to Akabane virus. Serum neutralization titers of 1:2 or more are considered evidence of fetal infection and the mean titer of infected goats tested in Israel was 1:18 (Kalmar et al. 1975). Titers measured using the hemagglutination inhibition test correlate closely with serum neutralization test results (Furuya et al. 1980). AGID and ELISA tests are also in use. If aborted fetuses or precolostral serum in kids are not available, increased titers from paired serum samples in does or in surviving kids will indicate recent infection.

Gross necropsy findings of hydrancephaly are a marked thinning or total disintegration of the cerebral cortex. Occasionally, cerebellar hypoplasia is also observed. In arthrogryposis, the joints are inflexible due to tendon contracture and the muscle bundles surrounding the long bones may seem absent or significantly reduced in volume. The muscles may appear fibrotic and grayish-white. If tendons around the joints are cut, the joints move freely and there are no lesions on articular surfaces. Scoliosis, kyphosis, and torticollis may be observed.

Microscopically, there is muscular dystrophy with loss of striation and disappearance of muscle fibers with replacement by fat and connective tissue. Lesions in the spinal cord include a dilated central canal and ventral fissure, cavitation of the ventral gray horns with neuronal degeneration, and edema. In the cerebrum, there is hydrocephalus or more extreme hydrancephaly, subependymal gliosis, and generalized edema. Edema may also be prominent in the cerebellum, and Purkinje cell degeneration is common (Nobel et al. 1971).

Virus may be present in tissues of affected kids or aborted fetuses, especially in the central nervous system and muscles (Kurogi et al. 1977). However, virus isolation is not usually successful because neutralizing antibody is also present in the kid.

Diagnosis

Akabane disease is diagnosed on the basis of arthrogryposis and/or hydrancephaly in newborn kids and the identification of a positive antibody titer in those kids or aborted fetuses. The possibility remains that other bunyaviruses which produce similar congenital disease in cattle and sheep may be reported to do so as well in goats, but so far this has not been confirmed. Currently, the differential diagnosis for congenital arthrogryposis-hydrancephaly in goats is limited to beta mannosidosis, the inherited lysosomal storage disease that can produce arthrogryposis but not hydrancephaly and occurs only in Nubian or Nubian-crossbred goats. Bluetongue is an important consideration in sheep, but goats, while frequently seropositive for bluetongue, rarely develop clinical disease. If they do, adult animals are also likely to show signs.

Treatment and Control

There is no treatment for Akabane virus infection. Affected kids do not survive long without a good deal of nursing care. There is no practical way to control the insect vectors. However, effective killed vaccines have been developed and are used in Australia and Japan, where epizootics have previously occurred. Vaccination should be carried out in advance of the breeding season.

BACTERIAL DISEASES

Mycoplasma arthritis

Mycoplasma infections account for serious morbidity and mortality in goats throughout the world. Several distinct disease entities are recognized, notably contagious caprine pleuropneumonia, contagious agalactia, and infectious keratoconjunctivitis. However, mycoplasma infections are usually septicemic, and polyarthritis frequently occurs in these and other *Mycoplasma* spp. infections of goats.

Etiology

The study of caprine mycoplasmosis remains an active and dynamic field, with new species and strains being identified and old species and strains being renamed and reclassified. The frequent identification of new isolates coupled with historical problems of erroneous taxonomic identification of old isolates has produced some considerable confusion about the various causes of caprine mycoplasmosis. The current status of important mycoplasma infections in goats has been recently reviewed (Ruffin 2001; Al-Momani and Nicholas 2006).

Genera of the prokaryotic class Mollicutes that infect goats include *Mycoplasma*, *Ureaplasma*, and *Acholeplasma*. Species of importance in goats are identified in Table 4.3; the main pathogens are *Mycoplasma* spp. The first four *Mycoplasma* spp. listed in Table 4.3 belong to the so-called *M. mycoides* cluster, a group comprised of six species with shared biochemical, serological, genomic, and antigenic characteristics. Four of these species are pathogenic for goats. This soon may be reduced to three because, at the time of this writing, there is a proposal under consideration by the International Organization for Mycoplasmology to reclassify *M. mycoides* subsp. *mycoides* large colony (LC) type as *M. mycoides* subsp. *capri* on the basis of 16S rRNA

Table 4.3. *Mycoplasma* spp. isolated from goats.

Mycoplasma species	Other hosts	Infected tissues		Associated diseases in goats	Pathogenicity	Geographic distribution
		Primary	Other			
M. capricolum subsp. *capricolum*	Sheep	Joints	Udder, lungs, ears, urogenital tract, eyes; septicemia possible	Polyarthritis, mastitis, pneumonia, neonatal death, keratoconjunctivitis	High	Australia, India, Europe, United States, Egypt
M. capricolum subsp. *capripneumoniae* (formerly strain F38)	Goats only	Respiratory tract	Potential for septicemia	Contagious caprine pleuropneumonia (CCPP)	High	Currently Near East, Africa
M. mycoides subsp. *capri**	Goats only	Respiratory tract	Joints, ears	Pleuropneumonia, arthritis	Moderate	Africa, Middle East, western Asia, southern and eastern Europe

Table 4.3. *Continued*

Mycoplasma species	Other hosts	Infected tissues		Associated diseases in goats	Pathogenicity	Geographic distribution
		Primary	Other			
M. mycoides subsp. *mycoides* (large-colony type)*	Rare in sheep; very rare in calves	Respiratory tract	Udder, joints, eyes, ears, potential for septicemia	Pleuropneumonia, mastitis, arthritis, keratoconjunctivitis, neonatal death, abortion	Moderate	Europe, Africa, Asia, Australia, North America
M. agalactiae	Sheep	Udder	Joints, eyes, urogenital tract, ears, rarely lungs	Contagious agalactia (CA), arthritis, pneumonia, keratoconjunctivitis, vulvovaginitis	High	Europe, United States, former USSR, Asia, North Africa
M. arginini	Sheep, chamois, many others	Respiratory tract	Urogenital tract, joints, eyes	Pneumonia, arthritis, keratoconjunctivitis, vulvovaginitis	Very low or non-pathogenic	Worldwide
M. conjunctivae	Sheep, chamois	Eyes	Respiratory tract, rarely joints	Keratoconjunctivitis, pneumonia, arthritis	Moderate	Worldwide
M. ovipneumoniae	Sheep	Respiratory tract	Eyes, urogenital tract	Initiator of pneumonia	Low	Worldwide
M. putrefaciens	Goats only	Udder	Joints, ears	Mastitis, arthritis	Variable	United States, France, Australia
M. mycoides subsp. *mycoides* (small colony type)	Primarily cattle; very rare in goats	Respiratory tract	Joints	Pleuropneumonia, polyarthritis	Unknown	Africa
M. bovigenitalium (same as ovine/ caprine M. serogroup 11)[+]	Primarily cattle and buffaloes; also sheep and goats	Reproductive tract	Udder, joints	Vulvovaginitis, cervicitis, endometritis, epididymitis, oophoritis, mastitis, arthritis	Variable with strain	Worldwide
Acholeplasma laidlawi	Many other hosts	Urogenital tract	Respiratory tract	No clinical disease produced	Non-pathogenic	Worldwide
Acholeplasma oculi	Sheep, cattle, horses, pigs	Eyes	Urogenital tract, lungs	Keratoconjunctivitis	Not well established	United States, United Kingdom, Japan, India
Ureaplasmas	Goat-specific strains exist	Urogenital tract	Respiratory tract	Vulvovaginitis	Not well established	Worldwide

*At the time of publication of this text, the International Organization for Mycoplasmology was considering action on combining *M. mycoides* subsp. *capri* and *M. mycoides* subsp. *mycoides* (large colony type) under the designation *M. mycoides* subsp. *capri* because they have been found to be identical in all but a few serological differences.

[+]At the time of publication of this text, it was proposed that *M. bovigenitalium* and ovine/caprine *Mycoplasma* serogroup 11 be combined under the designation *M. bovigenitalium* because of serological, structural, and genetic similarities (Nicholas et al. 2008).

sequencing which indicates a 99.9% phylogenetic similarity (Pettersson et al. 1996). The other two caprine pathogens in the *M. mycoides* cluster are *M. capricolum* subsp. *capricolum* and *M. capricolum* subsp. *capripneumoniae*.

Historically, there have been two forms of the species called *M. mycoides* subsp. *mycoides* in the *M. mycoides* cluster that shared similar immunologic and serologic characteristics but differed on the basis of colony morphology and specific biochemical tests (Cottew and Yeats 1978). The small colony (SC) type is the cause of contagious bovine pleuropneumonia (CBPP) and has been isolated from goats only rarely. The large colony (LC) type is principally a pathogen of goats and has a much wider geographic distribution. It only rarely infects cattle.

Reports of *M. mycoides* subsp. *mycoides* from diagnostic laboratories should clearly distinguish between these two organisms based on colony size and other discriminating factors to avoid confusion about the potential spread of CBPP to areas free from the disease, as CBPP is a highly regulated disease globally. This problem is less likely in the future as more sophisticated techniques such as PCR are applied for organism identification and because *M. mycoides* subsp. *mycoides* LC is likely to be reclassified and reported as *M. mycoides* subsp. *capri*, as mentioned above.

In addition to the established mycoplasmas identified in Table 4.3 as caprine pathogens, other mycoplasmas are reported from goats and new strains are continually being recognized. *M. bovis*, ordinarily a cattle pathogen, was isolated from a goat with pneumonia and found to be capable of causing caprine mastitis (Ojo and Ikede 1976). *M. bovigenitalium* has been isolated from the genital tracts of does with repeat breeding problems in India (Pathak et al. 1989), and recently it has been proposed that strains of the *Mycoplasma* ovine/caprine serogroup 11 be reclassified as *M. bovigenitalium* (Nicholas et al. 2008). The untyped strains G145 and A1343 have been isolated from goats in the United States (Al-Aubaidi 1972). Untyped strains identified as G, U, and V have been isolated from swabs of the ear canal of goats in Australia (Cottew and Yeats 1982). Several additional untyped strains have been isolated from ear swabs of California goats as well (DaMassa 1983).

Mycoplasmas are distinguished from other bacteria in that they do not have a rigid cell wall, and they possess only a cell membrane. They have the smallest genome of any free-living organism, but are capable of considerable phenotypic variation, producing variable surface proteins through complex genetic mechanisms which assist in evasion of the host immune system and adherence to host cells (Ruffin 2001). Mycoplasmas can be grown *in vitro* on culture medium but they are very fastidious and have numerous special growth require-

ments, including serum factors and yeast extracts. Many species produce characteristic spreading colonies with a "fried-egg" appearance. In general, these organisms are fragile away from the host and are rapidly inactivated by sunlight, dehydration, and heat, but are more resistant to cold. Effective disinfectants include formalin, phenols, cresols, peracetic acid, and iodophores. Procedures for the cultivation and differentiation of important caprine mycoplasmas have been reviewed (Nicholas and Baker 1998; Nicholas 2002).

Epidemiology

Arthritis caused by Mycoplasma in goats has been associated with numerous species. Major causes of importance include *M. agalactiae*, *M. capricolum*, *M. mycoides* subsp. *capri*, *M. mycoides* subsp. *mycoides* LC type, and *M. putrefaciens*. Minor causes include *M. arginini*, *M. conjunctivae*, and *M. mycoides* subsp. *mycoides* SC type.

M. agalactiae is the cause of contagious agalactia in goats and sheep and is discussed further in Chapter 14. Currently the disease is reported from Africa, Europe, Asia, and the Middle East, and is enzootic in much of the Mediterranean region. In the past, sporadic reports of *M. agalactiae* associated with arthritis and mastitis in individual goats have come from California (Jasper and Dellinger 1979; DaMassa 1983a). Goats are considered more susceptible than sheep. The highest incidence of disease is recorded in late spring and summer when does have kidded and are lactating. The morbidity can approach 100% and mortality ranges from 10% to 30%. The disease is characterized by the concurrent appearance of mastitis, arthritis, and keratoconjunctivitis, which are unlikely to be found together in a single animal, but are likely to be found throughout the herd. Respiratory involvement is minimal or absent. Transmission is by direct contact with infected animals or their discharges, including milk, urine, and lacrimal and nasal secretions. Introduction into the udder during milking is important in the spread of infection. Chronically ill or convalescent goats can sporadically shed the organism (Blaha 1989).

Contagious agalactia is considered by the World Organization for Animal Health (OIE) to be a transmissible disease of socio-economic importance within affected countries and also significant in the international trade of animals and animal products. As such it is regulated by governments in the international trade of livestock. Historically, *M. agalactiae* was recognized as the definitive etiologic agent of contagious agalactia. However, in recent years it has become clearer that *M. capricolum* subsp. *capricolum*, *M. putrefaciens*, and *M. mycoides* subsp. *mycoides LC* type (which may be identical to *M. mycoides* subsp. *capri*) also cause contagious agalactia syndromes in goats that are

largely indistinguishable from classic contagious aga-lactia. Therefore, the OIE now recognizes all four organisms as causes of contagious agalactia for regula-tory purposes (OIE 2004b). All four organisms fre-quently produce arthritis in goats in addition to mastitis, and they may also produce keratoconjuncti-vitis and/or pneumonia. The role of the various etio-logic agents in contagious agalactia syndrome has been reviewed (Egwu et al. 2000).

M. capricolum subsp. *capricolum* has a worldwide distribution and is considered to be highly pathogenic, yet disease due to this organism has been reported only sporadically from diverse geographic locations, including California (Cordy et al. 1955), France (Perreau and Breard 1979), Spain (Talavera Boto 1980), Australia (Littlejohns and Cottew 1977), Egypt (El-Zeftawi 1979), India (Banerjee et al. 1979; Sikdar and Uppal 1983), and Morocco (Taoudi 1988). Morbidity and mortality in these reports are quite variable. Arthritis is the pre-dominant sign in *M. capricolum* subsp. *capricolum* infection, but neonatal septicemia, pneumonia, keratoconjunctivitis, mastitis, and agalactia can also be seen. Transmission of *M. capricolum* subsp. *capricolum* occurs by direct contact with infected goats; inhalation of the organism from feces, urine, or respiratory dis-charges; and especially by ingestion of infected milk by sucking kids (DaMassa et al. 1983).

M. mycoides subsp. *mycoides* LC type, which may be identical to *M. mycoides* subsp. *capri* and soon renamed as such, has a worldwide distribution. It is a frequently reported caprine mycoplasma infection in the United States, particularly from eastern and western coastal states (DaMassa et al. 1983a; Kinde et al. 1994). Kids are more frequently and severely affected than adults. Though variable, mastitis may affect 25% to 33% of does, while morbidity and mortal-ity rates may exceed 90% in kids on the same premises.

The most common clinical findings in adults are fever, mastitis, pleuropneumonia, and arthritis. In kids, arthritis, septicemia, and meningitis are more common. In addition, polyserositis, osteomyelitis, keratocon-junctivitis, abscesses, and abortion are also reported. Reports from France, California, and Israel suggest that morbidity and mortality are highest in intensive commercial goat dairy operations (Bar Moshe and Rapapport 1981; Perreau et al. 1981; DaMassa et al. 1983a; East et al. 1983). In an outbreak in a goat dairy in North Carolina in 1996, forty-seven of sixty-five kids (72.3%) either died or had to be euthanized due to polyarthritis and/or septicemia (Butler et al. 1998). Economic losses caused by decreased production, diagnosis and treatment costs, and death of replace-ment stock can be devastating in severe outbreaks.

Infected, lactating does can be asymptomatic carri-ers, with high numbers of organisms being shed in the milk. These does may become clinically ill themselves as a result of management, nutritional, or climatic stresses. The most explosive disease outbreaks occur among kids after the onset of kidding season. The principal mode of transmission to kids is the oral route via daily ingestion of infected colostrum and milk (DaMassa et al. 1983a). The mode of transmission among adults is not as clear. Direct contact is possible but not very efficient (Rosendal 1983). Transfer of infection during the milking process by introduction into the teat seems to play a larger role, particularly because improvement of sanitary procedures slows infection rates in known-infected herds (East et al. 1983). Infection may be introduced into a herd by the introduction of subclinically infected milking does (East et al. 1983). In New Zealand, an outbreak of poly-arthritis in dairy calves due to *M. mycoides* subsp. *mycoides* LC type was linked to consumption of unpas-teurized bulk goat milk from an affected dairy goat herd (Jackson and King 2002).

From a historical perspective, it is worth noting that *M. mycoides* subsp. *capri* was long considered to be the primary cause of contagious caprine pleuropneumo-nia (CCPP). Though the organism can indeed produce a pleuropneumonia, the causative agent of the classi-cally described disease CCPP, which occurs exclusively in goats, is now known to be *Mycoplasma capricolum* subsp. *capripneumoniae*, and was formerly known as the *Mycoplasma F38* strain. While *Mycoplasma capri-colum* subsp. *capripneumoniae* infects only goats, *M. mycoides* subsp. *capri* can also infect sheep and cattle experimentally.

M. putrefaciens infects goats in the United States, Europe, and the Middle East. It was first isolated from mastitic goats in California in 1955 and identified as a distinct species in 1974. It has been identified with arthritis in kids in Spain (Rodríguez et al. 1994), mas-titis and arthritis in goats in France (Gaillard-Perrin et al. 1986), and mastitis and arthritis in goats in Cali-fornia. The potential for economic catastrophe with *M. putrefaciens* infection is pronounced. An outbreak in California in 1987 resulted in the destruction of an entire herd of 700 goats because of widespread masti-tis, arthritis, and abortions (DaMassa et al. 1987).

The major mode of transmission of this organism among adults is by introduction through the teat due to poor hygiene during milking. For kids, the disease is spread by feeding of infected colostrum or milk. Stresses such as crowding, poor nutrition, and lack of shelter from wind and rain may predispose kids to clinical disease. Intensive dairy operations are likely to be hardest hit. A serologic survey in California indicated that Angora goats recently imported from Texas had a higher prevalence of infection than indig-enous dairy breeds, but clinical disease caused by *M. putrefaciens* has not been recorded in Angoras

(Abegunde et al. 1981). In France, *M. putrefaciens* was identified as a cause of mastitis in a dairy goat herd and was treated with apparent success. However, at the beginning of the next lactation, *M. putrefaciens* could still be cultured from the udders, even though udders and milk were normal (Mercier et al. 2000).

All of the major mycoplasma species discussed above have been found in the ear canals and ear mites of normal goats. This represents an effective means for maintaining a carrier state and transmitting new infections to susceptible goats (Cottew and Yeats 1982; DaMassa 1983, 1990). In addition, all the species except *M. mycoides* subsp. *capri* have been isolated from the nasal and oral cavities and tonsils of clinically normal goats at necropsy (Cottew and Yeats 1981).

Among the minor causes of caprine mycoplasma arthritis, *M. arginini* is probably the least consequential. This ubiquitous organism causes minimal disease alone (Goltz et al. 1986) and is often isolated from clinically normal goats. It is frequently isolated in conjunction with other bacterial pathogens such as *Pasteurella* spp. from pneumonic lungs, and may serve as an initiator of bacterial pneumonia. There are occasional reports of *M. arginini* being isolated from the joints of arthritic goats (Barile et al. 1968; Al-Aubaidi et al. 1972), but the etiologic significance in arthritis is doubtful.

M. conjunctivae is found worldwide and associated primarily with keratoconjunctivitis in sheep and goats. However, it has the potential to become septicemic, and concurrent pneumonia and arthritis have been observed in at least one outbreak of keratoconjunctivitis caused by *M. conjunctivae* in a goat herd (Baas et al. 1977). The ocular disease is discussed in more detail in Chapter 6.

M. mycoides subsp. *mycoides* SC type is the cause of contagious bovine pleuropneumonia (CBPP). Although the disease is enzootic in cattle in many parts of Africa, and occurs sporadically in southern Europe with the last outbreak occurring in Portugal in 1999, the organism rarely infects goats. There are four published reports of caprine infection. The organism was isolated from joints of polyarthritic goats in New Guinea in 1955 and again from goats in Sudan and Nigeria in the 1960s. These represent, respectively, the O, P, and Vom strains (Cottew 1979). Most recently, it was isolated in Portugal from a ewe with mastitis and two goats with pneumonia (Brandao 1995). CBPP is a highly contagious disease and there is considerable effort to control its spread, particularly in Africa. There are concerns that goats may serve as a reservoir for *M. mycoides* subsp. *mycoides* SC type and thereby confound efforts to eradicate the disease in cattle (Sharew et al. 2005).

Mixed or concurrent mycoplasma infections causing arthritis and mastitis in goat herds can occur. An out-break in a Saanen herd in Spain involved *M. agalactiae* and *M. putrefaciens* (Gil et al. 1999) while a large goat herd in California experienced arthritis, mastitis, and sudden death due to *M. agalactiae* and *M. mycoides* subsp. *mycoides* LC type (Kinde et al. 1994). Both organisms were producing disease in the herd, but no affected individual goat was infected with both agents.

Pathogenesis

Mycoplasmal arthritis in goats always occurs as a result of septicemia. Therefore, it frequently involves multiple joints and is accompanied by generalized malaise, fever, and evidence of infection at other organ sites. Septicemic goats may die without manifestation of localizing signs.

Experimental infections with *M. mycoides* subsp. *mycoides* (LC type) in goats suggest that vasculitis, coagulopathy, and thrombosis play significant roles in the pathogenesis of mycoplasma septicemia, leading to infarction and necrosis in numerous organs (Rosendal 1981; Bolske et al. 1989). Complement activation by *M. mycoides* subsp. *mycoides* LC type may also be an important initiator of inflammation (Rosendal 1984). The pathogenic mechanisms of *M. mycoides* subsp. *mycoides* SC type have recently been reviewed (Pilo et al. 2007) and may serve as a framework for understanding mycoplasma pathogenicity in general.

Unlike other bacterial species whose virulence is determined by factors such as toxins and invasins, the virulence factors of *Mycoplasma* species seem to be determined by intrinsic metabolic or catabolic pathway functions or by proper constituents of the mycoplasmal outer surface. In *M. mycoides* subsp. *mycoides* SC type, a few virulence determinants have been identified, including capsular polysaccharide, which may give the organism the capacity to persist and disseminate in the host. In addition, there are adhesion factors, immunomodulating factors, and toxic metabolic pathway products, which exert cytotoxic effects. One example of the latter is the production of large amounts of cytotoxic H_2O_2 facilitated by the organism's capacity to import and metabolize glycerol.

Clinical Findings

Mycoplasma arthritis may be seen in all ages and breeds of goats but is most common in young kids and yearlings in dairy goat breeds. In many instances, there is a history of purchased goats introduced into the herd some months before onset of disease. Arthritis rarely occurs alone in an outbreak of mycoplasmosis. Mastitis, abortion, agalactia, pneumonia, or keratoconjunctivitis may occur concurrently or precede the onset of arthritis. The presentation may vary with age or production group. For example, mastitis may occur in

lactating does several months before arthritis is noted in kids. This underscores the importance of obtaining a thorough history. There is a tendency for disease incidence to increase around the kidding season.

Affected animals usually first show evidence of septicemia including fever of 104°F to 108.5°F (40°C to 42.5°C), anorexia, depression, weakness, and rough hair coat. One exception is in *M. putrefaciens* infection, where fever does not regularly occur (DaMassa et al. 1987). Some animals may die of septicemia without developing additional localizing signs. In most cases involving arthritis, lameness develops concurrently or within several days of the onset of fever but may precede the onset of joint swelling. Though a single joint may be affected, polyarthritis is the rule. Any diarthrodial joint may be involved but the carpi, tarsi, and stifle joints are most frequently affected, followed by the elbow and fetlock joints. The joints become swollen, hot, and painful. The pain is frequently so severe that affected goats refuse to bear weight on a single affected leg, or become persistently recumbent when multiple joints are involved. The clinical course is usually four to ten days and commonly ends in death if not treated. Occasional spontaneous recoveries occur, sometimes with complete resolution of joint swelling and lameness noted over several weeks. Morbidity and mortality are almost always higher in kids and yearlings than adults.

Goats with hot swollen joints should be carefully examined for indications of other organ system involvement, especially nasal discharges, increased lung sounds, corneal opacity or conjunctivitis, and mastitis or agalactia, all of which can occur in mycoplasmosis. Diarrhea is not usually associated with mycoplasmosis but has been reported in affected kids concurrently experiencing coccidiosis (East et al. 1983).

Clinical Pathology and Necropsy

Leukopenia with neutropenia is likely in the early stage of septicemia, and neutrophilic leukocytosis with hyperfibrinogenemia in the later stages. Synovial fluid analysis can be useful in diagnosing arthritic mycoplasmosis. While the volume of fluid may not be increased, the color is frequently yellow to red-brown, and cytologic examination reveals increased cellularity, particularly with increased numbers of neutrophils.

Diagnosis of mycoplasmosis requires isolation or identification of the organism or confirmation of serologic evidence of infection. Culture techniques are available for isolation of the organism, and have been improved in recent years, making culture a more reliable diagnostic method than in the past. Nevertheless, two species—*M. capricolum* subsp. *capripneumoniae*, the cause of CCPP, and *M. conjunctivae* are highly fastidious and remain more difficult to culture reliably.

The World Organization for Animal Health recommendations for preferred samples from living animals include: nasal swabs and secretions, milk from mastitic females or from apparently healthy females where there is a high rate of mortality/morbidity in kids, joint fluid from arthritic cases, and eye swabs from cases of ocular disease. Blood may yield mycoplasmas during the acute stage of the disease when there is mycoplasmaemia, but blood may also be taken for antibody detection from affected and non-affected animals. The ear canal can also be a productive source of pathogenic mycoplasmas, although the presence of nonpathogenic mycoplasmas in the ear canal may make confirmation difficult. At necropsy, samples should include: udder and associated lymph nodes, joint fluid, lung tissue taken at the interface of healthy and diseased lung and pleural/pericardial fluid. Samples should be dispatched quickly to a diagnostic laboratory in a moist and cool condition (OIE 2004b).

Biochemical tests still play an important role in differentiating isolates from culture, but identification of isolates can also be achieved using specific antisera in growth inhibition tests, film inhibition tests, the indirect fluorescent antibody (IFA) test, or a rapid dot immunobinding test. Polymerase chain reaction (PCR) assays have emerged as important diagnostic tools for identification of mycoplasmas. For instance, a set of PCR tests was developed that could detect all members of the *M. mycoides* cluster and distinguish *M. mycoides* subsp. *mycoides* LC type and *M. mycoides* subsp. *capri* from *M. capricolum* subsp. *capripneumoniae* and *M. capricolum* subsp. *capricolum* (Bashiruddin et al. 1994). Another PCR can specifically identify *M. capricolum* subsp. *capripneumoniae* (Woubit et al. 2004) and another specifically *M. agalactiae* (Tola et al. 1997). More recently, a new diagnostic test based on PCR of the 16S rRNA gene with *Mycoplasma*-specific primers and separation of the PCR product according to primary sequence using denaturing gradient gel electrophoresis (DGGE) allowed for the differentiation of sixty-seven *Mycoplasma* spp. of human and veterinary origin (McAuliffe et al. 2005).

PCR tests can be used directly on field samples when there is urgency in the need for a diagnosis, or they can be applied to organisms growing in culture. When used on field samples, false-negative results are possible.

Complement fixation tests, ELISA, and immunoblotting tests are used for serologic testing. ELISAs currently tend to be favored over complement fixation tests because of their greater sensitivity and ease of use for large scale testing (Nicholas 2002). Serologic tests are not generally used for the diagnosis of individual cases of mycoplasmosis, but can be valuable on a herd basis when acute and convalescent samples are obtained three to eight weeks apart. The application of

diagnostic techniques for small ruminant mycoplasmosis has been reviewed (Nicholas and Baker 1998) and details of test methods recommended by the OIE for contagious agalactia syndrome and contagious caprine pleuropneumonia are available on the Internet (OIE 2004b, 2004c).

A variety of gross necropsy findings may occur in goats with septicemic mycoplasmosis. These include patchy or diffuse pneumonia; pulmonary congestion or edema; a watery, yellow or red-tinged hydrothorax; fibrinous pleuritis with adhesions to the chest wall; fibrinous pericarditis; serous or fibrinous peritonitis; meningitis; mastitis with firm, hyperemic glandular tissue; swollen, edematous lymph nodes; and fibrino-purulent arthritis.

In acute or peracute arthritis, synovial fluid is as described above. In advanced or severe cases, the affected joint is filled with a white to yellow fibrinopurulent exudate. There may be erosions of the articular cartilage; the joint capsule and periarticular tissues are hyperemic, thickened, and edematous; and fibrin tags may be noted extending up tendon sheaths.

Histologically, the joint lesion is characterized by necrosis of the synovium and joint capsule with fibrin covering the joint surfaces. There is congestion and edema of the subsynovial tissue with invasion of neutrophils into necrotic tissue and the joint spaces. Vasculitis and thrombosis may be observed with perivascular infiltrates of macrophages. Neutrophilic infiltration of adjacent bone marrow and foci of osteomyelitis may be present. Pneumonic and mammary lesions are described, respectively, in chapters 9 and 14. Other possible microscopic lesions observable in septicemic mycoplasmosis include myocardial and adrenal cortical necrosis, renal infarction, glomerulitis, enteritis, focal hepatic necrosis, focal splenic necrosis with depletion of white pulp, and lymphadenitis.

Diagnosis

Definitive diagnosis of mycoplasmosis of goats depends on isolation or identification of a known pathogenic *Mycoplasma* spp. from affected tissues. This is increasingly being accomplished with the aid of PCR. Veterinarians should suspect mycoplasma infection when arthritis occurs in conjunction with fever and generalized malaise, and when other localized infections such as pneumonia, mastitis, abortion, and keratoconjunctivitis occur in the herd or flock, either concurrently or historically. Mycoplasma infection should be considered even when a single case of arthritis is observed in a herd or flock as morbidity is not always high, and sporadic cases may precede a generalized outbreak. The differential diagnosis for caprine arthritis is given earlier in the chapter. The differential diagnoses for pneumonia, mastitis, abortion, and keratoconjunctivitis are discussed elsewhere in the text.

Treatment

The prognosis for recovery is generally poor in clinical mycoplasmosis involving arthritis, pneumonia, and mastitis, even with aggressive therapy. An extended course of parenteral antibiotic therapy is required, usually ranging from five to fourteen days. Complications of lameness from repeated injections are common. Because mycoplasmosis can spread rapidly through a herd or flock, all contact animals should be treated at the same time when the disease is identified in individual animals. Treatment, no matter how successful in controlling clinical disease, may not eliminate the carrier state. In fact, under some regulatory guidelines, treated animals are regarded as infected.

In general, *Mycoplasma* spp. are most often sensitive to tetracyclines, the macrolide antibiotics (tylosin, erythromycin, oleandomycin, spiramycin, tilmicosin), and tiamulin. The aminoglycosides, including spectinomycin, are sometimes effective, as are nitrofurans and chloramphenicol. Lincomycin has also been used successfully. Susceptibility of the various *Mycoplasma* spp. to these different antibiotics is variable, even within the same drug class, so that *in vitro* culture and sensitivity should be carried out whenever possible (Adler and Brooks 1982; Al-Momani et al. 2006). Antibiotics that inhibit cell wall peptidoglycan synthesis are not effective, and it is not unusual for owners to have treated mycoplasma infections unsuccessfully with penicillin before calling the veterinarian. There is also evidence that *Mycoplasma* spp. develop resistance to antibiotics. The *in vitro* susceptibility of various caprine mycoplasmas to a wide range of antibiotics has recently been reported (Al-Momani et al. 2006; Antunes et al. 2007).

A wide range of doses has been suggested for treatment of caprine mycoplasmosis, and antibiotic therapy is often met with less than satisfactory results. All the doses given here are for once daily intramuscular injection administered for at least five days: oxytetracycline at 15 mg/kg bw; streptomycin at 30 mg/kg bw, tiamulin at 20 mg/kg, and tylosin at doses of 5 to 44 mg/kg bw, but most commonly at 20 mg/kg. Spiramycin has been given at a loading dose of 50 mg/kg followed by daily doses of 25 mg/kg (Perreau 1979). More recently, the fluoroquinolone danofloxacin was reported to be highly effective in the treatment of CCPP when given at a dose of 6 mg/kg bw SQ once and repeated at forty-eight hours (Ozdemir et al. 2006).

Tiamulin was reported to be severely irritating at the injection site, producing general excitation in young goats (Ojo 1984). In poultry and swine, tiamulin given in conjunction with monensin produces a toxic myopathy (Pott and Skov 1981). Although not reported in goats, caution is advised when monensin is used as a

coccidiostat at the time of tiamulin therapy. A combination of lincomycin at a dose of 5 mg/kg and spectinomycin at 10 mg/kg given intramuscularly once daily for 3 days produced recovery in 55% to 80% of treated goats and sheep with contagious agalactia in a field trial in Greece (Spais et al. 1981). Lincomycin used orally, however, has been associated with severe toxic reactions and high mortality in a large sheep flock in the United States (Bulgin 1988).

Control

Specific mycoplasmal diseases such as contagious agalactia and contagious caprine pleuropneumonia are of great regulatory concern to countries free of disease, and importation of goats from known infected countries is prohibited. Outbreaks are usually controlled by stamping out procedures. In enzootic regions, restrictions on animal movement, testing and culling of infected animals, and in some cases, vaccination are carried out. In France, vaccination for contagious agalactia is prohibited and control is based on test and slaughter.

A variety of vaccines are available and in use in various countries against *M. agalactiae, M. mycoides* subsp. *capri*, and *M. mycoides* subsp. *mycoides* LC type. In Europe, live mycoplasma vaccines are not acceptable and killed vaccines are used. Live vaccines may be more immunogenic but they also have been associated with transient infection and shedding of the organism, placing other animals at risk if they are not also vaccinated. An inactivated vaccine against *Mycoplasma capricolum* subsp. *capripneumoniae* to control CCPP is produced commercially in Kenya and is said to provide protection for one year (OIE 2004c).

There are several recommendations for controlling the introduction and spread of mycoplasmas in individual goat herds. Closed herds should be maintained where there is no history of mycoplasmosis, especially in commercial dairy operations. No animals should be purchased, and animals from the herd should not be brought to shows because of the risk of exposure to carrier animals.

When mycoplasmosis has occurred on the premises, management procedures should be evaluated, particularly in the areas of milking and kid rearing, and aggressive efforts made to reduce the risk of transmission (East et al. 1983; Rowe 2006). When mastitis has occurred, milk samples should be cultured from all lactating does, and infected, carrier does should be culled or at least managed as a separate string, housed and milked separately.

In the milking parlor, strict hygiene should be observed; a number of specific recommendations have been made (Rowe 2006). Does should be spray pre-washed or pre-dipped and individual paper towels used to dry the udder. Post-milking teat dipping is also essential. Milkers should wear gloves and disinfect them between does. Teat cups should be back flushed or dipped in disinfectant between does, and thorough clean-up of the pipeline and milking equipment must be done after each milking. Does with elevated California mastitis test (CMT) reactions, elevated somatic cell counts (SCC), or clinical mastitis should be removed immediately from the milking string and a milk sample frozen for culture. Dairies should have weekly samples frozen from the tank for routine monitoring, and increase in SCC or increase in CMT on the dairy should be aggressively pursued.

Infected groups of kids should be culled to slaughter. Then, new kids should be separated from dams at birth and fed heat-treated colostrum prepared as described earlier in this chapter for control of caprine arthritis encephalitis virus infection. Kids should then be housed separately from adults and fed pasteurized milk or milk replacer. When these kids mature and reach their first lactation, the milk should be cultured and the doelings hand milked until a negative culture allows them to enter the milk string. Long-term surveillance by milk cultures should be continued in herds that have previously experienced mycoplasmosis. Regular herd-wide treatment of ear mite infestations is also advisable because of the potential role of these parasites in mycoplasma transmission. Systemic ivermectin is effective against *Psoroptes cuniculi*, but may not be effective against *Raillietia capra*. It should not be used in lactating does.

Bacterial Polyarthritis

Bacterial polyarthritis, also known as joint ill, occurs predominantly in neonates as a sequela to omphalophlebitis or bacteremia.

Etiology and Pathogenesis

A variety of bacteria have been isolated from joints of goats with arthritis. The most commonly reported isolates from kids include *Arcanobacterium* (*Actinomyces*) *pyogenes*, *Escherichia coli*, *Streptococcus* spp., and *Staphylococcus* spp., all common environmental contaminants that can gain entry into kids via the umbilicus (Guss 1977; Adams 1983; Nayak and Bhowmik 1988). More recently, *Streptococcus dysgalactiae* (Blanchard and Fiser 1994), *Pasteurella multocida* (Bhowmik and Dalapati 1995), and *Klebsiella pneumoniae* (Bernabé et al. 1998) have been reported as causes of caprine arthritis. Polyarthritis occurs secondary to bacteremia, when circulating bacteria localize in joints and produce a destructive inflammatory response. Underlying immunodeficiencies can predispose to the development of bacterial polyarthritis.

Historically, *Erysipelothrix rhusiopathiae*, a soil-borne pathogen, has been responsible for a high incidence of polyarthritis in young lambs after castration and tail

docking, or as a result of navel infection. Improved hygiene and disinfection in lamb management have reduced the incidence of this disease and it is now considered to be of minor importance (Kimberling 1988). Some sources refer to *E. rhusiopathiae* polyarthritis as also occurring in kids (Guss 1977; Vaissaire et al. 1985). However, documented cases of infectious arthritis due to this organism in goats are scarce (Eamens et al. 1985). Similarly, texts or review articles sometimes refer to chlamydial arthritis in small ruminants. However, while the disease is well established in lambs, documentation of the condition in goats is lacking (Nietfeld 2001).

Epidemiology

Bacterial polyarthritis is most often seen in newborns and young kids after bacteremia. Factors that predispose these goats to bacteremia include kidding in contaminated environments, poor sanitation in housing, the development of omphalophlebitis after failure to disinfect the navel at birth, and failure of passive transfer of immunity via colostrum from the dam. Navel infection is not a prerequisite to bacteremia and polyarthritis. An outbreak due to *Klebsiella pneumoniae* occurred on a farm where navel disinfection was routine. It was postulated that infection occurred via the intestinal route in association with a recent switch to feeding artificial colostrum (Bernabé et al. 1998).

Bacterial polyarthritis is not restricted to young goats. An outbreak of infectious arthritis due to *Pasteurella multocida* affected twenty-two adult goats in a herd in India (Bhowmik and Dalapati 1995). Polyarthritis and limb edema with pain and reluctance to stand were seen in multiple adult Saanen does in a large California dairy goat herd. *Streptococcus dysgalactiae* was cultured from affected joints. While this organism is known to cause mastitis in cattle, mastitis was not a problem in this goat herd and the source of the infection was not identified. Interestingly, the herd was comprised of multiple dairy breeds but only Saanens were affected (Blanchard and Fiser 1994).

Clinical Signs

Affected kids have hot, swollen, painful joints, and may be reluctant to rise or walk. They usually have a fever in the range of 103°F to 105°F (39.4°C to 40.6°C). Carpi, stifles, and hocks are most often affected, but not exclusively. Any number of joints can be involved. Concurrent or previous episodes of diarrhea, pneumonia, or navel abscess are common. The umbilical stump should be palpated for evidence of omphalophlebitis.

Clinical Pathology and Necropsy

A neutrophilic leukocytosis or a leukopenia (in the case of Gram-negative sepsis) may be seen. Arthrocentesis reveals an abnormal, turbid, and flocculent synovial fluid with increased total protein and elevated cell counts consisting primarily of neutrophils (Nayak and Bhowmik 1990; Bhowmik and Dalapati 1995). Serum immunoglobulin levels are often low, reflecting the predisposing failure of passive transfer of colostral antibody. At necropsy, multiple joints may contain serofibrinous or purulent synovial fluid, and there is evidence of inflammation in the synovium and possibly cartilage erosion and hyperplasia of synovial villi. Evidence of infection may also be present in other organ systems, especially the lungs, gastrointestinal tract, and central nervous system. The umbilical remnant is often thickened and may contain focal abscesses.

Diagnosis

Bacterial polyarthritis and mycoplasma arthritis may occur in young goats under similar circumstances and with similar clinical presentations. Confirmation of the diagnosis and differentiation from mycoplasmosis depend on culture and identification of the causative agent.

Treatment

Successful therapeutic management of bacterial polyarthritis is difficult in goats, especially when economic constraints are present. Bacterial culture of affected joints and antibiotic sensitivity testing should be performed whenever possible. Joint lavage and intra-articular antibiotic therapy may be attempted in extremely valuable individuals. In most cases, practical therapy is limited to the parenteral administration of broad spectrum antibiotics and anti-inflammatory drugs. Little information is available about the concentration of various antibiotics in the joints of goats, and antibiotic selection is largely empirical. The prognosis for complete recovery in these cases is guarded.

Control

Bacterial polyarthritis is best managed by prevention. Extensively managed goats should have access to fresh, well-drained areas for kidding. For intensively managed goats, bedding should be changed frequently in kidding pens and pens disinfected regularly. Adequate and early ingestion of colostrum should be ensured. Umbilical cords should be left at least 4 cm long and dipped in disinfectant as soon after birth as possible. Tincture of iodine or strong (Lugol's) iodine solution are commonly used and effective. In problem herds, redipping navels on the second day may be helpful in controlling infection.

Osteomyelitis

Bacterial infections of the bone are infrequent in goats. When they occur, they most often result from
Figure 4.8. Cross section of the sternum of a goat showing a chronic abscess surrounded by much fibrous connective tissue, and with a tract penetrating the thorax. (Courtesy of Dr. M.C. Smith.)

Figure 4.9. Radiographic evidence of osteomyelitis in the ribs of a goat (note arrows). (Courtesy of Cummings School of Veterinary Medicine at Tufts University.)

septicemia or extension from local infections associated with puncture wounds or other types of trauma. The most common occurrence of osteomyelitis in goats involves the sternebrae secondary to skin trauma and chronic abscesses occurring in the soft tissues covering the sternum. These soft tissue lesions are associated with housing of goats on concrete or other hard surfaces with inadequate, wet, or unsanitary bedding and with prolonged sternal recumbency as is often associated with chronic CAE arthritis. If not treated early and aggressively, these infections become chronic and untreatable, leading to sternal osteomyelitis and possible extension into the chest, causing pleuritis and pneumonia (Figure 4.8). The prognosis is poor in these cases. Reports of successful treatment of osteomyelitis in goats with antibiotic therapy are lacking.

Other instances of osteomyelitis are sporadic. Infection of the femur has been reported in an eight-month-old Nubian buck secondary to septic gonitis. Lameness in the affected limb was severe. *Pseudomonas aeruginosa* was isolated from the stifle joint. The case was successfully managed by amputation of the affected limb (Ramadan et al. 1984).

Multifocal osteomyelitis due to *Corynebacterium renale* has been diagnosed in an eighteen-month-old French Alpine kid (Altmaier et al. 1994). The goat was lame on the right forelimb and radiographs revealed a fracture of the distal scapula associated with focal demineralization of bone and multifocal, lytic lesions in the ribs (Figure 4.9). At time of necropsy, osteomyelitis was confirmed and evidence of septicemia was present, with abscesses noted in intestine, lymph nodes, and liver.

An unusual multifocal *Rhodococcus equi* osteomyelitis of the skull and thoracic vertebrae has been recorded in a two-year-old Saanen doe in Australia. The clinical presentation was progressive posterior paralysis due to spinal cord involvement (Carrigan et al. 1988). Suppurative vertebral osteomyelitis and diskospondylitis have been reported in a three-week-old goat with acute hind limb paresis but the cause was not identified (Alexander et al. 2005).

Lyme Disease

Lyme disease or Lyme borreliosis is a tick-borne spirochetal disease of humans and animals originally described in people in Lyme, Connecticut, in 1977. The predominant clinical sign is arthritis. The disease is now known to occur in the northeastern, midwestern, and northwestern portions of the United States, as well as in Europe, Russia, China, Japan, and Australia, with a higher prevalence in forested regions. The causative agent is the spirochete *Borrelia burgdorferi* and it is transmitted mainly by *Ixodes* spp. ticks that normally complete their life cycle on deer and mice. Fragmentation of forest habitat and a concomitant increase in white-footed mouse (*Peromyscus leucopus*) populations relative to other small mammalian tick hosts is believed to be responsible for an increasing prevalence of the disease, at least in the United States (Ostfeld and LoGiudice 2003). Larval, nymph, and adult stages of *Ixodes* ticks are capable of transmitting the infection. While the different stages have different host feeding preferences among small and large mammals, all stages

feed on and can infect humans. Risk of transmission is highest in spring and fall when nymphs and adults are most active.

Seroepidemiological studies on Lyme disease have been carried out around the world on various mammals and many of these surveys have included goats. The seroprevalence of antibodies to *B. burgdorferi* in goats has been reported as 5% in Bolivia (Ciceroni et al. 1997), 8.5% in France (Doby and Chevrier 1990), 17.2% to 19.4% in Slovakia (Travnieek et al. 2002), 18% in Egypt (Helmy 2000), 36.8% in Italy (Ciceroni et al. 1996), 48% in Bulgaria (Angelov et al. 1993), and between 19.1% and 61.3% in different provinces of China, with goats in mountainous regions having much higher seroprevalence than those in plains regions (Zhang et al. 1998; Long et al. 1999). A serosurvey of humans in the Canary Islands noted that male goat farmers had significantly higher seroprevalence than men of similar age who were not goat farmers and that the rate of seropositivity in goat farmers was three times higher than that of the general population. This suggests that goats may serve as a reservoir for human infection or that goat herders at pasture are more frequently exposed to infected ticks (Carranza et al. 1995). Assays for detection of antibody to *B. burgdorferi* currently in use include ELISA, the indirect immunofluorescent antibody test, and the western blot.

Clinical Lyme disease is well described in humans and dogs and also occurs in horses and cattle (Steere 1989). The disease in humans (Hengge et al. 2003) and in horses (Butler et al. 2005) has recently been reviewed. Cattle with acute Lyme disease show fever, a stiff gait, swollen joints, and decreased milk production. They may also show edematous lesions on the hairless skin of the udder and chronic weight loss (Radostits et al. 2007).

While goats and sheep commonly show serologic evidence of infection, definitive confirmation of clinical Lyme disease, manifested as arthritis, remains elusive in small ruminants. Two cases of suspected Lyme borreliosis in lambs were reported from Norway in 1992. The lambs were from flocks in a district heavily infested with *Ixodes ricinus* ticks and both had high serum IgG antibodies to *B. burgdorferi* by ELISA test, but attempts to isolate spirochetes were unsuccessful (Fridriksdottir et al. 1992). Presumptive cases of Lyme disease in goats and sheep were reported from endemic regions of Connecticut (Baldwin 1990). Putative signs in affected goats include depression, fever, pain in joints sufficient to preclude weight bearing, back pain, a bow-legged stance, an unsteady gait in the hind end, and a stiff neck. Ticks may be difficult to find on the animal because the infective nymphal stages are only pinhead size. Alternate day benzathine penicillin therapy carried out for twenty-one to twenty-eight

days was reported as successful in these goats. In cattle, daily treatment with either penicillin or oxytetracycline for twenty-one days is recommended. A vaccine is now commercially available for use in dogs but is not approved or recommended for use in goats.

To date, the infective organism has not been isolated or identified from any presumed case of Lyme disease in goats. While affected animals had serologic evidence of infection, serologic surveys indicate that many individual animals with antibodies show no sign of clinical disease. Lyme disease may indeed occur in goats; however, definitive proof is still lacking. Presumptive diagnosis of Lyme disease should be made with caution and only in areas where the disease is known to occur in other animal species and only after other known causes of caprine arthritis, especially CAE and mycoplasmosis, have been definitively ruled out.

Confirmation of the presence of *B. burgdorferi* in affected tissues is still required for definitive diagnosis. Cultures are difficult to maintain and require several weeks to grow. Concentrations of organisms in affected organs or fluids may be very low, making culture problematic. However, alternatives to culture have become available for identifying the organism. PCR techniques can be used to identify *B. burgdorferi* in synovial fluid samples from affected joints or milk (Lischer et al. 2000) or from tissues at necropsy.

Clostridial Myositis and Myonecrosis

Blackleg and malignant edema (gas gangrene) are common, costly diseases of cattle and sheep caused by the "tissue invading" or "gas gangrene" group of clostridial organisms. In contrast, these clostridial diseases are uncommon in goats. One possible explanation is that the causative bacteria are soil-borne organisms that gain entry into livestock primarily through grazing of low lying, wet pastures. As browsing animals, goats may be less frequently exposed to clostridial spores in soil, though this hypothesis is unproven.

Etiology and Pathogenesis

Clostridium chauvoei, *C. septicum*, *C. sordelli*, and *C. novyi* are Gram-positive, rod-shaped, spore-forming, toxin-producing, anaerobic bacteria. They are ubiquitous in soil and persist for long periods under the protection of sporulation. They may also be present in the intestinal tract and liver of normal livestock without producing disease. Classical or true blackleg is caused by *C. chauvoei.* "False" blackleg, more appropriately referred to as malignant edema, is caused most often by *C. septicum*, but *C. novyi*, *C. sordelli*, *C. chauvoei*, and even *C. perfringens* have been isolated from lesions typical of malignant edema (Radostits et al. 2007).

The pathogenesis of blackleg is incompletely understood. It is thought that grazing animals ingest spores

of *C. chauvoei* that cross the alimentary epithelium and are carried to muscle tissue via the lymphatics and blood. Spores remain dormant until local conditions in muscle favor bacterial multiplication. This might involve muscle trauma or circulatory disturbances that create anaerobic conditions. The proliferation of bacteria is accompanied by release of toxins that produce a necrotizing myositis and a fatal toxemia.

Malignant edema occurs when spores are introduced into tissue by penetrating wounds, which often result from routine management activities such as vaccinations, disbudding, castration, and especially shearing. Fighting and head butting among bucks can also facilitate introduction of spores and produce a type of malignant edema known as "swelled head." Tissue damage associated with wounds creates anaerobic conditions that allow bacterial proliferation. Toxins are released that produce severe localized inflammation and generalized, fatal toxemia. Local inflammation is often characterized by tissue necrosis with accumulation of edema and gas. Subcutaneous and connective tissue is often more directly involved than muscle, but muscle can be affected.

Epidemiology

Clostridial myositis has been reported infrequently in goats, mostly from southern Africa, Australia, and New Zealand. Angora or feral goats are most often affected, but this may reflect the preponderance of such goats in these locations rather than a breed predisposition. In the United States, it has been observed that blackleg and malignant edema are virtually unknown in goats, even where the diseases occur frequently in other animals on the same premises (Guss 1977).

A review of clostridial diseases in Australia indicated that classical blackleg due to *C. chauvoei* is virtually unreported and that goats may be less susceptible to the disease than sheep (King 1980). Mortality due to navel infections with *C. septicum* is also seen less frequently in kids than in lambs. More common is *C. novyi* infection in fighting bucks, leading to swelled head. The relationship of *C. novyi* infection to hepatic "black" disease in goats is discussed in Chapter 11.

In New Zealand, a group of 460 Angora and feral does were given intramuscular injections of cloprostenol to induce abortion. Fourteen of them (3%) died from *C. chauvoei* infection within six days after injection (Day and Southwell 1979). Gas gangrene after intramuscular injections with various medications is not uncommon in other livestock species.

In South Africa, the shearing of sheep is commonly associated with *C. chauvoei* infection, while shearing of Angora goats is not (Van Tonder 1975). It is presumed that the nature of the fleece and the relative absence of

skinfolds and body pleats in goats produce fewer shearing wounds, with less secondary invasion of clostridial spores. When post-shearing clostridial infections do occur, they are more often caused by *C. septicum.* Gangrenous metritis caused by mixed clostridial infections with *C. septicum*, *C. novyi*, and/or *C. chauvoei* is the most common clostridial problem seen in Angora goats in South Africa. The condition is associated with the penning or kraaling of does during the kidding period (Bath et al. 2005). Morbidity is variable, but case mortality rates can approach 100% (Van Tonder 1975). In Namibia, spontaneous deaths of grazing adult cattle, sheep, and goats have been recognized as caused by *C. septicum* (Wessels 1972).

Clinical Signs

In blackleg, the clinical course is short and affected animals are usually found dead or recumbent and moribund. A sanguinous discharge from the nostrils or anus may be present. If there is a chance to observe animals early in the course of disease, lameness or a stiff gait may be noted when limb musculature is involved.

In malignant edema, which is associated with wounds or injections, there is usually heat, swelling, pain, and erythema at or around the wound site from twelve to forty-eight hours after introduction of the infection. As the infection progresses, skin becomes discolored and cold and subcutaneous gas may be identifiable as crepitus. Animals rapidly become weak and shocky and exhibit a high fever exceeding 106°F (41.1°C), and will die within hours.

Swelled head is seen primarily in group-housed bucks that fight. Large edematous swellings occur, usually beginning around the eyes and extending down the face and neck, sometimes to the chest. The swelling is quite disfiguring. The taut skin cracks and yellows, and edematous fluid seeps from the cracks. Affected bucks become extremely depressed and weak, with heads held low. They fall over and remain recumbent, dying within one to two days of onset of signs (King 1980).

Clinical Pathology and Necropsy

Impression smears and swabs taken from wound sites or subcutaneous aspirates may aid in the antemortem diagnosis of malignant edema or swelled head. Gram staining, fluorescent antibody testing, and anaerobic culturing can all be performed. In blackleg and many cases of malignant edema, necropsy is the primary approach to diagnosis. For bacteriologic confirmation, it is imperative that fresh necropsies be performed, preferably within one hour of death. Otherwise, clostridial organisms present in the alimentary tract or liver can invade tissues post mortem and produce false-positive diagnoses.

At necropsy, goats with blackleg may exhibit crepitant swellings over heavy muscle groups as well as gas bubbles in liver, kidney, and uterus and excessive accumulations of serosanguinous fluids in all body cavities (Pauling 1986). Goats with malignant edema may demonstrate generalized and advanced decomposition of the carcass, even when necropsy is performed shortly after death. There is a characteristic smell of clostridial decomposition and gelatinous infiltration of the pericardium. Pericarditis and myocarditis may be observed (Wessels 1972). In malignant edema and swelled head, there is marked accumulation of yellow or serosanguinous edema fluid in subcutaneous and intermuscular spaces, especially around wound sites.

Diagnosis

Definitive diagnosis of clostridial myositis in goats depends on confirmation of the presence of the causative clostridial organisms from tissues or wound sites of affected animals before or immediately after death. This can be accomplished by anaerobic culture, fluorescent antibody staining, or as has been recently reported, multiplex PCR (Sasaki et al. 2002).

When goats are found dead in the field, the differential diagnosis should include tympany, lightning strike, poisonings, and anthrax, especially because the latter condition is also associated with post mortem nasal and anal sanguinous discharges. If there is any suspicion of anthrax, the carcass should not be opened.

Treatment

Opportunities to treat blackleg are limited due to the rapid, fatal outcome. Individual cases of malignant edema, swelled head, or genital gas gangrene are more likely to be detected early enough for therapeutic intervention. In malignant edema and swelled head, the skin over affected regions should be liberally incised and serial fasciotomy performed on underlying muscles to allow aeration and drainage of infected tissues. Intravenous penicillin therapy at a dose of 20,000 IU/kg every six to eight hours should be initiated immediately and maintained until the patient is stabilized. The animal can then be placed on intramuscular procaine penicillin G for continued treatment. As animals are toxemic and often in shock, parenteral fluid therapy, steroids, and nonsteroidal anti-inflammatory drugs may also be indicated. The prognosis in advanced cases is always guarded.

Control

Vaccination in the face of an outbreak is indicated when blackleg or malignant edema occurs in a flock or herd. Numerous, multivalent clostridial vaccines manufactured throughout the world protect against the common causes of clostridial myositis. When vaccinating in the face of an outbreak, animals at risk should be treated with long-acting penicillin preparations at the same time that they are vaccinated to reduce losses while immunity develops.

Ideally, animals should be vaccinated routinely before outbreaks occur. However, the incidence of blackleg and malignant edema in goats is so low relative to sheep and cattle that widespread vaccination of goats may be difficult to justify economically except in those circumstances where the disease is predictably known to occur. When goats are routinely vaccinated against enterotoxemia caused by *C. perfringens*, use of multivalent clostridial vaccines may fit readily into the existing vaccination program. Where genital gas gangrene is known to occur, does should be vaccinated annually with appropriate multivalent clostridial vaccine three weeks before kidding. To control swelled head, bucks should be routinely vaccinated and housed separately to minimize fighting.

Foot Scald, Foot Rot, and Foot Abscesses

Infectious foot problems are not as widely reported in goats as in sheep but the pattern of disease is similar. Foot scald, also known as interdigital dermatitis, or benign foot rot, is defined as an infection confined to the interdigital epidermis with weakly virulent strains of *Dichelobacter (Bacteroides) nodosus*. Foot rot, also known as infectious foot rot or virulent foot rot, is defined as a co-infection of the interdigital epidermis with virulent strains of *D. nodosus and Fusobacterium necrophorum*, with extension of inflammation and infection into the horny and laminar structures of the foot. Foot abscess is an infection of the deep structures of the foot caused by bacteria other than *D. nodosus*, usually *Fusobacterium necrophorum* or *Arcanobacterium (Actinomyces) pyogenes*.

Etiology

Fusobacterium necrophorum, a Gram-negative anaerobic bacteria, is a common environmental organism that can colonize the interdigital epidermis when epithelial integrity is compromised and by itself can produce foot scald. *F. necrophorum* is also a co-pathogen with *Dichelobacter nodosus* in virulent foot rot. *F. necrophorum* can also be introduced into the deep structures of the foot by trauma and puncture wounds. *F. necrophorum* or *Arcanobacterium* (*Actinomyces*) *pyogenes* are the most common organisms associated with foot abscesses.

Dichelobacter (Bacteroides) nodosus is also a Gram-negative, anaerobic bacillus. In smears of exudate, it can be recognized by its characteristic morphology as a large, slightly curved rod with bulbous ends. It is an obligate anaerobe that is adapted to the interdigital epidermis of ruminants and survives only to a maximum of four days in the environment when

passed in discharges from infected feet (Seaman and Evers 2006). Therefore, while the presence of *F. necrophorum* is required for virulent foot rot to develop, *D. nodosus* is considered the inciting pathogen because it must be introduced into a naïve herd or flock for foot rot to develop, whereas *F. necrophorum* is generally already present in the environment. Different strains of *D. nodosus* vary in their virulence based on their degree of keratolytic and elastolytic activity. The presence of proteases and elastases contribute to the invasiveness of horny hoof tissues. Caprine isolates of *D. nodosus* with high elastase activity were demonstrated to be virulent for sheep (Claxton and O'Grady 1986). The potential for cross-transmission of *D. nodosus* between goats and sheep must be taken into account when devising control programs.

Eight major serogroups of *D. nodosus* have been identified on the basis of agglutination responses to surface pili found on the organism. This is important regarding the efficacy of vaccination when vaccines comprised of pilus antigens are used because the degree of cross-protection varies between different serogroups.

Epidemiology

Foot scald, foot rot, and foot abscesses are most common in temperate regions of the world and occur most frequently in the spring and early summer in association with warm temperatures and heavy rainfall. The combination of wet pasture and warm temperatures (above 50°F [10°C]) facilitates transmission of the disease by softening and moistening the skin of the foot, thus predisposing to dermatitis and traumatic injury, and also by allowing the bacteria to persist away from the host for longer periods on pasture. In contrast, foot rot is rarely observed in hot, arid regions, even when large numbers of sheep or goats are maintained.

Other environmental and management factors predispose goats to infectious foot problems. These include wet, muddy yards or poorly drained pastures, overgrown hooves, overcrowding, the introduction of infected goats or sheep to a susceptible herd or flock, return of animals from shows or breeding stations, and turnout of goats onto contaminated pastures (Baxendell 1980). Goats are prone to excessive growth of the hoof when maintained in confinement. When the abaxial hoof wall overgrows the sole it may cause inward compression of the digits leading to excessive irritation of the interdigital skin (Claxton and O'Grady 1986). Dairy goat breeds are considered to be more susceptible to foot rot than fiber and meat goat breeds and some family lines of dairy goats are particularly prone to having "bad feet," requiring more frequent trimming (Skerman 1987). Heritability estimates have been reported in different breeds of goats regarding

susceptibility to foot rot, suggesting that improved resistance is possible through selection (Banik and Bhatnagar 1983).

Transmission occurs by contact when infected and susceptible animals are commingled together at pasture under suitable conditions of moisture and temperature. The organism is present in discharges from animals with clinical lesions and can invade the damaged epidermis of the foot of susceptible goats. In sheep, the carrier state is known to be important in the spread of infection into susceptible flocks when carrier animals are newly introduced. This is also presumed to occur in goats. It has been reported that at least some strains of *D. nodosus* transmit readily between sheep and goats, so the risk of cross-species transmission must be considered and control efforts must be applied to both goats and sheep when the animals are kept together (Ghimire et al. 1996).

There may be differences in susceptibility between sheep and goats. In one study, few goats showed marked underrunning lesions of the hoof while sheep developed more severe lesions consistent with virulent foot rot when infected with the same strains. It was suggested that this might be because the *stratum corneum* of the interdigital skin is considerably thicker in goats than in sheep and therefore goats may be more resistant to maceration of the interdigital skin and subsequent invasion of *D. nodosus* (Ghimire et al. 1999).

Foot rot is less prevalent in goats than in sheep, and until 1985, confirmation that the condition in goats was caused by *D. nodosus* was notably lacking (Merrall 1985; Claxton and O'Grady 1986; Egerton 1989). Foot scald and, to a lesser extent, foot rot, are increasingly recognized as economic constraints on both fiber and milk goat production in the wetter regions of Australia and New Zealand (Anonymous 1987). While morbidity and mortality information for goats is scant, foot scald is cited by New Zealand goat farmers as the second most important disease of goats after enteric diseases (Merrall 1985).

Foot scald and foot rot can be important causes of economic loss in Angora goats in South Africa during periods of unusually wet weather (Van Tonder 1975). A seasonal prevalence of foot abscesses in Angora and Boer goats in South Africa is related to seasonal increases in populations of ticks with long mouth parts, notably *Hyalomma* spp., *Amblyomma* spp., and *Rhipicephalus glabroscutatum*. Adult ticks produce deep wounds in the interdigital space while feeding, and these wounds become secondarily infected, mostly by *Arcanobacterium (Actinomyces) pyogenes* (McIvor and Horak 1987; Bath et al. 2005). Foot rot occurs sporadically in dairy goats in the United States and Europe when they are maintained under conditions of poor management as described above (Guss 1977; Pinsent 1989).

Pathogenesis

The pathogeneses of foot scald, foot rot, and foot abscesses have not been expressly studied in goats. The development of these diseases is presumed to be similar to that described in sheep (Radostits et al. 2007). Wet conditions and softened hooves allow for infection of the interdigital skin and skin-horn junction with *F. necrophorum*. This can produce inflammation and hyperkeratosis and the relatively benign condition known as foot scald. However, the inflammation produced by *F. necrophorum* can facilitate the introduction of *D. nodosus* if that organism is present in the flock. In virulent foot rot, *D. nodosus* attaches to the foot with the aid of adherence pili and colonizes the interdigital epithelium. When these *D. nodosus* strains are virulent and keratolytic, the keratolytic activity allows invasion and underrunning of the horny hoof tissue. The interaction of *D. nodosus* and *F. necrophorum* causes marked inflammation and affected tissues are severely compromised, leading to necrosis. As a result, adherence of the hoof corium to the basal epithelium may be destroyed, resulting in detachment of the horny hoof from the underlying soft tissue. Treponemes are also associated with foot rot in sheep but their role in the pathogenesis of the disease remains uncertain (Egerton 2007).

Clinical Findings

There may be a mild lameness in foot scald. Careful inspection of the feet reveals erythema or swelling of the interdigital epidermis. There is usually little or no odor, and minimal underrunning of the horn at the coronet.

In foot rot, lameness can be quite pronounced when there is necrotic underrunning of the horn. Severely affected goats may walk on their carpi, and when all four feet are involved, may refuse to walk at all. In general, lesions of caprine foot rot are less severe than commonly seen in sheep (Claxton and O'Grady 1986). Swelling of the interdigital epidermis or possible separation of the hoof at the skin-horn junction may be noted. A small quantity of pus also may be visible at the coronet and detached horn can be readily pared or pulled off. The characteristic necrotic smell of foot rot may be detected.

Chronically affected animals may show a marked loss of body condition and decreased production. In addition, myiasis and tetanus are two possible sequelae of foot rot. Chronic cases may show hoof deformities after healing.

Foot abscesses may affect the heel or the toe. In contrast to foot rot and foot scald, only one foot may be involved, and only one claw of that foot. There may be a history of trauma or puncture. The foot is hot and swollen and very painful to the touch. The animal may carry the leg rather than bear weight. Swelling or draining pus may be present above the coronet.

Clinical Pathology and Necropsy

Gram-stained smears of exudate from underrun horn of affected feet can be used to identify the characteristic *D. nodosus* organisms in foot rot cases. Samples can be submitted for anaerobic culture. Serotyping of isolates can be important to determine the potential effectiveness of commercial vaccines. In early cases, evaluation of the virulence of isolates by measurement of proteolytic activity can be valuable in anticipating the severity of an impending outbreak. Radiography may be helpful in diagnosing goats with foot abscess and may assist in prognosis by identifying the presence of secondary osteomyelitis in the distal phalanx. At the time of necropsy, lesions are limited to the affected feet and reflect what is observed antemortem. Sagittal section of the distal limb may indicate the extent of foot abscesses and the occurrence of secondary osteomyelitis in the distal phalanx.

Diagnosis

Presumptive diagnosis of foot rot and foot scald is based on the onset of lameness, swelling at the interdigital space, and underrunning of the horn of the foot. Definitive diagnosis is based on culture of *D. nodosus* from lesions. Diagnosis of foot abscess depends on identifying a pus pocket in the deeper structures of the foot by paring of the sole or heel.

The differential diagnosis for the sudden onset of lameness in groups of goats should include foot and mouth disease and bluetongue. Lesions at the coronet may be seen in both diseases, but oral and muzzle lesions also occur in some affected individuals with bluetongue and FMD. Clinical bluetongue is rare in goats. Laminitis after grain engorgement can occur in groups of goats, but other signs such as diarrhea and bloat accompany or precede the lameness. Selenium toxicosis produces cracks in the hoof that become secondarily infected and may mimic foot rot except that the course is more chronic. The differential diagnosis for foot abscesses, when one leg is affected, include fractures, subluxations, and soft tissue injuries of the distal limb.

Treatment

Because of the highly contagious nature of foot scald and foot rot, recognition of even a single case of the disease calls for examination and potential treatment of all feet of all goats in the herd. As in sheep, several elements of therapy need to be considered, namely, paring of feet, use of antibacterial footbaths, topical or systemic antibiotic therapy, and vaccination, which can be used as an aid for control of outbreaks as well as for prevention. These various approaches

can be used alone or in combination depending on the number of goats involved, their value and use, and the severity of the disease. A comparison of cost effectiveness of various treatments used in sheep has been reported (Salman 1988).

Paring of the feet is a critically important component of therapy in severe cases of foot rot, as removal of dead tissue exposes deep-seated *D. nodosus* organisms to oxygen and the antibacterial effects of subsequent footbaths or topical antibiotics. Paring feet is especially important in foot abscesses to find pus pockets and drain them to relieve pressure in the sore foot. Paring knives should be disinfected in 10% formalin between goats to avoid additional spread of infection.

Disinfectant footbaths are a useful way of treating large numbers of goats. However, goats are high jumpers and have a distinct aversion to walking in water. Footbath design, then, must be considered carefully. A circular bath with a central feeding trough is commercially available in New Zealand. This design encourages goats to wade into the bath to be rewarded with grain (Yerex 1986). Footbath solutions must be nonirritating if the owner expects the goats to enter the bath a second time. Zinc sulfate solutions of a 10% to 20% weight-to-volume ratio are both mild and effective, and are currently the solution of choice. The efficacy of the solution may be enhanced by addition of surfactants such as sodium lauryl sulfate at a concentration of 2% volume-to-volume ratio. In severe cases, one-hour foot soaks repeated weekly for three treatments may be required.

Formalin and copper sulfate footbaths are less desirable. A 5% formalin solution is an effective treatment but has several drawbacks including the production of irritating fumes, painful stinging of aggressively pared feet, hardening of the hoof, and the potential for permanently damaging the skin if concentrations are not strictly regulated. If formalin is used, the solution should be changed daily to ensure that evaporation has not resulted in excessive concentration. Goats stung by formalin footbaths are unlikely to enter them again voluntarily. Copper sulfate solution at a 10% weight-to-volume ratio is also effective but stains the hair or fleece blue-green and is potentially toxic if consumed. Splashing of solutions on the goats' bodies can be reduced by lining the footbath with wood chips, peat moss, or wool tags. After dipping, goats should be turned out on dry ground or slotted floors to permit drying of footbath solutions on hooves.

A number of topical disinfectants and antibacterials can be used after paring, in lieu of footbaths. Zinc sulfate, copper sulfate, copper naphthenate, the quaternary ammonium compound cetrimide (20% alcohol tincture), oxytetracycline, penicillin, and other compounds are available in different countries as paints, powders, or sprays for direct application to the hoof. Putting a bandage on the hoof after application may enhance healing. The feeding of zinc sulfate at a rate of 0.5 g/head/day for twenty-one days during the treatment period has also been recommended when the diet is known to be deficient in zinc.

Parenteral antibiotic therapy has also been used effectively in sheep. The *in vitro* effectiveness of beta-lactam antibiotics against caprine isolates of *Dichelobacter* spp. and *Fusobacterium* spp. has been reported (Piriz Duran et al. 1990). Azlocillin, mezlocillin, and piperacillin were most effective against the largest number of isolates. Penicillin G and ampicillin were almost as effective, and cefuroxime, cefoperazone, cefotaxime, cefoxitin, and imipenem were generally less effective. Current recommendations for antibiotic treatment in sheep are: a single IM dose of penicillin/streptomycin at 70,000 U/kg bw penicillin and 70 mg/kg dihydrostreptomycin, a single IM dose of erythromycin at 10 mg/kg bw, a single IM dose of long-acting oxytetracycline at 20 mg/kg bw, or a single SQ dose of lincomycin/spectinomycin at 5 mg/kg bw lincomycin and 10 mg/kg bw spectinomycin (Radostits et al. 2007).

Treated animals should not be turned back into wet or muddy yards, nor should they be put out to pasture that has not been free of infected animals for at least seven days. Parings from trimmed feet should be considered as fomites and removed from the premises or burned. It is recommended that goats with foot rot be given tetanus antitoxin or reimmunized as the anaerobic environment of the affected foot may predispose to tetanus.

Vaccines are available against *F. necrophorum* and other vaccines are available against *D. nodosus*. In both cases, manufacturers indicate that vaccination can be helpful in the treatment of foot rot in sheep that are experiencing the problem as well as to prevent foot rot in herds not experiencing the problem. Neither vaccine is approved for use in goats in the United States.

Control

Premises with no history of foot rot or foot scald may remain free by maintaining completely closed herds. This means not purchasing any new stock and not taking animals to shows or breeding stations. Transport vehicles and common housing facilities can be contaminated with *D. nodosus* if not thoroughly cleaned and disinfected. If new animals are purchased, they should be from sources free of foot rot. Feet of purchased animals must be carefully inspected for lesions and if any doubt exists, the animals should be run through a foot bath or treated with parenteral antibiotics, quarantined for four weeks, and reexamined before joining the new herd.

When foot rot already exists on the premises, control is directed toward maintenance of proper hoof care, prophylactic use of footbaths, vaccination, and breeding programs.

Feet should be monitored for excessive overgrowth. Provision of rock piles for climbing and playing may help goats to naturally wear off excessive hoof growth. Regular trimming may be necessary to keep the hoof wall from overgrowing the sole and to keep toes from growing too long.

Use of walkthrough footbaths once a week during high-risk periods of wet, warm weather helps to control spread of infection. Zinc sulfate baths are preferred for repetitive use.

A commercial foot rot vaccine based on multiple pili of *D. nodosus* is available in Australia, New Zealand, the United States, and elsewhere for use in sheep. There are no controlled studies to evaluate efficacy in goats and anecdotal reports suggest that there are mixed results when vaccination is applied to goats (Merrall 1985; Skerman 1987). Antibody titers produced in goats are comparable to those of sheep (Skerman 1987). The vaccine is initially given twice at a thirty-day interval. The duration of immunity may only be twelve weeks so vaccination should be timed to precede those periods when transmission of the disease is most likely to occur (Egerton 2007).

The vaccine should be given subcutaneously but still may produce a sizable reaction at the injection site, particularly after the second injection. Owners should be so advised, particularly if show animals are involved. Commercial *D. nodosus* vaccines may contain up to ten different strains of the organism to represent the most common serogroups associated with foot rot, though inclusion of too many strains and their associated immunogenic pilus or fimbrial antigens may actually diminish the immune response. For *D. nodosus* vaccines to be effective, they must contain a strain or strains immunogenically related to those occurring in the affected flock. This was illustrated in Nepal, where an autogenous vaccine containing only two virulent serogroups isolated from local sheep and goats was more effective in reducing foot rot in both species than an imported, multivalent commercial vaccine in a controlled field study (Egerton et al. 2002).

A *Fusobacterium necrophorum* bacterin is also now available in the United States; it is approved for treatment and prevention of foot rot in sheep. Initial immunization requires two doses given three to four weeks apart IM or SQ and an annual booster dose.

The selection of goats with apparent resistance to foot rot for breeding programs is considered to offer long-range benefits to the goat industry for foot rot control. Culling goats with poor foot conformation is a good place to begin.

Control and eradication of foot rot is possible but it can be a long, complicated, and challenging process, and veterinarians need to work with producers so that this is understood. There is no magic bullet, and no single intervention will successfully eliminate the condition once established on a farm. Vaccination, for example, is more effective when carried out in association with hoof paring and/or foot bathing then when done alone. Additional details on eradication and control of foot rot in sheep, which serves as the model for goats, is available elsewhere (Egerton 2007).

PARASITIC DISEASES

Cestodiasis

Goats and sheep serve as intermediate hosts for the canid tapeworm *Taenia multiceps*. The cysts produced by the intermediate stage of the parasite are usually found in the brains of small ruminants and the resulting disease, coenurosis, or gid, is discussed in detail in Chapter 5. In goats more often than sheep, cysts may develop at sites outside the central nervous system, especially in the intermuscular fascia. Cases of goats affected in this way have been reported from the Sudan and India (Ramadan et al. 1973; Dey et al. 1988). Metacestodes in muscle connective tissue produce visible or palpable swellings in muscle masses, accompanied by discomfort, restricted gait, poor appetite, and general malaise. Cysts may number in the hundreds. They feel firm rather than fluctuant and may exceed 7 cm in diameter. They can be distributed all over the body, including the face, but are most common in the thighs and shoulders. Attempts to manage these cases by surgical removal of multiple cysts have not been particularly successful, but this may be due to the advanced debilitation of affected goats at the time of presentation. There is no other known effective therapy.

Muscle cysts may also occur in goats infected with metacestodes of *Taenia ovis*, though sheep are the principal intermediate host of this canid tapeworm. In the case of *T. ovis*, muscle is the primary site of metacestode formation, with cysts most commonly found in the heart, diaphragm, and masseter muscles. This canid tapeworm has a cosmopolitan distribution and is responsible for economic wastage through condemnation and trimming of small ruminant carcasses at slaughter.

Besnoitiosis

Infection with the protozoan parasite *Besnoitia* in goats is most commonly recognized as a granular conjunctivitis, as discussed in Chapter 6. However, *Besnoitia* infection can be generalized, producing respiratory disease, orchitis, and dermatitis, such as seen in goats in Iran (Bazargani et al. 1987). On post mortem examination, multiple small, white, gritty granules may be

present in tissues of the musculoskeletal system, including ligaments, tendons, tendon sheaths, synovial membranes, and muscular connective tissue. These granules represent cysts containing large numbers of bradyzoites of *Besnoitia*.

Sarcocystosis

Sarcosystosis, also known as sarcosporidiosis, is a protozoal infection. The life cycle of *Sarcocystis* spp. involves predatory canids as definitive hosts and various species of livestock as intermediate hosts. The role of the goat as an intermediate host has been described (Collins and Charleston 1979; Collins et al. 1980; Dubey et al. 1984). *Sarcocystis* spp. affecting goats include: *S. capracanis*, with the dog, coyote, and fox as definitive hosts; *S. hircicanis*, with the dog as definitive host; and *S. moulei*, with the cat as definitive host. Muscle cysts containing host-specific *Sarcocystis* spp. have long been recognized in carcasses at slaughter plants and have been a cause of condemnation. Beyond that, the condition was thought to be incidental.

More recently, experimental studies have indicated that *Sarcocystis* spp. may produce a variety of clinical signs, including anemia, fever, vasculitis, myositis, abortion, chronic wasting, and sudden death in ruminants. The experimental disease in goats, produced by challenge with *Sarcocystis capracanis*, has been studied extensively (Collins et al. 1980; Dubey et al. 1981; Dubey 1981; Lopez-Rodriguez et al. 1986). It is hard to describe typical clinical signs in goats because the clinical response is clearly dose dependent, and a wide range of oral challenge doses of sporocysts has been used, from 4×10^3, which produced no clinical signs (Gomes et al 1992); to 7×10^4, which produced anemia, loss of appetite, and fever (Ivanov 1998); to 5×10^5, causing fever, loss of appetite, muscle tremors, and weakness (Dey et al. 1995). A dose of 1×10^4 sporocysts produced abortion in pregnant does (Juyal et al. 1989). In general, the most consistent signs of experimental infection are fever, which is often biphasic, anemia, and loss of appetite. At necropsy, streaky hemorrhage of skeletal muscles and petechiation of lymph nodes and serosal surfaces of abdominal viscera are prominent signs. Liver, kidneys, and spleen may also be swollen and friable (Wadajkar et al. 1995).

Despite the evidence for clinical disease in experimental work, cases of naturally occurring clinical caprine sarcocystosis have not been reported, save for one naturally occurring case of congenital sarcocystosis in a stillborn kid from a Saanen milking herd in Australia experiencing abortions (Mackie and Dubey 1996). Naturally occurring clinical disease has been confirmed in sheep. Sporozoan encephalomyelitis has been reported in the UK, affecting animals under one year of age. Clinical signs included ataxia, generalized tremors, compulsive nibbling, and hind limb paresis (Caldow et al. 2000; Sargison et al. 2000). Other manifestations in sheep without neurologic presentation include anemia, retarded growth, and reduced wool production. There is also a reported case of congestive heart failure and vegetative endocarditis associated with sarcocystosis in a young ram (Scott and Sargison 2001). Anticoccidial drugs such as amprolium and salinomycin may be effective in sarcocystosis.

Subclinical caprine infections with characteristic muscle cysts predominantly in esophagus, diaphragm, and heart, as well as other sites, are well documented around the world, usually from slaughterhouse surveys (Seneviratna et al. 1975; Chhabra and Mahajan 1978; Collins and Crawford 1978; Perez Garro et al. 1978; Barci et al. 1983; Saym and Ozer 1984; Dubey and Livingston 1986). Prevalence of subclinical infections may be greater than some survey reports suggest. A recent slaughterhouse survey from Iran detected grossly evident sarcocysts in twenty-eight of 169 goats by visual inspection. However, when impression smears of target tissues were examined microscopically, 168/169 had *Sarcocystis* spp. present and 169/169 were positive when tissues were subjected to pepsin digestion, centrifuged, and examined microscopically (Shekarforoush et al. 2005). Control of sarcocystosis requires separating dogs and goats, restricting access of goat offal to dogs, cooking meat fed to dogs, and burying dead goats.

NUTRITIONAL AND METABOLIC DISEASES

Nutritional Muscular Dystrophy

Nutritional muscular dystrophy (NMD), or white muscle disease, is the most common manifestation of selenium and/or vitamin E deficiency in goats. Suboptimal levels of these nutrients impair the animals' ability to control oxidative reactions in cells, which can result in extensive muscle necrosis. Cardiac muscle, the diaphragm, and other skeletal muscles may be affected, resulting in a wide range of clinical presentations that make accurate diagnosis a clinical challenge.

Etiology and Pathogenesis

Naturally occurring pro-oxidants, including hydrogen peroxide, superoxide radical, and hydroxyl ion, are generated through normal metabolic activities. These so-called reactive oxygen species can be toxic if allowed to accumulate. In particular, they can damage polyunsaturated fatty acids that are an integral part of cell membranes and the limiting membrane of cellular organelles through the process of oxidation. Muscle cells may be particularly prone to damage by oxidation because of their high metabolic activity. Both selenium and vitamin E participate in enzymatic reactions that control oxidative processes in cells of mammalian tissues via oxidation-reduction reactions.

Selenium is a cofactor of the enzyme glutathione peroxidase that reduces H_2O_2 to H_2O. The selenoprotein glutathione peroxidase is found in cells of numerous tissues, including muscle and red blood cells. While the enzyme activity in red blood cells is not directly related to the pathogenesis of nutritional myopathy, whole blood can be readily sampled and assayed for such activity as an indirect measure of selenium content in the body.

Vitamin E, or alpha tocopherol, also functions independently as an antioxidant, primarily protecting membrane polyunsaturated fatty acids against oxidation. Rather than reducing existing peroxides, it prevents their formation. The antioxidative role of vitamin E increases in importance with increased levels of polyunsaturated fats in the diet. Further details of the pathophysiology of selenium and vitamin E deficiency as they relate to cellular oxidation are available elsewhere (Van Metre and Callan 2001).

Dietary deficiencies of vitamin E and/or selenium can lead to reduced enzymatic activity and reduced protection of tissues from the adverse effects of peroxides. Muscle damage can be severe, with hyaline and granular degeneration of muscle fibers, necrosis, and replacement of muscle by proliferating connective tissue. Deficiency of only selenium or only vitamin E may not lead to clinical abnormalities if the other nutrient is available in abundant supply because their mechanisms of action, though distinct, may provide an adequate degree of physiologic cross-protection.

The location and severity of muscle damage dictates the various clinical manifestations observed in NMD. Sudden death may be observed when cardiac muscle is involved, or, if less acute, there may be signs of congestive heart failure. When the diaphragm is involved, there is labored respiration that may mimic pneumonia. When the limb muscles are involved, affected animals become stiff gaited initially or recumbent. Muscles of the thigh are most commonly affected. Involvement of the tongue or pharyngeal muscles may affect nursing and eating and suggest neurologic disease. Death may occur as a direct result of the effects of myopathy or due to secondary complications such as predation, starvation, exposure, or supervening infections, including inhalation pneumonia.

Epidemiology

Selenium deficiency is associated with selenium-deficient soils and the inadequate uptake of selenium by forages grown on those soils. Legumes are less able to extract soil selenium than grasses. Selenium-deficient areas in North America are discussed in Chapter 19 (Figure 19.3). In addition, the following countries have regions with selenium-deficient soils: most countries of Latin America, northern Europe, Australia, New Zealand, Indonesia, the Philippines, and China, and in Africa, Kenya, Sudan, Uganda, Swaziland, and South Africa (National Research Council 2007). In Australia, the disease in goats is associated with regions of high rainfall and acid soils and the application of superphosphate fertilizers (Baxendell 1988). Acidic soil pH and a high soil content of sulfates or phosphorus inhibit the absorption of Se by plants.

Vitamin E deficiency is independent of soil type and more closely reflects forage quality. Prolonged storage of feedstuffs results in degradation of vitamin E content. Housed goats fed stored feeds with no access to green feeds are more likely to experience deficiency. The feeding of excessive polyunsaturated fats in the diet may tax the ability of marginal or even adequate vitamin E levels to successfully perform their antioxidant function.

Numerous clinical syndromes of vitamin E/selenium deficiency are recognized in ruminants, horses, and pigs, (Radostits et al. 2007), as well as poultry. In goats, NMD is the most common disease manifestation and is recognized as a consequential caprine disease in the United States (Guss 1977), Australia (King 1980a), New Zealand (Thompson 1986), and some European countries (Tontis 1984; Roncero et al. 1989), as well as on the Mexican plateau, where it was identified as the main cause of death in extensively managed kids between eight and ninety days of age (Ramírez-Bribiesca et al. 2001). All breeds appear susceptible and the condition may develop under extensive or intensive management systems. In the former case, animals are grazing selenium-deficient pastures; in the latter, they are consuming feeds grown on selenium-deficient soils. The condition has been recorded in wild mountain goats *(Oreamnos americanus)* in Canada (Hebert and Cowan 1971) and in zoo goats (Biolatti and Vigliani 1980). Goats may be more susceptible to NMD than other ruminants, as cattle and sheep in New Zealand grazing the same areas as goats did not show the condition (Anonymous 1987a; Rammell et al. 1989).

Clinical disease is most common in young kids up to six months of age and less likely in adults. The selenium and vitamin E status of the dam is critical to the occurrence of NMD in her offspring. Stillborn and weak newborn kids have been attributed to nutritional muscular dystrophy in Australia (King 1980a). In parts of New Zealand, nutritional muscular dystrophy is the most common recognized cause of mortality in kids between one and nine weeks of age (Buddle et al. 1988). Mortality in New Zealand outbreaks is as high as 20% on some premises (Anonymous 1987a). Sudden, unaccustomed exercise is a common prelude to clinical muscular dystrophy in kids. This may occur when kids are turned out for cleaning of pens or put out to pasture for the first time.

In feeding trials with adult goats, selenium deficiency has been shown to impair reproductive perfor-

mance and milk production. Conception rates were lower in selenium-deficient goats compared with control goats. Though no abortions were noted, kid survival rates were also reduced. During the first two months of lactation, selenium-deficient goats gave 23% less milk than control goats with relative reductions of 11% in milk fat content and 12% in milk protein content (Anke et al. 1989). A selenium-responsive dermatosis has been recognized in goats and is discussed in Chapter 2. Other clinical manifestations of vitamin E/selenium deficiency in adult goats have been suggested. These include fetal resorption, dystocia caused by decreased uterine tone, retained placenta, post partum recumbency, generalized ill thrift, and reduced semen quality.

Selenium deficiency may also increase susceptibility to infection in goats by reducing neutrophil function (Aziz et al. 1984; Aziz and Klesius 1986) and alter immune responses by inhibiting production of leukocyte migration inhibitory factor in caprine lymphocytes (Aziz and Klesius 1985). More is known about the effects of selenium and vitamin E on the immune responses of other domestic animal species and the subject has been reviewed (Finch and Turner 1996).

Clinical Findings

Nutritional muscular dystrophy is most often brought to the attention of veterinarians when previously healthy kids from three days to six months of age are found dead, recumbent, having difficulty rising, or exhibiting a stiff-legged gait. Faster-growing kids are more often affected. Recumbent kids are usually mentally alert but may be depressed. They may struggle to rise, and these efforts may be interpreted as convulsions or neurologic signs by the owner. If assisted to rise, they may be unable to stand or they may exhibit muscle tremors from the effort made, particularly in the hind limbs. Fever is a variable finding, usually associated with secondary infections. A history of unaccustomed exercise in the preceding few days can often be elicited. If untreated, kids with nutritional muscular dystrophy often will die within several days of the onset of signs.

Other clinical presentations may not immediately suggest nutritional muscular dystrophy but are consistent with localized muscle damage. The inability to nurse or swallow, with milk exiting through the nostrils or quidding of solid feed, may be seen when the tongue or pharyngeal muscles are involved. Dyspnea, increased respiratory rate, moist lung sounds, and coughing can occur when the diaphragm or left heart muscle is involved. Delivery of stillborn or weak, poorly suckling kids can be caused by severe *in utero* deficiencies of selenium or vitamin E. In this instance, a herd history may include complaints of dystocia and a high prevalence of retained placenta in adult does.

Clinical Pathology and Necropsy

Direct confirmation of selenium or vitamin E deficiency in the live animal can be obtained by measuring their concentrations in blood. In practice however, this is not commonly done because the assays are complex, expensive, and not widely available. Reference values for goats have been published (Van Metre and Callan 2001). Adequate selenium concentrations in caprine serum are reported from different laboratories to be 0.05 to 0.16 ppm or 80 to 100 ng/mL with values less than 60 ng/mL representing deficiency. For caprine whole blood the normal range for selenium is 0.15 to 0.25 ppm with less than 0.05 considered deficient. For vitamin E, 60 to 150 µg/dL in caprine serum is considered an adequate concentration. Experimental studies in goats indicate that plasma vitamin E concentrations less than 1.5 µmol/l in does and less than 1 µmol/l in kids increase the risk of myopathy (Jones et al. 1988).

An alternative but indirect method of determining selenium deficiency is to measure glutathione peroxidase activity in red blood cells from heparinized whole blood. Normal mean activity in goat kids has been reported as 113 IU activity/ml of red blood cells (Jones et al. 1988). When using this assay as an indicator of response to selenium therapy, it should be noted that there is a lag period of at least two weeks before parenterally administered selenium leads to measurable increases in glutathione peroxidase activity in whole blood. This is because selenium is incorporated into developing red cells in the bone marrow before their release into the blood and has no effect on cells already in circulation. Concerns have been raised about the glutathione peroxidase assay, including instability of the enzyme in storage even when samples are refrigerated, inconsistent expression of enzyme activity among laboratories, and wide variation in values between laboratories. As a result, use of the test has declined (Van Metre and Callan 2001).

Measurements of serum creatine kinase (CK) and serum aspartate aminotransferase (AST) are commonly used as indicators of muscle necrosis for making a presumptive diagnosis of nutritional muscular dystrophy. Creatine kinase is a muscle-specific enzyme. Mild to moderate elevations of serum CK may be seen secondary to trauma or prolonged recumbency from any cause, including birth, but marked elevations are seen in the acute phase of nutritional muscular dystrophy. Normal serum CK for goats is reported to be 49.1 ± 2 IU/l (Stevens et al. 1994), while other sources report a normal range of 14 to 62 IU/l (Garnier et al. 1984). Serum CK levels of 1,000 IU/l to more than 50,000 IU/l may be observed in NMD depending on acuteness and severity. Subclinically affected animals may also have elevations exceeding 1,000 IU/l. Serum AST will also be elevated, but AST is not muscle specific, so

elevations of AST without concurrent elevations of CK may not indicate muscle damage. The serum half-life of CK is several hours, while the AST half-life is in days. Therefore, when both are increased, muscle damage is probably ongoing, whereas a decrease in CK with a persistent elevation of AST is more favorable, suggesting resolution of active muscle necrosis.

At necropsy, muscles of the limbs, diaphragm, heart, tongue, and pharynx should be carefully examined. Affected muscle appears white to gray, like cooked poultry, and stands out in contrast to adjacent, normal, red-brown muscle. The surface of the lesion may appear chalky when calcium has accumulated in degenerated muscle. The lesions in limb muscles are bilaterally symmetrical. Large muscle bellies may be abnormal, such as the semimembranosus muscles in the thighs, and patchy hemorrhage may occur in addition to pale discoloration (Figure 4.10). Especially in the heart and diaphragm, whitish yellow streaks or patches may be present within normal muscle masses. Heart lesions may extend through the myocardium to the endocardium and involve the papillary muscles as well. When the heart is involved, there may be evidence of congestive heart failure such as ascites, hydrothrorax, pericardial effusion, pulmonary edema or congestion, and/or a swollen, congested, friable liver. Fibrin tags have been observed on the liver surface (Thompson 1986). Aspiration pneumonia may be observed secondary to swallowing difficulties. Tongue

Figure 4.10. Gross post mortem lesions in the rear limb muscles of a goat with nutritional muscular dystrophy. Normal muscle is seen at the left (open arrow). The white chalky areas of muscle at the bottom of the picture are severely affected (black arrow). The lesion is demarcated by an area of hemorrhage (white arrow). (Courtesy of Dr. T.P. O'Leary.)

and pharyngeal muscles should be examined carefully in these cases.

Histologically, the muscle lesion is characterized by hyaline degeneration of striated muscle cells with coagulation necrosis, a pattern of degeneration referred to as Zenker's necrosis. Ultrastructural studies indicate that the lesion primarily involves the contractile components of the muscle cell cytoplasm.

Determination of selenium levels in liver at necropsy can give some indication of the severity of selenium deficiency. Normal liver selenium level in the goat has been reported at 1.00–4.80 ppm dry weight with concentrations of less than 0.40 ppm considered deficient (Van Metre and Callan 2001).

Diagnosis

Definitive diagnosis of nutritional muscular dystrophy depends on identification of typical muscle lesions in affected kids at necropsy or decreased levels of selenium and/or vitamin E in blood or tissues. A presumptive diagnosis in the field can be made on the basis of typical clinical signs, supportive laboratory findings, and a favorable response to treatment with parenteral administration of vitamin E and selenium.

When stillborn or weak kids are involved, other causes of infectious and noninfectious abortion must be considered, as discussed in Chapter 13. Sudden death in young kids may also be caused by gastrointestinal parasitism, especially haemonchosis and coccidiosis, colisepticemia, and enterotoxemia. Cases of nutritional muscular dystrophy may appear very similar to enterotoxemia when the heart muscle is involved because of the presence of pericardial and peritoneal effusions. Histologic examination of the heart is necessary for diagnosis. When dyspnea, coughing, and other signs of respiratory distress are observed, bacterial, viral, and verminous pneumonias must be considered.

Difficulties in swallowing in young goats may be associated with cleft palate or neurologic diseases such as listeriosis or polioencephalomalacia. When a stiff-legged gait is observed, tetanus must be considered. The differential diagnosis for recumbency in young goats includes musculoskeletal trauma, enzootic ataxia, and the neurologic form of caprine arthritis encephalitis. In enzootic ataxia and CAE virus infection, recumbency is usually preceded by a progressive ataxia that is characterized more by weakness than stiff leggedness, and with a more prolonged course.

Treatment

Parenteral administration of combination sodium selenite/alpha-tocopherol preparations is the treatment of choice in the acute phase of nutritional muscular dystrophy. Administration of both compounds together results in a higher rate of recovery in kids than either compound administered alone (Baran

1966). Combination products are marketed widely for administration either subcutaneously or intramuscularly. When dosage information is not specifically given for goats, one to two times sheep doses are appropriate. A recommended dose for sheep is 1 mg selenium as sodium selenite and 50 mg (68 IU) of alpha tocopherol/ 18 kg (40 pounds) of body weight, but label dosages can be followed for specific products (Van Vleet, 2005).

Affected goats usually respond favorably to a single treatment within twenty-four hours, though recovery may not be complete depending on the severity and extent of pre-existing muscle damage. Animals that do not respond may be retreated one time again at twenty-four hours. If no improvement is seen after the second treatment, then a poor prognosis must be offered, or an alternative diagnosis pursued. Excessive, repeated use of parenteral selenium can result in selenium toxicity. In some herd situations, vitamin E deficiency may play a greater role in the development of disease than selenium deficiency, and when combination products are not producing a desired therapeutic effect, administration of additional vitamin E or nutritional supplementation of vitamin E should be considered (Byrne 1992).

As nutritional muscular dystrophy indicates a nutritional deficiency, herd-wide administration of parenteral selenium/vitamin E preparations in the short term is justified at the time confirmed clinical cases are being treated in order to prevent additional cases. In the United States, recent reports of abortion in some sheep receiving parenteral injections have resulted in these products being disallowed for use in pregnant ewes. Abortions have not been reported in does, but caution should be exercised in using these products in pregnant does and clients advised of the risk. Alternatively for pregnant does, oral administration of selenium can be initiated, up to 0.3 mg Se/kg dry matter of the total ration.

Control

Selenium deficiency should be anticipated in goats in regions known to have selenium-deficient soils. Several approaches to correcting nutritional deficiency are possible, and the choice depends on economic, management, and regulatory factors. Feed supplementation with selenium is a desirable approach to control, though there may be regulatory constraints against the practice. In the United States, selenium supplementation of feed has been approved for use in sheep and beef for some time, but it was not until 2005 that allowance was made for goats. As of 2005, selenium can be supplemented in a complete ration for goats as selenium yeast at a level up to 0.3 ppm added selenium (FDA 2005). This is considered adequate to prevent occurrence of NMD.

Where feed supplementation is not permitted by regulation or is impractical, strategically timed parenteral administration of selenium/vitamin E preparations is an effective means of control during periods of high risk. Does can be given therapeutic doses of a combination preparation at the onset of breeding season and again four to six weeks before kidding, observing the caveats mentioned above in the treatment section regarding pregnant does. Kids should be given a therapeutic dose at birth and again at one month of age. In herds where clinical cases are observed in older kids, this can be repeated again at two or three months of age. Bucks should receive the preparation twice a year with the first administration timed to the onset of breeding season. Drenching forms of sodium selenite are available in some areas. This allows selenium administration to be conveniently incorporated into other preventive medicine activities such as parasite control. Sheep doses can be used.

Other control methods are being increasingly applied to cattle and sheep but have not been evaluated in goats. Injectable barium selenate, a repository form of selenium, maintains adequate selenium levels for as long as six months. Use of the preparation has been reported in goats in Spain. When given to dairy goats at a dose of 1 mg Se/kg bw fifteen days before breeding, seven- to eight-fold increases in glutathione peroxidase activity were still measurable at the time of kidding as compared to no change in untreated controls (Sánchez et al. 2007). However, it is not clear if increased selenium levels were present in milk, which would be a significant regulatory concern in the United States.

Orally administered selenium pellets can provide adequate levels for up to one year in sheep. A sodium selenite, four-month, constant-release bolus is approved for oral use in cattle in the United States, but not for small ruminants.

Topdressing of pasture with sodium selenate at a rate of 10 g/ha may be an economic alternative to individual animal treatment and will prevent selenium deficiency for as long as twelve months (Kimberling 1988). The risk of inadequate vitamin E in the diet still exists when these techniques are used, and vitamin supplementation is indicated, as discussed in Chapter 19. In contrast to selenium, vitamin E is reported to be nontoxic to goats (Ahmed et al. 1990).

Rickets

Rickets is a metabolic abnormality of growing bone. It is characterized by a failure of mineralization in newly formed bone matrix at the epiphyses of long bones. As such, it is a disease of young, growing animals. The condition is classically attributed to an absolute deficiency of vitamin D_2 arising from the housing of young stock in buildings devoid of sunlight

or the provision of green feeds not cured in the sun. However, chronic deficiencies of either calcium or phosphorus in the face of adequate vitamin D can also produce the condition. Inadequate mineralization at the epiphyses leads to structural weakness and abnormal growth, particularly in the long bones, which will show enlargements at the end plates and deformation due to the stresses of weightbearing.

Clinical and subclinical rickets has been described in young goats (Yousif et al. 1986). Clinically affected animals show stiffness of gait, a tendency to remain recumbent, a bowing deformity of the forelimbs, swollen carpi, and enlargements of the costochondral junctions, a lesion commonly described as the rachitic rosary. Loosening of the shoulder blade attachments and a dropped withers have also been identified with caprine rickets, and may be the only signs seen (Guss 1977). Subclinically affected animals may show only signs of anorexia and a stunted growth rate.

The most consistent clinical pathologic finding in rickets is an elevation of serum alkaline phosphatase. Abnormalities in serum calcium and phosphorus levels are less consistent, though in at least one report, clinically affected goats had both hypophosphatemia (mean, 2.76 ± 0.15 mg/dl) and hypocalcemia (mean 7.05 ± 0.18 mg/dl), with a ratio of serum calcium to serum phosphorus consistently more than $2:1$. Affected goats were also hypoproteinemic, and had decreased serum zinc, iron, copper, and magnesium levels compared with control goats (Yousif et al. 1986). Hypophosphatemia, hypocalcemia, hypovitaminosis D_3 and increased serum alkaline phosphatase were identified as the main biochemical abnormalities in two- to six-month old goats with rickets in Egypt (El-Sayed and Siam, 1992).

Radiographically, there is decreased density of affected bones, with widening and lipping of the non-mineralized growth plates. Antemortem biopsy of the costochondral junction or histologic examination of growth plates of long bones at necropsy confirms the failure of mineralization in the zones of provisional calcification in growth plates.

Successful treatment and control of rickets require accurate determination of the underlying cause through careful history taking, examination of housing and access to sunlight, and nutrient analysis of rations followed by correction of identified deficiencies. Nutrient requirements of vitamin D, calcium, and phosphorus are discussed in Chapter 19.

Epiphysitis

Epiphysitis is seen in young, rapidly growing goats that are fed excessive calcium. The lesion involves an unequal growth rate across the epiphyses of long bones, especially in the distal radial, distal metacarpal, and distal metatarsal epiphyses and can result in pre-mature closure of the growth plate either axially or abaxially. The result is a clinically obvious valgus or varus angular deformity of the limb around the affected epiphyses.

The exact pathogenesis of the lesion and its relation to excessive calcium feeding are not completely understood. The condition is similar to that seen in rapidly growing, overconditioned foals with a calcium/phosphorus imbalance in the ration. In one published report involving a twelve-month-old pregnant Nubian doe, analysis of the total ration indicated a calcium-to-phosphorus ratio in the diet of 4.4:1 (Anderson and Adams 1983). The author has seen severe bilateral bowing deformity of the carpi in a twelve-month-old Saanen doe on a ration of alfalfa hay, a commercial goat chow supplemented with calcium, and free-choice dicalcium phosphate as a mineral lick (Figure 4.11).
Figure 4.11. Bowing deformity of the forelimbs due to carpal epiphysitis associated with excessive calcium feeding in a yearling Saanen doe. (Courtesy of Dr. David M. Sherman.)

Elimination of the mineral and reduction of the goat chow in the diet resulted in some straightening of the forelimbs over the next two months.

Young, growing goats with painful epiphysitis may be reluctant to rise, have a stilted gait, or even walk on their knees. Overconditioned or pregnant goats may be especially painful due to the excessive burden of weight-bearing. Joints associated with affected epiphyses may appear swollen. Angular limb deformities may be pronounced, depending on the duration of the condition.

Serum calcium, phosphorus, and alkaline phosphatase levels are normal. Radiographs reveal an unequal growth rate across affected physes with lipping, or overgrowth, of new bone on the margins of the physeal plate.

Management of epiphysitis in young goats requires ration analysis and correction of excessive feeding of calcium. The normal calcium-to-phosphorus ratio in the diet should be in the range of 1.5:1 to 2:1. In active cases, use of nonsteroidal anti-inflammatory drugs such as flunixin meglumine, removal from hard surfaced flooring, and proper foot trimming may offer some clinical improvement.

Bentleg or Bowie

This is a condition most commonly seen in growing lambs grazed on pastures with phosphorus deficient soils, notably in South Africa, New Zealand, and Australia. Affected animals develop *genu valgum* (bentleg) or *genu varum* (bowie). The condition has also been reported in three- to four-month-old Saanen kids in New South Wales, Australia (Murphy et al. 1959). Affected kids developed a severely knock-kneed (*genu valgum*) appearance at the carpi and were also bent in at the fetlock with inward rolling on the medial claws. The condition was ascribed to an imbalance of calcium and phosphorus in the ration. In experimental trials, cases of bentleg were significantly reduced when a diet containing calcium and phosphorus in a ratio less than 1.4:1 was fed compared to a diet with a Ca:P ratio greater than 1.8:1 (Murphy et al. 1959). In New Zealand, mature does in late pregnancy are reported to experience bentleg (Merrall 1985).

Bentleg, at least in goats, may be a manifestation of epiphysitis associated with excessive calcium feeding. However, the roles of other mineral imbalances, including iron excess, copper deficiency, and manganese deficiency, as well as plant toxicities, in the pathogenesis of bentleg have not been completely clarified. The etiology of bowie or bentleg in lambs is still considered to be unknown, though supplementing the diet with phosphorus or topdressing pastures with superphosphate usually results in disappearance of the disease (Radostits et al. 2007).

Fibrous Osteodystrophy (Osteodystrophia Fibrosa)

Etiology and Pathogenesis

This bone disease is an example of nutritional secondary hyperparathyroidism that results from a chronic, sustained intake of excessive dietary phosphorus. Increased phosphorus intake leads to an analytically imperceptible hyperphosphatemia that suppresses serum calcium levels. The resulting hypocalcemia triggers an increased secretory response of parathyroid hormone. Parathyroid hormone mobilizes calcium from bone to restore normal serum calcium levels. In the face of chronic, excess phosphorus intake, this secondary hyperparathyroidism ultimately results in severe, generalized demineralization of bone and a fibrous reaction of the bony matrix.

Epidemiology

The condition is well known in goats (Carda Aparici et al. 1972; Naghshineh and Haghdoust 1973; Saha and Deb 1973; Andrews et al. 1983). It arises under circumstances of prolonged or monotonous feeding of rations with high phosphorus content. This often involves a diet high in grain and cereal hays with little or no access to leguminous forages or calcium-based mineral supplements. Bran feeding is a common factor in many cases. The condition was described in the 1930s in goats experimentally fed flaked maize and bran with a minimum amount of hay (Glock and Murray 1939). All breeds and ages of goats are susceptible when weaned.

Clinical Signs

The initial signs may be nonspecific and involve progressive lethargy, difficulty in eating and drinking, weight loss, and a preference for recumbency. Though all bones may be affected, there is a propensity for the mandibles to first show detectable abnormalities. There is a visible bilateral swelling of the mandibles, particularly over the rami, which may progress over several months and be quite pronounced (Figure 4.12a). These cases are frequently mistaken for lumpy jaw (actinomycosis) which is uncommon in goats. The jawbone may be palpably soft. The goat's ability to open the mouth widely may be restricted. Salivation may be present and the tongue may hang from the mouth. Disruptions of the dental arcades with displacement of individual teeth is common. Teeth may actually point horizontally instead of vertically. Affected animals may have a stiff or painful gait, or be recumbent, due to pathologic fractures that may spontaneously occur in dystrophic bones.

Clinical Pathology and Necropsy

Enlargement and rarefaction are evident and displacements of the teeth can be identified in radiographs

Figure 4.12. Clinical appearance and radiographic findings in fibrous osteodystrophy. (From Andrews et al. 1983; reproduced by permission of *Veterinary Record*.)

a

Figure 4.12a. Typical swelling of the face caused by mandibular distortions associated with fibrous osteodystrophy.

b

Figure 4.12b. Mandibular radiograph of the same goat. Note that in this advanced case, the occlusal surfaces of the teeth are directed medially.

of the mandible (Figure 4.12b). Fractures of long bones, especially incomplete fractures, may also be confirmed radiographically. Serum chemistry results are variable. Elevation of serum alkaline phosphatase is the most consistent abnormality. Hyperphosphatemia and hypocalcemia may also be noted but their absence does not rule out fibrous osteodystrophy.

At necropsy, affected bones are soft, and in severe cases, the mandibles can be cut easily with a knife. The gross enlargement and distortion of the mandibles are evident on cross section. Ribs are rubbery and flexible. Histologically, there is osteoporosis with marked demineralization of bony trabeculae surrounded by a loose fibrous connective tissue matrix. Hyperplasia of the parathyroid glands is present, principally involving increased numbers of light chief cells with extensive vacuolation and margination of cell nuclei (Carda Aparici et al. 1972).

Treatment and Control

Reversal of clinical lesions is possible, if recognized early, by dietary management involving reduction of phosphorus levels and correction of the calcium-to-phosphorus ratio. Additions of leguminous hay and/or ground limestone to the diet are practical ways of increasing calcium in the diet without increasing phosphorus content. For grain-fed small ruminants in Brazil, addition of 1% to 1.5% calcium carbonate to the grains improved the Ca:P ratio and prevented fibrous osteodystrophy (Riet-Correa 2004).

Osteopetrosis

Osteopetrosis has been described by one authority as a bony abnormality of adult male goats fed diets excessive in calcium (Guss 1977). It is postulated that such diets promote hypercalcitoninism and the excessive deposition of calcium into bone. The condition is believed to be similar to the disease ankylosing spondylitis that occurs in breeding bulls on high calcium diets. However, this has not been confirmed experimentally.

The condition is said to occur in mature dairy bucks that are fed rations formulated for lactating does on the same farm. Such rations usually contain calcium in excess of that required for a nonlactating, nongrowing male. Bucks show clinical signs only after they have ceased to grow and have been on the offending diet for many months. They develop proliferative calcification around the joints that leads to palpable enlargements, a stiff gait, and possible ankylosis with reduced range of motion in affected joints. Radiographs confirm the proliferative lesion. When bony proliferation is observed around joints in lame goats, caprine arthritis encephalitis virus infection must also be considered in the differential diagnosis, particularly if mineralization of tendons and joint capsule is also present.

There is no treatment, because the lesions are not reversible. Prevention is based on dietary management. Grass hay should serve as the basis of the diet, and calcium supplementation of the concentrate feed should not exceed 0.5%. If bucks are fed pure alfalfa hay, then no additional calcium supplementation should be offered, and addition of monosodium phosphate to the concentrate at a rate of 1% may be indicated.

Laminitis

Laminitis, or founder, is an aseptic inflammation of the sensitive laminae of the hooves. Acute and chronic forms occur in goats that result in lameness and possible deformities of the hoof.

Etiology and Pathogenesis

The causes and pathogenesis of laminitis in hoofed stock are not completely understood. The principal lesion appears to be vascular, associated with abnormal circulation within the corium, or dermis, of the hoof. Acute engorgement of vessels of the sensitive laminae leads to intense pain in the feet. Chronic circulatory dysfunction leads to both a breakdown of the connection between the corium and the hoof wall, allowing separation and rotation of the third phalanx within the hoof, and a distortion of new horny growth of the hoof.

Epidemiology

Laminitis in goats is seen more often in intensive management settings than extensive ones. Its occurrence following sudden ration changes, excessive feeding of grain, or overt cases of engorgement toxemia suggests lactic acidemia as a predisposing factor. Experimental induction of lactic acidosis in goats by overfeeding of grain resulted in lameness (Tanwar and Mathur 1983). The occurrence of laminitis after kidding in association with retained placenta, metritis, pneumonia, mastitis, and enterotoxemia suggests the action of bacterial toxins in the pathogenesis of the condition.

Laminitis has also been observed after normal kidding, and in association with unspecified allergic conditions (Guss 1977). Chronic laminitis is more often recognized clinically in goats than acute laminitis.

Clinical Signs

Because acute laminitis often occurs in conjunction with other medical conditions such as grain overload that produce overt clinical signs, the presence of laminitis should not be overlooked. Affected goats may appear anxious and uncomfortable and grind their teeth from pain. Fever caused by underlying infectious diseases may be present. The goat may refuse to walk or even stand. The affected hooves are warm to the touch, particularly in the area just distal to the coronary band. Laminitis is almost always bilateral. The forelimbs are more often involved than the hind limbs, but all four feet can be affected. Goats with acute laminitis of the forelimbs may walk on their knees.

In chronic laminitis earlier episodes of acute laminitis may not have been seen, or recognized, so the onset may appear insidious. There is usually a vague lameness or an increasing tendency for animals to walk on their knees. The animal may stand with the hind limbs placed well forward under the torso. Though heat is not palpable in the feet in chronic laminitis, the conformation of the hoof becomes distorted. The hoof wall becomes thickened with a loss of distinction between the wall and sole, and the feet become characteristically overgrown in a "slipper foot" or "sled runner" shape with the unworn toes turned upward. This is due to rotation of the third phalanx causing convexity of the sole with the result that weight bearing is rocked back onto the heel (Pinsent 1989).

Clinical Pathology

There are no specific clinical laboratory abnormalities to support the diagnosis of laminitis, although the presence of lactic acidemia, endotoxemia, or a hemogram characteristic of inflammation may provide evidence of a likely underlying disease problem. Diagnostic radiography is rarely employed to confirm the diagnosis of laminitis in goats. The incidence of rotation of the third phalanx in caprine laminitis is unreported, and chronic laminitis is usually apparent from the gross appearance of the foot.

Diagnosis

The presumptive diagnosis of acute laminitis is based on a history of predisposing management and disease factors, an acute reluctance to walk or stand, and heat in the feet, especially the front feet. Foot rot and puncture wounds must be ruled out. In chronic laminitis, arthritis must be ruled out when goats walk on their knees. Chronic selenosis must be considered in regions where it occurs when the hooves appear

abnormal in association with lameness. Simple neglect of routine foot trimming must also be considered.

Treatment

In acute laminitis, it is important to identify and aggressively treat any predisposing disease process, such as engorgement toxemia or toxic metritis, correcting lactic acidosis, dehydration, and bacterial toxemias when present. Therapy directed at the laminitis consists primarily of analgesics to reduce pain in the feet and keeping the animal mobile. Nonsteroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine are particularly useful in this regard, because, as prostaglandin inhibitors, they probably also reduce the deleterious effects of endotoxins. Phenylbutazone can be given orally at a dose of 10 mg/kg once a day or flunixin parenterally at a dose of 1 mg/kg once a day with the treatment tapering off over several days. Phenylbutazone should be avoided in animals for milk or meat production because of residue concerns. Enforced exercise may be helpful in the acute phase to promote normal circulation. Affected goats should be fed only grass hay while they recover and then brought back onto richer feeds cautiously. The value of antihistamines in the treatment of acute laminitis remains unproven. The use of corticosteroids is controversial because they have been shown to induce laminitis in horses.

Management of chronic laminitis involves reduction of grain in the ration, avoidance of sudden ration changes, and frequent corrective foot trimming to approximate as normal a hoof conformation as possible. The foot is trimmed to reduce the height of the heel and to remove the convexity of the sole to minimize the downward pressure of the tip of the third phalanx. When separation of the white line has occurred, the abaxial hoof wall should be trimmed back to the top of the pocket; otherwise dirt and debris will pack in and deepen the lesion. When necessary, administration of analgesics may help to control pain and promote mobility. For long-term analgesic therapy, aspirin is useful because of low cost. Goats can be started at a dose of 100 mg/kg orally twice a day and titrated down to whatever lesser dose is needed to maintain comfort. Extended therapy at the starting dose could possibly lead to gastrointestinal ulceration or anorexia.

Control

To prevent laminitis in goats, abrupt feed changes should be avoided and grain feeding should be kept to a minimum. When high energy rations are indicated for milk or hair production, addition of buffers such as sodium bicarbonate to the diet should be considered to reduce the risk of lactic acidosis. Regular hoof trimming should be carried out.

Zinc Deficiency

Zinc deficiency in ruminants is most often recognized as a proliferative dermatitis (parakeratosis) as discussed in Chapter 2. Zinc also plays a role in the normal development of bone and hoof. Zinc is most concentrated in bone in the Haversian system and participates in the calcification of preosseous tissue either as an enzyme cofactor or as a metallic salt promoting crystal seeding during mineralization (Hidiroglu 1980). Dietary zinc requirements in goats are given in Chapter 19.

Zinc-deficient goats may display skeletal and hoof abnormalities in addition to dermatitis. Affected goats adopt an abnormal posture in which the back is arched and the feet are held closely together. Bowing of the hind limbs and swollen hocks may also be seen. The dermatitis may involve the coronets leading to inflammation of the hooves. Feet may be painful on palpation. Deep, transverse ridges may encircle the hoof wall. Zinc-deficient goats also show poor growth rates, decreased feed intake, loss of condition, excessive salivation, and testicular dysfunction (Neathery 1972). They may have impaired immune function, often dying of secondary pneumonic infections (Miller et al. 1964). Dwarfism has been reported in male goats in experimentally induced zinc deficiency. This was considered an indirect effect of zinc on pituitary function rather than a direct effect of zinc on bone development (Groppel and Henning 1971).

In experimental feeding trials, goats on limited zinc diets had mean plasma zinc levels in the range of 0.49 to 0.79 ppm, while the range in normal control goats was 0.83 to 1.1 ppm (Neathery 1972). In field cases of zinc deficiency in goats, plasma zinc levels in affected goats were in the range of 0.46 to 0.54 ppm (Nelson et al. 1984). Mean dry bone concentrations of zinc in goats on experimental zinc-deficient diets were 71 ppm, significantly less than the mean of 84 ppm in control goats (Groppel and Henning 1971). Hair samples can also be used to confirm zinc deficiency, with deficient goats having hair zinc concentrations less than 90 ppm (Neathery 1972).

Successful treatment of hoof and postural problems was reported with oral administration of 250 mg of zinc sulfate daily for four weeks (Nelson et al. 1984).

TOXICOLOGICAL DISEASES

Hypervitaminosis D

Vitamin D toxicity can result from excessive administration of parenteral or oral vitamin D. Such cases have been reported in cattle, horses, and pigs (Radostits et al. 2007). Excess vitamin D causes increased absorption of calcium from intestine, reabsorption from bone, and retention of phosphorus by the kidney. There is a

tendency for thinning of bone and calcification of soft tissues to occur, especially muscle and vascular tissue, with multiple clinicopathologic consequences.

The risk to goats of iatrogenic vitamin D toxicity has been demonstrated experimentally (Singh and Prasad 1987). Goats given cholicalciferol injections weekly for two to eight months developed clinical signs of dullness, depression, rough hair coat, inappetence, diarrhea, polyuria, polydipsia, and reduced growth rate. Muscle weakness and a stiff gait were observed in some animals. Hypercalcemia and hyperphosphatemia were consistent findings. Serum alkaline phosphatase levels, however, were quite variable.

Enzootic calcinosis, caused by consumption of *Trisetum flavescens*, is discussed later in this chapter. It is considered to be a naturally occurring form of vitamin D toxicity, because the plant contains high levels of 1,25 (OH)$_2$D$_3$. It is reported in goats in Europe.

Fluorosis

Fluorosis in goats is a chronic intoxication caused by prolonged exposure to fluoride compounds in feed, water, and soils. The incorporation of excessive fluorine into the skeletal or dental matrices causes abnormal development of teeth and bone, especially in growing animals.

Etiology and Epidemiology

Animals may come into contact with fluorine in many ways. The element is found in high concentration in phosphate-rich soils in some regions of the world, particularly in North Africa. Although plants do not take up fluoride readily, grazing animals may ingest soil along with plants while feeding, thus increasing their exposure to fluoride. When vegetation does incorporate fluoride, a process enhanced by acid soils, then stems and leaves have higher concentrations than grains. Deep well water is a source of excessive fluoride in Australia and South America and volcanic ash is a source of pasture contamination in the Andes and in Iceland (Radostits et al. 2007).

Rock phosphate, rich in fluoride, is mined commercially for manufacturing fertilizers and mineral supplements for animal feeds. Unless these mineral supplements are specifically defluorinated before incorporation into animal feeds, they may provide dangerous levels of fluoride. Water and tailings from mining operations can be sources of excess fluoride to animals living nearby due to runoff or careless disposal. This occurs in many parts of North Africa. In west central Morocco, for instance, where phosphate mining is a major industry, fluorosis is recognized as an important clinical problem in human and livestock populations, and is known as darmous (Kessabi and Abdennebi 1985). Soils in endemic areas contain fluo-

ride in the range of 1,450 to 4,085 ppm DM. Pasturage in these regions has fluoride concentrations in the range of 95 to 260 ppm DM; hay, 85 to 180 ppm DM; and barley grain, 11 to 18 ppm DM. Clear water has an average of 1.4 ppm fluoride. However, drinking water in these areas is often turbid, containing much soil and rock particulate matter, and the average fluoride concentration of turbid water is 14 ppm. Fluorosis is likely to develop in livestock when the long-term ration concentration of fluorine exceeds 100 ppm DM. In the wet season, grazing is identified as the major source of fluoride ingestion, while in the dry season, it derives from increased water consumption. In Egypt, chronic fluorosis has been reported in goats kept in the vicinity of a superphosphate factory emitting airborne hydrofluoric acid as a byproduct (Karram 1984).

Fluoride is also found frequently in ores processed for aluminum and iron. Smelting and milling operations release fluoride into the air, thus contaminating fields, crops, and water sources through settling of particulates. Animals grazing nearby can ingest sufficient deposited fluoride to develop toxicity as reported in goats near an aluminum smelter plant in India (Sahoo and Ray 2004). In Inner Mongolia in China, industrial fluoride pollution has a serious impact on cashmere goat production. The life span of goats may be reduced to two to three years due to impaired pasturing, mastication, and inanition resulting from teeth deformed by fluorosis (Wang et al. 2002).

Fluorine exposure from the sources discussed above involve inorganic fluoride compounds and toxicity usually arises from chronic exposure. Acute fluorine toxicity may also occur in livestock accidentally exposed to large doses of organic fluorides such as sodium fluoroacetate, which is used as a rodenticide and in predation control. Acute fluoride toxicity from such accidental poisoning has not been reported in goats, though they are presumably susceptible.

An unusual form of acute monofluoroacetate poisoning of goats in South Africa occurs after ingestion of the plant *Dichapetalum cymosum*, also known as gifblaar, which accumulates monofluoroacetate. The clinical manifestation is usually rapid death due to heart failure, as discussed in Chapter 8.

Pathogenesis

Chronic fluorosis results from prolonged but not necessarily continuous ingestion of excessive fluoride compounds. Tolerance levels for goats have not been reported, but safe ration concentrations for breeding ewes up to 60 ppm and for feeder lambs up to 100 ppm have been established (Osweiler et al. 1985). In experimental studies involving daily administration of sodium fluoride, the response of goats appears to be similar to that of sheep (Milhaud et al. 1983). Fluorides

are readily absorbable from the digestive tract, though the availability and digestibility of fluorides varies with the source. In goat studies, fluoride was 75% available from sodium fluoride, 65% from ground raw rock phosphate, 34% from defluorinated phosphate, and 38% from dicalcium phosphate (Clay and Suttie 1985).

Though fluorine accumulates in all tissues, the manifestations of chronic fluorosis are referable to fluorine accumulation in hard tissues, namely, bone and teeth (Milhaud et al. 1980).

Fluorine can be incorporated into bone throughout the life of the animal, but accumulates in teeth only during development. Therefore the presence or absence of lesions in teeth erupting at different ages gives some indication of the duration and onset of exposure to fluoride. The effect of excessive fluoride on developing teeth is to impair normal mineralization of the pre-enamel, predentine, and precementum matrices. There is evidence that high fluoride interferes with normal collagen synthesis to produce imperfect collagen or even noncollagenous protein, which alters the tooth matrix structure and results in abnormal tooth morphology (Wang et al. 2003). Affected teeth are softer, appear mottled, and wear more quickly. Typical staining of affected teeth results from oxidation of exposed organic material in the tooth. Affected animals may have difficulty drinking cold water, and due to excessive tooth wear, may have difficulty in prehension and mastication. These animals grow poorly and are underconditioned as a result of impaired feed intake.

The adverse effects on bone include disruption of osteogenesis, acceleration of bone remodeling, development of exostoses and sclerosis, and osteoporosis. An important underlying mechanism for abnormal bone development in fluorosis is the impact of fluoride on collagen metabolism leading to structural changes in collagen fibers that affect the extracellular matrix of bone. Recently it was reported that at the molecular level, collagen gene expression is altered in goats with fluorosis (Li et al. 2006, 2007). Animals with skeletal fluorosis may have visible swellings on bones and exhibit a stiff and painful gait or intermittent lameness. Chronic fluorosis can also produce anemia in affected livestock through accumulation in the bone marrow and suppression of erythropoiesis.

Clinical Findings

Signs of chronic fluorosis may be nonspecific and include anorexia, a stiff gait, a history of intermittent lameness, emaciation, a rough, dry hair coat, and pale mucous membranes suggesting anemia. Morbidity rates can be high, especially in endemic areas. Careful observation of animals while they eat and drink may reveal difficult mastication or mouth pain. Specific examination of the teeth and palpation of the skeleton are necessary to correlate these general findings with a diagnosis of fluorosis. Incisors are most easily examined. Affected teeth show streaky or splotchy yellow to brown to black staining, and have a mottled chalky appearance to the enamel surface (Figure 4.13). Teeth may be worn beyond expectation

Figure 4.13. Typical dental lesions of chronic fluorosis. Note mottling and staining. (From Milhaud et al. 1980a.)

for the age of the animal, and some individual teeth may be prematurely lost. The number of teeth involved will vary depending on when exposure to fluorides began. However, pairs of teeth, for example, corner incisors, are bilaterally affected because they developed at the same time.

Palpation of the skeleton may reveal a general thickening of bones or focal swellings caused by exostoses, particularly on the mandibles, ribs, and metacarpal and metatarsal bones. Overt lameness or recumbency may be due to either bone pain or fractures occurring secondary to fluorotic changes in bone. Rib fractures are common in smaller does that have been mounted by large bucks at breeding.

Clinical Pathology and Necropsy

Normal plasma fluorine levels in goats have been reported in the range of 0.09 to 0.22 mg/l, while goats with signs of chronic fluoride intoxication have concentrations of 0.6 to 1.1 mg/l (Milhaud et al. 1980a). Urine fluoride levels of more than 15 ppm suggest chronic fluorosis in cattle, but diagnostic levels in goats have not been reported.

Anemia may be documented in the hemogram of goats with chronic fluorosis (Karram et al. 1984). In other species, serum calcium and phosphorus levels are usually within normal limits but serum alkaline phosphatase is often elevated. In experimental chronic fluorosis in goats, serum alkaline phosphatase levels were normal, as were serum calcium and phosphorus levels (Milhaud et al. 1980). In a naturally occurring field outbreak, affected goats were hypocalcemic and hyperphosphatemic, but alkaline phosphatase was not measured (Karram 1984).

Radiographically, the severity and extent of detectable lesions depends on the duration, degree, and onset of exposure to fluoride. In the jaws, maxillary borders become hazy and irregular. Bone structure becomes more porous with reduced density of cancellous bone. Compact or cortical bone is thinned. Molar and premolar tooth roots become less opaque and less substantial and abnormal tooth wear is apparent. In long bones, increased porosity and decreased density are also noted. Physeal cartilage of the metatarsal and metacarpal bones becomes hazy and double lines are noted at the growth plate. Osseous bridging across the growth plate may also be seen and joint spaces may be narrowed. Pseudoarthroses may be seen when rib fractures are present. Periosteal hyperostosis is a consistent finding in advanced, severe chronic fluorosis in cattle, but was not reported in experimental chronic fluorosis of goats (Milhaud et al. 1980).

At necropsy, the carcass may be in poor flesh. There are no gross or histologic lesions in soft tissues. Bones may be brittle and have a chalky white appearance with a roughened, irregular surface. They may be thicker and heavier than normal. Mandibles and metatarsal and metacarpal bones are most commonly affected. Fluorotic molars and premolars may show staining, mottling, chalkiness, and excessive wear similar to affected incisors. The staining, which involves the organic matrix of the tooth, cannot be scraped off, in contrast to superficial food staining. Microscopically, bones may show varying degrees of osteopetrosis or osteoporosis depending on the type, intensity, and duration of fluoride exposure. When fluorosis is suspected, bone should be analyzed for fluoride content. Mandible, rib, metatarsal, and metacarpal bones are most commonly submitted. In normal goats, fluorine concentration in these bones is reported to be less than 17.5 ppm/fat-free dry matter (Milhaud et al. 1983).

Diagnosis

Presumptive diagnosis is based on a history of chronic exposure to fluorides, lameness or stiff gait, characteristic dental lesions, and consistent radiographic findings. Fibrous osteodystrophy, which occurs on high phosphorus diets, may produce lameness, jaw swelling, and disruption of normal dental alignment, but mottling and chalkiness of teeth are absent. Diagnosis is most challenging in the early stages when ill thrift or stiff gait may be the only presenting complaints. Definitive diagnosis requires confirmation of increased fluoride levels in bone samples taken by biopsy or at necropsy.

Treatment and Control

There is no specific treatment for chronic fluorosis beyond removal of animals from the fluoride source, which is difficult when the source is industrial or environmental. Attempts should be made to identify all sources of fluorine and their relative danger. When possible, management should allow young, growing stock access to the least contaminated pastures, feeds, and water supplies to reduce the incidence of dental fluorosis. Turbid water sources should be allowed to settle and clear water only offered to goats. Water can be pretreated with slaked lime at a rate of 500 to 1,000 ppm and allowed to settle for six days. When fluoride exposure is unavoidable, daily feeding of aluminum salts such as aluminum sulfate, aluminum chloride, or calcium aluminate can help reduce fluorine absorption and its toxic effects. A dose of 30 g/head/day has been recommended in cattle, but no dosages have been found for goats.

When mineral supplements are fed to goats, raw rock phosphate and superphosphate should be avoided or at least checked for fluorine levels before use. Defluorinated phosphate supplements are recommended. Suitable products should have a phosphorus-to-fluorine ratio of 100:1 or more (Osweiler et al 1985).

Extensively defluorinated products, however, are generally more expensive due to increased refining costs and may not be attractive to producers.

In parts of China, where industrial fluorosis is a major problem for grazing goats, a number of interventions have been attempted to reduce the problem, including: removal of goats from high to low fluoride areas, use of stored green grass in the dry season as fodder, trimming of affected teeth, and mineral supplementation. However, the best results for controlling the wearing down of affected teeth was to supply supplemental protein-rich feed to goats in high fluoride areas (Wang et al. 2002).

Chronic Selenium Poisoning

Chronic selenium poisoning is characterized by deformation and sloughing of the hooves with marked lameness and secondary emaciation in grazing animals resulting from decreased locomotion.

Etiology and Epidemiology

Chronic selenium poisoning of livestock occurs mostly in regions of the world where soil selenium levels are high. Seleniferous soils are found in the Rocky Mountains and Great Plains of North America, parts of Australia and India, as well as Israel, Ireland, New Zealand, portions of the former Soviet Union, and elsewhere. Plants growing on seleniferous soils absorb selenium and prolonged consumption of these plants by livestock leads to toxicosis. Indicator or converter plants, such as *Astragalus* spp., require selenium for growth and contain particularly high concentrations. Though often unpalatable, livestock will eat these plants under conditions of deprivation or overgrazing. Facultative plants may also absorb selenium from the soil but do not require it for growth. Grains such as corn, when grown on seleniferous soils, may contain toxic levels of selenium. More detailed information on seleniferous soil characteristics and soil-plant interactions is available elsewhere (Dhillon and Dhillon 2003).

Chronic selenium poisoning associated with prolonged ingestion of indicator plants assumes two clinical forms. The first, alkali disease, is characterized by weight loss and musculoskeletal abnormalities and is presented here. The second, blind staggers, is characterized by signs of neurologic dysfunction. In recent years the role of selenium in blind staggers has been called into question and the theory proposed that this condition is actually a manifestation of polioencephalomalacia resulting from excessive sulfur intake (O'Toole et al. 1996). Blind staggers is discussed further in Chapter 5.

Chronic selenium poisoning may also occur when selenium supplements are improperly mixed into feeds at excessive amounts. Experimental studies dem-onstrated that goats fed sodium selenite at a rate of 6 mg/kg bw daily became sick and died within four to nineteen days after feeding began. Goats fed 3 mg/kg bw daily showed no adverse effects after ninety days (Pathak and Datta 1984). Acute selenium poisoning has been produced experimentally in goats. Single oral doses of sodium selenite in the range of 40 to 160 mg/kg bw killed goats in a matter of hours. Repeated daily doses in the range of 5 to 20 mg/kg bw produced signs of inappetence, diarrhea, hind limb weakness, arching of the back, weight loss, recumbency, and death over a period of days to several weeks (Ahmed et al. 1990a).

Clinical Signs

Chronic selenosis seen in grazing goats in India appears clinically similar to the disease as seen in cattle and buffalo (Gupta et al. 1982). Animals introduced into seleniferous regions of Punjab develop signs within six months after arrival. All ages and both sexes are affected. The earliest signs are visible cracks in the horns and hooves, with irregular new growth at the coronary bands. The cracks gradually deepen and separate the older distal segments of the hoof from the new growth above. Hooves become deformed and elongated. Infection often occurs in the deep cracks of the hoof wall. The foot emits a necrotic odor and becomes extremely painful as pus accumulates. Affected goats have increasing difficulty standing, move with a staggering gait, or exhibit overt lameness. Severely affected animals remain recumbent. Impairment of locomotion drastically reduces feed intake and goats become weak, depressed, and emaciated. Decreased conception and increased abortion rates are also seen. Death is by inanition, predation, or secondary infection.

Clinical Pathology and Necropsy

Necropsy lesions are not particularly helpful in the diagnosis of alkali disease, but tissue samples should be collected to determine selenium levels. Specific toxic tissue levels have only infrequently been reported in goats. In other herbivores, levels of selenium in liver and kidney in the range of 4 to 25 ppm are found in chronic poisoning. Affected hoof tissue has selenium levels in the range of 8 to 20 ppm (Osweiler et al. 1985). In goats with selenium toxicosis from eating maize grown on seleniferous soils in China, blood Se concentrations greater than 0.2 μg/g were an indicator of early Se toxicity. Overt signs of Se poisoning appeared when blood and hair values were over 0.5 and 0.3 μg/g, respectively (Hou et al. 1994). Mean liver and kidney concentrations of selenium in these affected goats were 20.46 ± 0.89 μg/g and 20.96 ± 1.21 μg/g respectively, while liver and kidney selenium concen-

trations in control goats were $0.50 \pm 0.16\,\mu g/g$ and $8.92 \pm 2.20\,\mu g/g$, respectively.

Treatment and Control

There is no effective treatment for selenium poisoning. Some practical recommendations for rangeland management have been offered to aid in control (Davis et al. 2000). Soils should be tested to identify high selenium content and livestock fenced out of the worst affected areas. Avoid overgrazing so as not to oblige livestock to consume seleniferous plants. Practice rotational grazing to limit the length of time animals spend on soils with high selenium levels. Graze animals on pastures with higher selenium concentrations only in the fall and winter, when grasses are more mature and have lower selenium content. Practice weed control because broadleaf plants are greater selenium accumulators than grasses. Unless soil sulfate levels are already high, selenium uptake by plants can be reduced by applying sulfur or gypsum to soil because sulfur is competitive with selenium in plant uptake. Avoid use of phosphate fertilizers which themselves may have a high selenium content and can also enhance selenium uptake in plants by displacing selenium bound to soil. When economically feasible, supplementary feeding with feedstuffs derived from nonseleniferous regions is the best method to dilute the uptake of selenium in chronically exposed animals. Feeding of supplemental copper and sulfur in a mineral mix can be beneficial in counteracting a high selenium diet as can an increase in the overall protein content of the diet.

Plants Toxic to the Musculoskeletal System

Senna (Cassia) roemeriana

Ingestion of *Senna* (*Cassia*) *roemeriana* (twin leaf senna) has caused death due to skeletal myopathy in grazing cattle and sheep in the southwestern United States and northern Mexico. Experimental feeding of the dried plant to adult Spanish goats at a rate of 5 or 7 g/kg bw for an average of twenty-four days resulted in toxic effects related to muscle damage. After about two weeks of intake, affected goats demonstrated decreased appetite, weight loss, increased heart and respiratory rates, and progressive weakness of the hind limbs, leading to recumbency. Elevations in serum creatine kinase as high as 43,800 IU/l were also detectable after two weeks. At necropsy, muscles were pale, especially in the hindquarters. There were also pericardial and pleural effusions and pulmonary edema in some goats. Histologically, affected muscle shows necrosis and fragmentation of myofibers with infiltration of necrotic sarcoplasm by neutrophils and macrophages (Rowe et al. 1987). In naturally occurring cases, nutritional muscular dystrophy would be the principal differential diagnosis.

Karwinskia humboldtiana

This shrub is indigenous to the southwestern United States and northern Mexico and is responsible for coyotillo poisoning, or limberleg, in livestock. The condition, which principally causes a neuropathy, is discussed in more detail in Chapter 5. However, it has been demonstrated that the fruits of *K. humboldtiana* can produce widespread skeletal and cardiac muscle degeneration in addition to neuropathy (Dewan et al. 1965). The lesion in skeletal muscle is one of hyaline degeneration, similar to that seen in nutritional muscular dystrophy. At least some of the incoordination and weakness observed in limberleg may be due to muscle damage in addition to neurologic dysfunction.

Trisetum flavescens

In alpine regions of Europe, a condition of livestock known as enzootic calcinosis is ascribed to the ingestion of *Trisetum flavescens*, or yellow oat grass, at pasture or in harvested forages. The plant contains high concentrations of 1,25-dihydroxycholicalciferol, the active metabolite of vitamin D. This metabolite markedly increases the intestinal absorption of calcium by herbivores. Chronic ingestion results in calcification of selected soft tissues, notably the great vessels, heart, lungs, tendons, and ligaments. A reluctance to walk and constant shifting of weight from leg to leg are common signs of tendon and ligament involvement. Further information on the cardiac effects of enzootic calcinosis are available in Chapter 8.

Enzootic calcinosis has been recorded in milk goats in Switzerland on a farm where yellow oat grass comprised 8% to 34% of the herbage on various fields (Kessler 1982). Twelve goats died over a three-year period. Affected goats showed progressive wasting, decreased milk production, increased heart and respiratory rates, and altered locomotion. Serum calcium, phosphorus, and alkaline phosphatase levels are increased in affected goats (Wanner et al. 1986). Evidence of calcification of soft tissues should be sought at necropsy. Paratuberculosis of goats also produces chronic wasting and calcification of the aorta, and this must be ruled out.

Delaying harvesting of *T. flavescens* reduces the toxic effect of the plants because young plants have greater vitamin D activity. Silage made with yellow oat grass is more toxic than hay.

A similar syndrome of soft tissue calcification caused by increased vitamin D activity occurs with ingestion of *Solanum malacoxylon* by herbivores in the Caribbean, South America, and Hawaii and from *Cestrum diurnum* ingestion in the southern United States. Reports of toxicity in goats from either of these plants were not found.

Lupinosis

Several forms of lupine toxicity occur in livestock and all are poorly documented in goats. The neurologic and hepatopathic forms are mentioned briefly in their respective Chapters, 5 and 11. In calves, a congenital skeletal form also occurs and is known as "crooked calf disease" in the western United States. The development of skeletal deformities results from transplacental transfer of a lupine alkaloid, anagyrine, during the second month of gestation. There is circumstantial evidence from California that the condition also may occur in developing goat fetuses whose dams consume *Lupinus latifolius* during pregnancy. Arthrogryposis, torticollis, and scoliosis are the characteristic signs. In addition, similar skeletal deformities have been observed in a human infant in California whose mother drank local goat milk during pregnancy, though a definitive causal link was not established (Kilgore et al. 1981).

INHERITED AND CONGENITAL DISEASES

Myotonia Congenita

Myotonia congenita is an inherited disease of goats that manifests as transient tetanic spasms of the skeletal musculature initiated by visual, tactile, or auditory stimuli. The condition represents an involuntary persistence of a voluntary muscle contraction. Goats affected are commonly known as fainting goats, fainters, or wooden-legged goats. Caprine myotonia congenita is used as an animal disease model for studies of human myotonia congenita, also known as Thomsen's disease.

Etiology and Pathogenesis

Caprine myotonia congenita appears to be inherited as an autosomal dominant gene with incomplete penetrance. Two classes of affected goats exist regarding clinical signs: mild and severe. The mildly affected goats are assumed to be heterozygous and severely affected goats homozygous for the responsible gene. Breeding studies argue against the condition being sex-linked.

Only voluntary striated skeletal muscles are involved in this disease. The defect appears to be at the level of the muscle fiber membrane and may be caused by a reduced number of chloride channels in myotonic fibers (Bryant and Owenburg 1980). This leads to a reduction in chloride conductance with decreased accommodation, increased membrane excitability, and abnormal repetitive muscle firing (Bryant et al. 1968; Adrian and Bryant 1974). The myotonic discharge may be triggered by any sustained depolarization such as a burst of nerve impulses in response to surprise, noise, or handling. The disease is characterized by a generalized, sustained tetanic contraction of skeletal muscles lasting for several seconds to approximately one minute. For reasons unclear, withholding water from myotonic goats for up to three days results in disappearance of the myotonic response. Reintroduction of water is accompanied by return of myotonia (Hegyeli and Szent-Gyorgyi 1961). The condition is also exacerbated by cold exposure and ameliorated by exercise (McKerrell 1987).

Epidemiology

Caprine congenital myotonia was first recognized in goats in Tennessee in the 1880s and was first described in the veterinary literature in 1904 (White and Plaskett 1904). Such goats were favored because they did not wander or easily escape confinement. They also became popular as an amusement. Recognition of these goats as a model for human myotonia congenita received growing attention in the 1930s (Kolb 1938).

Veterinarians may encounter myotonic goats in research herds maintained for studies of human myotonia congenita. The goats are also maintained as pets or curiosities, and their popularity as such seems to have grown in recent years, at least when gauged by media publicity. A few breeding herds exist to supply the research and pet markets and there are at least two breed registries for fainting goats. These animals are also being used increasingly as meat goats because of the heavy muscling that occurs in their hindquarters. Both males and females can be affected. Crossbreeding of a myotonic goat and a nonmyotonic breed of goat can produce a myotonic offspring.

Clinical Findings

The myotonic condition is not usually recognized in affected goats younger than two weeks of age and is clearly recognizable by six weeks. Younger goats may show some slight stiffening during handling. Buck kids tend to show more pronounced signs than females. Episodes of myotonia congenita can be triggered by visual, auditory, or contact stimuli such as the sudden appearance of strangers, clapping, or handling for vaccinations. Mildly affected goats develop maximal rigidity in the hind limbs. They visibly stiffen and when running away exhibit a "bunny hopping gait" caused by impaired mobility of the hind limbs. Severely affected goats show general muscular rigidity, stiffen, and fall over. Hyperextension of muscles can be so severe that recumbent animals involuntarily roll over on their backs with legs extended in the air. Some animals may temporarily stop breathing because of rigidity of thoracic muscles. Affected animals maintain a normal sensorium even during the tetanic episodes that may last up to a minute. Upon recovery from each episode, the goat will be stiff gaited for a short period

and then return to normal. Affected goats become conditioned to intentional repeated stimulations and the veterinarian is less likely to be able to induce a myotonic episode as the examination progresses. The condition persists for life.

Clinical Pathology and Necropsy

There are no detectable abnormalities in hematology or clinical chemistry. Routine necropsy and histologic examination reveal no lesions. Electromyographic studies of the live animal may be helpful in diagnosis. Affected goats produce a distinctive response characterized by an audible "divebomber" sound typical of the persistent, high frequency discharge of muscle associated with a hyperexcitable muscle cell membrane (Steinberg and Botelho 1962). Myotonic goats have some characteristic ultrastructural abnormalities. Mitochondria from myotonic fibers have an altered lipid composition (Harris 1983). Isomyosins from myotonic fibers have a characteristic distribution with increased fast isomyosins (Martin et al. 1984).

Diagnosis

The presumptive diagnosis is based on the characteristic pattern of intermittent, sustained muscle stiffening in response to external stimuli in goats with a history of myotonic lineage. When the background of goats is unknown, electromyography tests can support the diagnosis. Tetanus is a progressive condition in which muscular rigidity becomes persistent rather than intermittent. The author has seen a pygmy goat with intermittent rigid collapse that, on necropsy, had extensive lesions of CAE virus infection in the cerebrum.

Treatment and Control

Goats with myotonia congenita are not usually treated. In humans, the condition is managed by daily administration of quinine sulfate or procainamide. Because fainting goats are often bred with the goal of maintaining the defect for research purposes, control is not an appropriate topic of discussion. Intentional breeding of these goats for amusement purposes should be discouraged on humane grounds.

Various Congenital Skeletal Abnormalities

Achondroplastic dwarfism is a breed characteristic of pygmy and dwarf goats. Akabane virus infection is discussed earlier in the chapter as an infectious cause of congenital skeletal deformity. Lupinosis is also discussed above as a possible phytotoxic cause. Ingestion of *Veratrum californicum* by does during gestation also has the potential of producing hypoplasia of metatarsal and metacarpal bones in kids in addition to the more commonly known sign of cyclopia (Binns et al. 1972). There are numerous reports of spontaneous congenital skeletal deformity in goats of unknown etiology. Hemivertebra of the fourth thoracic vertebra causing spinal injury and hind limb weakness was seen in a two-month-old Saanen cross kid and presumed to be hereditary (Rowe 1979). Increased limb length with knuckling of unknown cause was recognized in an Osmanabadi kid as a cause of dystocia (Kulkarni and Deshpande 1987). Tibial agenesis has been reported in a newborn Toggenburg kid (Giddings 1976). Radial agenesis and ulnar hypoplasia occurred in two Saanen kids from the same kidding (Baum et al. 1985). Complete absence of a forelimb at birth has also been observed in a West African Dwarf goat (Onawunmi et al. 1979). Lateral luxation of the patella secondary to a hypoplastic lateral trochlear ridge may be congenital in goats, though the condition is usually not observed until goats are older than one year of age (Baron 1987). Various other sporadic congenital deviations of the forelimbs and hind limbs have also been described (Koch et al. 1957).

An inherited condition of short tendons occurs in 0.03% to 4.5% of Australian Angora goats. Severely affected kids may die, but milder cases are correctable by splinting or plaster casting. The trait is transmitted as a recessive autosomal allele (Baxendell 1988). An inherited metacarpal gait has been reported in Saanen goats in Iran (Bazargani and Khavary 1976). Believed to be a recessive, sex-linked trait, only males of twins of different sexes were affected at birth. These animals walked on their metacarpi and died within a few weeks of age.

TRAUMATIC DISEASES

Predation

Predation can be a serious constraint on goat production. It is generally associated with death loss, particularly of neonates. However, nonfatal maiming of older goats occurs in certain situations, particularly those involving domestic dogs. Predation is discussed in the present chapter because musculoskeletal trauma is a common outcome in these instances.

Epidemiology

The subject of predator/prey relationships involving livestock is very complex and is fraught with economic, ecologic, ethical, and sociologic issues. For a more complete discussion of predation in general, the reader is referred to other sources (Gaafar et al. 1985; Rollins 2001; Shelton 2004).

Predation of goats is reported as a problem in Australia, the United States, and widely throughout the tropics. In Australia, predator importance varies with the type of goat involved and their geographic location, but is generally recognized as a major cause of kid mortality (Holst 1986). Feral goat kids are lost to

foxes, dingoes, feral pigs, and hunters. Milk goats, more likely kept in semirural or suburban areas, are preyed upon primarily by domestic dogs. Angora kids are lost to foxes, eagles, and urban and wild dogs. In Southern Australia, fox predation occurs in Cashmere goat flocks. Attacks are nocturnal and kids are the primary target. Nevertheless, kid losses caused by predation by foxes may be less than those caused by mismothering and pregnancy wastage (Long et al. 1988).

In the United States, predation of hair goats and dairy goats has been studied. In south Texas, attacks on Angora goats were caused primarily by coyotes and secondarily by bobcats. Dramatic reductions in kid crop were attributable to predation, though aggressive predation control had little effect on reducing losses. Adult goats were not preyed upon until kids were decimated. It was concluded that in areas of high coyote density, intense local predator control would be insufficient to prevent heavy kid losses (Guthery and Beasom 1978). In 1999, in Arizona, New Mexico, and Texas, three major goat-producing states, 61,000 goats and kids were lost to predators, with losses valued at $3.4 million (Howery and DeLiberto 2004).

On eighty-four goat farms located in rural and semirural areas of Louisiana, domestic dogs were the most commonly recognized predators (Hagstad et al. 1987). Attacks occurred most commonly during periods of reduced light. Of those attacked, 80% were killed outright or required slaughter while 20% survived or recovered. Four management factors were identified as reducing the likelihood of attacks: penning of goats at night, the use of a night light, keeping goats near an occupied residence, and the presence of a dog belonging to the owner. Anecdotal reports from around the United States support the finding that domestic dogs allowed to run free at night are largely responsible for attacks on dairy goats. However, dairy goat owners in New England are increasingly complaining about attacks on kids by a growing coyote population.

Predation is cited as a cause of lost productivity throughout the tropics and housing goats at night is suggested as the most basic means of reducing losses (Devendra and Burns 1983). In a central Mali study, 17% of deaths in goats were ascribed to "lost" kids presumably taken by predators. Uncontrolled domestic dogs and lax herding practices were considered responsible (Traore and Wilson 1988). In West Timor, Indonesia, goat herders identified predation by dogs and pigs as the third largest cause of kid death after navel infection and enteritis (Gatenby 1988).

Domestic dogs are more likely than wild predators to maim rather than kill goats, because the pursuit of goats begins more as a game than as an earnest attempt at food acquisition. Domestic dogs often form packs

that can wreak havoc in a flock or herd of goats with limited routes of escape. Far more goats are injured than could possibly be consumed as food. Goats and sheep make relatively easy targets for dogs because of their small size and nonaggressive behavior.

Clinical Signs and Diagnosis

Evidence of predation is variable. Predation is often assumed when young kids are lost in areas where predators are endemic. Owners and herders may actually witness acts of predation or the presence of predators near flocks or herds. In the aftermath of an unobserved predator attack, evidence may suggest the type of predator involved (Guthery and Beasom 1978; Squires 1981; Long et al. 1988). Coyotes, for example, most often attack young kids and devour them completely. The presence of coyote spoor containing mohair in the vicinity of livestock areas may be the only circumstantial evidence that coyotes are involved. Foxes may partially bury a carcass, and rather than devouring it completely, may slash open the abdomen and consume the entrails. When only small pieces of the carcass remain, and there is wide scattering of blood, pigs are the likely predators. Two to four, deep, focal penetrations of the skull, rib cage, or abdomen suggest killing by eagles. Primarily predation must be differentiated from scavenging of animals dead of other causes. In predation, there is extensive hemorrhage and free blood around the site of wounds while in scavenging, such as caused by crows, there is no hemorrhage and little free blood. Evidence of crow scavenging includes removal of eyes or tongue and evisceration through the anus or umbilicus.

In dog attacks, flesh wounds are common on the flanks and hindquarters, indicative of a chase, and carcasses may show no evidence of consumption. Animals surviving attack may show varying degrees of injury from superficial skin and muscular trauma to severe trauma with extensive blood loss and shock. Injuries may include crushing fractures of bones and visceral damage caused by deep bites. All bites can lead to secondary infection. While flesh wounds are relatively obvious, bites penetrating the abdomen and thorax should not be overlooked due to the threat of secondary peritonitis or pyothorax.

Treatment

The approach to management of goats after a predator attack depends a great deal on economics. When pet goats or valuable show or breeding stock are attacked and survive, aggressive medical therapy can be economically justified. Treatment of shock or blood loss with fluids, blood transfusion, and corticosteroid therapy is indicated. Broad-spectrum, parenteral antibiotic therapy should be initiated immediately and maintained for at least ten days in cases of severe

attack. Surgical interventions to manage visceral trauma may be immediately necessary, though orthopedic interventions can usually wait until patients are stabilized. If animals are brought for veterinary attention shortly after attack, primary closure of skin and flesh wounds can be attempted. These should be left open or drains installed if it appears that much necrotic muscle will develop in wounds. Topical insecticide sprays should be used when fly strike is a potential problem. Affected animals should be kept in clean, warm, dry surroundings and fed a high-quality forage during convalescence. Tetanus prophylaxis is indicated.

In commercial flocks, treatment of individual survivors may be economically constrained and the veterinarian should help the owner to minimize economic losses subsequent to dog attacks where large numbers of animals may be involved. Some suggestions made for the care of sheep flocks after predator attack are applicable to goats as well (Dille 1985).

It may be possible to shear hair goats and salvage the fleece. Hides may also be salable if not severely damaged. If fresh, carcasses may be sold as feed for animal consumption, for example, to mink farms. Carcasses can also be used as bait to trap predators where trapping is allowed or used as evidence to derive compensation from owners of dogs involved in attacks. There may be government compensation in some places for losses to predators.

Live animals that are seriously wounded and unlikely to recover can be butchered for human consumption, unless there is a cause for suspecting rabies in the attacking animals. Animals with elevated or subnormal temperatures should not be butchered. Areas around bite wounds should be liberally trimmed. Animals unable to walk after attack and animals with evidence of penetration of body cavities by bite wounds should be considered for emergency slaughter.

Control

At the flock or herd level, losses to predation may be controlled in a number of ways. Active destruction of predators through trapping, poisoning, or shooting may be subject to local regulation and may or may not be economically justified when the costs of predator control are weighed against losses. Each situation should be evaluated on its merits. When domestic dogs are involved, stock owners must be sure that local ordinances controlling unleashed dogs are adequate and rigidly enforced. Poison baits for controlling predators have been withdrawn from use in the United States sine 1972 and other methods, such as trapping, snaring, M-44 sodium cyanide ejectors, gas cartridges for denning coyotes, and livestock protection collars have been restricted or eliminated by ballot initiatives in some states (Andelt 2004).

As predator control options have become more restricted, the use of livestock guarding animals has emerged as a cost effective and humane approach to protecting small ruminants from predation and their use has been recently reviewed (Andelt 2004). A number of dog breeds selectively developed in Europe and Asia to protect livestock from bears have become popular as guarding dogs for small ruminant flocks in the United States. These include the Great Pyrenees, Akbash, Anatolian Shepherd, and Komondor breeds, as well as the Maremma and Shar Planinetz breeds. Guard dogs in the United States are reported to be effective against coyotes, black bears, grizzly bears, and mountain lions, but may not be effective against wolves (Andelt 2004). Donkeys and llamas are also used as herd guardians with the advantage that they eat what the goats eat and thus do not require separate feeding as do dogs. Llamas are particularly effective against dogs, coyotes, and foxes because they are naturally aggressive toward canids. Intact males may try to breed ewes, so female llamas or geldings are preferred. Fencing is a costly and often inefficient means of predator control, though in Australia, dingo-proof fencing has been helpful to sheep farmers.

At a minimum, where predators are a problem, surveillance of the flock should be increased during kidding times and goats confined to a restricted kidding area when management conditions permit. Goats should be kept in a pen at night and the holding area should be illuminated. Control is improved if the holding area is near an occupied residence.

Fractures

Fractures are common in goats, though epidemiologic data on prevalence and predisposing factors is limited.

Epidemiology

Environmental hazards are often implicated in the occurrence of fractures. All forms of gating, fencing, and penning material should be evaluated carefully for the likelihood of goats catching limbs or necks in structural spaces before the material is used. The curiosity and climbing instincts of goats ensure that they will find a way to become entangled whenever possible. In the author's experience, chain link fences especially predispose to limb fractures in intensively managed goats. The animals stick their legs through the fence and then, if frightened or crowded by other goats, are unable to extricate the limb. Fracture secondary to struggling is a likely outcome. Trauma from dog attacks is another common cause of limb bone fractures in goats in the United States. Preexisting bone diseases such as osteomyelitis, chronic fluorosis, fibrous osteodystrophy, or rickets can predispose to fractures.

Two surveys from India give differing perspectives on the occurrence of caprine fractures. In Hisar, most fractures occurred in goats between one and three years of age. In order of decreasing frequency, fractures were observed in femur, tibia, metacarpus or metatarsus, phalanx, humerus, radius, and ulna (Singh et al. 1983). The prevalence of femoral fractures was attributed to free ranging goats around villages being hit from behind by vehicles with bumpers at thigh level. In Ranchi, fractures occurred most commonly in goats younger than six months of age. The most commonly involved bones were, in descending order of frequency, metacarpus, metatarsus, femur, tibia, radius and ulna, humerus, and phalanx. Forelimb and hind limb fractures occurred with approximately equal frequency. The occurrence of fractures was believed to be predisposed by soil calcium and phosphorus deficiencies and the hilly terrain in the region. Causes of fracture identified by history included slipping while grazing on hillsides (54%), playing or gamboling (24%), automobile accidents (18%), and trapping of limbs in wire enclosures (4%) (Dass et al. 1985).

Clinical Signs and Diagnosis

Fractures are usually identifiable by an acute onset of lameness, deviation of limbs, and/or palpable crepitus. Fractures secondary to nutritional deficiency rather than trauma are less likely to displace or be recognized on physical examination. Radiographic studies help to define the nature of the fracture and suggest therapeutic approaches.

Treatment

In young kids, simple splinting of distal limb fractures is frequently adequate and economically advantageous. Toothbrushes and split sections of PVC pipe are examples of splints that permit closed fractures of young kids to heal within three weeks. Adults may require five to six weeks to heal. The reader is referred to textbooks of large animal surgery for discussions of surgical repair of fractures. Suffice it to say here that numerous approaches to successful fracture management have been reported in goats including compression plating of radial and ulnar fractures (Bacher and Potkay 1975) and full limb casting of tibial fractures followed by application of a Robert Jones bandage (Mbiuki and Byagagaire 1984). Use of plaster casting alone was found to be an unsatisfactory method of managing radial and ulnar fractures (Buchoo and Sahay 1987).

When fracture repair and return to normal function are complicated by osteomyelitis or permanent nerve damage, limb amputation has been demonstrated to be a reasonable salvage operation in goats (Misk and Hifny 1979). The pelvic limb can be disarticulated at the hip or stifle, or amputated at the mid femoral level.

Treated goats show excellent adaptation to three-legged locomotion.

Control

When fractures occur more than sporadically in a given herd or flock, underlying problems of structural hazards or nutritional deficiencies must be considered as predisposing to an increased incidence of skeletal trauma. Careful attention must be paid to calcium, phosphorus, and vitamin D levels in the ration.

NEOPLASTIC DISEASES

Primary and metastatic neoplasms of bone and muscle are rare in goats. There are reports of an osteochondrosarcoma in the rib and sternum of a goat (Cotchin 1960), an osteogenic sarcoma at a previously repaired fracture site in the humerus of a ten-year-old Toggenburg wether, and an osteoma of the mandible in a ten-year-old female Toggenburg-cross goat that resulted in dislocation of the jaw (Steinberg and George 1989).

Several nonbony tumors have been reported to secondarily affect the mandible or maxilla of goats, resulting in visible distortion of the face, dislocation of teeth, dysphagia, or stridor if the maxillary sinus is involved. These include oral adenocarcinoma (Lane and Anderson 1983), ossifying fibroma (Pritchard 1984), nasal papillary adenoma (Pringle et al. 1989), and lymphosarcoma (Craig et al. 1986). The latter has also been found to infiltrate the marrow of long bones.

Nervous System

Information on the prevalence of neurologic disease in goats is limited. One American survey indicated that neurologic disease was diagnosed in 5% of all goat cases at necropsy (Lincicome 1982). Despite this low number, neurologic diseases are an important aspect of caprine practice. Diseases such as rabies and listeriosis represent serious potential zoonoses and demand accurate diagnosis. Certain nervous diseases of goats, such as organophosphate toxicities or pseudorabies, can result in high morbidity or mortality rates on individual farms despite a low general prevalence. Still others, such as polioencephalomalacia or neonatal meningoencephalitis, suggest management problems and the need for client education. Diseases such as scrapie need to be recognized and reported so that appropriate regulatory intervention can be initiated. Finally, accurate diagnosis and management of neurologic disease in goats can be a stimulating and satisfying clinical challenge for the veterinarian.

Most of the neurologic diseases of goats are presented in this chapter, with some exceptions. Pregnancy toxemia, hypomagnesemia, and milk fever are primarily nutritional diseases and are discussed in Chapter 19. Cowdriosis or heartwater produces both neurologic and cardiac signs and is essentially a vasculitis. It is discussed in detail in Chapter 8. The

neurologic aspects of caprine arthritis encephalitis (CAE) are discussed in this chapter in conjunction with maedi-visna, a closely related retroviral disease. However, CAE is covered in more detail in Chapter 4, because arthritis is the most common presenting sign. Finally, the causes of hepatoencephalopathy are discussed in Chapter 11.

BACKGROUND INFORMATION OF CLINICAL IMPORTANCE

Anatomy and Physiology

An atlas of the caprine brain in twenty-three transverse sections has been published (Yoshikawa 1968). The gross anatomy of the caprine central nervous system (CNS) and peripheral nerves has been described elsewhere and compared with sheep and cattle (Dellmann and McClure 1975; Godhinho and Getty 1975; Ghosal 1975). Published studies on the neurophysiology of goats are uncommon and no neurophysiological attributes of clinical importance unique to the species have surfaced.

Thalamic melanosis has been reported frequently as an incidental finding at post mortem in goats with brown hair coats and occasionally white coats, but has no clinical significance (Bestetti et al. 1980). One anomaly of the goat that could affect the clinical evaluation of the nervous system is a high frequency of variation in vertebral body numbers and the occurrence of transitional vertebrae (Simoens et al. 1983). This variation can complicate the technique of cerebrospinal fluid collection at the lumbosacral site and confuse interpretation of spinal radiographs and myelography. Details concerning vertebral anomalies are given in Chapter 4.

Neurologic Examination

The small size and reasonably cooperative nature of goats facilitate the performance of a thorough neurologic examination. A consistent, systematic approach should be taken. Protocols and procedures for neurologic evaluation of small ruminants have been published and are similar to those used in small animal medicine (Brewer 1983; Constable 2004). The examination must always include assessments of five major factors: mental status and behavior, cranial nerve functions, postural reactions, locomotion, and spinal reflexes. A summary of the types of signs associated with lesions in different regions of the CNS is given in Table 5.1 and details of the evaluation of cranial nerve function are given in Table 5.2.

Cerebrospinal Fluid Analysis

Analysis of cerebrospinal fluid (CSF) can be used to diagnostic advantage in caprine medicine (Smith 1982). Two sites, the atlanto-occipital and the lumbosacral site, are routinely used for collection of CSF from the subarachnoid space. Heavy sedation or general anesthesia of the goat is required to accomplish an atlanto-occipital tap. Several methods have been recorded, including use of intravenous diazepam (5 to 10 mg total dose), intramuscular xylazine at a dose of 0.1 mg/kg bw, intravenous thiopental sodium at a dose of 15 mg/kg, or inhalation anesthesia with halothane (Brewer 1983; Chandna et al. 1983). The lumbosacral tap may be accomplished using tranquilization or, if the risks of medication are high, manual restraint. A lumbosacral CSF tap without chemical restraint is best attempted only in comatose, paralyzed, or severely paretic goats. Because abnormal CSF is not necessarily homogeneous in character, the site of collection should be closest to the suspected lesion to maximize the value of the sample. Regardless of the site selected, the procedure should be done using strict aseptic techniques to avoid iatrogenic meningitis.

For atlanto-occipital puncture, the goat is laid in lateral recumbency. The head is flexed at a right angle to the cervical spine and positioned so that the head and neck are in a single plane parallel to the ground or table. This extreme flexion of the neck may compromise air movement through the trachea, particularly when a flexible tracheal tube is in place. The site of skin penetration is on the dorsal midline at the point of intersection with an imaginary line connecting the anteriormost aspects of the wings of the atlas. Ideally, a styletted, 2.5-inch (6.4 cm), 20-gauge spinal needle should be used, but an ordinary 1.5-inch (3.8 cm) 20- or 22-gauge disposable needle can be used if necessary (Brewer 1983). The needle should be directed toward the lower jaw as it penetrates the skin. The usual depth to the subarachnoid space is 1- to 1.5-inch (2.5 to 3.8 cm), but the needle should not be passed the full depth without stopping frequently to remove the stylette and check the progress. The advancing needle should remain perpendicular to the dorsal midline to avoid hemorrhage from entering the paravertebral venous sinuses.

The CSF should rise readily up the needle when the subarachnoid space is reached and the stylette removed. The fluid may be allowed to drip into a collecting tube, or aspirated gently with a syringe. If it runs forcefully from the needle, this may suggest increased CSF pressure and rapid egress or aspiration of fluid could result in caudal herniation of the brain. A manometer can be attached to the needle hub via a three-way stopcock to record CSF pressure. If CSF pressure is not increased, up to 0.22 ml of CSF/kg of bw may be extracted safely. On average, the total volume of CSF in adult goats is 20 to 25 ml, 8 to 12 ml of which is in the ventricles (Pappenheimer et al. 1962).

Table 5.1. Clinical signs associated with lesions in different regions of the nervous system.

Region of nervous System	Clinical signs possibly observed
Autonomic nervous system	Miosis or mydriasis, salivation, increased or decreased gut motility, changes in fecal and urinary continence, muscle twitching
Cerebrum	Changes in mental status, mania, hyperexcitability, hysteria, depression, nonresponsiveness, coma
	Changes in behavior, convulsions, opisthotons, head pressing, teeth grinding, constant chewing or vocalizing, yawning, inability to chew, blindness with normal pupillary responses
	Changes in gait, compulsive walking or circling, contralateral proprioceptive deficits
Cerebellum	Incoordination with no accompanying weakness, hypermetria in all limbs, base-wide stance, possible intention tremors, loss of menace response (also involves cranial nerves, cerebrum, and brain stem)
Vestibular system	Ipsilateral head tilt, circling, hemiparesis with staggering gait, resting nystagmus
Brain stem	Ipsilateral weakness, incoordination, spasticity, proprioceptive deficits
Cranial nerves	Deficits in vision, smell, hearing, or swallowing; changes in tone, motor control, or sensation of facial structures; abnormal eyeball position; carriage of head or balance
Spinal cord C1 to C6	Incoordination and weakness in affected limbs with loss of proprioception, potentially all four limbs affected, usually worse in rear limbs, reflexes are hyperactive in all affected limbs, skin sensation diminished in affected dermatomes
Spinal cord C7 to T2	Incoordination and weakness in affected limbs with loss of proprioception, forelimb deficits often equal rear limbs deficits, hyporeflexia of forelimbs, hyperreflexia of hind limbs, loss of skin sensation in affected dermatomes
Spinal cord T3 to L3	Incoordination, weakness and loss of proprioception in one or both hind limbs, hind limb reflexes hyperactive, forelimbs normal in all respects, loss of skin sensation in affected dermatomes
Spinal cord L4 to S2	Incoordination, weakness and loss of proprioception in one or both hind limbs, hyporeflexia of hind limbs, forelimbs normal in all respects, loss of skin sensation in affected dermatomes
Spinal cord S1 to S3	Distended bladder and loss of anal and tail tone; caprine spinal cord ends at spinal cord S_3 and the subarachnoid space extends to the second caudal vertebra
Peripheral nerves	Deficits of extension, flexion, or adduction; muscle atrophy in a single limb; localized loss of skin sensation on affected portions of limb; possible hyporeflexia
Neuromuscular junctions	General weakness, muscle twitching, or tremors

C = cervical spinal segment, T = thoracic spinal segment, L = lumbar spinal segment, S = sacral spinal segment.

For a lumbosacral tap, the animal is restrained in lateral recumbency and the spine markedly flexed with the plane of the midline parallel to the supporting surface. The puncture site is located on the dorsal midline where it intersects an imaginary line connecting the anteriormost aspects of the two *tuber sacrale*. There is frequently a palpable depression in the skin at this point. A local skin block of the puncture site with lidocaine is advised if the goat is not sedated. The occurrence of transitional lumbosacral vertebrae may make it difficult to identify and penetrate the lumbosacral space in goats. If frequent attempts are met with failure, the tap should be attempted in the L5–L6 intervertebral space. This is accomplished by palpating the two caudalmost dorsal spinous processes identifiable cranial to the sacrum and passing the needle between them on the midline, just anterior to the more caudal spinous process. The L4–L5 space can be used similarly.

A technique for placement of a styletted, stainless steel cannula in the third ventricle of the goat under anesthesia has been described (Mogi et al. 2003). This allows for repeated collection of CSF during research studies requiring multiple samples over time.

Some interpretation of the CSF is possible without laboratory support. Normal CSF is clear and colorless. Cloudiness suggests inflammation caused by increased cells or protein. Xanthochromia, or yellow discoloration, suggests earlier presence of blood in the CSF frequently associated with trauma. Increased CSF pressure may be recorded in cases of polioencephalomalacia, hydrocephalus, or other causes of cerebral edema. Reagent test strips designed for urinalysis may be applied to CSF in the field (Brewer 1983). Protein content more than 1+ is abnormal, blood should not be present, and the absence of glucose may suggest bacterial meningitis.

Table 5.2. Evaluation of cranial nerve function in goats.

Activity, condition, or test response observed in normal goats	Cranial nerves and other components of nervous system responsible for normal activity, condition, or response
Goat can see	II, cerebrum, connecting pathways, eye
Normal menace response (eyelids close in response to noncontact threatening gesture)	II, VII, cerebrum, cerebellum, brain stem
Bilaterally similar pupil size	II, III, sympathetic nervous system, brain stem
Normal pupillary light response	II, III
Eyes normally positioned in head	III, IV, VI, VIII
Eyeball retracts when cornea is touched	III, V, VI
Jaw tone and nostril sensation are normal	V
Eyelids close when canthus is touched	V, VII
Ear twitches when inside of ear is touched	V, VII, X
Lips retract when probe is introduced into commissure of lips	V, VII
Nostrils held symmetrically and move normally	VII
Ears held in normal position	VII
Eyelids held open normally	III, VII, sympathetic nervous system
Goat responds to sound	VIII
Head is held in normal position	VIII, cerebrum
Eyeballs drop slightly and evenly when head is tilted upward	VIII
Normal vestibular nystagmus is seen when head is turned to side, fast component is toward turned side	III, IV, VI, VIII, brain stem
No spontaneous nystagmus is observed	VIII
Swallowing and tongue movement are normal	IX, X, XII
Tongue tone is normal	XII

I = olfactory n., II = optic n., III = oculomotor n., IV = trochlear n., V = trigeminal n., VI = abducens n., VII = facial n., VIII = vestibulo-cochlear n., IX = glossopharyngeal n., X = vagus n., XI = spinal accessory n., XII = hypoglossal n.

Normal laboratory values reported for cellular and chemical constituents of caprine CSF are given in Table 5.3. Glucose levels in the CSF are normally 60% of those in blood. When xylazine is used to sedate goats for a CSF tap, glucose concentration in the CSF may double within thirty minutes of administration (Amer and Misk 1980).

Imaging Techniques

Plain radiography is useful to identify bony lesions that may affect the integrity of the brain and spinal cord. Myelography can aid in identification and localization of intramedullary and extramedullary lesions of the spinal cord and meninges. Preparation and positioning of goats for myelography are similar to that described above for the CSF tap, and procedures and applications for myelography of goats at both the atlanto-occipital and lumbar sites have been described (Chandna et al. 1978; Rowe 1979; Chandna et al. 1983). Cerebral angiography has been used in goats to assist in the diagnosis and surgical treatment of coenurosis (Sharma et al. 1974). Scintigraphy with radiolabelled ^{99m}Tc-ciprofloxacin was used as a diagnostic aid in a case of vertebral osteomyelitis and diskospondylitis in a three-week-old goat with acute hind limb paresis (Alexander et al. 2005). Image quality was best four hours after injection of the radiolabelled drug.

A topographic study of the cranioencephalic structures of the goat using computed tomography (CT) has been reported (Arencibia et al. 1997), though the use of CT in clinical practice has been limited in goats. CT has been used as a diagnostic aid in a case of paraplegia in an adult Boer goat (Levine et al. 2006). The scan revealed the presence of diskospondylitis and a compressive myelopathy. CT was also employed in the diagnosis of a glioma in the right frontoparietal cortex of the brain of an adult male goat that presented with a one-week history of circling (Marshall et al. 1995).

Magnetic resonance imaging (MRI) has been used to identify spinal cord compression due to a mass in the lumbar region of an adult goat with paraparesis (Gygi et al. 2004). At necropsy the mass was determined to be a lymphosarcoma. MRI has also been used to identify lesions in the thoracolumbar region of the spinal cord as an aid in diagnosing the neurological form of caprine arthritis encephalitis (CAE) in a five-

Table 5.3. Selected normal values for constituents of cerebrospinal fluid of goats.

Constituent	Unit	Mean	Range (or ± standard deviation)	Reference
Aspartate aminotransferase	IU/l	79.8	(±27)	Aminlari and Mehran 1988
Calcium	mg/dl	4.6*		Kaneko 1980

*Characteristics of goats not specified.

**Pregnant does only, n = 20.

***The Pandy test is a semiquantitative precipitation test that identifies the presence of globulin in the cerebrospinal fluid. Normally, there is no globulin present.

****Cells normally present may be lymphocytes, macrophages, or intact neutrophils. Red blood cells are not found in the normal caprine cerebrospinal fluid.

month-old goat with posterior paresis (Steiner et al. 2006). Most recently, the use of MRI was reported as an aid in the diagnosis of polioencephalomalacia in a two-month old Boer goat kid, identifying bilateral symmetric high-water-content lesions of the fronto-parietal cortex (Schenk et al. 2007).

Electroencephalogram (EEG)

The normal EEG of goats has been recorded in varying states of consciousness and in reference to rumination (Sugawara 1971; Bell and Itabisashi 1973). The EEG of goats also has been recorded under experimental disease conditions including urea poisoning (Itabisashi 1977) and Bermuda grass-induced tremors (Strain et al. 1982), as well as in a clinical case of partial epilepsy in an adult Nubian doe (Olcott et al. 1987) and in a group of goats with putative *Solanum viarum* toxicity (Porter et al. 2003).

Several physiological studies have also included recordings of the EEG in goats (Sugawara et al. 1989; Bergamasco et al. 2005, 2006). Determination of the bispectral index of the EEG was reported to be useful in monitoring the depth of isoflurane anesthesia in goats (Antognini et al. 2000). The use of visual-evoked brainstem potentials (VEP) and electro-retinograms (ERG) in the clinical assessment of polioencephalomalacia in a goat has been reported. The ERG was normal but the VEP was abnormal in the acute phase of disease when the goat was clinically blind. At one year post treatment, vision was restored and the VEP showed an almost normal recording (Strain et al. 1990).

DIAGNOSIS OF NEUROLOGIC DISEASE BY PRESENTING SIGNS

It is unusual for a goat to show a single, isolated sign of neurologic disease, and multiple signs may be exhibited serially or simultaneously during the course of disease. Therefore, in the following discussion of diagnosis of neurologic disease by presenting sign, the same disease may show up repeatedly under different headings as a possible cause of clinical signs. When using this list, you may start with the most predominant sign of the case at hand and then refer to the

detailed discussion of the disease elsewhere in the text. The potential causes of a given sign are not presented by frequency of occurrence because this can vary considerably with geography and type of management. Instead, they are presented by etiologic grouping.

Signs of Altered Mental State or Behavior

Excitability, Mania

Signs of excitation or mania include behaviors such as excessive bleating, resistance or overreaction to touch or handling, hyperesthesia, obvious fear or aggression, frenzy, aimless running, compulsive walking, head pressing, constant chewing, teeth grinding, or fluttering of the eyelids.

Infectious causes include rabies, pseudorabies, Borna disease, cowdriosis, scrapie, and bacterial meningoencephalitis. Thermal meningoencephalitis secondary to hot iron horn bud removal also occurs. Possible parasitic causes include coenurosis (gid), aberrant *Oestrus ovis* larval migration into the brain (false gid), trypanosomosis, and *Strongyloides papillosus*.

Metabolic causes include polioencephalomalacia, pregnancy toxemia, and hypomagnesemic tetany. Hepatoencephalopathy secondary to liver disease can produce hyperesthesia or head pressing.

Toxic agents that can cause excitation in goats include organophosphates, chlorinated hydrocarbons, cyanide, nitrates, urea, nitrofurans, and the coyotillo plant *(Karwinskia humboldtiana)*.

Levamisole or ivermectin given parenterally at therapeutic doses by injection may result in a transient excitatory reaction in some goats. Affected goats run around frantically after injection, throwing their heads in the air. Virtually all return to normal within several minutes and there is no residual effect. This is presumed to be caused by local irritation at the site of injection. In contrast, actual overdosing with levamisole can produce true neurotoxicity with excitatory signs.

Coma

Infectious causes include meningoencephalitis, pseudorabies, and enterotoxemia. Metabolic causes include polioencephalomalacia, pregnancy toxemia, and milk fever. Hepatoencephalopathy secondary to liver disease may result in coma, as can uremia.

Toxic causes include milkweed *(Asclepias)* poisoning; oxalate poisoning; salt poisoning; and organophosphate, carbamate, or chlorinated hydrocarbon insecticide toxicities.

Head trauma with subdural hemorrhage can result in coma. It is the nature of goats to frequently butt heads but this does not preclude the possibility of occasional serious injury.

Signs of Cranial Nerve Deficits

See Table 5.2.

Ocular Abnormalities

The differential diagnoses for abnormalities of pupillary function, blindness, ocular position, lid function, and sensation associated with the cranial nerves are discussed in Chapter 6.

Facial Nerve Paralysis

Characteristic signs include ear droop, eyelid droop, slack facial muscles with accumulation of feed in the buccal space, collapsed nostril, and drooling.

Infectious causes include CAE, listeriosis, brain abscess, otitis media, or otitis interna. Rupture of the tympanic membrane secondary to ear mite infection with *Psoroptes cuniculi* has resulted in facial nerve paralysis and signs of vestibular disease (Wilson and Brewer 1984). Trauma to the facial nerve, which is superficial along much of its course, can also occur.

Dysphagia

Potential neurologic causes of difficult swallowing include rabies, CAE, bacterial meningoencephalitis, and listeriosis. The numerous, non-neurologic causes of dysphagia are discussed in Chapter 10. Gloves should be worn when examining a goat that presents with difficulty in swallowing due to the risk of rabies.

Head Tilt

Persistent tilting of the head (one ear higher than the other) indicates vestibular dysfunction. Infectious causes of head tilt in goats include CAE, listeriosis, brain abscess, otitis media, and otitis interna.

Parasitic causes include cerebral nematodiasis caused by *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp. or *Setaria digitata*, coenurosis (gid), or rupture of the tympanic membrane secondary to ear mite infection (Wilson and Brewer 1984).

Lymphosarcoma infiltrating the pituitary gland and producing a head tilt has been reported in a goat. Lymphosarcoma is discussed in Chapter 3. A choroid plexus carcinoma in a goat also produced a head tilt.

Deafness

On clinical examination, evaluation of deafness is difficult and interpretation subjective. However, deafness has been identified in neonatal kids with congenital beta mannosidosis. Otitis can also lead to deafness.

Signs of Involuntary Activity

Muscle Tremors

Some goats naturally tremble or shiver due to fear during an examination. This must be differentiated from nervous dysfunction. Infectious causes of tremors

include rabies, scrapie, CAE, border disease, Borna disease, and bacterial meningoencephalitis. Tremors may also be an early sign of tetanus. Metabolic and nutritional causes include hypoglycemia, polioencephalomalacia, hypomagnesemic tetany, hepatoencephalopathy, and enzootic ataxia or swayback.

Toxicologic causes include plant poisoning with bitterweed or rubberweed (*Hymenoxys* spp.), neem tree (*Azadirachta indica)*, coyotillo *(Karwinskia humboldtiana)*, tropical soda apple (*Solanum viarum*), *Ipomoea carnea*, and possibly Bermuda grass hay *(Cynodon dactylon)*, as well as cyanide poisoning, nitrate poisoning, oxalate poisoning, salt poisoning, boron ingestion, organophosphate, carbamate or chlorinated hydrocarbon insecticide poisonings, urea poisoning, levamisole overdose, and diesel fuel consumption. A hereditary cause of muscle tremors is beta mannosidosis.

Convulsions (Seizures)

Infectious causes include pseudorabies, Borna disease, enterotoxemia, tetanus, bacterial meningoencephalitis, and cowdriosis (heartwater).

Parasitic causes can include coenurosis (gid) and aberrant *Oestrus ovis* migration into the brain (false gid). Metabolic causes include polioencephalomalacia, hypomagnesemic tetany, pregnancy toxemia, hypoglycemia, and hepatoencephalopathy.

Toxic causes include the poisonous plants bitterweed or rubberweed (*Hymenoxys* spp.) and milkweed (*Asclepias* spp). Non-phytogenic poisonings include organophosphate, carbamate, and chlorinated hydrocarbon insecticides, levamisole overdose, dinitro herbicides, and pentachlorophenol wood preservatives. Lead and salt poisonings are potential causes of convulsions but are poorly documented in goats.

Lidocaine in sheep produces convulsive signs at an approximate dose of 6 mg/kg intravenously and circulatory collapse at a dose of 37 mg/kg intravenously (Morishima et al. 1981). Overdosing is most likely to occur in small kids when lidocaine is used as a local anesthetic.

Partial epilepsy of unknown cause has been reported as a cause of convulsions in an adult Nubian doe (Olcott et al. 1987).

Nystagmus

Infectious causes include rabies, CAE, listeriosis, brain abscess, and otitis. Parasitic causes include cerebrospinal nematodiasis with either *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp., or *Setaria digitata* and coenurosis (gid). Metabolic causes include polioencephalomalacia.

Toxic causes include locoism caused by consumption of locoweeds (*Astragalus* spp.) and possibly salt poisoning. Hereditary beta mannosidosis causes nystagmus in affected newborn kids.

Pruritus

Primary dermatologic diseases are the most common cause of itching in goats, as discussed in Chapter 2. Pruritus of neurogenic origin tends to be more severe and animals frequently itch to the point of self-mutilation. All the neurogenic causes of pruritus in goats are of infectious or parasitic origin and include rabies, pseudorabies, scrapie, *Parelaphostrongylus tenuis*, and *Elaphostrongylus* spp.

Gait Abnormalities

Circling

Circling in goats may be cerebral or vestibular in origin. Animals with circling caused by cerebral disease usually have other abnormalities of behavior or mental status to suggest cerebral involvement. Signs associated with circling caused by vestibular lesions are usually more localized and may be limited to head tilt, nystagmus, hemiparesis, and other specific cranial nerve deficits such as facial nerve paralysis.

Infectious causes of circling include rabies, CAE, Borna disease, listeriosis, brain abscess, otitis media or interna, and cowdriosis (heartwater).

Parasitic causes can include cerebrospinal nematodiasis with either *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp. or *Setaria digitata*, trypanosomosis, coenurosis (gid), and aberrant *Oestrus ovis* migration into the brain (false gid).

Metabolic and nutritional causes are limited to polioencephalomalacia.

There is a report of neoplasia as a cause of circling. This was in an adult goat with a glioma in the cerebrum (Marshall et al. 1995).

Toxic causes include plant poisonings with *Burttia prunoides*, or selenium accumulating *Astragalus* spp., as well as chlorinated hydrocarbon insecticide toxicity and nitrofuran overdose.

Hypermetria

A high stepping gait with overflexion of joints has been reported in coenurosis (gid), coyotillo *(Karwinskia humboldtiana)* poisoning, and enzootic ataxia. The author has observed pronounced hypermetria in an adult Saanen buck that, on necropsy, had a focal meningioma impinging on the anterior cervical spinal cord.

Ataxia (incoordination)

Ataxia or incoordination in goats most frequently suggests spinal cord lesions, but cerebellar, vestibular, and occasionally cerebral lesions can produce ataxia. Signs include a staggering gait, swaying or weaving from side to side, difficulties with abduction or adduction of the limbs, crossing of legs when standing

or walking, general unawareness of placement and position of feet, and pivoting on the inside limb when circled. When paresis accompanies ataxia, it can be difficult to differentiate the effects of the two processes.

Infectious causes include rabies, scrapie, CAE, listeriosis, bacterial (or thermal) meningoencephalitis, brain abscess, and cowdriosis (heartwater).

Parasitic causes include cerebrospinal nematodiasis with either *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp., or *Setaria digitata*; coenurosis (gid); aberrant *Oestrus ovis* migration into the brain (false gid); tick paralysis; trypanosomosis; and possibly *Strongyloides papillosus*.

Metabolic and nutritional causes include milk fever, polioencephalomalacia, hypomagnesemic tetany, and enzootic ataxia.

Toxic causes include plant poisonings resulting from ingestion of coyotillo *(Karwinskia humboldtiana)*, locoweeds (*Astragalus* spp.), guajillo *(Acacia berlanderi)*, cycad palms (*Cycas*, *Zamia*, *Microzamia*, and *Bowenia* spp.), milkweed (*Asclepias* spp.), larkspur (*Delphinium* spp.), fool's parsley *(Aethusa cynapium)*, tropical soda apple (*Solanum viarum*), *Ipomoea carnea*, maize contaminated with the fungus *Diplodia maydis*, and possibly rye grass and Bermuda grass hay *(Cynodon dactylon)*. The incoordination occurring with *Astragalus* spp. consumption may be due either to locoism or selenium toxicosis.

In addition to plant toxicities, incoordination can be seen with bromide, lead, salt, oxalate, urea, cyanide, or nitrate poisonings; organophosphate, carbamate, or chlorinated hydrocarbon insecticide intoxications; diesel fuel consumption; and nitrofuran or levamisole overdosage.

Neoplastic causes of ataxia have been reported sporadically. Lymphosarcoma associated with the brain or meninges has resulted in incoordination (Craig et al. 1986). A choroid plexus carcinoma in a goat also produced ataxia.

Congenital or hereditary causes include congenital vertebral or spinal abnormalities such as hemivertebra (Rowe 1979). There is a report of atlanto-axial malarticulation in two young Angora goats which led to spinal cord degeneration at the level of the atlanto-axial joint resulting in ataxia (Robinson et al. 1982).

Diseases of unknown etiology that can produce incoordination include polyradiculoneuritis and caprine encephalomyelomalacia.

Postural Abnormalities

Opisthotonos

Opisthotonos is a backward arching of the head and neck caused by spasm of extensor muscles. It may be observed in standing or recumbent animals. The list below includes those diseases in goats for which observation of opisthotonos has been specifically reported. However, opisthotonos may be observed during convulsions and the list of causes of convulsions should be consulted when the two signs are seen together.

Infectious causes include rabies, CAE, enterotoxemia, tetanus, brain abscess, and bacterial (or thermal) meningoencephalitis.

Disseminated toxoplasmosis is rare in goats and only one report has identified clinical signs of encephalitis, including opisthotonos, torticollis, and paresis (Fatzer 1974). Nevertheless, evidence of brain involvement may be common on necropsy of stillborn kids or fetuses (Nurse and Lenghaus 1986). Trypanosomosis is another potential protozoal cause of opisthotonos.

Metabolic and nutritional causes include hypomagnesemic tetany and polioencephalomalacia. Toxic causes include plant poisonings by bitterweed or rubberweed (*Hymenoxys* spp.), locoweeds (*Astragalus* spp.), salt poisoning, and chlorinated hydrocarbon toxicity.

Paresis (Weakness)

Neurogenic impairment of motor function leading to weakness may result from lesions of the brain stem, spinal cord, peripheral nerves, or neuromuscular junctions. Tetraparesis, paraparesis, hemiparesis, or involvement of a single limb may occur. Signs can include difficulty in rising, dragging of one or more limbs, trembling when standing, difficulty in standing for long periods, and collapse or buckling of the limbs. When hemiparesis is present, leaning, falling or rolling to one side may be noted. Careful observation and thorough neurologic examination are necessary to distinguish ataxia from paresis when both are present.

Infectious causes of paresis include rabies, CAE or visna, listeriosis, and botulism. Parasitic causes include cerebrospinal nematodiasis with either *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp., or *Setaria digitata*; coenurosis; and tick paralysis.

Metabolic and nutritional causes include milk fever, pregnancy toxemia, and enzootic ataxia or swayback. Toxic causes include plant poisonings by coyotillo *(Karwinskia humboldtiana)*, locoweeds (*Astragalus* spp.), carpetweed *(Kallstroemia hirsutissima)*, milkweed (*Asclepias* spp.), tropical soda apple (*Solanum viarum*), *Ipomoea carnea*, and maize contaminated with the fungus *Diplodia maydis.* Toxic causes other than plant poisoning include salt poisoning, bromide intoxication, boron toxicity, organophosphate and carbamate insecticide poisoning, and pentachlorophenol toxicity.

Neoplastic causes of paresis are uncommon but reports include lymphosarcoma sporadically associated with the brain or meninges (Craig et al. 1986) and malignant melanoma metastasized to the vertebral canal (Sockett et al. 1984).

Congenital or inherited causes include hydrocephalus and progressive paresis of Angora goats. Caprine encephalomyelomalacia, a disease of unknown etiology, can also produce paraparesis or tetraparesis.

Paralysis

Paralysis is the complete loss of motor function in any part of the body. Many of the conditions that cause paresis progress to paralysis. Regarding the limbs, tetraplegia, paraplegia, or hemiplegia may be observed. Paralysis of the limbs may be flaccid or spastic depending on the location of the lesions. The former is associated with hyporeflexia and the latter with hyperreflexia.

Infectious causes include rabies, pseudorabies, CAE or visna, Borna disease, botulism, and brain abscess. Parasitic causes include cerebrospinal nematodiasis with either *Parelaphostrongylus tenuis*, *Elaphostrongylus* spp. or *Setaria digitata*, and tick paralysis.

Metabolic causes include milk fever and enzootic ataxia or swayback. Toxic causes include mycotoxicosis caused by consumption of maize contaminated with the fungus *Diplodia maydis* and organophosphate or carbamate insecticide toxicity.

Congenital or hereditary causes include hydrocephalus and congenital malformations of the vertebral canal or spinal cord, such as hemivertebra, and progressive paresis of Angora goats.

Trauma is the usual cause of peripheral nerve injuries leading to paralysis. While injury may occur to any of the peripheral nerves, the most common peripheral nerve dysfunction in goats is damage to the sciatic nerve from mechanical injury caused by poor intramuscular injection technique or the introduction of irritating medications on or near the nerve. The problem may be aggravated by the secondary development of abscesses. Typical signs of sciatic nerve injury include flaccid carriage of the entire hind limb with the dorsum of the hoof dragging on the ground during walking and a loss of skin sensation over most if not all of the limb. A case of hind limb paralysis caused by a metastatic malignant melanoma of the sciatic nerve has also been reported (Sockett et al. 1984).

Radial nerve paralysis related to trauma occurs in goats. Signs include flaccid carriage of the forelimb with a dropped elbow and an inability to extend the carpus and fetlock joints. The limb is dragged on ambulation. Skin sensation loss occurs on the anterior aspect of the pastern, fetlock, and digit. Restoration of limb use in a goat with radial paralysis by transplantation of the *flexor carpi radialis* tendon has been described (Batcher and Potkay 1976).

Trauma to the vertebral column can lead to paralysis by damage to the spinal cord. Vehicular injuries and fighting between goats are the most common causes of vertebral trauma, but fractures of the vertebrae may be predisposed by the presence of abscesses or osteoporosis associated with rickets.

Caprine encephalomyelomalacia, a disease of unknown etiology, can also produce paraplegia or tetraplegia.

SPECIFIC DISEASES OF THE NERVOUS SYSTEM

VIRAL AND PRION DISEASES

Rabies

Though the occurrence of rabies in goats is infrequent, rabies should not be left out of the differential diagnosis of caprine neurologic disease for two reasons: one, rabies is a consistently fatal zoonotic disease, and two, the signs of rabies are highly variable and may mimic other neurological conditions.

Etiology

Rabies virus is a bullet-shaped, enveloped, single-stranded, negative-sense, non-segmented, RNA virus in the genus Lyssavirus of the family Rhabdoviridae. The viral genome encodes for five proteins: nucleoprotein, phosphoprotein, matrix protein, glycoprotein, and an RNA polymerase. The Lyssaviruses are neurotropic viruses, well adapted to replication in the mammalian nervous system. There are seven genotypes in the genus Lyssavirus based on sequencing of the nucleoprotein (N) gene. In addition to the rabies virus (genotype 1), they include: Lagos bat virus (genotype 2), Mokola virus (genotype 3), Duvenhage virus (genotype 4), European bat virus 1 (genotype 5), European bat virus 2 (genotype 6), and Australian bat virus (genotype 7), all of which have demonstrated capacity to be animal and human pathogens causing encephalitis.

With the exception of rabies virus, which occurs essentially worldwide, these Lyssaviruses have distinct but sometimes overlapping geographic distributions. Australian bat virus is found solely in Australia. The European bat viruses are distributed among insectivorous bats in Eurasia. Lagos bat virus, Duvenhage virus, and Mokola virus have not been encountered outside of Africa (Markotter et al. 2006). Neutralizing antibody to Mokola virus has been identified in goats in Nigeria (Kemp et al. 1972; Nottidge et al. 2007).

Within the rabies virus genotype, virus variants associated with particular host species and geographic areas are recognized. They can be identified by reactions with panels of monoclonal antibodies or by genetic analysis of nucleotide substitutions (Rupprecht et al. 2002). In the continental United States, for example, there are three distinct rabies virus variants infecting skunks, found in California, the upper Midwest and the lower Midwest, while a raccoon adapted variant predominates on the eastern coast.

Two gray fox adapted variants are found focally in Arizona and Texas and separate variants adapted to red foxes and arctic foxes are found in Alaska. In addition, however, there are numerous independent reservoirs of rabies variants in insectivorous bats whose overlapping ranges essentially make the entire United States enzootic for rabies (Blanton et al. 2006).

The rabies virus grows in tissue culture, embryonating chicken eggs, and suckling mice. It has a short survival time outside the mammalian host and it becomes non-viable in dried saliva within a few hours. It is a relatively fragile virus, readily inactivated by ultraviolet irradiation and common disinfectants. For this reason, thorough cleansing and disinfection of bite wounds immediately following their occurrence is a very important and useful aspect of rabies prophylaxis.

Epidemiology

Several countries, islands, and regions are rabies-free, including Antarctica, Australia, New Zealand, Scandinavia, Great Britain, Cyprus, Japan, Papua New Guinea, and Hawaii. However, in much of the world, rabies is still endemic. In Europe and North America, most reported rabies is sylvatic, occurring primarily in wildlife reservoirs such as foxes, skunks, raccoons, and insectivorous bats. In much of Asia, Africa, and the Middle East, rabies is still largely urban, with dogs and cats comprising the majority of cases. In Latin America, rabies is an important problem, especially in dogs and cattle, with bites by vampire bats the primary source of livestock infection. Though Australia is still considered to be free of rabies, the related Lyssavirus, Australian bat virus, was identified in the mid-1990s and has produced fatal encephalitis in humans. To date, there is no evidence of infection or spillover of Australian bat virus into terrestrial mammal populations.

Rabies remains a serious zoonotic disease worldwide, particularly in developing countries of Asia, the Middle East, and Africa, where comprehensive programs to control rabies in dogs may be lacking and access to or awareness of post exposure prophylaxis is limited. Worldwide, there are an estimated 55,000 human deaths due to rabies each year (WHO 2007). India alone accounted for up to 60% of the world's rabies cases annually during the 1990s, although improved public education and greater availability of post exposure prophylaxis has improved the situation somewhat in recent years (Sudarshan et al. 2007). In the developing countries, domesticated dogs continue to be the major reservoir of rabies and dog bites the major cause of human cases. Dog bites are most likely the major cause of goat cases as well.

Goats are moderately susceptible to rabies, in the same category with sheep, cattle, and dogs (Crick 1981). While epizootics in goats are uncommon, goat rabies does occur sporadically in all enzootic regions.

In the United States in 2005, for example, there were 6,418 cases of rabies reported in animals. Wild animals accounted for 5,923 (92.3%) of these cases and domestic animals, 494 (7.7%). Only six of these domestic animal cases occurred in goats (Blanton et al. 2006). In forty-one countries of Europe, including the Russian Federation, Ukraine and Turkey, there were 9,831 rabies cases documented in 2005. Wildlife accounted for 5,806 (59.1%) and domestic animals 3,980 (40.5%) of these cases (WHO 2007a). Goats and sheep, reported together, accounted for only 123 of the domestic animal cases.

In the United States, the principal reservoirs of sylvatic rabies are raccoons (*Procyon lotor*) on the east coast, skunks (mainly *Mephitis mephitis*) in the Midwest and California, and foxes (mainly *Vulpes vulpes*) along the Texas-Mexico border. However, insectivorous bat reservoirs have major public health significance. From 1900 through 2005, forty-eight human rabies cases were confirmed in the United States, with ten infections originating outside the country. Of the remaining thirty-eight cases, thirty-five (92.1%) were infected with bat rabies variants (Blanton et al. 2006).

In Europe, the principal reservoir is the red fox (*Vulpes vulpes*). The raccoon dog (*Nyctereutes procyonoides*) has been growing in significance in recent years, especially in the Baltic states of northeastern Europe as the raccoon dog population migrates westward from Asia (Holmala and Kauhala 2006). Oral rabies vaccination campaigns targeting red foxes have been extremely effective, with many countries of western and central Europe declaring rabies free status in recent years. The continued expansion of the raccoon dog population in Europe therefore is a major concern.

In tropical portions of Mexico and in northeastern Brazil, cases of goat rabies have been associated with vampire bat bites (Batalla et al. 1982; Silva and Silva 1987; Shoji et al. 2006). In Nigeria, where rabies continues to be a serious problem in humans and dogs, and goat populations are high, only eight goat cases were documented nationwide over thirty-three years. All were presumed associated with dog bites except one attributed to a genet bite (Okoh 1981). In Bombay, India, 3% of 265 animal rabies cases diagnosed in 1981 and 1982 were goats maintained in urban settings and bitten by dogs (Jayarao et al. 1985).

Pathogenesis

All mammals are susceptible to rabies infection. Though rabies can be transmitted rarely by aerosol infection of mucous membranes, rabies virus is most likely introduced into the goat by the bite of a rabid animal whose saliva is infected with the virus. Replication of the virus occurs initially in muscle at the site of introduction and the infection may remain localized at the initial site for many days. The virus then enters

local nerves and moves centripetally up nerve trunks to the CNS. Variations in incubation times and clinical presentation are largely a function of the distance the virus must migrate to the central nervous system and whether it first reaches the brain or spinal cord. When an animal is bitten on the face, the incubation time tends to be shorter and the clinical presentation is one of encephalitis. When an animal is bitten on the hind limb, there is a longer incubation period and the early clinical signs suggest an ascending myelitis. Wherever it first reaches the CNS, the virus continues to replicate and extend throughout the brain and spinal cord. At the same time, it begins to move centrifugally back down nerve trunks to nerve endings. In this manner, virus becomes present in saliva via nerve endings in the salivary gland. Hematogenous spread of rabies is extremely rare.

When canine-derived virus was injected into the masseter muscles of experimental goats, incubation periods for clinical rabies ranged from fourteen to twenty-four days (Umoh and Blenden 1982). Immunofluorescence studies indicated that virus was abundant in brain tissues, but little or no virus was evident in distal sections of cranial nerves. Whether this low concentration of virus in peripheral nerves was a function of the experimental design or an indication that goats may not shed virus extensively during clinical rabies is unclear. No documented cases of human rabies resulting from exposure to goats could be found in the literature during preparation of this text.

Clinical Findings

Clinical reports of rabies in goats are rare. A ten-year retrospective of rabies in South Africa identified eighteen cases of caprine rabies. The furious form appears more commonly than the dumb form in goats. Aggressive behavior was the most common sign, occurring in 83% of the cases. Excessive bleating was observed in 72% of cases, salivation in 29%, and paralysis in only 17%. In no cases were hydrophobia, straining, pica, or circling observed (Barnard 1979). The clinical course is usually between one and five days and always results in death.

In experimental caprine rabies, early signs observed in nineteen goats were variable and included hyperexcitability, apparent blindness, anxiety, aggressiveness with piloerection, pruritus with self-mutilation, salivation, frothing, depression, standing off in corners, shaking of the head, and fine tremors, especially in the thighs. Later signs included frothy salivation, which was common, incoordination, staggering, circling, torticollis, extensive muscle tremors, protrusion of the tongue, and inability to eat. Terminally, goats showed posterior paralysis, lateral recumbency, paddling, nystagmus, and pupillary dilatation. Many goats had food hanging from the mouth (Umoh 1977).

In a separate report of experimental caprine rabies involving two male goats three to four months of age infected with a fox-derived isolate in the masseter muscle, both goats initially showed an exacerbation of sexual behavior, priapism, and aggressiveness followed progressively by incoordination, recumbency, opisthotonos, and myoclonia. The two goats died three and five days after onset of signs (Gomes et al. 2005).

Clinical Pathology and Necropsy

Laboratory confirmation of rabies antemortem is difficult. Immunofluorescent staining of corneal scrapings or hair follicles in skin biopsies taken during clinical disease is confirmatory if positive, but false-negative results occur (Umoh and Blenden 1982).

Gross lesions are minimal at necropsy. There may be evidence of trauma caused by maniacal behavior. The meninges and brain may be congested and edematous. Histologically, neuronal degeneration with swelling and necrosis may be present throughout the brain with a striking absence of inflammatory response. The most significant finding is Negri bodies in the cytoplasm of neurons, particularly in the hippocampus and in Purkinje cells. This finding has been considered diagnostic for rabies in the past, but false-positive interpretations may occur.

Currently, immunofluorescence staining of brain sections is routinely carried out for rapid, accurate diagnosis of rabies, and the direct fluorescent antibody (DFA) test remains the gold standard in rabies diagnosis. Impression smears of hippocampus, medulla, cerebellum, or gasserian ganglion are the preferred samples. Smears from brain stem, thalamus, and pons may also be diagnostic. If brain samples are submitted they should be fresh or glycerol preserved, because formalin fixation impairs performance of the DFA test. Peroxidase conjugate may be used on sections of formalin-fixed tissue for immunohistochemical tests in lieu of the DFA test.

Not all countries have the laboratory capacity to run the DFA test because it requires expensive, specialized fluorescent microscopes, so alternative test methods may be used. For example, the use of an avidin-biotin dot ELISA has been reported for detection of rabies antigen from the brains of suspect animals, including goats, with results comparable to the DFA test (Jayakumar et al. 1995) Immunohistochemistry including immunoperoxidase staining is also used.

The most definitive, but cumbersome, diagnostic test is intracerebral inoculation of mice with brain, spinal cord, or salivary tissue of suspect cases. When positive, weanling mice develop rabies and virus can be identified by immunofluorescence in their brains. Cell culture in neuroblastoma cell lines with confirmation by fluorescent antibody testing is now available as an alternative to mouse inoculation (OIE 2007).

Diagnosis

Regardless of the species of animal affected, rabies is one of the most difficult diseases to diagnose clinically because of the diversity of potential presentations. Veterinarians working in rabies endemic countries should always consider rabies in the differential diagnosis when goats show any behavioral change or neurologic abnormality. Potentially, rabies can mimic all of the various neurologic diseases of goats. As has been so aptly stated, rabies is an unpredictable disease—the only characteristic feature is that it is uncharacteristic in its presentation (Rupprecht et al. 2002). Every reasonable attempt should be made to arrive at a definitive diagnosis other than rabies while the goat is alive. If the animal dies undiagnosed, it is incumbent upon the veterinarian to pursue a postmortem diagnosis of rabies.

Treatment and Control

There is no treatment for rabies. The zoonotic potential of rabies must always be considered when dealing with suspect cases. Such cases should be isolated and human contact kept to a minimum. Gloves and masks should be worn during examination or when performing necropsies and hands washed thoroughly afterward with disinfectant soaps. When the suspicion of rabies is high, euthanasia should be recommended to expedite a definitive diagnosis at necropsy. A careful history of human contact should be documented and all people potentially at risk should be apprised of the situation and referred to physicians for post-exposure counseling in the event that the suspect animal is confirmed as positive.

With regard to post-exposure prophylaxis for goats exposed to rabies, the information available suggests that it is unreliable and should not be attempted. Repeated vaccination alone or with administration of antisera prolonged the incubation period for as long as 174 days in experimentally infected goats, but in no case did it prevent development of clinical disease (Umoh and Blenden 1981).

Based on incubation times reported in experimental caprine rabies, goats with suspect exposure should be strictly isolated and observed for at least one month in anticipation of the possible development of clinical rabies. Given the limited amount of information available on rabies in goats, it is possible that the incubation period for goats might exceed one month. Therefore, any goat showing clinical signs consistent with rabies during (or after) the observation period should be euthanized and submitted for necropsy diagnosis.

Vaccination of goats in endemic areas may be possible according to local regulations. However, there is currently no vaccine specifically approved for use in goats in the United States, though several killed rabies vaccines derived from cell cultures are approved in the country for use in cattle and sheep. The lack of an approved vaccine for goats is a source of great frustration for American goat owners and the veterinarians who serve them (de la Concha-Bermejillo et al. 1998). In sheep and cattle, the vaccine is given initially at three months of age or older and then repeated annually or, in sheep, triennially depending on the product used.

According to data from the Food and Agriculture Organization, rabies vaccination in goats is permitted in approximately twenty countries worldwide including Brazil, India, Nepal, and the former Soviet Union (FAO 1989). The use of modified live rabies vaccines not approved for use in goats is strongly discouraged or prohibited.

Complete control of rabies depends on national and international efforts. Beyond vaccination there is little that individual herd or flock owners can do to control rabies except to know the likely reservoirs in their areas and minimize goat contact with them through housing, fencing, or animal control measures.

Pseudorabies

This acute fatal viral disease, also known as Aujesky's disease, infectious bulbar paralysis, or mad itch, is primarily a disease of swine and is reported only sporadically in goats. Clinical signs include peracute death or hyperexcitability, intense pruritus, convulsions, and terminal coma. Reported cases of caprine pseudorabies have invariably included direct or indirect contact with pigs.

Etiology

The causative agent is a double stranded DNA, enveloped, alphaherpesvirus. It is known by several names including pseudorabies virus (PRV), porcine herpesvirus type 1 (PHV-1), and most recently, suid herpesvirus type 1 (SuHV-1). The virus is quite stable. It can survive in saliva, carcasses, and clean, damp bedding for several months in winter, and several weeks in summer. Free, unprotected virus can persist for one to two weeks. However, the virus can be inactivated by a number of disinfectants including sodium hypochlorite, formalin, peracetic acid, phenolics, and quaternary ammonium compounds.

Epidemiology

The virus is extremely well adapted to domestic swine, which serve as the agent reservoir. Adult pigs usually show only mild disease when infected, though abortions or early embryonic death can occur in pregnant sows. Affected piglets may show signs of neurologic disease and high mortality. Typical of the herpesviruses, latent infections and a carrier state occur in infected, recovered swine that can shed the virus in saliva and nasal discharges. All other suscep-

tible species, including goats, cattle, sheep, dogs, and cats are essentially dead-end hosts. They develop acute neurologic disease and die quickly.

In reported cases of caprine pseudorabies, the goats have been housed with or in fence contact with pigs (Herweijer and De Jonge 1977; Baker et al. 1982). The pigs may be latent carriers that shed virus but show no evidence of infection. Other potential sources of exposure include transport vehicles in which infected swine have recently been hauled as well as modified live virus vaccines. Pseudorabies has occurred in sheep that were given parenteral medication using an uncleaned syringe previously used to vaccinate pigs for pseudorabies.

Transmission of virus is by inhalation or via skin abrasions. Morbidity can be high, with 80% of exposed goats contracting the disease in an outbreak in the Netherlands (Herweijer and De Jonge 1977). The mortality rate is 100%.

Pathogenesis

The incubation period is one to four days. When the virus is introduced through the skin, it enters peripheral nerves and produces the characteristic localized pruritus that is observed in some cases of ruminant pseudorabies ("mad itch"). The virus then moves centripetally and enters the CNS, producing a rapidly fatal encephalitis or myeloencephalitis. With inhalation of the virus, signs of encephalitis occur without a prodrome of pruritus.

Clinical Findings

All ages, breeds, and sexes can be affected. Goats may be found dead with no warning. Alternatively, they may show signs of intense rubbing or licking and even self-mutilation associated with severe, localized neurogenic pruritus (Figure 5.1). In cases where pruritus does not occur, initial signs may include agitation or excitation, repeated lying down and rising, hysterical bleating, profuse sweating, and convulsions. Fevers as high as 106.7°F (41.5°C) may be recorded. These excitatory signs give way to recumbency, paralysis with bloat and dyspnea, coma, and finally death. The clinical course may be only several hours up to twenty-four hours.

Clinical Pathology and Necropsy

While serology is useful in the identification of infected swine, it has no application in caprine pseudorabies because goats become clinically ill and die before an antibody response can develop. At time of necropsy, attempts should be made to isolate the virus from brain tissue. There are no obvious gross necropsy findings, but there are histologic lesions of severe, focal, nonsuppurative encephalitis and myelitis. Eosinophilic intranuclear inclusion bodies typical of herpes-

Figure 5.1. Periorbital alopecia and inflammation due to excessive rubbing of the face from pruritus due to pseudorabies infection in a goat having fence line contact with pigs. (From Baker et al. 1982. Reproduced by permission of the Journal of the America Veterinary Medical Association.)

viruses may be found in degenerating neurons. Immunofluorescence and immunoperoxidase methods can be used to confirm the identity of the SuHV-1 in infected brain tissue.

Diagnosis

When pruritus is present, primary dermatologic conditions, particularly ectoparasites, must be ruled out. Scrapie, rabies, and cerebrospinal nemotodiasis can also produce neurogenic pruritus in goats. When encephalitic signs predominate, consider also rabies, heartwater, polioencephalomalacia, and hypomagnesemia. The acute nature of the disease also suggests poisonings, notably cyanide, nitrates, urea, organophosphates, and chlorinated hydrocarbons.

Treatment and Control

There is no treatment for pseudorabies. Control depends on recognizing the risks of commingling

goats with pigs whose pseudorabies status is unknown. If pigs must be housed with goats, the pigs should be serologically negative for pseudorabies before purchase. National regulatory programs to eradicate pseudorabies in commercial swine greatly reduce the risk of goats contracting the disease. In the United States, a pseudorabies eradication program was initiated in 1989, and by 2004 all fifty states were declared free of pseudorabies in commercial swine.

Pseudorabies is not considered a public health risk. However, there have been some putative reported cases of pseudorabies from Europe in people exposed to cats. Antibodies to pseudorabies virus were documented in these individuals (Mravak et al. 1987). Therefore, veterinarians and others working directly with the virus or with pseudorabies infected animals or carcasses should observe appropriate safety precautions.

Scrapie

Scrapie is an infectious, contagious, degenerative neurologic disease that occurs naturally only in sheep and goats. It belongs to the group of diseases known as transmissible spongiform encephalopathies (TSEs) which are believed to be caused by abnormal proteins known as prions. Prions are unique as infectious agents in that they contain no genetic material. Other TSEs include bovine spongiform encephalopathy (BSE) of cattle; chronic wasting disease of deer and elk (CWD); transmissible mink encephalopathy of farmed mink (TME); and several diseases of humans including Kuru, Creutzfeldt-Jakob disease (CJD), and variant Creutzfeldt-Jakob disease (vCJD).

Scrapie is characterized by an extended incubation period of months to years. When clinical signs ultimately develop, they may include weight loss, incoordination, changes in mental status, progressive debilitation, and pruritus. Historically, clinical reports of scrapie in goats have been far less common than in sheep, but the disease has become a major concern for the goat industry because goats are now regularly included in regulatory surveillance and control programs for TSEs, including scrapie. Veterinarians, and the goat owners they serve, must be aware of the details of these control programs because they can affect management and commercial aspects of goat production.

Interest in and knowledge of scrapie have increased dramatically in the last twenty years as a result of the emergence of bovine spongiform encephalopathy (BSE), a TSE that is transmissible to humans. BSE has numerous clinicoepidemiological similarities to scrapie and this has sparked concerns that BSE could also occur in small ruminants and therefore needs to be differentiated from scrapie. As a result, better tools are now available for the diagnosis of scrapie, there is a clearer understanding of the pathogenesis, and because of active surveillance programs, there is also more epidemiological knowledge about scrapie in goats. Despite similarities to BSE, scrapie of sheep and goats is not considered to be transmissible to humans.

Etiology

The generally accepted cause of scrapie and other TSEs in animals is the expression of the abnormal form of a naturally occurring, cellular protein called PrP^c. This protein is found in cells throughout the body but is of clinical and diagnostic interest primarily in the nervous system and the lymphoreticular system. It is a membrane glycoprotein bound to the outer surface of neurons, lymphocytes, and other cells. The normal function of PrP^c is not completely known, but it may be involved in copper transport and homeostasis (Waggoner et al. 1999) and neuro-protection, signal transduction, or circadian rhythm regulation (Huber et al. 1999). The structure and pathobiology of prions and the diseases they cause in animals and humans have been reviewed (Prusiner 1998; Aguzzi and Heikenwalder 2006; Aguzzi 2006)

Through mechanisms not fully understood, the development of scrapie is associated with abnormal replication of normal host prion protein, PrP^c (also referred to in the literature as PrP^{sen}) to produce a prion protein of modified structure, PrP^{Sc} (also referred to in the literature as PrP^{res} or PrP^d), the accumulation of which occurs simultaneously with degeneration of nervous tissue and other manifestations of disease. This process is complex, with several factors involved: exposure of the animal to abnormal, exogenous forms of the PrP protein PrP^{Sc} which induce abnormal replication of PrP^c in the host; variations in the strain of PrP^{Sc} encountered; and variations in the genetic composition of the animals exposed to PrP^{Sc}. Together these factors can influence host susceptibility to the production of abnormal endogenous PrP^{Sc} following exposure, the incubation period for manifestation of disease, and the severity of disease. The details of these interactions are currently topics of active research.

PrP^c protein is comprised of 210 amino acids. Structurally, it contains a highly flexible N-terminal domain and a structured C-terminal domain consisting of three helices with α-helical folding and a short β-sheet. The molecule contains two N-glycosylation sites and the naturally occurring protein may be comprised of mono-, di-, or non-glycosylated forms. The fully glycosylated form has a molecular weight of 33 to 35 kDa. The ratio of the three forms in tissue extracts of PrP^{Sc} is referred to as the glycotype. Differences in patterns of glycosylation are one tool used to differentiate various strains of the scrapie prion.

In scrapie, as in most other TSEs, the key factor in the pathogenesis of the disease is the conversion of normal PrP^c protein into an isoform, PrP^{Sc}, which is characterized by insolubility and partial resistance to

degradation by proteases. The isoform demonstrates important secondary structural change as compared to the normal PrP^c protein. This is manifested as aberrant folding of the protein molecule that results from one of the three normal α-helices being replaced by β-sheet or β-helix structure. The conversion from PrP^c to PrP^{Sc} has been described as a stabilization of a proto-β-helical motif by a neighboring PrP^{Sc} molecule and subsequent extension to form the complete β-helix (Wille et al. 2002).

The agent produces no detectable immune response in the host and the absence of scrapie-induced antibody is a major obstacle to detecting the disease in live animals. However, monoclonal antibodies against various components of the PrP^{Sc} molecule are now being routinely produced and these have proven to be most valuable in the laboratory, particularly with regard to identifying various prion strains and the development of rapid immunoassays for detecting the prion protein in tissue.

In recent years, it has become apparent that so-called atypical strains of scrapie exist which have different molecular characteristics and produce different histopathologic lesion patterns than the scrapie prion which produces classical scrapie. The first of these atypical strains was reported from Norway in association with five clinical cases of atypical sheep scrapie with unusual clinical and pathologic features, the first of which was seen in 1998. The strain has been designated as Nor98. Among its unusual features are the fact that it produced disease in sheep with genotypes ordinarily associated with resistance to scrapie; an atypical distribution of lesions in the brain, with a notable absence of lesions at the level of the obex; the absence of detectable PrP^{Sc} in lymphoid tissues using immunohistochemistry and ELISA; and a distinctive molecular PrP^{Sc} profile on western blot assay which indicates a glycotype that is distinct from classical scrapie strains and the prion strain producing BSE (Benestad et al. 2003). In 2007, the first sheep in the United States, originating from Wyoming, was confirmed with the Nor98 strain of scrapie through slaughter surveillance (USDA 2007).

There is also evidence for the existence of other atypical scrapie strains in European sheep in addition to the Nor98 strain (Buschmann et al. 2004; DEFRA 2005). Furthermore, by 2005, France had reported six atypical scrapie cases in goats to the European Commission, and a case of atypical scrapie in a Swiss goat was reported in 2007 that included a comprehensive description of the neuropathic and biochemical characteristics of the atypical prion (Seuberlich et al. 2007). The existence of such strains and their behavior may have significant implications for scrapie surveillance programs and the overall strategies for control of the disease as discussed further below.

Scrapie prions are very resistant to physical and chemical destruction and are believed to persist on pastures for months and possibly years when excreted by infected sheep or goats. Standard disinfectants do not destroy prions. Recommended disinfection procedures include deactivation with 2% sodium hydroxide solution, steam sterilization at 132°C for one hour, or incineration.

Epidemiology

Most nations where small ruminants are raised have never reported scrapie to the OIE, the world regulatory body for animal health. However, it is unclear whether these countries are actually free of the disease or if the disease exists undetected or unreported due to the lack of active surveillance programs and a lack of recognition by farmers of the clinical picture of scrapie. An informative overview on the epidemiology of scrapie with an extensive bibliography has been published by the OIE (Detwiler and Baylis, 2003).

Scrapie is enzootic in many countries of Europe, including the UK, as well as in Iceland, the United States and Canada. It also has been reported in Australia, New Zealand, India, South Africa, Kenya, Brazil, and Colombia as a result of sheep importations from the United Kingdom from the 1930s through the 1970s. Australia and New Zealand subsequently eliminated the disease in the 1950s and have remained free through surveillance and strict importation rules. South Africa's last reported case was in 1972.

Recent studies from Iceland suggest that iron and manganese content of soils and forages may influence the occurrence of scrapie in that country. Forages from scrapie-afflicted farms had significantly higher iron concentrations and Fe/Mn ratios than forages from scrapie-free farms. It was speculated that manganese may in some manner inhibit absorption of prions from the gut and that high iron levels suppress manganese in the diet and thereby facilitate absorption of prions (Gudmunsdóttir et al. 2006).

In recent years, as a result of increased surveillance associated with bovine spongiform encephalopathy in the European Union, information on the occurrence of caprine scrapie is improving (European Commission, 2006). Between 2002 and 2005 inclusive, for all twenty-five EU member countries, a total of 420,299 goats were tested for scrapie and 1,669 (0.4%) were positive. These goats included healthy animals at slaughter as well as animals dead on farm and suspect clinical cases. In comparison, 1,511,375 sheep were tested during this same period and 8,930 (0.6%) were positive. It is noteworthy that large scale data collection suggests that the prevalence of scrapie infection in the goat population is not that different from the sheep population. The conventional wisdom has long been that scrapie, at least clinical scrapie, occurs less frequently in goats

than sheep. A different perspective may emerge as more active surveillance of sheep and goats expands and continues. It is also noteworthy that one goat from France, tested in 2002 through this active surveillance effort, was ultimately diagnosed with BSE instead of scrapie. A second BSE suspect goat was identified from the UK in 2005 with the final diagnosis pending at the time of this writing. All other goats and sheep in the EU program that tested positive for TSEs were positive for scrapie.

Increased surveillance in Europe has also increased the discovery of atypical scrapie cases in small ruminants. From the initiation of the surveillance program in 2002 through 2004, 325 atypical scrapie cases were detected and reported to the European Commission, 319 in sheep and six in goats. Countries reporting atypical cases included Spain, Portugal, the United Kingdom, Germany, France, the Netherlands, Sweden, Ireland, Finland, Belgium, and Norway (European Food Safety Authority 2005). All six affected goats were from France. There are concerns that even greater numbers of atypical cases may be occurring but are not being detected because most surveillance programs limit sampling and examination of neurologic tissue to the caudal brainstem and possibly cerebellum, while in some atypical scrapie cases these areas may be free of lesions which instead are in more rostral areas of the brain not being sampled. Furthermore, some of the approved screening tests for BSE which are in use in scrapie surveillance do not consistently detect the atypical strains so that unless a full complement of screening tests is performed, atypical scrapie cases may be missed (Seuberlich et al. 2007).

Reports of naturally occurring clinical scrapie in goats are uncommon. It is not clear if this is due to a comparatively low incidence or failure to recognize the disease in goats. Naturally occurring caprine scrapie was reported in France in 1942 (Chelle, 1942), the United States in 1969 (Hourrigan et al. 1969), Canada in 1975 (Stemshorn 1975), Switzerland in 1982 (Fankhauser et al. 1982), Cyprus in 1989 (Toumazos and Alley 1989), and the UK on several occasions through the 1960s and 1970s (MacKay and Smith 1961; Brotherston 1968; Harcourt and Anderson, 1974). More recently, clinical caprine scrapie has been reported from Italy in 1998 (Capucchio et al. 1998), Greece in 2002 (Billinis et al. 2002), and Finland in 2002 (Government of Finland, 2002). In the United States, from 1990 to 2007, there were nineteen cases of caprine scrapie confirmed by regulatory authorities. The distribution of these cases was five in California; three in Colorado; two each in Washington, South Dakota, and Ohio; and one each in Wyoming, Nebraska, Illinois, Michigan, and New Hampshire (USDA 2007a).

In the majority of caprine cases occurring worldwide, there is a history of contact between affected goats and infected sheep, though direct contact with sheep does not appear to be an absolute prerequisite for caprine infection. In the Canadian report, five years had elapsed between the last case of ovine scrapie on a property and the first case in goats, although sheep remained on the farm (Stemshorn, 1975). In one report from the UK, there was no discernible contact of four affected Saanen goats with scrapie-infected sheep (Harcourt and Anderson, 1974). Wood et al. (1992) reported on twenty caprine scrapie cases seen at the U.K. Central Veterinary Laboratory since 1975. In at least seven of those cases, it was established that there had been no direct or indirect contact with sheep.

Iatrogenic transmission is also possible. Outbreaks of scrapie involving goats in Italy between 1997 and 1999 were linked to vaccination of goat and sheep herds with a *Mycoplasma agalactia* vaccine for contagious agalactia. The vaccine had been prepared from ovine CNS, lymph node, and mammary tissues which apparently contained the scrapie prion (Agrimi et al. 1999; Caramelli et al. 2001).

It is generally accepted that the principal method of natural transmission from sheep to goats is horizontal via direct contact with infected placentas or by indirect contact with pastures or bedding contaminated by such placentas (Pattison et al. 1972). The presence of the infective agent PrP^{Sc} has been confirmed in placentas of infected sheep (Tuo et al. 2001). Experimental attempts to transmit scrapie to progeny indicate that vertical transmission is unlikely to occur by sexual contact or transplacental infection (Pattison 1964). Goat-to-goat transmission, if it occurs, is also most likely by the horizontal route (Hadlow et al. 1980).

The role of semen and embryo transfer in the spread of scrapie requires further investigation, particularly because of significant implications for international trade. To date, various research studies have given mixed indications regarding the importance of embryos in transmission. Semen appears unlikely to be involved in transmission but more studies are warranted. The role of various body fluids in horizontal transmission of the disease also requires further investigation because current information appears paradoxical. The infective agent has not been identified in feces, saliva, colostrum, or milk, yet it has been found in gut tissue, salivary glands, and blood. This suggests that the infective agent may be in the various secretions derived from those sources, but the tools currently available for detection are not sensitive enough to detect it (Detwiler and Baylis, 2003).

Pathogenesis

Experimentally, the disease has been produced in goats by subcutaneous and intracerebral inoculation of the agent and by feeding of fetal membranes from infected sheep (Pattison 1957; Pattison et al. 1972;

Hadlow et al. 1974). In naturally occurring scrapie, it is most likely that oral ingestion of the infective prion initiates new infections. Following ingestion, the portal of entry for the scrapie agent may be the Peyer's patches of the ileum (Heggebø et al. 2000) from which it is transported via blood or lymphatics to other sites in the lymphoreticular system (LRS), including tonsil, spleen, and retrophyaryngeal and mesenteric lymph nodes. Presence in the gut associated lymphoid tissues likely facilitates access of the infective agent to the enteric autonomic nerves which may in turn provide access to the CNS, though the precise mechanisms for neuroinvasion in the CNS remains an area of active research. Replication in the LRS continues for weeks to months before infectivity can be detected in the brain and it may be years before there is clinical manifestation of disease.

In experimentally infected goats, inoculated intracerebrally or subcutaneously, the infective agent is disseminated to a variety of tissues in different levels of concentration, based on subsequent mouse inoculation assays conducted with titrations of various tissues (Hadlow et al. 1974). Brain and spinal cord had the highest levels of infectivity. Moderate levels were found in retropharyngeal, superficial cervical and subiliac lymph nodes, spleen, tonsil, and adrenal gland. Low levels were found in cerebrospinal fluid, sciatic nerve, pituitary gland, nasal mucosa, ileum, proximal colon, distal colon, liver, thymus, mediastinal and bronchial lymph nodes, and parotid salivary gland. No infectivity was found in blood clot, submaxillary salivary gland, thyroid, heart, lung, kidney, skeletal muscle, bone marrow, pancreas, ovary, and saliva.

Once the infective agent has reached the brain, it induces the normal cellular form of PrP to undergo a conformational change, resulting in increased β-sheet folding and subsequent appearance of PrP^{Sc}, often as scrapie-associated fibrils in the nervous tissue. The exact mechanisms of this process at the molecular level are currently an area of active research. The net result of this protein misfolding and fibril accumulation is a progressive degeneration of nervous tissue characterized by a sponge-like pattern of vacuolation, which leads to the general description of scrapie and other TSEs as spongiform encephalopathies. The brain lesions of scrapie are described further below in the section on necropsy findings.

Susceptibility to disease and the incubation period are now known to be genetically controlled in sheep and goats, though less is currently known about the latter species. The genetics of scrapie in sheep and goats has recently been reviewed (Baylis and Goldmann, 2004). The mammalian PrP gene, depending on species, is composed of two or three exons with the entire open reading frame (ORF) contained in the last exon. The gene that codes for PrP protein in goats and

sheep has an ORF of 256 codons in length, with post-translational processing resulting in a mature PrP^c protein of 210 amino acids. Polymorphisms occur in the protein coding region of the PrP gene that are known to be associated with susceptibility to scrapie and the incubation period of the disease in sheep. Such relationships are also likely in goats, but currently are less well defined.

At present, three specific ovine PrP polymorphisms are definitively known to affect the development of the disease in exposed sheep. These occur at codons 136, 154, and 171 and are expressed as A136V, R154H, and Q171R/H, respectively. The amino acid valine (V) instead of alanine (A) is encoded at 136, histidine (H) instead of arginine (R) at codon 154, and arginine (R) or histidine (H) instead of glutamine (Q) are incoded at position 171. There are numerous additional polymorphisms in sheep that have been identified in recent years in the PrP gene but their effects on the elaboration of scrapie are not yet fully established.

Unfortunately, knowledge about the genetics of goats relative to scrapie lags behind that of sheep. This is due in part to the fact that naturally occurring scrapie in goats is less common in sheep and infected herds have been less available for relevant genetic studies. Nevertheless, a number of polymorphisms have been identified in scrapie-infected goats from herds representing different breeds, though no definitive picture has yet emerged as to the significance of these various polymorphisms relative to the susceptibility to scrapie in goats or whether their importance extends beyond the specific breeds studied.

Polymorphisms in the caprine PrP gene that were identified in the review of Baylis and Goldmann (2004) included W102G, T110P, G127S, I142M, H143R, R154H, P168Q, R211Q, Q220H, and Q222K. Association with disease was noted for three of these polymorphisms, namely I142M, H143R, and R154H, and according to Baylis and Goldmann (2004), may also be expected for P168Q and Q222K. Polymorphism I142M in particular is associated with scrapie incubation period in response to various prion strains (Goldmann et al. 1996). Additional polymorphisms have been noted for the gene expressing caprine PrP and previously recognized polymorphisms have been reconfirmed in different breeds. Billinis et al. (2002) reported additional polymorphisms for V21A, L23P, and G49S in goats in Greece. For the Ionica breed of goats in Italy, Vaccari et al. (2006) reported polymorphisms for G37V, T110P, H143R, R154H, Q222K, and P240S, with the suggestion that the polymorphism at codon 154 is associated with resistance to classical scrapie and susceptibility to atypical scrapie, while the presence of lysine (K) at codon 222 is associated with resistance to classical scrapie.

Two additional polymorphisms not previously reported in goats were identified in Italian goats by Acutis et al. (2006), namely L133Q and M137I. In addition, they also noted a protective role against scrapie in goats for the glutamine to lysine mutation at codon 222 (Q222K). Zhang et al. (2004) evaluated five Chinese breeds of goats for PrP polymorphisms. All breeds possessed the R154H polymorphism and they also identified a previously unreported polymorphism in two of the breeds, I218L. The known polymorphisms of the PrP gene in goats and their possible roles in modulating scrapie infection are summarized in Table 5.4.

Even in sheep, where the role of genetics is better established, there are still many unanswered questions on the pathogenesis of the disease as it relates to genotype. Notably, in 2005, it was reported that sheep homozygous for A136/R154/R117, the known scrapie-resistant PrP genotype, were infected with the strain Nor98 prion protein and that their infection was transmissible to transgenic mice (Le Dur et al. 2005). Additional evidence that atypical strains can produce scrapie in sheep with genotypes known to confer resistance to classical scrapie has since been reported (Arsac et al. 2007). This raises concerns about the ultimate effectiveness of scrapie eradication programs based on genetic selection and also about the role of different agent strains on the pathogenesis of scrapie. It is known that phenotypically distinct strains of prions occur and that they can be distinguished by specific characteristics such as the distribution of spongiform changes they induce in the brain, the molecular profile of protease resistant PrP^{Sc}, and the fraction of PrP^{Sc} that is detected after treatment with proteinase K.

Clinical Signs

Naturally occurring clinical scrapie has been seen only in adult goats from two to eight years old. The clinical presentation may vary. Typically, the clinical course is slowly progressive over one to six months. The onset of signs is insidious, often beginning with a loss of inquisitiveness and the development of an irritable disposition which often first manifests as a resistance in lactating does to being milked. Early on, affected goats often show a characteristic posture of carrying the rear limbs forward so that the rump is elevated and the withers are held low. In addition the tail is held up, cocked forward over the rump, and the ears are frequently pricked forward suggesting heightened alertness (Pattison et al. 1959). Restlessness increases and goats become hypersensitive to handling. Affected goats may attempt to flee, bleat uncon-

? = role unknown, A = alanine, G = glycine, H = histidine, I = isoleucine, K = lysine, L = leucine, M = methionine; P = proline, Q = glutamine, R = arginine, S = serine, T = threonine, V = valine, W = tryptophan. In these polymorphisms for specific codons, the expected amino acid to be produced is identified to the left of the codon number and the actual amino acid produced as a result of the polymorphism is identified to the right of the number.

trollably, or stiffen with muscular rigidity when handled. Left alone, they may hold the head down and stomp as if bothered by imaginary flies. Fine tremors may be observed.

Pruritus is a prominent and often dramatic sign in sheep. The name of the disease derives from the act of sheep scraping themselves raw on inanimate objects in response to the intense itching they experience. Pruritus is also a predominant sign of scrapie in goats but is often less severe than observed in sheep. Some goats may show localized pruritus, particularly over the withers or tail head. Horned goats may lean their heads back and scratch this area persistently with the horn tips or scratch, dog-like, with their hind limb if the itchy spot is reachable.

Over time, hyperesthesia may give way to drowsiness or seeming drunkenness. Incoordination becomes more pronounced with increased stumbling and falling and increased difficulty in rising. Other signs may include teeth grinding, salivation or slobbering, regurgitation of rumen contents, and impaired vision. Weight loss may become marked and anorexia develops in the terminal stages (Figure 5.2). Affected animals eventually become prostrate and die if not destroyed first. Fever does not occur in the course of the disease.

Clinicians and goat owners should recognize that the clinical presentation in individual goats may vary considerably. One documented case of scrapie in a goat showed no signs other than listlessness, progressive weight loss, and premature cessation of milk production (Harcourt and Anderson, 1974). In another confirmed case, the only apparent clinical sign was regurgitation of rumen contents (Wood et al. 1992).

Clinical Pathology and Necropsy

There are no consistent hematological, biochemical, or gross pathological changes in animals with clinical or preclinical scrapie that are diagnostic of the disease. However, genotyping has become an important tool in identifying sheep that are susceptible or resistant to scrapie. To date, this testing is not applicable to goats because genetic polymorphisms that impart resistance or susceptibility have not been worked out to the extent that allow for genotyping of goats to be used as an effective disease management tool.

Scrapie has been known as a disease of small ruminants for more than 250 years, yet it is only in the last decade or so that new laboratory tests have started to become available for confirmation of the disease. One major obstacle has been a lack of understanding about the nature of the causative agent and the inability to culture it *in vitro* or identify it *in vivo*. A second important obstacle is that prion infection produces no detectable host humoral immune response so that no serologic tests for detection of antibodies have been possible. While serologic tests remain unavailable, scientists now are able to produce monoclonal antibodies to specific components of the PrP^{Sc} protein, and this has become a tremendously useful tool for better characterizing the scrapie agent and for identifying PrP^{Sc} in tissues through the use of immunobiological tests such as immunohistochemistry and electrophoresis followed by immunoblotting.

Before the application of these techniques, diagnosis of scrapie was limited to histologic examination of affected brain tissue to identify characteristic lesions

Figure 5.2. Clinical progression of a laboratory-confirmed case of scrapie in a Saanen wether goat. Figure 5.2a shows the goat robust and healthy prior to the onset of clinical signs, and actively working as a pack goat. Figure 5.2b shows the same goat in an advanced state of debilitation and emaciation five months later at seventy-one months of age. In addition to the apparent weight loss, the goat developed fearful behavior, difficulty swallowing, and pruritus, with hair loss over the face and forequarters. The goat herd from which this animal came had no history of association or contact with sheep. (Courtesy of Dr. David M. Sherman).

and confirmation of infectivity by inoculation of mice with tissues taken from suspect cases, a cumbersome procedure that can take one to two years to yield results. Fresh brain homogenates also could be examined by transmission electron microscopy to detect scrapie-associated fibrils (SAFs) (Cooley et al. 1999). The diagnostic procedures currently available for scrapie and their appropriate use have been reviewed (OIE 2004; Gavier-Widen 2005).

Immunohistochemistry (IHC) can be used to detect the presence of PrP^{Sc} in formalin fixed tissues. IHC techniques can be applied to biopsy materials taken from live animals or from sections of tissue obtained at necropsy. IHC has been used in live animals to detect PrP^{Sc} from tonsil, lymphoid tissue in the third eyelid (nictitating membrane), and rectal mucosa.

Immunoblotting by the western blot technique is performed on fresh tissues. It is used in regulatory surveillance and monitoring programs to screen for TSEs, including scrapie. Reference laboratories use Western blot to distinguish different strains of scrapie prion and to differentiate PrP^{Sc} from that of the prion causing bovine spongiform encephalopathy (BSE). These differentiations are based on conformational differences that may be revealed by immunoblotting using peptide-specific antibodies to the flexible tail of the disease-specific PrP^{Sc}.

In addition to the western blot assay, there are now several commercially available immunoassays using ELISA and other techniques that can be used as rapid screening tests in TSE surveillance programs (Moynagh et al. 1999). They were initially approved for use in screening cattle for BSE in 1999, but in 2002, the EU expanded their use to include screening of goats and sheep for scrapie. Since that time, additional rapid tests are being developed and evaluated (Deslys and Grassi 2005). Tests currently in use in the EU are an indirect ELISA, a colorimetric sandwich ELISA, a chemiluminescent sandwich ELISA, and a western blot assay.

The approved immunoassays are being applied primarily for confirmatory post mortem diagnosis of scrapie using CNS tissues or lymphoreticular tissues. The OIE (2004) recommends that tests to confirm the presence of PrP^{Sc} in tissue be performed in addition to histological examination of brain sections in suspect cases to minimize the risk of false negative results. Vacuolation of neurons is the most consistent histopathological finding in animals with scrapie. However, individual scrapie cases and at least one experimental sheep scrapie inoculum are recorded in which neuronal vacuolation is virtually undetectable by light microscopy, indicating that a clinical diagnosis of suspected scrapie cannot be absolutely refuted by a failure to find significant vacuolar changes in the brain.

The presence of the scrapie agent in lymphoreticular tissue has offered the opportunity for the diagnosis of scrapie in live animals because some lymphoreticular tissues, such as found in tonsil and third eyelid (nictitating membrane), can be readily obtained from the live animal by non-invasive means. O'Rourke et al. (2000) described the technique for antemortem biopsy of nictitating membrane by using topical anesthetic and a restraint apparatus. This technique is now in use by USDA APHIS for antemortem diagnosis in the U.S. scrapie control program. Schreuder et al. (1998) have described the procedure for tonsillar biopsy in anesthetized sheep for collection of palatine tonsil for preclinical diagnosis of scrapie.

Through use of tonsillar biopsy, preclinically affected animals were identified one and a half years before clinical signs normally appear in sheep of known genotypes with predictable incubation periods. While this represents a significant breakthrough in the antemortem diagnosis of scrapie, techniques that depend on identification of the scrapie agent in lymphoreticular tissue must be used with caution. This is because there is a significant potential for false negative results, as the presence of PrP^{Sc} in such tissues of infected animals depends on the age of the animal, its genotype, the strain of the scrapie agent involved, and possibly other factors yet unknown. In the study of Schreuder et al. (1998), for example, there was a difference in the presence of PrP^{Sc} in animals between three and a half months of age and four months of age. Similarly, Monleón et al. (2005) compared the presence of PrP^{Sc} in CNS tissue and lymphoreticular tissue at post mortem in sheep of a specific genotype in a known infected herd and reported that in some preclinical cases, the agent was present in tonsil and lymph node but not in brain while in some advanced and terminal clinical cases, the reverse was true with the agent present in brain but not in tonsil or lymph node.

Additional, new, non-invasive tests are now being evaluated that may further improve the prospects for antemortem diagnosis. These include detection of prion protein in the buffy coat fraction of blood taken from preclinical, scrapie-infected sheep using immunocapillary electrophoresis (Yang et al. 2005; Jackman et al. 2006), identification of PrP^{Sc} by western blot in rectal biopsies taken from live sheep without the use of anesthesia (Espenes et al. 2006; Gonzalez et al. 2006), and identification of PrP^{Sc} in placentas of infected sheep (Race et al. 1998). It may be necessary to evaluate these tests specifically in goats to assess their value in the ante-mortem diagnosis of caprine scrapie.

Histologic examination of the CNS still remains a critical element in the definitive diagnosis of scrapie. At necropsy, gross findings, if present at all, are limited to evidence of cachexia, and dermabrasion if pruritus is a component of the clinical picture. Sections from the

entire brain and spinal cord should be examined histologically. The principal lesion is a progressive degeneration of the gray matter. The most consistently affected part of the brain is the tegmentum and its connections (Zlotnik 1961). Lesions are most constant in the thalamus, midbrain, cerebellar cortex, and medulla oblongata and are uncommon in the cerebral cortex and spinal cord (Hadlow 1961). They are characterized by neuronal degeneration and shrinkage with vacuolation as well as astrocyte hypertrophy.

Vacuolation of neurons is considered the most significant finding. Vacuolated neurons are observed on histologic section of the medulla only rarely in clinically healthy goats, while vacuoles are seen in large numbers in the medulla of goats with advanced scrapie (Pattison et al. 1959). There is a notable absence of inflammatory response. The spongiform appearance of the brain classically described in sheep is less commonly observed in goats (Hadlow et al. 1980). Other tissues are not affected histologically.

In a more recent study of goat natural scrapie cases, vacuolation was detected in some instances as far forward as the neocortex and striatum (Wood et al. 1992). Widespread spongiform changes in the midbrain, thalamus, and basal ganglia, but not cortical regions, were found in goats infected by intracerebral challenge with BSE (Foster et al. 1993).

With regard to sampling, a 3 to 10 gm sample of cervical spinal cord and/or medulla caudal to the obex is best for possible detection of PrP^{Sc} by western blotting or for detection of scrapie-associated fibrils (SAFs) by transmission electron microscopy. That sample should be unfixed and frozen. The rest of the brain should be fixed in neutral buffered 10% formol saline for histological examination. If necessary, the immunoassays as well as electron microscopic examination for scrapie associated fibrils can be conducted on autolyzed brain tissue.

The OIE (2004) cautions that the absence of lesions is clearly not evidence of the absence of scrapie infection, because infection can exist in the absence of either clinical signs or pathological changes. For this reason, immunohistochemistry on tissue sections and/or immunoblotting/ELISA methods on fresh tissues to demonstrate accumulation of PrP^{Sc} should be carried out in parallel with routine histology in suspected cases. This is also recommended where lesions are mild in severity and considered equivocal. Where a rapid differential diagnosis is required by histopathological examination, and tissues have been fixed for less than one week, PrP^{Sc} detection should also be used to resolve possible uninterpretable observations.

Diagnosis

Clinical diagnosis of scrapie is presumptive on the basis of slowly progressive neurologic disease in an adult goat and is confirmed by identification of characteristic lesions histologically in the CNS and the presence of PrP^{Sc} by immunohistochemistry or immunoblotting in nervous or lymphoreticular tissue. In some cases, mouse inoculation studies may be carried out using tissue from suspect cases to confirm the diagnosis.

If chronic pruritus is a component of the clinical picture in goats, differential diagnoses should include lice, mange, paraelaphostrongylosis, elaphostrongylosis, and primary or hepatic photosensitization. If the onset of pruritus is rapid and the course of disease short, then pseudorabies and rabies should be considered. When tremors and progressive incoordination are the predominant signs, CAE, pregnancy toxemia, enzootic ataxia, parelaphostrongylosis, elaphostrongylosis, gid, spinal cord abscesses, Borna disease, and the dumb form of rabies should be ruled out. However, none of these conditions are likely to be as slowly progressive as scrapie. Unexplained weight loss with no other localizing signs can be consistent with scrapie in goats. The differential diagnosis of unexplained weight loss is discussed in Chapter 15.

Treatment

There is no treatment for scrapie. Even if therapeutic options were available, there would likely be little or no opportunity to use them because scrapie is becoming a reportable and highly regulated disease worldwide. Suspect cases are increasingly likely to be euthanized for diagnostic purposes by the appropriate authorities. Nonetheless, concerns about TSEs in human beings have prompted research into possible therapeutic regimens that in principle could be applicable to animals with scrapie. Obstacles and opportunities for treatment of TSEs have been reviewed (Liberski 2004; Weissmann and Aguzzi 2005).

Control

Control of scrapie at the herd level involves improved awareness of the disease among producers, implementation of appropriate management practices to minimize risk of infection, and in the case of sheep, genotyping of animals to develop a herd that is genetically resistant to infection with the scrapie agent. Unfortunately, the latter option is not yet available to goat farmers because specific genotypes that confer resistance to scrapie in goats have not yet been definitively identified or established.

Goat owners need to be educated about the insidious nature of scrapie and be able to recognize the potentially varied clinical signs of disease. In terms of improved management, the risk of scrapie can be reduced in herds by minimizing outside purchases of stock and reducing opportunities for horizontal transmission. Sheep and goats should not be commingled

when the infection status of sheep is unknown. During kidding season, placentas and other fetal membranes should be found and removed immediately. Bedding should be changed in kidding pens between kiddings and the soiled bedding burned or buried. Any animals showing tremors, incoordination, or pruritus should be isolated from the herd and a definitive diagnosis attempted. There are currently no vaccines available for controlling scrapie.

At the national level, strong regulatory programs need to be established and enforced. Once scrapie becomes endemic in a country, it is difficult to eliminate. However, as the experience of Australia and New Zealand in the 1950s demonstrated, if scrapie is recognized early on and aggressive stamping out measures are instituted, the disease can be eliminated and strict border controls and importation requirements can keep it out. The scrapie status of many sheep- and goat-producing countries in the world remains unknown at present due to the absence of active surveillance programs. From 2001 to 2003, the United States Department of Agriculture (USDA) conducted the Scrapie Ovine Slaughter Surveillance Study (SOSS) on healthy, mature market sheep to determine the national prevalence of the disease, which was determined to be 0.2% (USDA 2004). Goats were not included in that national study. However, a goat prevalence study was initiated by USDA in May 2007 and by September 30, 2007 1,515 goats were tested for scrapie. All were negative (USDA 2007a).

In the United States, several approaches to sanitary control have been implemented since 1952. They have been modified in response to changing views on, and understanding of, the factors involved in scrapie transmission. Historically, these approaches have included depopulation of infected flocks, source flocks, and exposed flocks; slaughter of infected animals and all their blood relations regardless of flock of origin; slaughter of female blood relations and lateral contact sheep; and until recently slaughter of female blood relations only. None of these approaches was completely successful.

In October 1992, as a result of a negotiated rule-making process between government, industry, and producer groups in the United States, a new Voluntary Scrapie Flock Certification Program was enacted as part of the National Scrapie Eradication Program. This voluntary program allowed flocks to be certified as scrapie-free after a five-year period. Voluntary participation involves careful animal identification and record keeping, constraints on animal movement and purchase, and regular monitoring of flocks by APHIS veterinarians. The program applies to goats and sheep.

In 2001, APHIS announced the accelerated National Scrapie Eradication Program (NSEP) with the stated goal of eliminating scrapie in the nation's sheep and goat flocks by 2010 and having official OIE recognition of the United States as being scrapie free by 2017. The key elements of the accelerated NSEP, which encompasses the Voluntary Scrapie Flock Certification Program, include identifying pre-clinical infected sheep through live-animal testing and active slaughter surveillance; making it possible to effectively trace infected animals to their flock/herd of origin through new identification requirements; and providing effective cleanup strategies that allow producers to stay in business, preserve breeding stock, and remain economically viable.

To facilitate effective clean-up strategies, USDA/APHIS provides indemnity for high-risk, suspect, and scrapie-positive sheep and goats, which owners agree to destroy; scrapie live-animal testing; genetic testing; and testing of exposed animals that have been sold out of infected and source flocks/herds. While the program applies to both sheep and goat flocks, genetic testing currently is not applied to goats because the genetics of goat susceptibility and resistance to scrapie are not as well understood as in sheep. More detailed information about the national scrapie eradication program, targeted to veterinarians and producers, is available online at http://www.aphis.usda.gov/vs/nahps/scrapie/eradicate.html.

Scrapie has been a notifiable disease within the European Union since January 1993. Active surveillance programs for scrapie in sheep and goats were legislated in the EU in 1998, and in 2001, regulation (EC) No. 999/2001 of the European Parliament established rules for the prevention, control, and eradication of certain transmissible spongiform encephalopathies in the European community, including scrapie. Genotyping of confirmed positive sheep was mandated in this legislation and rules governing the import and export of sheep and goats and their products were spelled out.

Until 2003, it was left to member states to determine what to do with herds and flocks from which scrapie had been confirmed. However, Commission Regulation (EC) No. 260/2003 set community-wide rules for the compulsory disposition of known positive flocks and herds. All animals in goat flocks must be destroyed. In sheep flocks, there is an option to genetically test and cull susceptible genotypes only. In 2004, the UK adopted a Compulsory Scrapie Flocks Scheme in place of their voluntary scheme to harmonize with the new European approach. EU regulations concerning control of TSEs change regularly to accommodate new knowledge and tools. All TSE legislation of the EU is available at http://ec.europa.eu/food/food/biosafety/bse/chronological_list_en.pdf.

Scrapie control remains a subject of active research and much policy debate. The occurrence of atypical scrapie cases in sheep with genotypes considered resis-

tant for classical scrapie, such as ARR/ARR, casts doubt on the ultimate success of scrapie eradication programs that depend on genetic selection of sheep as the basis of control. Their effectiveness remains to be determined.

Bovine Spongiform Encephalopathy

BSE, like scrapie in goats and sheep, is one of the prion-associated diseases classified as a transmissible spongiform encephalopathy (TSE). BSE was first recognized as a disease of cattle in the United Kingdom in 1986. Then, in 1996, it was reported that a new, fatal, human TSE, called variant Creutzfeldt-Jakob disease (vCJD), was thought to be associated with the consumption of contaminated animal products derived from BSE-infected cattle. Thus, BSE became a zoonotic disease, a major public health concern, a catastrophe for cattle farmers, and the focus of enormous international media attention.

There are two reasons for including a discussion of BSE in this textbook of caprine medicine. First, because BSE can be produced in goats by experimental inoculation, and second, because in 2005, a naturally occurring case of BSE was confirmed in France in a goat tested at slaughter in 2002 through the TSE surveillance program of the European Commission.

The identification of this BSE-positive goat has significant implications for the goat industry worldwide. It raises questions, not yet fully answerable, about whether or not a potentially fatal zoonotic disease could be transmitted to humans through the consumption of goat-derived products. This will no doubt result in increased research related to the occurrence of BSE in goats and its potential for transmission to humans. It also will likely lead to more stringent regulatory controls on trade in live goats and goat products. Therefore, veterinarians and the goat producers they serve need to be aware of BSE as a possible disease in goats.

A comprehensive presentation of what remains primarily a bovine disease is beyond the scope of this book. The discussion here is limited to what is relevant and known about the disease in goats and its implications for the goat industry. A more detailed review of BSE in cattle can be found elsewhere (Prince 2003).

Etiology and Pathogenesis

The etiologic agent of the TSEs has yet to be fully characterized. The predominant theory for the causative agent is believed to be the result of an abnormal folding of a naturally occurring, cell membrane-associated, prion protein called PrP^C, which is a ubiquitous protein found in cells throughout the host animal. The abnormal conformation of this cellular protein is triggered by the introduction into the host animal of an infectious form of the PrP protein, known as PrP^{Sc}, but also referred to in the literature as PrP^{res} or PrP^d. It is proposed that during the infectious process this abnormal isoform of the prion protein binds to and changes the normal PrP^C three-dimensional conformation, with at least a portion of the PrP^C-associated α-helical structure assuming the form of β-sheets which is characteristic of PrP^{Sc}. In many cases the accumulation of this abnormal PrP^{Sc} in the grey matter of the brain leads to a histologically apparent degeneration characterized by sponge-like vacuolation of affected brain tissue that gives the disease its descriptive name. Alternate theories on the pathogenesis of TSEs also persist; for example, that the wall-less bacterium *Spiroplasma* may be a transmissible agent of TSEs (Bastian 2005).

It is now well documented in sheep that the genotype of the host animal plays some role in the animal's susceptibility or apparent resistance to scrapie infection. Results of experimental infection of sheep with BSE indicate that these genetic factors may also influence the ovine response to BSE, though a recent study demonstrated that sheep with the most scrapie resistant genotype ARR/ARR could be orally infected with BSE and have significant amounts of PrP^{Sc} in their spleens (Andréoletti et al. 2006). As discussed in the scrapie section of this chapter, genotype of goats may also play a role in modulating the response to scrapie infection but the details of this relationship are less well documented at this time and there is little or no evidence concerning the role of genotype in experimental caprine BSE infection. Genetic factors play little if any role in the susceptibility or resistance of cattle to BSE infectivity.

Epidemiology

BSE was first recognized in cattle in the United Kingdom in 1986. It manifested as a neurological disease with characteristic behavioral changes that led to the popular name of "mad cow" disease. While the cause of the disease was unknown, epidemiological studies strongly suggested that the disease was being spread through the feeding of concentrate feed that contained animal protein by-products derived from ruminants. It was hypothesized that removing ruminant protein from cattle feed supplements would lead to a reduction of disease occurrence and in fact, this turned out to be correct (Wilesmith et al. 1992; Anderson et al. 1996). A ban on feeding ruminant-derived meat and bone meal (MBM) to cattle in the UK was instituted in 1988. Following that ban, the UK epizootic peaked in 1992 with 37,280 confirmed cases and has declined steadily since, with only 225 cases confirmed in 2005 and 114 in 2006 (OIE 2007a).

No other food-producing animals manifested signs of BSE during the course of the UK BSE epizootic, though there are still ongoing investigations

concerning the presence of BSE in sheep and goats. In zoological parks, some exotic ruminants that likely received prion-contaminated livestock feed became infected with a TSE. These included greater kudu, nyala, eland, gemsbok, and oryx. Similarly, twenty captive exotic felids, including cheetahs, lions, ocelots, pumas, and tigers developed TSEs, most likely from being fed meat or offal from BSE-infected cattle. In addition, eighty-nine domestic cats diagnosed with feline spongiform encephalopathy (FSE) in the UK were associated with the BSE epizootic (DEFRA 2007). Several other countries have also detected cases of FSE. These include Norway, Liechtenstein, France, Portugal, Italy, and Switzerland.

Unfortunately, livestock feeds containing MBM had also been exported to other countries, as had infected livestock from the UK, and ultimately, additional cases of BSE were found in numerous countries in Europe and elsewhere, though never to the extent that occurred in the UK By the end of 2006, twenty-four countries had reported at least one case of BSE. This includes twenty countries in Europe as well as Israel, Japan, Canada, and the United States (OIE 2007a). As a result, the European Union and many other nations have also instituted bans on feeding ruminant-derived protein to ruminant livestock. In Europe, problems with cross contamination of feed for ruminants and non-ruminants has prompted the bans to include prohibiting the feeding of most animal proteins to food-producing animals. As experimental studies and field observations indicate that horizontal transmission does not occur from cow to cow, the feed ban is the most effective tool there is to control the spread of the disease in livestock. Studies have also been done to determine whether BSE can be transmitted by frozen cattle semen and frozen cattle embryos. This does not appear to be a risk. Similarly, researchers were unable to transmit BSE via goat embryos (Foster et al. 1999).

The first human death due to vCJD occurred in a nineteen-year old British man in 1995 and by 1996 the likely link between BSE and vCJD was acknowledged. It became accepted that consumption of bovine meat products which were contaminated with nervous tissue of infected cattle was the most likely route of transmission of BSE prions to humans in cases of vCJD. As a result, the European Union and other countries with BSE-infected cattle instituted new restrictions on the bovine slaughter industry to exclude so-called specified risk materials (SRM) from meat products derived from slaughter plants.

The SRM are tissues with the potential to contain significant amounts of BSE infectivity in infected animals. This SRM restriction was not instituted in the United States until 2004, since the first bovine case of BSE in the country was only diagnosed in 2003. This intervention appears to have had the desired effect of limiting the occurrence of vCJD. The annual incidence of vCJD in the UK peaked in 2000 and has declined since. From 1995 through June of 2007, 162 human cases of vCJD were reported in the UK; twenty-two in France; four in Ireland; three in the United States; two in the Netherlands; and one each in Canada, Italy, Saudi Arabia, Japan, Portugal, and Spain (National Creutzfeldt Jakob Disease Surveillance Unit 2007). All three affected individuals diagnosed in the United States had lived outside the country for extended periods—two in the UK and one in Saudi Arabia.

The origin and character of the infective prion initially consumed by cattle to produce the epizootic of BSE in the UK has never been established. One of the original theories is that the infective prion was originally the scrapie prion introduced into the food chain via infected sheep tissues and that the prion was somehow transformed into a unique species-specific agent affecting cattle. An alternate theory is that a spontaneous mutation of normal bovine prion with the capacity for infectivity entered the animal food chain via affected slaughter cattle from whom meat and bone meal was derived. This theory is now being examined in greater depth since the finding of atypical manifestations of BSE in cattle (Biacabe et al. 2004; Casalone et al. 2004; Brown et al. 2006) and the reported capacity of one atypical BSE prion strain to undergo transformation after serial passage in mice to produce a neuropatholological and molecular disease phenotype that was indistinguishable from that of mice infected with the class BSE prion strain (Capobianco et al. 2007). Regardless of the origin, the prion that produces classical BSE can be differentiated from various strains of the scrapie prion due to advances in laboratory techniques now available for characterization of prion proteins. It remains to be seen if the atypical strains of BSE currently being identified will confound this laboratory capacity for differentiation.

The clinicopathological similarities of BSE and scrapie have spurred research on prion diseases in small ruminants, including investigations on the potential of sheep and goats to become infected with BSE. Successful experimental infections have demonstrated that both sheep and goats are susceptible to BSE infection and can manifest clinical disease. The first experimental transmission of BSE to goats was reported by Foster et al. (1993). Six goats were inoculated with brain homogenates of known BSE-infected cows either intracerebrally or orally. Three of three Anglo-Nubian goats challenged intracerebrally developed clinical signs of BSE 506 to 570 days after challenge and two of three goats challenged orally developed the disease 941 and 1,501 days after challenge (Foster et al. 1993, 2001). This indicated that the presumed natural route of infection, i.e., oral ingestion, could produce BSE in goats.

The results of such studies, and the general concern of the zoonotic potential of TSEs, spurred the establishment and/or expansion of active surveillance programs for the presence of BSE and scrapie in cattle, sheep, and goats. The European Commission was particularly active in implementing such programs. Beginning in 2002, the EU countries started to test sheep and goats in large numbers for TSEs. The samples included healthy animals sent to slaughter, animals culled as part of ongoing scrapie eradication programs, reported suspect TSE cases, and other suspect animals such as fallen stock or animals which had died on farm. With regard to goats, the EU countries tested 54,444 in 2002, 63,022 in 2003, 36,115 in 2004, and 265,489 in 2005 (European Commission, 2003, 2004, 2005, 2006). In contrast, through 2006, approximately 800 goats in the United States were tested at slaughter for TSEs, though goat slaughter surveillance activities were increased in 2007.

On January 28, 2005, the EC announced that an apparently healthy two-and-a-half-year-old goat slaughtered in France in October, 2002 and tested under the active TSE surveillance system had been confirmed as a positive case of BSE. As a precaution, the French authorities culled the entire herd of origin; no animals or animal products were allowed to enter the human or animal food chains. All other of the approximately 300 adult goats in the herd were tested, with no detectable evidence of a TSE found. Samples from the one positive goat were sent from France to the OIE Reference Laboratory for BSE, the Veterinary Laboratories Agency at Weybridge, UK, for further assessment. Mouse inoculation studies conducted at Weybridge confirmed this to be the first known case of naturally occurring BSE in a goat (Eloit et al. 2005).

In February of 2005, UK authorities announced that samples from a goat which had initially tested positive for scrapie in 1990 had been reevaluated as part of a research effort to assess newer, more sensitive testing methods for discriminating scrapie from BSE in goats (DEFRA 2005a). The case is now being considered as a possible suspect BSE case, but at the time of this writing, final confirmation is pending the outcome of ongoing transmission studies (Jeffrey et al. 2006).

These two cases, one confirmed and one suspect, establish that naturally occurring BSE can occur in the goat. However, many questions remain unanswered about the origin of these infections, the risk that BSE may spread through goat populations, and whether goats and goat products may act as a source of infection for vCJD in humans.

The confirmed BSE-positive French goat was born before the EU initiated its extensive animal protein feed ban in 2001, so the possibility exists that oral consumption of the BSE prion in contaminated feed was the source of exposure for this goat. Similarly, the UK goat was born in 1987, before the 1988 U.K. feed ban on meat and bone meal. Even before the emergence of these two reports, there was considerable concern among experts that BSE would be identified in small ruminants, though the focus of concern was more on sheep than goats due to the greater numbers of sheep in Europe and the greater economic value of the sheep industry (Schreuder and Somerville 2003).

The Scientific Steering Committee (SSC) of the European Commission issued an opinion on the risk of infection of sheep and goats with the BSE agent in 1998 (European Commission 1998). In summary, the committee believed that the transmission of the BSE agent to small ruminants was possible and if it occurred, it would likely be through the same mechanism by which cattle were infected, namely by consumption of concentrate feed containing prion-contaminated animal protein. Because the route was likely to be the same, the geographic distribution of small ruminant cases would also likely be the same, with the occurrence in small ruminants reflecting the occurrence in cattle. It was also recognized that dairy goats were more likely to have consumed contaminated concentrate feed with a possible higher risk of exposure to prion contamination than sheep and goats kept for other purposes. By 1998, it was already clear that the feed ban on animal protein in the UK had effectively dampened the BSE epizootic in cattle there, with fewer cases being reported each year. While it might be assumed that the risk of infection in small ruminants would subside in a similar fashion, the SSC expressed concern that it was not known if BSE in small ruminants would behave like scrapie in sheep, where there is evidence of lateral transmission, or like BSE in cattle, where transmission is limited to feed sources.

In BSE of cattle, there is no indication that the disease is transmitted either horizontally or vertically between animals. Virtually all bovine cases are presumed to derive from direct consumption of contaminated feed. In contrast, scrapie can be transmitted between small ruminants, either directly or indirectly. Horizontal transmission has been demonstrated in both sheep and goats, and in sheep, the possibility of vertical transmission has not been completely ruled out (Detwiler and Baylis 2003). Thus, if BSE were to behave like scrapie in small ruminants, the infection could continue to be maintained in sheep and goat populations and continue to spread despite the feed ban.

One study has shown that BSE appears to be able to spread from infected dams to lambs, though it was not clear if this occurred *in utero* or in the perinatal period (Bellworthy et al. 2005). The fact that only one goat and no sheep have been confirmed with BSE since the SSC issued their opinion in 1998 suggests that BSE

has not been widely circulated or maintained in small ruminant populations at highest risk. The increase in active surveillance for TSEs in small ruminants which began in the EU in 2002 will help to clarify the status of BSE in the small ruminant populations of those countries which had the most bovine BSE. However, there is an important caveat. It is possible that serial passage of natural BSE may change the biochemical signature of the prion, making it very difficult, if not impossible, to distinguish it from scrapie (Ronzon et al. 2006).

The other major concern is the possible risk to humans of BSE occurring in small ruminants. The issue is whether or not the controls now in place to protect humans from zoonotic prion infection from bovine products are sufficient to protect humans from BSE in small ruminants. Again, this depends on whether or not BSE in small ruminants behaves like scrapie in small ruminants or like BSE in cattle. The distribution of prions in host tissues is the key factor for consideration in this regard. Several studies have now been completed on the experimental infection of sheep with BSE (Foster et al. 1993, 2001; Jeffrey et al. 2001; Bellworthy et al. 2005a). These studies indicate that experimental BSE in sheep behaves like scrapie, with a wide distribution of PrP^d (another designation of PrP^{sc}) in tissues of the lymphoreticular system and the enteric nervous system in the preclinical stages of infection. Among the PrP^d positive tissues identified were submandibular, retropharyngeal, prescapular, mesenteric, ileocecal, and mediastinal lymph nodes; tonsil; and spleen. In the enteric system, PrP^d was identified in association with lymphoid tissue or enteric nervous tissue in the large and small intestine. Of interest was the observation of PrP^d in the abomasum (Jeffrey et al. 2001). This PrP^d was found in macrophages associated with focal inflammatory lesions presumed to be induced by gastrointestinal parasites.

The notion that PrP^d-laden macrophages can be drawn to sites of infection as part of the inflammatory response is both intriguing and alarming. It suggests the possibility that, in cases of mastitis, even subclinical mastitis, macrophages containing PrP^d could be drawn to the udder and thereby be present in milk. In fact, this process has been observed in mastitic sheep with scrapie (Ligios et al. 2005). Clearly, classification of milk as a specified risk material would have devastating consequences for dairying in small ruminants. The fact that prions are not destroyed by standard methods of pasteurization does not help matters. A recent study reported that normal PrP^c protein could be identified in store-bought, pasteurized cow, sheep, and goat milk in Switzerland with the use of a new technology that binds prions in bodily fluids with high affinity and specificity (Franscini et al. 2006). The finding of normal PrP^c in this context is not surprising,

and further studies are warranted to determine if abnormal prion protein can be detected in milk using similar technologies.

The risk potential of transmitting TSEs via milk in sheep and goats to humans needs to be specifically addressed through vigorous research so that zoonotic disease control policy can be properly based on science. A similar concern derives from reports that experimental BSE in sheep can be transmitted via blood transfusion to other sheep, even when the donor sheep are in the preclinical stages of infection (Houston et al. 2000; Sisó et al. 2006). The presence of infectivity in blood in naturally infected sheep and goats, if it were confirmed to occur, could have dire implications for the marketing of all small ruminant-derived food products intended for human consumption.

A cautionary note on the research to date is warranted. Some experimental transmissions of BSE have involved routes of infection, e.g., intracerebral, or large challenge doses not likely to occur under conditions of natural infection. In addition, because of the considerable time and expense involved in conducting transmission and infectivity studies in prion diseases, very few animals have been involved in these reported experiments. The largest number of sheep involved in any of these studies was sixty and the largest number of goats was six.

Initially, at least in sheep, it appeared that the genetic polymorphisms known to affect susceptibility and resistance to scrapie seemed to also hold for susceptibility and resistance to experimental BSE (Bellworthy et al. 2005a). However, more recent research calls this assumption into question. Scrapie resistant sheep of the ARR/ARR genotype have been experimentally infected with BSE (Andréoletti et al. 2006; Bencsik and Baron 2007). In one report, ARR/ARR sheep so infected were still clinically normal for up to six years after infection, suggesting that these sheep may even serve as silent carriers for BSE (Ronzon et al. 2006). In goats, similar to the situation with scrapie, the role of genetics remains uncertain for BSE infection.

So, while research findings to date suggest cause for concern regarding the potential for small ruminants to contract BSE, transmit it horizontally, and possibly infect humans, much more research needs to be done to develop precise quantitative risk assessments. As recently as 2006, investigators reporting on the accumulation of PrP^d in the brains of goats experimentally infected with BSE acknowledged that the distribution of PrP^d in the peripheral tissues of such goats remains undocumented (Jeffery et al. 2006). The most pressing question at present is whether or not the increase in active surveillance of sheep and goats in the EU for naturally occurring TSEs, along with the improved laboratory capacity to distinguish scrapie from BSE, will reveal additional cases of BSE in goats and sheep.

Clinical Findings and Diagnosis

Because the only known case of BSE in a goat was identified in a healthy animal at slaughter through the EC active surveillance program, there are no descriptions of the clinical signs of naturally occurring BSE in the goat. Clinical BSE has been produced in goats by experimental infection and signs of the experimentally induced disease have been described (Foster et al. 1993, 2001). These descriptions should be understood in the context in which they were produced. The routes of infection and dosages of infective material used under experimental conditions may not produce the clinical manifestations of the disease as likely to be seen under natural circumstances, particularly with regard to the temporal course of clinical disease, which appears relatively short when compared to natural BSE in cattle or natural scrapie in goats and sheep.

Foster et al. (1993, 2001) reported that three goats inoculated intracerebrally with a brain homogenate from BSE-infected cattle developed clinical disease between 506 and 570 days post inoculation. Two of three goats dosed orally developed clinical disease at 941 and 1,501 days, respectively, and a third remained healthy at 1,720 days post challenge. All three intracerebrally inoculated goats and one of the orally dosed goats developed sudden and pronounced ataxia which progressed so acutely, once manifest, that each of these goats had to be euthanized within six days after the onset of ataxia for reasons of welfare. The other orally dosed goat that developed clinical signs did not show signs of ataxia. Rather, it simply became lethargic and lost weight over a period of three weeks before it was culled. None of the five affected animals developed pruritus, a sign characteristic of scrapie, the more common TSE of small ruminants.

Given the uncertainty of the clinical presentation of BSE in goats at this time, and given the serious regulatory concerns associated with all TSEs in ruminant animals, it is prudent for veterinary practitioners to consider both of the TSEs, scrapie and BSE, in the differential diagnosis of neurological disease in goats, particularly chronic or progressive neurological disease. It is reasonable to assume that were clinical BSE to occur naturally in goats, it would appear similar to BSE in cattle or scrapie in goats and sheep.

In cattle with natural BSE, the onset of disease is insidious and the course is long. The predominant clinical signs are neurological in nature and include apprehension, hyperesthesia, and ataxia, the latter progressing to the point at which affected animals may be unable to rise. It is important to note that clinical signs of the TSEs may be very subtle and often go unnoticed until near the end stage. The clinical disease in cattle is described in more detail elsewhere (Radostits et al. 2007). The clinical signs of scrapie in goats are described in this chapter in the discussion of scrapie, along with the likely differential diagnoses for consideration in both scrapie and BSE.

Clinical Pathology and Necropsy

There are no consistent hematological, biochemical, or gross pathological changes in animals with clinical or preclinical BSE that are diagnostic of the disease. BSE produces characteristic spongiform lesions in selected regions of the brain similar to those described for scrapie (Foster et al. 2001). However, in small ruminants, discriminatory tests such as immunohistochemistry and western blot using certain antibodies are required to determine if the characteristic lesions are due to scrapie or BSE (OIE 2004a). In those clinical cases where practitioners suspect that TSEs may be involved, regulatory authorities must be notified so that suitable samples of brain tissue can be collected for analysis if deemed necessary. Detailed descriptions of the necropsy techniques for collecting appropriate tissue samples for diagnosis of TSEs in goats and sheep are available on the Internet (Canadian Food Inspection Agency 2005; USDA 2007b).

A three-tiered testing program is currently in effect in the EU to identify BSE in small ruminants. Brain tissue from sheep and goats is first screened in active surveillance programs for TSE using approved rapid screening tests that can identify proteinase K resistant prion fragments in samples, but cannot distinguish between BSE and scrapie. As of February, 2006, the EC had approved eight such rapid tests under EC Regulation No. 253/2006 for use with ovine and caprine samples. These include two sandwich immunoassays, three chemiluminescent assays, a conformational dependent immunoassay, a western immunoblot assay, and an immunocapture assay (European Commission, 2006a). The second tier of testing involves application of discriminatory tests to TSE-positive samples, such as immunohistochemistry or a modified western immunoblotting technique. The third phase is confirmatory testing, which involves inoculation of inbred or transgenic mice with BSE suspect material and then conducting discriminatory tests on the brains of inoculated mice.

Mouse inoculation studies are laborious and take upwards of a year or more for the mice to develop disease and for final tests to be completed. Such delays can hamper prompt, effective regulatory action. Not surprisingly then, the development of new discriminatory methods for quickly differentiating BSE and scrapie in small ruminants is an area of active research. New approaches include evaluation of the molecular size and glycosylation pattern of the prion protein accumulated in the brain of affected animals as well as epitope mapping studies using monoclonal antibodies directed at different portions of the prion molecule

with comparative analysis of the ratios of antibody binding (Lezmi et al. 2004; Thuring et al. 2004). Jeffrey et al. (2006) reported that in goats with experimental BSE, intra-neuronal PrP^d was labeled only by antibodies recognizing epitopes located C-terminally of residue His99, whereas in scrapie cases, PrP^d was also detected by antibodies to epitopes located between residues Trp93 and His99.

With regard to the French goat confirmed with BSE, Eloit et al. (2005) reported that the animal was first identified as a TSE case through the EU active surveillance program in 2002. It was subsequently subjected to further testing at four separate, independent labs using additional western blot and ELISA assays. The results obtained at all the labs were convergent and the French goat sample results were indistinguishable from results of samples derived from goats and sheep experimentally infected with BSE. The French goat sample was subsequently inoculated into four strains of wild type and transgenic mice used to assay BSE infectivity. The inoculated mice developed disease with incubation times compatible with those resulting from inoculation with experimental ovine BSE. The mice also produced a histological lesion profile in the brain identical to the lesion profile characteristic of experimental ovine BSE. Finally, western blot profiles produced by brain samples from inoculated mice showed that the French goat profile was again indistinguishable from those obtained with experimental ovine BSE. The suspect caprine BSE case from the UK was identified by application of immunohistochemical epitope mapping of archived brain tissue samples of caprine TSE cases diagnosed originally as scrapie (Jeffrey et al. 2006). Results of mouse inoculation studies are pending at the time of this writing.

Treatment and Control

There is no treatment for BSE. Even if therapeutic options were available, there would likely be little or no opportunity to use them because the disease is reportable and highly regulated worldwide. Suspect cases would be euthanized for diagnostic purposes by the appropriate authorities. Nonetheless, concerns about TSEs in humans have prompted research into possible therapeutic regimens which in principle could be applicable to animals with TSEs, including BSE. Obstacles and opportunities for treatment of TSEs have been reviewed (Liberski, 2004; Weissmann and Aguzzi, 2005).

Different countries have different specific regulations for the control of BSE, but the basic principles apply in all cases. The key element in controlling the spread of BSE has been the ban on feeding ruminant-derived meat and bone meal to ruminant animals, which was later expanded in some countries to a ban on the use of most animal-derived protein in the rations

of all farm animal species. The global prevalence of BSE in cattle has progressively decreased since these measures were adopted, first in the UK in 1988 and then elsewhere. In addition, countries without BSE strive to keep it out by establishing import restrictions on live ruminants and a varying array of ruminant products, including, in some cases, semen and embryos of cattle, sheep, and goats. BSE-free countries may also establish surveillance programs to ensure that the disease has not been introduced despite import regulations.

Countries with BSE have instituted stamping out measures to help control the disease. Initially, in countries other than the UK, herds containing BSE-confirmed animals were depopulated. As it became clearer that horizontal or vertical transmission did not occur in cattle, depopulation was limited to birth cohorts of BSE-confirmed animals on the assumption that they were most likely exposed to the offending feed at an early age. In addition, active surveillance programs have been implemented to detect new cases of BSE and track the overall prevalence in countries with BSE. Active surveillance programs usually include sampling a sub-population of healthy animals at slaughter, as well as suspect BSE cases, fallen or "downer" animals, and animals that have died on the farm. Scrapie eradication programs in many countries, including the United States, have been intensified as a result of concerns about BSE and these initiatives dovetail nicely with efforts to detect or eliminate TSEs in small ruminant populations.

The establishment of a zoonotic link between BSE in cattle and variant CJD in humans around 1996 resulted in additional control measures to prevent the transmission of infective prions to humans through the food chain. The identification of specified risk materials (SRM) to be removed from the human food supply during slaughter and meat processing has been the main intervention. SRM are tissues that are removed from the carcass because they pose a potential increased risk of carrying infective prions due to the predilection of infective prions for nervous and lymphoreticular tissue. As a precaution, the UK took measures to remove certain of these high-risk tissues from food in 1990. Again, there may be variation between countries in the tissues selected and the age of the animals included, but in general, for cattle, SRM include brain, eyes, skull, spinal cord with dorsal root ganglia, tonsils, vertebral column, intestines, and mesentery. Because the distribution of BSE in small ruminants may be more similar to that of scrapie in small ruminants than BSE in cattle, the list of SRM for sheep and goats may encompass a wider range of tissues and a different age range. For example, the EU does not designate the spleen as an SRM for cattle, but removal of spleen is required for all ages of sheep and goats. It should be

noted that if BSE were to be confirmed as a disease of sheep under natural conditions, the current SRM bans for both sheep and goats would likely become more stringent.

Initially, efforts to monitor and control BSE in goats and sheep were a secondary concern of regulatory agencies facing the daunting challenge of controlling this dangerous new disease in cattle. However, two things prompted a greater focus on BSE in small ruminants. The first was the link between BSE and vCJD which demonstrated the risk that products of animal origin could be a source of TSEs for humans. The second was the confirmation of the case of BSE in the goat from France in 2005. Because Europe was the source of most of the world's BSE cases in cattle, the vCJD cases in humans, and the single goat with BSE, it is not surprising that the strongest and quickest regulatory response with regard to small ruminants came from the European Union.

In May 2001, the European Parliament approved EC Regulation No. 999/2001 (European Commission 2001), laying down rules for the prevention, control, and eradication of certain transmissible spongiform encephalopathies. This comprehensive legislation addressed numerous key issues: establishment of a national status category for countries relative to the presence of TSE based on quantitative risk analysis; establishment of active surveillance programs for TSEs in sheep and goats (scrapie and BSE) with minimum sample sizes identified for each member state; identification of specified risk materials for small ruminants and cattle; establishment of regulatory procedures for the diagnosis of TSE and destruction of sheep and goat flocks confirmed with either scrapie or BSE along with guidelines for compensation of owners; rules for import and export of live animals, semen, embryos, and animal products relative to TSE status of importing and exporting countries; identification of TSE reference laboratories; and identification of approved sampling and laboratory methods.

The enhanced surveillance of sheep and goats for TSE which began in earnest in 2002 has already had two significant consequences. It demonstrated that the prevalence of scrapie in both sheep and goats is higher than previously suspected, and it led to the identification of the BSE-positive goat from France.

Identification of the caprine BSE case led to an immediate response from the EC regarding concerns that goat products could serve as a source of TSE infection for humans. The European Food Safety Authority ordered its Scientific Panel on Biohazards to conduct a risk assessment of goat meat and goat meat products with regard to BSE and report by June 2005. The panel noted that very little is known about the behavior of BSE in goats because information from experimental caprine infections is extremely limited at present. The panel also noted that it is possible that the tissue distribution of BSE in goats, both clinically and preclinically, could be similar to that of scrapie, indicating a wider distribution than found in BSE of cattle. More goat-specific experimental studies were called for, particularly to assess tissue distribution of infective prions in the preclinical stages of disease. The panel also pointed out that there was presently limited information available about the consumption patterns of goat meat by consumers in the EU, and such information would be necessary to undertake a truly quantitative risk analysis (Scientific Panel on Biological Hazards 2005).

Nevertheless, the panel concluded that a "qualitative risk assessment (RA) on goat meat could be made considering the existing risk management (RM) measures in place since 2001 and the results of the recently increased level of surveillance in goats and the discriminatory testing. For such a qualitative RA on goat meat, account is taken of a number of facts including that the goat found positive was born before the feed ban in 2001, and that currently, goats slaughtered for human consumption at a young age and born after the introduction of the feed ban, would present a lower risk than the adult population. Also other risk management measures in place (e.g. Specified Risk Material [SRM] list, rendering) contribute to the further reduction of the risk to the consumer. Moreover, the initial results of increased testing and discriminatory testing have not indicated any additional suspect BSE cases in goats or sheep. Therefore, the current risk in terms of BSE, related to the consumption of goat meat and goat meat products is considered at this time to be small for goats born after the feed ban, i.e. in 2001 and later." (Scientific Panel on Biological Hazards 2005).

Since the panel issued this statement, however, three unusual TSE cases in sheep, two from France and one from Cyprus, have been identified by routine surveillance for which testing to date could not definitively rule out BSE. Samples from these sheep have been submitted for discriminatory testing using the mouse bioassay test but the results of these tests are not available at the time of this writing (European Commission 2006b).

With regard to goat milk and goat milk products, the EC drew on an earlier opinion of the Scientific Panel on Biological Hazards (2004). Again, the panel cautioned that little specific information is available about the distribution of BSE infectivity in experimentally infected goats and that more studies are required to make quantitative risk assessments. They pointed out that prion infectivity could potentially cross the blood/milk barrier in the case of inflammation of the mammary gland (Scientific Panel on Biohazards 2004). Nevertheless, the EU advised no change in current consumption of goat milk or cheese as long as milk is

not derived from TSE-positive goats, and that goats are healthy and without mastitis.

The true risk of BSE from goat-derived products remains to be quantitatively determined. It appears that at present, regulatory authorities are hopeful that the BSE-positive French goat and the BSE-suspect UK goat represent the end, not the beginning, of detection of BSE cases in small ruminants. This hopeful position is bolstered by the facts that both animals were born before feed bans were fully in place and both came from countries where BSE in cattle was common. Furthermore, since the confirmation of the French goat case, hundreds of thousands of goats have been tested for TSEs in Europe and no additional cases have been found. In 2006 alone more than 200,000 goats were tested, and in 2005, 153 scrapie-suspect goat samples were subjected to discriminatory testing with no cases of BSE detected (European Commission 2006).

However, only time, additional research, and an active ongoing surveillance program will determine if BSE in goats is a problem with serious consequences for the goat industry. In the meantime, goat producers and veterinarians should consider the possibility of BSE in all cases of neurological disease of goats and report suspect cases to regulatory authorities.

Caprine Arthritis Encephalitis (CAE) and Maedi-Visna (MV)

Caprine arthritis encephalitis (CAE) is a disease of goats caused by a retrovirus belonging to the small ruminant lentivirus (SRLV) serogroup. There are five main clinical presentations for CAE, namely, arthritis, which is predominant, mastitis, pneumonia, a neurological form, leukoencephalomyelitis, and progressive weight loss. The focus of the discussion here is the neurological form of the disease. A second small ruminant lentivirus, known as maedi-visna virus (MVV), affects sheep and produces similar clinical conditions in that species, with the pneumonic form being predominant.

In the past, some cases of neurological disease in goats were attributed to infection with MVV. Clinically and histopathologically, these cases were strongly suggestive of CAE but occurred at a time when relatively little was known about the CAE virus (CAEV) and its relationship to MVV. The neurological disease of goats caused by small ruminant lentiviruses is described below and new relevant information about the relationship of CAEV and MVV is presented. The arthritic, pneumonic, and mastitic forms of CAE are discussed further in Chapters 4, 9, and 14, respectively.

Etiology

CAEV and MVV are viruses in the family *Retroviridae* in the genus *Lentivirinae*. The lentiviruses are also known as slow viruses because they cause persistent infections that slowly manifest as progressive, clinical disease. More detailed information about the physico-chemical, genetic, and immunological aspects of the SRLV is available in the main discussion of CAE in Chapter 4.

The lentiviruses are classified into five serogroups reflecting the hosts with which they are associated. CAEV and MVV belong to the SRLV serogroup and cause maedi-visna in sheep and caprine arthritis encephalitis in goats. The other serogroups include the cattle serogroup associated with bovine immunodeficiency disease, the equine serogroup associated with equine infectious anemia, the feline serogroup associated with feline immunodeficiency disease, and the primate serogroup which contains the simian immunodeficiency virus (SIV) and the human immunodeficiency virus (HIV). The latter is responsible for acquired immunodeficiency syndrome or AIDS in people.

The close relationship of the small ruminant lentiviruses to HIV has spurred a great deal of research in the last twenty years on CAEV and MVV. Though neither is zoonotic, the diseases they cause, CAE and maedi-visna, have served as models for the study of AIDS. As a result of this heightened interest, the veterinary community now has a better understanding of the small ruminant lentiviruses, their relationship to each other, and the diseases they produce.

MVV is the prototype small ruminant lentivirus, first described in the 1950s, whereas CAEV was first described in the 1970s. Historically, MVV and CAEV have been considered as distinct viral entities with well defined host specificity for sheep and goats, respectively. However, ongoing advances in phylogenetic analysis and studies of cross-transmission now indicate that the two viruses may be more closely related than previously thought.

Zanoni (1998) reported phylogenetic studies of small ruminant lentiviruses based on available sequence data for fragments of their *env*, *pol*, and *gag* genes and their long terminal repeats (LTR). The results indicated that at least six different clades could be differentiated with no clear separation of SRLV strains derived from goats (CAEV) or sheep (MVV). The first clade consisted of the prototype Icelandic visna virus and related MVV strains. The second clade included North American ovine lentivirus strains, the third SRLV from Norway, and the fourth SRLV from France. The fifth clade notably included the prototype North American CAEV strain, CAC-CO, as well as CAEV strains from France and Switzerland along with North American ovine lentivirus strains. The sixth clade included French SRLV. Based on this phylogenetic analysis, in which there was no clear resolution of clades according to host species origin, it was concluded that the SRLV may cross the host species barrier with ease and it was hypothesized that all the SRLV strains derive originally from MVV.

More recently, Shah et al. (2004) reported additional phylogenetic studies using a larger number of virus isolates and longer sequences of the *gag* and *pol* genes. Though the specifics of the classification system that emerged differed from that of Zanoni (1998), a key observation was reconfirmed—namely, that the SRLV do not segregate phylogenetically according to host specificity. In this more recent analysis, four of nine designated subtypes of SRLV contained both sheep and goat isolates. It was also noted that Swiss strains in the so-called B1 subtype differed no more from French, Brazilian, or United States strains than from each other, suggesting virus propagation through international livestock trade. Furthermore, isolates in subtypes A3 and A4 were derived from both goats and sheep. This was documented from specific herds where there was contact between the two species, providing further evidence for interspecies transmission of the SRLV (Shah et al. 2004, 2004a). In a separate study, phylogenetic evidence of transmission of SRLV subtype B1 from goats to sheep in mixed flocks was also reported (Pisoni et al. 2005).

Epidemiology

MV was first described in South Africa as a chronic respiratory disease of sheep in 1915. It was later reported from the United States in 1923 and subsequently in Iceland where it was first recognized in the respiratory form (maedi is Icelandic for dyspnea) and then later in the neurologic form (visna is Icelandic for wasting), which occurred only in flocks of sheep with the respiratory form of the disease (Clements and Zink 1996). Intensive epidemiological, pathological, and virological studies in Iceland in the 1950s led to the recognition and characterization of the respiratory and neurological forms of the disease as being due to a single, slow virus infection (Sigurdsson 1954; Sigurdsson and Palsson 1958; Sigurdsson et al. 1952, 1957, 1960, 1962). Respiratory disease is the dominant manifestation of MVV infection. In North America, the disease is known as ovine progressive pneumonia, in France as *la bouhite*, in South Africa as Graaff-Reinet disease, and in Holland as *zwoegerziekte*. MVV in sheep has been reviewed elsewhere (Pépin et al. 1998). MV occurs in most major commercial sheep producing countries except Australia and New Zealand. However, those countries do have CAE in their goat populations. The status of MV in many developing countries is unknown because surveillance programs are lacking.

Sporadic occurrences of a neurological disease in goats characterized by granulomatous encephalomyelitis were recorded in West Germany in 1969 and 1978 and Sweden in 1981 (Stavrou et al. 1969; Weinhold and Triemer 1978; Sundquist et al. 1981). At the time, these were considered to be putative cases of visna or a visna-like disease of goats. The German reports each involved a single goat herd and the Swedish report involved multiple herds in north and central Sweden. In all these cases, a neurologic disease syndrome occurred in adult, dairy breed goats, characterized clinically by progressive paresis and histologically by two key features—granulomatous encephalitis and demyelination. In the later West German report, neutralizing antibodies to sheep visna virus were identified in affected goats (Weinhold and Triemer 1978). A visna-like virus was isolated from the Swedish goats (Sundquist 1981). Notably, the virus isolated from the Swedish goats formed syncytia in tissue culture but was not cytopathic. This is characteristic of CAEV, whereas MVV viruses usually produce syncytia and a cytopathic effect (Quérat et al. 1984).

While the neurologic form of CAE (viral leukoencephalomyelitis) is most common in young goats between two and six months of age, clinical cases do occur beyond this limited age range, extending well into adulthood (Norman and Smith 1983). Therefore, the occurrence of these putative visna cases in adult dairy goats is not inconsistent with CAE. In addition, adult goats with the arthritic form of the disease commonly show histologic evidence of neurologic involvement at necropsy. While CAE virus rarely induces neutralizing antibody, such antibody may develop over time (Ellis et al. 1987).

Given the better understanding of the phylogenetic relationship of some MVV and CAEV isolates and the growing evidence for cross species transmission, it is most likely that these early cases of putative visna in adult dairy goats in Europe were actually CAE (Andrésdóttir et al. 2005).

New evidence on cross species transmission of SRLV also has implications for control programs. Switzerland has a national CAE control program based on testing, culling, and indemnification that has been very effective in reducing the infection in goats from more than 50% of the Swiss goat population in the 1980s to about 0.3% in 2003 (Perler 2004). However, it has been observed that some herds participating in the program, which had been seronegative for extended periods, inexplicably became positive again. Recent investigations indicate that these herds often contain sheep or have a history of contact with sheep. Shah et al. (2004, 2004a) specifically demonstrated that virus obtained from goats in the control program that were commingled with sheep was phylogenetically related to the virus obtained from sheep. This means that for CAE control programs to be fully effective, strict segregation of goats and sheep must be a core element of the program.

Pathogenesis

While knowledge has increased considerably, some aspects of the pathogenesis are still unknown.

Additional information on the transmission and early stages of infection with CAEV is provided in Chapter 4 in the section on caprine arthritis encephalitis. The pathogenesis of neurological disease caused by SRLV in goats and sheep has been recently reviewed (Andrésdóttir et al. 2005) and is summarized as follows.

Cells of the monocyte lineage in the bone marrow and spleen are the primary targets of CAEV. Replication in these cells is restricted until the monocytes differentiate into macrophages, which appears to be regulated at the transcriptional level. The mechanism by which infected macrophages cross the blood-brain barrier and enter the CNS is not fully understood. It most likely occurs via the bloodstream with monocytes crossing non-specifically in their capacity as immune surveillance cells, or it may be in response to signals from activated T cells in response to inflammation or other infections. Other possibilities for introduction include lentivirus infection of brain capillary epithelial cells or choroid plexus with subsequent release of virus to the brain. Once in the brain, virus may infect a variety of cell types including lymphocytes, plasma cells, macrophages, endothelial cells, pericytes, fibroblasts, and choroidal epithelial cells. However, replication may be limited to macrophages. Different strains of SRLV show varying neurotropism and varying neurovirulence, and the two attributes appear to be independent.

Very few cells in infected brains are found to contain viral DNA. This suggests that lesions are not due to viral replication but rather the induction of an immune inflammatory response. One possible initiator is the tat protein produced by SRLV, certain peptides of which have experimentally produced microgliosis, astrocytosis, and neuronal loss in rodents. Goats and sheep produce a strong humoral and cell mediated immune response to SRLV infection. The host immune response likely plays a significant role in the development of lesions; experimentally, administration of immunosuppressive drugs almost abolished early lesions of visna in sheep. The host immune response is likely directed against virus induced antigens rather than host antigens and amplification of the immune response by infection results in a large influx of macrophages and lymphocytes and secretion of cytokines which contribute to the development of the lesions described below in the section on necropsy.

Infection with CAEV is lifelong. How and why the infection remains dormant for long and variable periods of time is not fully understood. For example, it is interesting that the neurologic form of CAE occurs more commonly in young animals while visna in sheep is more common in adults. Strain differences and variations in neurotropism and neurovirulence as well as host factors may play a role.

Clinical Findings

In the neurologic form of CAE, the majority of affected animals are dairy breed kids between one and six months of age, though older goats also can be affected. The disease develops slowly over a period of weeks and is characterized by a progressive paresis and paralysis of the limbs, suggesting principally a spinal cord involvement. The hind limbs are almost always affected, but tetraparesis is common and asymmetric limb involvement may also occur. Kids may initially show some knuckling and inappropriate placement when standing and incoordination when walking, particularly in the hind limbs (Figure 5.3a). Gradually, the animal may have increased difficulty rising and then be unable to rise at all (Figure 5.3b).

a

Figure 5.3a. Lack of proprioception manifested by cross-legged rear limb stance and knuckling of hind foot.

b

Figure 5.3b. More advanced stage with inability to stand on hind limbs.

Figure 5.3. Progressive paresis in a kid with the nervous form of caprine arthritis encephalitis virus (CAEV) infection. (Both photos courtesy of Dr. Linda Collins Cork.)

Reflexes and muscle tone are likely to be increased, but are sometimes found to be decreased if the gray matter of the spinal cord is involved. When the hind limbs are more affected than the forelimbs, which is common, the goat may pull itself around on the ground with the forelimbs. At least in the early stages of disease, many affected kids remain bright and alert and continue to eat and drink despite locomotor difficulties. Eventually, affected kids usually succumb to pneumonia, exposure, or other secondary disease problems if not euthanized first. Rarely, recoveries have been reported.

Clinical signs of CAE are not always limited to locomotor deficits. In a retrospective of thirty cases, additional neurologic signs were observed in more than 50% of the cases. These signs included depression, blindness, abnormal pupillary response, nystagmus, opisthotonos, head tremor, head tilt, torticollis, circling, facial nerve deficits, and dysphagia. A variable increase in body temperature was also noted in the majority of cases (Norman and Smith 1983).

Clinical Pathology and Necropsy

Serology, using AGID or ELISA tests, may be helpful in establishing the presence of retroviral infection. However, identifying antibody does not confirm that clinical disease is caused by retrovirus, because animals can be subclinically infected with CAEV yet have neurologic disease due to other causes. Conversely, serum antibody levels may fall below the sensitivity threshold of the agar gel immunodiffusion (AGID) test, resulting in false negative results. Polymerase chain reaction assays on peripheral blood mononuclear cells from whole blood samples may be useful to identify the presence of viral antigen in suspect animals that are seronegative.

The CSF may suggest a viral encephalomyelitis without indicating the definitive cause. Total protein content and white blood cell counts tend to be mildly to moderately increased. In most cases, the increase in cellularity is caused by lymphocytes and monocytes, but increased neutrophils have also been observed. Median CSF total protein concentration in cases of CAE has been reported as 80 mg/dl and median white blood cell counts as 26.5/mm^3 (Smith 1982; Norman and Smith 1983). The hemogram is variable and of little diagnostic value.

At necropsy, gross lesions, when present, are limited to cloudiness of the meninges, focal brownish discoloration of the white matter in the brain and spinal cord and the ventricular surfaces, and/or swelling of the spinal cord. Microscopic lesions described in adult goats in Germany and Sweden initially presumed to have visna or visna-like disease (Stavrou et al. 1969; Dahme et al. 1973; Griem and Weinhold 1975; Sundquist et al. 1981) were similar to those described for the neurologic form of CAE (Cork et al. 1974; Norman and Smith, 1983). The lesions are similar to those originally described in sheep with visna (Sigurdsson et al. 1962).

Histologically, SRLV infections are characterized by a multifocal, mononuclear inflammatory leukoencephalomyelitis accompanied by extensive demyelination. The inflammatory response is principally perivascular and is comprised of aggregates of lymphocytes, macrophages, and plasma cells. In all cases, areas of inflammation are ringed by areas of increased astrocytes and microglia. Demyelination of nearby axons is a prominent finding. Axons are destroyed and there is general malacia in severely affected areas. In general, lesions are distributed periventricularly and periaqueductally and extend into the white matter along vessels. In severe cases, lesions may be found in adjacent gray matter. Lymphocytic infiltration of the meninges and the choroid plexus is a common finding.

Early reports of caprine visna and CAE suggested a possible difference in the two diseases based on location of lesions in the CNS, with CAE less likely to involve the brain and more likely to involve selected regions of the spinal cord (Cork et al. 1974). However, later studies of CAE demonstrated that brain lesions are common, occurring in as many as 60% of cases either with or without concurrent spinal cord lesions and that spinal cord lesions are widely distributed and not often restricted to the cervical or lumbar regions (Norman and Smith 1983). Mononuclear inflammatory responses similar to those described in the CNS may also be found in the joints, lungs, and other tissues of goats with CAE.

Diagnosis

Currently the presumptive diagnosis of the neurologic form of CAE is based on a history of other forms of CAE in the herd, e.g., arthritis or mastitis, characteristic clinical signs, evidence of antibody in the affected goat, and typical neuropathology at time of necropsy. Definitive diagnosis of any CAE infection depends on *in vitro* cultivation of virus from affected tissues.

The predominant sign in neurologic disease caused by CAEV is progressive paresis and paralysis. In young kids, the differential diagnosis must include enzootic ataxia due to copper deficiency, vertebral body or spinal cord abscesses, congenital abnormalities of the spinal cord or vertebral column, and cerebrospinal nematodiasis. If the onset is reported to be acute because early signs of paresis were overlooked, then enzootic muscular dystrophy, spinal trauma, tick paralysis, and polyradiculoneuritis also must be ruled out. Multiple conditions may be concurrent as in the reported cases of CAE and enzootic ataxia occurring in goat kids in the northeastern United States (Lofstedt et al. 1988).

In adult goats, cerebrospinal nematodiasis, abscesses, possible delayed organophosphate neurotoxicity, and scrapie must be considered in the differential diagnosis. Unlike in sheep, intense pruritus is not commonly reported in caprine scrapie and therefore the condition may look more like an SRLV infection than it would in sheep.

When lesions suggestive of brain involvement are observed, polioencephalomalacia and listeriosis should then also be considered in the differential diagnosis. In all cases, rabies should be considered because it can also present as an ascending paralysis.

Treatment and Control

There are no known treatments for retroviral infections of small ruminants in veterinary medicine. In the case of CAE, the control methods described in Chapter 4 for the arthritic form of the disease also apply to the neurologic form.

Border Disease

Border disease, also known as "hairy shaker" disease in lambs, is an infectious, contagious viral disease of sheep and goats. It causes abortions, infertility, stillbirths, weak lambs and kids, and a characteristic pattern of tremors, or shaking, in newborn lambs and kids. In lambs, it also produces a characteristic hairy appearance to the fleece and histologic changes in the skin. These skin changes are not seen in affected kids.

Etiology

Border disease is caused by a pestivirus. The pestiviruses are enveloped, single-stranded, positive sense, RNA viruses in the family *Togaviridae*. The pestivirus genus includes four related species responsible for livestock diseases: border disease virus (BDV), bovine virus diarrhea virus-1 (BVDV-1), bovine virus diarrhea virus-2 (BVDV-2), and classical swine fever (hog cholera) virus (CSFV). The viruses share physical, chemical, and biological properties including a shared common soluble antigen. Cross-species infections are known to occur as antibodies against pestivirus have been identified in more than forty ruminant species (Hamblin and Hedger 1979).

Definitive classification of the pestiviruses is currently a work in progress. Recent phylogenetic analysis of the pestiviruses based on the N^{pro} gene encoding for the non-structural protein N^{pro} indicate that indeed, these viruses do not segregate according to their traditional classifications based on host species origin (e.g., bovine versus porcine versus ovine) (Becher et al. 1997). Based on this analysis, three pestivirus isolates derived from goats were classified in the BVDV-1 genotype rather than the BDV genotype traditionally associated with border disease in sheep and goats. BVDV-1 was subsequently isolated from goat kids from mixed

sheep and goat flocks in Italy with signs consistent with border disease while BVDV-2 was identified in sheep from those flocks (Pratelli et al. 2001). More recently, an isolate from goats with border disease type signs in the Republic of Korea was classified in the BVDV-2 genotype, again on the basis of phylogenetic analysis of the N^{pro} gene (Kim et al. 2006).

Additional phylogenetic analysis of pestivirus isolates indicated that the BDV genotype could be further divided into four subgroups: BDV-1, BDV-2, BDV-3, and BDV-4 (Becher et al. 2003; Arnal et al. 2004). Subsequent to that, a pestivirus isolated from caprine fetuses in a mixed sheep and goat herd in central Italy experiencing abortions was characterized phylogenetically as a BDV, but based on its N^{pro} sequence, could not be included in one of the existing subgroups. Therefore, an additional new BDV subgroup was proposed (De Mia et al. 2005). At present, it would seem that goats may be infected with different species and genotypes of pestivirus and manifest clinical disease consistent with a diagnosis of border disease.

Epidemiology

The incidence of border disease in goats and its impact on the goat industry are unclear. The disease in sheep occurs in North America, Europe, Australia, and New Zealand. In contrast, naturally occurring, clinical border disease in goat kids has been reported only sporadically. While the disease was first described in sheep in 1959, the first naturally occurring case of border disease in a goat herd was not reported until 1982, from Norway (Løken et al. 1982). However, there was a report of a pestivirus isolated from the lungs of four-week-old kid with pneumonia in Australia the previous year (Fraser et al. 1981). Since then there has been little additional documentation of clinical border disease in goat flocks, save for some reports of goat cases along with sheep cases in mixed flocks in Italy (Pratelli et al. 1999; De Mia et al. 2005). These goat related cases may have involved BVDV virus as well as BDV virus.

Despite the relative lack of clinical reports, serologic surveys performed on goats in Canada (Elazhary et al. 1984; Lamontagne and Roy 1984), the United States (Fulton et al. 1982), Austria (Krametter-Frötscher et al. 2007), Norway (Løken 1989), Nigeria (Taylor et al. 1977), Chile (Celedon et al. 2001), and Brazil (Flores et al. 2005) indicate the presence of antibodies to BVDV or BDV in the range of 3% to 16% of goats tested. The significance of antibody responses in goats is not clear. They may merely represent an exposure to sheep with BDV, cattle with BVDV, or actual caprine infection. It is clear at least that the exposure of goats to pestivirus has a wide geographic distribution.

It is possible that clinical border disease in goats is frequently unrecognized because of a different disease

pattern in goats than sheep. In experimental caprine infection, early abortion, fetal resorption, and mummification occur more commonly than in sheep, while the delivery of live, weak, term kids, or kids with tremors, occurs less commonly. In a New Zealand study, border disease was implicated or suspected in 23% of caprine abortions (Orr et al. 1987; Orr 1988). In an episode of naturally occurring caprine border disease in Norway, only one shaker kid was identified, but 43% of does in the herd were seropositive, a considerably higher percentage than observed in general field surveys (Løken et al. 1982). An outbreak of border disease affecting five goat herds was reported from Norway in which the source of infection was an orf vaccine contaminated with pestivirus (Løken et al. 1991). There was notable reproductive failure with barrenness, abortion, and birth of weak or dead kids, but no live offspring showed characteristic signs of border disease, though lambs present in one flock did show neurologic signs.

Pathogenesis

Horizontal and vertical transmission of the virus occurs. Horizontal transmission is believed to be by ingestion or aerosol inhalation of virus. The fetus is infected transplacentally. The outcome of intrauterine and fetal infection depends to a great extent on the time of infection, although virus strain variation and breed factors are believed to also play roles. In an experimental challenge of goats, infection at forty days of gestation resulted in no live kids born, infection at sixty days resulted in 11% live kids born, and infection at one hundred days in 73% live kids born (Løken and Bjerkås 1991).

Intrauterine infection produces a more severe placentitis in goats than in sheep and this may account for more frequent fetal death and less frequent delivery of full term shaker kids when compared with sheep (Barlow et al. 1975; Huck 1973). Fetuses infected *in utero* can result in birth of immunotolerant kids if infection occurs as late as one hundred days of gestation. Healthy appearing kids as well as shaker kids born to infected does can carry and shed the virus, serving as a source of new infections (Løken and Bjerkås 1991).

Goat fetuses and kids from experimentally infected does all show some characteristic CNS lesions, regardless of whether they show clinical signs of tremors after birth. Goat kids, however, do not have the characteristic dermal follicular changes associated with the hairy fleece in affected lambs (Orr and Barlow 1978).

Clinical Findings

Shaker kids and lambs show muscle tremors right from birth. These rhythmic tremors are most prominent in the hindquarters but may extend up the trunk and neck. The general impression is one of jerkiness. Affected young have difficulty rising and when they do, they have an awkward gait. Nursing is difficult and affected young may become quickly hypothermic and hypoglycemic. They appear weak, listless, and depressed if not attended to. The long bones of the limbs may feel finer than usual, and the head appears narrowed and exaggeratedly convex in the frontal area. No abnormalities of the hair coat or skin occur in affected goats (Orr and Barlow 1978). Does show no clinical signs other than a history of barrenness, abortion, stillbirth, or fetal mummification.

It is possible that clinical manifestations may vary depending on the specific pestivirus species or genotype infecting goats. For example, a border disease-like syndrome occurring in the Republic of Korea since 1998 included diarrhea and a high mortality rate in addition to the expected signs of abortions, stillbirths, and kids with neurologic signs. Laboratory investigations revealed that the causative agent was bovine viral diarrhea virus genotype 2 (BVDV-2) (Kim et al. 2006).

Clinical Pathology and Necropsy

Seroconversion against pestivirus antigens in association with abortion in a herd is suggestive of border disease. In the one reported field outbreak in Norway, 90% of does with serum neutralizing antibodies to the BVD virus had titers of 1:500 or more (Løken et al. 1982). In affected kids, absence of antibody does not rule out border disease, due to the possible development of *in utero* immunotolerance. For definitive diagnosis of border disease in abortion cases, it is recommended that formalin fixed fetal brain, fresh fetal kidney and liver, and maternal serum be submitted for histology, virus isolation, and serology (Orr 1988).

No gross lesions are observed at necropsy of affected kids. Histologic lesions in the CNS are characterized by pronounced hypomyelinogenesis, hypergliosis, and vasculitis, particularly in the white matter of the cerebrum and cerebellum. There is perivascular gliosis and infiltration of vessel walls with lymphocytes and histiocytes. Corpora amylacea are also noted. In aborting does, there is a marked placentitis with necrotizing carunculitis. Virus may be isolated from uterine contents or vaginal discharges. Fetuses may be autolyzed, mummified, or grossly normal, but may show reduced numbers of myelinated fibers in the ventral spinal tracts histologically.

Diagnosis

Diagnosis is based on a history of reproductive failure, occurrence of newborn shaker kids, and laboratory confirmation of infection. The differential diagnoses for reproductive failure and abortion are discussed in Chapter 13. Hypoglycemia, septicemia, or meningitis may produce convulsions in newborn kids

that could be mistaken for border disease shakers. When kids have difficulty rising, the following should be considered: nutritional muscular dystrophy, congenital vertebral malformations, spinal trauma, and swayback.

Treatment

There is no specific treatment. Supportive care to ensure regular feeding promotes kid survival, but the overall herd status must be considered with regard to the advisability of keeping potential carrier animals in the herd.

Control

All does that abort, regardless of cause, should be isolated from the herd. The border disease virus is present in vaginal discharges after abortion or kidding. In general, goats should be maintained separately from cattle and sheep. Does producing shaker kids should be culled on the presumption that they themselves are infected. Elimination of infection from the herd based on serologic testing is problematic because some non-reactors may in fact be persistently infected, immunotolerant shedders of the virus. In sheep, total depopulation with repopulation from virus-free flocks is suggested as the only possible means of disease eradication (Radostits et al. 2007).

The use of BVDV vaccine has been suggested in sheep flocks suffering annual outbreaks of border disease, but this pattern of disease has not been reported in goat herds. If vaccines are used, vaccine failures may occur because different strains of BVDV and BDV virus may not be cross-protective.

Louping-ill

Louping-ill, also known as ovine encephalomyelitis, is an acute, non-contagious, encephalomyelitis caused by the louping-ill virus (LIV), an enveloped, positive sense, single-stranded RNA virus in the genus *Flavivirus*. LIV is included in the tick borne encephalitis virus complex (TBEV) that also includes Kyasanur Forest disease virus and Alkhurma virus. Phylogenetic studies have been conducted on LIV (Gao et al. 1997; McGuire et al. 1998). The disease is documented to occur only in Scotland, England, Wales, Ireland, and Norway. There is also evidence of infection of sheep and goats with two additional Flaviviruses that have been recognized in Europe: the Greek goat encephalomyelitis virus (Papa et al. 2008) and the Spanish sheep encephalomyelitis virus that can cause disease similar to louping-ill (Gould et al. 2003).

The LIV is maintained primarily in populations of sheep, red grouse, and mountain hares on tick-infested moors or pastures. It is transmitted by the three-host tick vector *Ixodes ricinus*, which can transfer the virus transtadially but not transovarially. The virus may also be transferred by blood-contaminated needles, instruments, and contact with infected tissues.

Clinical disease occurs most commonly in sheep, but other animals are sporadically reported to be affected, including goats, dogs, horses, cattle, pigs, farmed red deer, and most recently llamas (Macaldowie et al. 2005). Louping-ill has serious zoonotic potential; the virus can produce fatal meningoencephalitis in humans. Because of the zoonotic risk, veterinarians and producers should observe proper safety precautions when handing sick animals or carcasses.

In sheep, the clinical signs include fever during the initial viremic stage followed by neurologic signs once the virus enters the CNS. These include fine muscle tremors, ataxia, nibbling motions, weakness, and collapse, with death occurring one to three days following onset of signs. During the course of the disease, the sheep may walk with jerky, stiff, almost bouncy movements, which account for the name louping-ill. There is one report of suspected louping-ill occurring in a goat recently arrived on the Scottish island of Islay (Gray et al. 1988). The suspect goat showed fever, trembling, forelimb weakness, and retching, became recumbent, and died. It had a high reciprocal hemagglutination inhibition antibody titer to the louping-ill virus and had characteristic histologic lesions in the brain.

Goats can be experimentally infected but appear to be more resistant than sheep (Reid et al. 1984). All challenged does became viremic and shed the virus in their milk for up to nine days after challenge. This resulted in infection of suckling kids with more severe clinical disease. These findings suggest that subclinically infected dairy goats could potentially transmit louping-ill to people consuming unpasteurized milk.

Confirmation of the disease requires histologic examination of the brain, virus isolation from CNS tissue, and serology using serum neutralization or hemagglutination inhibition assays. Recently, the use of TaqMan® reverse transcription polymerase chain reaction was reported to identify the virus in clinical specimens. The technique was faster than cell culture and identified virus in some specimens which gave negative cell culture results, presumably due to antibody interference (Marriott et al. 2006).

There is no specific treatment, but some affected animals may recover with nursing and supportive care. An inactivated tissue culture vaccine, which can be given to sheep, goats, and cattle, is in use in the U. K. A single dose should be administered four weeks before turn out to tick-infested pastures. Immunity is considered to last for at least two years.

Borna Disease

Borna disease is a non-suppurative viral polioencephalomyelitis which historically has affected horses

and sheep in central Europe. Recent studies suggest that the virus is more widely distributed than previously thought, that species other than horses and sheep may be infected, and that the disease also may be an emerging zoonosis, though the latter point remains controversial. Goats can be infected experimentally (Ihlenburg 1962) and there is evidence that naturally occurring caprine cases have occurred, though rarely. Several reviews of progress in the understanding of Borna disease and the controversies surrounding it have been published (Ludwig and Bode 2000; Staeheli et al. 2000; Dauphin et al. 2002; Dürrwald et al. 2006).

Etiology

The causative virus is now identified as Borna disease virus in the newly created family *Bornaviridae* in the order Mononegavirales. It is an enveloped, single-stranded, negative sense RNA virus measuring 100 to 130 nm in diameter. Several unique aspects of the virus led to the creation of the new *Bornaviridae* family as summarized by Dauphin et al. (2002). Borna disease virus is the only negative, non-segmented, single-stranded RNA animal virus with a nuclear site of replication and transcription. Its genome compaction is overcome by the overlapping of ORF and transcription units and by post-transcriptional RNA splicing. The virus is characterized by strict neurotropism. It is noncytolytic and has a low rate of replication and persistence in the CNS. Unlike the majority of other RNA viruses, the Borna disease virus genome sequence is extremely stable over time.

Epidemiology

The disease has been known for almost two centuries in horses in southwestern Germany and the name is associated with the town of Borna in Saxony where the disease later emerged and peaked in the 1890s. The disease is also recognized to affect sheep. Reports of the disease in those two species remained localized to Germany for most of the history of the disease until it spread through the Rhine valley to Switzerland, Austria, and Liechtenstein starting in the 1970s. In this enzootic region of central Europe, horses and sheep remain the principal species affected, but there have also been confirmations in small numbers of cattle, donkeys, dogs, deer, rabbits, South American camelids, and goats. The goat cases were recorded in Switzerland, two from a single premises in 1987 and a single case in 1995 (Caplazi et al. 1999). The diagnoses were retrospective by immunohistochemistry. No clinical descriptions were provided.

In the 1960s, there were reports of a neurologic condition in the Middle East. It was first described as Near East Equine Encephalitis but then later proposed as Borna disease based on clinical and histopathological similarities, including the presence of Joest-Degen bodies in the brains of affected horses, a characteristic of Borna disease (Daubney 1967). Two cases of putative Borna disease in goats in Lebanon were included in those reports (Daubney 1967). It now appears unlikely that these were truly cases of Borna disease (Rott et al. 2004).

Contemporary understanding of Borna disease suggests that the cases described were caused by a virus other than Borna disease virus because Borna disease virus does not produce a cytopathic effect in cell culture. Moreover, the lesion profile described is not consistent with the histopathology of classical Borna disease, and the inclusion bodies initially identified as Joest-Degen bodies may in fact have been multiple nucleoli, which occur quite often in large neurons (Ehrensperger, personal communication 2007).

More recently, Borna disease virus has been reported to be responsible for disease occurrences in ostriches in Israel (Malkinson et al. 1993), cats in Sweden (Lundgren and Ludwig 1993), and horses in Japan (Taniyama et al. 2001) and Iran (Bahmani et al. 1996). The virus appears to have a much more cosmopolitan distribution that goes beyond the enzootic region of central Europe. In 2006, subclinical infections were reported in Chongqing goats in China based on detection of Borna disease virus p24 gene in brain tissue and peripheral blood mononuclear cells (Zhao et al. 2006)

Borna disease has also been considered as a possible cause of neurologic and psychiatric disease in humans in various countries including the United States, Japan, and Germany (Rott et al. 1991). The role of Borna disease virus in human disease remains controversial and the evidence for and against has been recently reviewed (Chalmers et al. 2005; Dürrwald et al. 2007).

In the enzootic region of central Europe, Borna disease historically has a seasonal occurrence with a peak in the spring. This has led to the presumption that an agent reservoir exists, most likely in wildlife populations, though considerable efforts have been undertaken to identify such reservoirs without definitive success. Most recently it has been suggested that the bicolored, white toothed shrew (*Crocidura leucodon*) may serve the role of agent reservoir (Hilbe et al. 2006).

Knowledge of the transmission of Borna virus is incomplete. The virus is shed in nasal, salivary, and conjunctival secretions and inhalation and ingestion are considered to be important routes of transmission. Viral RNA and proteins are also found in peripheral blood mononuclear cells so blood-borne infection may be possible. However, some efforts to demonstrate horizontal transmission from horse to horse or sheep to sheep have been unsuccessful (Staeheli et al. 2000). Infected animals develop an antibody response but it is not protective. The role of carrier animals in transmission remains unclear.

Clinical Findings

Clinical findings in goats are not well documented. In other species, the clinical presentation reflects neurologic disease, but specific signs may vary between affected animals and include behavioral changes, paresthesia, motor dysfunction, incoordination, paralysis, and death. In sheep, disturbances of sensory function are more pronounced than signs of motor dysfunction, which are more predominant in horses. However, head pressing, staggering, and ataxia are reported in sheep as the clinical course progresses over a period of four to ten days (Ludwig and Bode 2000).

In the putative cases of caprine Borna disease reported from Lebanon, the clinical findings included fever, anxiety, bleating, salivation, champing of the jaws, partial facial paralysis, fine tremors, head pressing, circling, paraplegia, convulsions, and death (Daubney 1967).

Clinical Pathology and Necropsy

Serologic tests can be applied to blood or cerebrospinal fluid. Western blot, ELISA, and immunofluorescence assay (IFA) have been applied with the latter considered to be the most sensitive. Antibody levels may be low in acute clinical cases of Borna disease so serological tests must have a high sensitivity. Antibodies may be undetectable in subacute and chronic cases (Dauphin et al. 2002). For these reasons, efforts to identify virus or viral antigen should also be pursued.

Virus isolation in cell culture can be attempted from the brain tissues of affected animals but the number of infectious particles may be low, leading to false negative results. Immunohistochemistry may be more rewarding. Reverse transcriptase-polymerase chain reaction is now being used to detect virus in blood and brain tissue.

Gross lesions are non-specific and may include mild leptomeningitis, congestion of cerebral vessels, and hemorrhage between the cerebrum and cerebellum. Histological changes are consistent with viral encephalitis and are characterized by perivascular and parenchymal infiltration of lymphocytes in affected portions of the brain. Characteristic inclusion bodies, known as Joest-Degen bodies, may be present in the nuclei of infected neurons but their presence is variable.

Diagnosis

A presumptive diagnosis may be made on the basis of encephalitic signs in goats in countries or regions where Borna disease is enzootic, with the realization that the disease is quite rare in goats and that there are more common causes of caprine encephalitis. Definitive diagnosis is by laboratory confirmation. Other possible causes of acute encephalitic signs in goats include rabies, pseudorabies, polioencephalomalacia, bacterial meningoencephalitis, and possibly CAE.

Treatment and Control

There is no treatment for Borna disease and the prognosis for recovery is guarded. In species other than goats, affected animals sometimes recover spontaneously but then relapse. The disease does not occur commonly in goats and specific control measures directed toward goats are not formulated. Given the possible zoonotic potential of Borna disease and other conditions such as rabies that may appear like Borna disease, proper precautions should be taken when handling clinical cases or during necropsy.

West Nile Encephalomyelitis

West Nile encephalomyelitis is caused by West Nile virus (WNV), a mosquito-borne flavivirus. WNV can infect numerous species of mammals, birds, and even some reptiles, but causes clinical, neurologic disease mainly in horses and humans. To date there are no confirmed cases of the disease in goats from anywhere in the world, though antibodies to WNV are readily detectable in goats in those regions where WNV is present and circulating through mosquito populations. This indicates that goats can be infected with WNV following the bite of mosquitoes and that they mount an immune response but their likelihood of developing clinical disease is very low. Therefore, a diagnosis of West Nile encephalomyelitis should not be made in a goat with neurologic disease based solely on the presence of antibody to WNV in a single serum sample. A four-fold rise in titer between acute and convalescent serum samples taken ten to fourteen days apart and initiated at the onset of disease would be far more convincing, but other causes of neurologic disease in goats should nevertheless be ruled out.

Etiology and epidemiology

West Nile virus is a single-stranded RNA virus in the genus *Flavivirus* and is a member of the Japanese encephalitis virus serocomplex. Members of this group of flaviviruses have a close antigenic relationship, which accounts for serologic cross-reactions that occur in laboratory diagnosis. These viruses include WNV, Japanese encephalitis, St. Louis encephalitis, Murray Valley encephalitis, and Kunjin virus (Petersen and Marfin 2002).

WNV is an arbovirus and is maintained in a primary enzootic cycle involving *Culex* spp. mosquitoes and wild birds of many species. Migratory birds may carry the infection to new locations and infection may become established in those locations if there are suit-

able mosquito hosts present. In temperate regions, mosquitoes hatch in the late spring and feed on birds through the spring and summer so that the virus population in birds and mosquitoes is much amplified by late summer/early autumn. At that time, certain populations of mosquitoes which serve as "bridge vectors" also feed on humans and horses and other mammals, as well as on birds, creating a secondary cycle that can lead to clinical disease in humans and horses and possibly other animals. Humans, horses, and other mammals, however, do not produce sufficient viremia in response to WNV infection to pass the virus back to mosquitoes and are therefore dead-end hosts. The primary bird/mosquito cycle is required to maintain the WNV reservoir.

The name of the virus derives from the fact that it was first isolated from a woman with fever in the West Nile district of Uganda in 1937. The first documented disease epidemic in humans associated with WNV occurred in Israel in 1951 (Bernkopf et al. 1953). The virus became recognized or established in many countries of Africa, the Middle East, western Asia, and southern Europe in subsequent years, affecting horses as well as humans. In 1999, the disease was introduced to North America with the first cases recognized in birds in New York City. By 2005, the virus was present in *Culex* spp. mosquitoes and/or wild bird populations in all forty-eight of the continental United States and most states had reported human and/or equine cases. The disease is now widespread in Mexico and Canada as well. It is not clear how the disease was introduced into North America.

Among the domestic animals, horses and other equids are the most likely to exhibit clinical disease following infection, and among domestic poultry, geese and very young chickens are most likely to become ill. Farmed alligators have been definitively diagnosed with West Nile encephalitis in Georgia and Florida (Miller et al. 2003; Jacobson et al. 2005). Clinical illness in ruminants is rare and experimental infection of ruminants is not consistently achieved (McLean et al. 2002). There have been no reported cases in goats, even from countries such as Israel which has a reasonably large goat population and where the virus has been endemic for more than fifty years (Zamir 2007). A case of West Nile encephalitis in a six-month-old sheep from Nebraska was confirmed by reverse transcriptase polymerase chain reaction (RT-PCR) assay in 2002 (Callan and Van Metre 2004) and a second two-year-old sheep from Missouri was confirmed with West Nile encephalitis by similar methods the same year (Tyler et al. 2003). In camelids, eight of seventeen alpacas demonstrating neurologic signs were confirmed as having West Nile encephalitis by PCR in Colorado in 2003 (Callan and Van Metre 2004).

While there are no reported clinical cases in goats, there are numerous reports of goats with circulating antibody to WNV. Countries where serologic surveys have revealed WNV antibody-positive goats include Romania with 3.2% of goats sampled testing positive (Topica et al. 1971), Greece with 8.7% (Koptopoulos and Papadopoulos 1980), Pakistan with less than 5% (Go 1990), India with 6.75% (Mall et a1. 1995), and Nigeria with 18% (Olaleye et al. 1990). Antibody to WNV has also been identified in goats in the United States (Bowen 2007). This data underscores the fact that goats are regularly exposed to WNV in enzootic countries. The lack of clinical case reports suggests that they are either resistant to infection or that the low level viremia associated with ruminant species is unlikely to result in clinical manifestation of disease. There are concerns, however, that more virulent strains of WNV are emerging and the disease patterns in mammalian species may change in the future as a result (McLean et al. 2002).

Clinical Findings

Because there are no reported confirmed cases in goats, no reliable clinical findings can be reported for this species. In humans, the most common presenting signs are fever, weakness, nausea, vomiting, and changes in mental status or confusion (Petersen and Marfin 2002). In horses, a retrospective study of 569 cases indicated the following signs present, in decreasing order of frequency: incoordination, muscle tremors, twitching of the face or muzzle, weakness or paralysis of limbs, caudal paresis, recumbency or difficulty rising, lip droop, teeth grinding, fever, circling, and blindness. Of the 569 horses, 345 (61%) recovered, 126 (22%) died, and ninety-eight (17%) had an unknown outcome (Schuler et al. 2004).

In the two reported cases in sheep, both animals presented in recumbency of five to seven days duration. One sheep showed muscle fasciculation as well as hyperesthesia with brief muscle spasms and extensor rigidity when touched. It also exhibited tonic clonic convulsions of short duration on presentation. These convulsions became more frequent and severe and the animal was euthanized (Tyler et al. 2003). The second sheep was mentally depressed, unable to stand, and exhibited spontaneous nystagmus as well as muscle fasciculation. It too was euthanized (Callan and Van Metre 2004).

Clinical Pathology and Necropsy

There are no reports of laboratory or necropsy findings in goats with West Nile virus encephalitis. In other species, CSF analysis may reveal an elevated protein and increased cellularity comprised of lymphocytes and large mononuclear cells.

At necropsy, in other species gross lesions in the CNS are limited to focal hemorrhage in the brain or spinal cord on cut section. Histologically, there is mild to moderate, multifocal, lymphocytic polioencephalomyelitis with perivascular cuffing, microgliosis, and some neuronal degeneration in severely affected areas (Cantile et al. 2001).

Diagnosis

In horses, the most commonly affected domestic mammal, diagnosis of WNV is currently based on observation of compatible clinical signs such as ataxia, paresis, paralysis, hyperesthesia, muscle fasciculation, seizures, or fever, and on one or more of the following: virus isolation or reverse transcriptase–polymerase chain reaction (RT-PCR) detection of WNV from tissue, blood, or cerebrospinal fluid; a four-fold increase in plaque reduction neutralization test (PRNT) antibody titers between paired serum samples taken two weeks apart (in temporal association with clinical signs of disease); detection of IgM antibody to WNV by IgM-capture ELISA; or a neutralizing titer of more than 1:10 by PRNT in a single serum sample (Kleiboeker et al. 2004).

As the intensity of viremia and the strength of the antibody response may differ in goats relative to horses, it is not clear that these same diagnostic criteria would apply to goats. The most reliable criterion for goats would likely be documentation of a four-fold rise in titer between two serum samples, one taken at the start of clinical disease and the other ten to fourteen days later.

A necropsy should be performed with histopathologic examination of the CNS in goats that die with neurologic signs, as much to rule out other important diseases as to rule in WNV infection. The differential diagnosis should at least include rabies and listeriosis in any goat, pregnancy toxemia in pregnant females, and caprine arthritis encephalitis in young goats. If other conditions are ruled out and WVN is still under consideration, then immunohistochemistry and/or PCR techniques on brain and spinal cord should be conducted to identify WNV antigen.

Treatment and Prevention

There is no specific treatment for WNV encephalitis. Affected animals may recover, so efforts to provide supportive and nursing care are justified to ensure proper nutrition and hydration and to prevent injuries associated with incoordination or prolonged recumbency. Efforts to control mosquitoes around goats and goat barns may be justified. Commercial WNV vaccines are available for use in horses, but they are not approved for use in goats or other ruminants. Given the absence of reports of confirmed clinical disease in goats, there is no apparent economic justification for the use of WNV vaccines in goats.

BACTERIAL DISEASES

Listeriosis

Listeriosis is an important infectious disease of goats most commonly associated with neurologic disease, but also capable of causing septicemia and abortion. The organism can be shed in the milk of healthy-appearing carrier goats as well as in the milk of sick goats. The zoonotic potential of listeriosis from milk and dairy products is a growing concern.

Etiology

Listeria monocytogenes is a motile, aerobic and facultative anaerobic, small, Gram-positive rod. It produces a narrow zone of beta hemolysis on blood agar. It is capable of growth over a wide pH range of 5.5 to 9.6 and a temperature range of 37.5°F to 113°F (3°C to 45°C), but optimal growth occurs at pH 7 to 7.2 and a temperature range of 68°F to 104°F (20°C to 40°C). Isolation of the organism from tissues and organic materials such as animal feeds can be difficult, so dispersion of tissues in a blender, cold enrichment of samples, subculturing from tryptose phosphate enrichment broth, and use of selective media such as trypaflavine nalidixic acid serum agar have been recommended (Dijkstra 1984). Newer selective plating media are now available, including polymixin acriflavine LiCl cetazidime esculin mannitol (PAL-CAM) and Oxford agar, which isolate *Listeria* on the basis of esculin hydrolysis, as well as chromogenic media, which allow rapid visualization of *Listeria* colonies and differentiation of *L. monocytogenes* and *L. ivanovii* from other *Listeria* spp. *L. ivanovii* is considered non-pathogenic to humans but is pathogenic for mice and has been associated with abortions in sheep and cattle (Low and Donachie 1997). In one recent report, abortions were reported in sheep in a mixed sheep and goat flock, but the goats were not affected (Santagada et al. 2004).

Though easily killed by common disinfectants, *L. monocytogenes* can survive in feces, silage, and tissue for five or more years (Dijkstra 1984a). There are now sixteen known serotypes with numerous subtypes. Serotype 4, especially type 4b, and to a lesser extent serotype 1 have been associated with encephalitis and septicemia in goats. Abortion is associated primarily with serotype 1 (Deligaris et al. 1975; Kummeneje 1975; Løken et al. 1982a; Dijkstra 1984b). In one outbreak of listeriosis in goats, the same serotype, 4b, was recovered from goats with encephalitis and from goats with abortion (Wiedmann et al. 1999). It was hypothesized that transmission in this herd outbreak was by the venereal route. Serotypes 1/2a, 1/2b, and 4b are the serotypes most commonly isolated from human cases of listeriosis and from livestock cases.

Because *L. monocytogenes* is widely distributed in nature, characterization of environmental isolates by serotyping or phylogenetic analysis is necessary to confirm their association with disease outbreaks. Techniques such as pulse field gel electrophoresis (PFGE) and ribotyping have become useful tools of molecular epidemiology to improve understanding of the ecology and transmission of *L. monocytogenes* on farms and in food processing facilities and to track the origin of pathogenic strains associated with food-borne outbreaks of listeriosis (Sauders et al. 2003). There is growing evidence that strains of the organism are not host-specific and that food animals and farms may serve as a reservoir for strains of *L. monocytogenes* that can lead to human infections (Nightingale et al. 2004; Okwumabua et al. 2005).

Epidemiology

As many as forty species of birds and mammals, including humans, can be infected with *L. monocytogenes* and the organism has been isolated on six continents. Listeriosis is a well known, sporadic clinical problem in intensively managed dairy goats in North America and Europe. In France, 4.9% of fecal samples from sheep and goats in ninety-eight flocks yielded *L. monocytogenes* (Nicolas et al. 1974). A seroepidemiologic study in Spain identified infection in 5% of goat herds tested (Perea-Remujo et al. 1984). Caprine listeriosis has also been reported from Japan (Asahi et al. 1954), South Africa (Du Toit 1977), Australia (Baxendell 1980), India (Phadke et al. 1979; Chattopadhyay et al. 1985), Brazil (Rissi et al. 2006), and Turkey (Borku et al. 2006). In New Zealand, it was reported as the most common neurologic disease of goats identified at necropsy (Thompson 1985).

Factors predisposing to clinical listeriosis in goats are similar to those reported for other farm animals and include sudden changes in weather, feeding regimens, or general management procedures; confinement in winter, particularly if overcrowded and with poor sanitation; increased stress from poor nutrition, parasitism, or other concurrent disease; advanced pregnancy; and the feeding of silage, particularly poor quality silage. The feeding of silage is often emphasized as a key predisposing factor in ruminant listeriosis (Morin 2004). However, a history of silage feeding is not a prerequisite in outbreaks of caprine listeriosis (Wood 1972; Du Toit 1977). The author has been engaged in several outbreaks of encephalitic listeriosis in goats in which there was no history of silage feeding. Johnson et al. (1996) reported on the occurrence of encephalitic listeriosis in goat herds in Missouri. None of the herds in which the disease was diagnosed had access to silage; all of the affected herds had woody browse as their main source of feed and Angora goats were the most commonly affected breed.

An increased occurrence of listeriosis in fall and winter has also been observed in goats, though cases can occur year-round. The disease is most common in adult goats. Based on experimental challenge studies, goats are more susceptible to *L. monocytogenes* infection than sheep (Gupta et al. 1980). A survey from Greece based on microbial cultures of brains from animals with neurologic signs of disease also found that goat herds were affected with encephalitic listeriosis more frequently than sheep flocks, with serotype 4b being predominant (Giannati-Stefanou et al. 2006).

The source of infection in herds is not always clear. Wild mammals and birds may be original sources of the bacteria, which then persist in soil and on plants. Goats exposed to such soil and crops may become latent carriers. During periods of stress they may become clinically ill, or shed large numbers of organisms in the feces, spreading the infection to other goats, particularly under intensive rearing conditions. Purchase of latent carrier animals may introduce the infection into previously naive herds.

Active proliferation of the bacteria in silage occurs in silage-associated outbreaks, resulting in heavy challenge to animals eating the material. Proliferation of bacteria is enhanced by poor silage quality with pH levels above 5. In one caprine outbreak, pieces of a pheasant were found chopped into the silage and the tissues of the bird were positive for *L. monocytogenes* (Dijkstra 1984b). In addition to the presence of the bacteria, the feeding of silage has been shown to have some intrinsic immunosuppressive effect in sheep, leading to decreased circulating lymphocyte numbers and reduced serum total protein. This may additionally aggravate susceptibility to *Listeria* organisms present in the feed.

Recent studies have identified some differences in the ecology and transmission of *L. monocytogenes* on cattle farms as compared to sheep and goat farms in upstate New York. Cattle farms had a higher level of environmental contamination with *L. monocytogenes* than small ruminant farms whether the cattle had a history of clinical listeriosis (case farms) or not (control farms). When small ruminant case farms were compared with bovine case farms, isolation of *L. monocytogenes* in small ruminant fecal samples was significantly less common than in bovine fecal samples. However, the organism was significantly more common in feed samples from small ruminant case farms than from bovine case farms, indicating that listeriosis on goat and sheep farms is more likely transmitted via feed than feces. On all farms, soil samples were positive more commonly than were feed samples, indicating that soil is an important source of feed contamination with *L. monocytogenes*.

These findings suggest that small ruminants are less likely to appreciably amplify ingested *L. monocytogenes*

than cattle (Nightingale et al. 2004). In a related study (Nightingale et al. 2005), it was noted that the prevalence of *L. monocytogenes* on small ruminant farms peaked during the winter and the prevalence of *L. monocytogenes* in all samples collected from small ruminant farms was notably lower during the summer and fall. The number of healthy animals on cattle and small ruminant farms that were shedding *L. monocytogenes* in feces was most affected by season, with the prevalence of fecal shedding peaking in the winter and spring. Confinement housing and the quality of feeds fed in winter were believed to contribute to this pattern.

While direct transmission of *L. monocytogenes* from animals to humans can occur, it is uncommon. In such cases human symptoms are usually limited to localized cutaneous infections. Much more common is the transmission of the infection to humans via foods of animal origin. Zoonotic infection from goat milk and goat milk products is a very real concern. *Listeria monocyto*genes can be shed in the milk of clinically affected goats as well as normal-appearing latent carriers. Shedding is less likely in the encephalitic form of the disease than in the septicemic or abortion forms. In latent carriers, the intensity of shedding is increased toward the end of gestation (Grønstøl 1984). *Listeria monocytogenes* has resisted pasteurization at 143°F (61.7°C) for thirty-five minutes, but is killed by high-temperature short-time pasteurization at 160.9°F (71.6°C) for fifteen seconds. The intraleukocytic location of some of the organisms in milk presumably contributes to this pasteurization resistance (Blenden et al. 1987). Experimentally, the organism has been reisolated from semi-soft, aged, goat milk cheeses made from unpasteurized, *L. monocytogenes*-inoculated goat milk as long as eighteen weeks after preparation (Tham 1988). The organism has been isolated from retailed, pasteurized, fluid goat milk in the UK (Roy 1988). In a study in Sri Lanka, *L. monocytogenes* was recovered from raw goat milk, standard pasteurized milk, and cheese, but not from sterilized milk, ultra-high temperature (UHT) milk, yogurt, or curd (Jayamanne and Samarajeewa 2001).

Not all listerial contamination of processed dairy products has the original milk as its source. Cross-contamination or recontamination after pasteurization can occur in processing plants if the strictest sanitation and hygiene are not observed. It is known that *L. monocytogenes* readily produces biofilms, which are microbial communities that strongly adhere to underlying surfaces. Biofilms can persist on processing equipment that is not scrupulously cleaned and disinfected. This can also occur on the farm, in that biofilms on milking machines can be a recurring source of contamination of bulk tank milk (Zundel et al. 2003). In a survey of 405 goat dairies in Spain, 2.56% of bulk tank samples were positive for *L. monocytogenes*. The isolates were most common in samples taken in the fall and winter and were rare in spring and summer (Gaya et al. 1996).

When goats have the septicemic or abortion form of listeriosis, the organism may be present in large numbers in feces, milk, birth fluids, placenta, fetuses, and newborn kids. Given the zoonotic potential of these materials for veterinarians and animal caretakers, appropriate precautions should be taken against infection when handling such tissues.

Pathogenesis

In the encephalitic form of listeriosis, the organism gains entrance to nerve endings in the oral cavity via breaks in the oral mucosa caused by coarse food, dental abrasions, or the loss of deciduous teeth. It then migrates up the nerves to the brain stem, where it stimulates a localized inflammatory response in the form of microabscesses comprised primarily of neutrophils. It is believed that *L. monocytogenes* primarily induces a cell-mediated immune response in the host and the severity of the resulting lesions may be mediated by the degree of immune recognition of the organism. Microabscesses are most common in the medulla and lead to destruction of cranial nerve nuclei, notably nerves V through IX. The cranial nerve deficits seen clinically reflect this process. Occasionally, generalized meningitis can occur in addition to focal encephalitis. The incubation period in the encephalitic form may be two to three weeks.

In the septicemic form, the incubation period may be as short as one day. The organism is believed to gain entry through the intestinal mucosa. There is an initial bacteremia with fever. This may be followed by recovery, development of a latent carrier state, or progression to more severe clinical disease. Because the morbidity rate is often low in outbreaks of septicemic listeriosis, it is presumed that many animals handle transient bacteremia effectively and are only subclinically infected. When animals do become ill they may die within forty-eight hours or the illness may last for several weeks. Pregnant does abort several days after the initial fever and aborted fetuses also show evidence of septicemia. Septicemic goats may excrete the organism in feces and milk during and after clinical illness. Newborn kids exposed to the colostrum or milk of infected does can show signs of septicemia in the first few days of life. Seroconversion is marked in goats after septicemic listeriosis but mild in goats after encephalitic listeriosis (Løken and Grønstøl 1982).

Ocular forms of listeriosis are also reported in cattle and sheep (Morin 2004). Keratoconjunctivitis and iritis appears to result from direct contact of the eye with *Listeria* present in silage during the act of feeding ("silage eye"). The condition is not well documented

in goats. Harwood (2004) reports unilateral or bilateral keratoconjunctivitis occurring in a goat herd concurrently with the encephalitic form of listeriosis, but not specifically in association with silage feeding.

Clinical Findings

The encephalitic form is the most common in goats. Though unusual, septicemic and encephalitic listeriosis have been reported in the same goat herd (Løken and Grønstøl 1982).

The initial signs of the encephalitic form are nonspecific and include depression, decreased appetite, a decrease in milk production, and a transient fever of up to 107.6°F (42°C). These prodromal signs may be followed by incoordination and hemiparesis with a tendency for the goat to lean, stumble, or move in one direction only. This tendency progresses to obvious torticollis and circling in the same direction. In advanced cases, the goat may be recumbent with the head pulled tightly into the flank, unable to straighten the neck voluntarily (Figure 5.4a).

Deficits of the facial nerve are also common and may occur with or without concurrent hemiparesis and circling. The signs are usually unilateral and include ear droop, ptosis, flaccid buccal muscles with accumulation of feed in the buccal pouch, salivation, and a collapsed nostril (Figure 5.4b). Slack jaw, weak tongue, impaired swallowing, and nystagmus may also be seen. When lesions are bilateral, some of these deficits may be paradoxically less obvious since the abnormalities are symmetrical. Keratitis may be observed as a sequela to abnormal eyelid function. Loss of excessive saliva through drooling and the inability to swallow can lead to acid-base imbalance, electrolyte and fluid losses, dehydration, and weakness. The course of encephalitic listeriosis in goats is usually one to four days, which is shorter than that observed in cattle. The morbidity rate is variable, but the mortality rate can be high.

The septicemic form also begins with depression, loss of appetite, decreased milk production, and fever up to 107.6°F (42°C). In these cases, fever may persist and the animal grows progressively weaker over the next several days. Neurologic signs rarely develop, but diarrhea, often bloody, is a common finding in goats. Goats may die within a few days or remain ill for several weeks. Pregnant does abort several days after the onset of septicemia. They may not necessarily show severe signs of septicemia.

Clinical Pathology and Necropsy

The hemogram may remain normal, particularly in the encephalitic form of the disease, or show a neutrophilic leukocytosis. The monocytosis seen in laboratory animals does not occur in ruminants. Analysis of the cerebrospinal fluid may be helpful. Protein levels and cell counts are typically moderately elevated. The cells are predominantly monocytes and lymphocytes, with some neutrophils also present. Bacteria are rarely seen in the CSF, and culture from the CSF is almost always unrewarding.

Historically, serology, while useful for epidemiologic studies, has not been widely applied for diagnosis of individual cases (Morin 2004). A number of different serodiagnostic techniques have been employed using crude antigens, but a general limitation for all these techniques was a lack of specificity, with cross reactions to other Gram-positive organisms being common (Low and Donachie 1997). Another practical limitation is that in cases of encephalitic listeriosis, affected animals do not appear to mount a consistent, detectable humoral immune response, in contrast to cases of septicemic listeriosis. An increase in indirect hemagglutination titer is reported after septicemic listeriosis, but not after the encephalitic form (Løken et al. 1982a). Sero-agglutination was found to be unsatisfactory as a screening test for accurately identifying herds with enzootic listeriosis (Nicolas et al. 1974).

ELISA tests have been developed in recent years to detect antibodies against a specific antigen, listeriolysin O, which is an extra-cellular 58 kDa haemolysin, produced by all the pathogenic strains of *L. monocytogenes* (Elezebeth et al. 2007). As with other tests, it does not appear to be a reliable indicator of acute phase disease in cases of encephalitic listeriosis. The kinetics of the antibody response to listeriolysin O in experimentally infected goats has been reported (Rekha et al. 2006).

Culture of *L. monocytogenes* should be attempted for definitive diagnosis, recognizing that the organism may be difficult to isolate without special enrichment methods. In the septicemic and abortion forms of the disease, feces, milk, and aborted fetuses are suitable specimens. Experimentally infected septicemic goats shed *L. monocytogenes* in the feces for twenty-eight days after infection but only two days in milk. Stomach contents, spleen, and liver of the fetus are tissues most likely to be positive on direct culture without enrichment (Gupta et al. 1980). In the encephalitic form, fresh brain should be submitted for culture, especially brain stem. Grinding of brain tissue and refrigeration at 39°F (4°C) before culturing can improve the chance of a positive culture. Occasionally goats with the encephalitic form are fecal culture positive. Culture of silage is also indicated when silage is implicated. However, the distribution of organisms in silage may be uneven and the offending portions may be long gone by the time clinical disease is observed.

Gross post mortem findings are uncommon in the encephalitic form of the disease, though visible, focal gray discoloration and malacia of the brain stem have been observed in affected goats (Wood 1972). The CSF may be cloudy and the meninges congested. In most cases, lesions are identified histologically, and consist of focal microabscesses principally in the medulla but also in the pons and cerebellum. These abscesses are comprised primarily of neutrophils. Perivascular cuffing with mononuclear cells and neutrophils, diffuse microgliosis, and a mononuclear infiltrate of the meninges may also be seen. For definitive diagnosis, a large portion of the brain with brain stem should be submitted fresh for bacterial culture. However, recent reports indicate that immunohistochemistry performed on CNS tissues is much more reliable than bacterial culture for confirming the presence of *L. monocytogenes* in tissues (Ehrensperger et al. 2001; Loeb 2004).

In the septicemic form, multiple foci of necrosis may be seen in liver, spleen, kidney, and heart. Multiple, small yellowish spots on the liver of aborted fetuses are highly suggestive of listeriosis. Placentitis and endometritis may also be observed in does that abort. Successful culture is most likely from the liver, spleen, lung, and uterus of septicemic adults.

Diagnosis

Neurologic diseases that can produce localizing signs consistent with a diagnosis of listeriosis include the neurologic form of CAE, focal brain abscesses, cerebrospinal nematodiasis, coenurosis, middle ear infections, bacterial meningitis, early rabies, and trauma to the facial nerve. Recumbent animals in advanced stage of encephalitic listeriosis may be misdiagnosed. In a survey of sixty-seven encephalitic listeriosis cases in goats and sheep, twelve of the animals were not diagnosed with the disease until necropsy. Six had a working diagnosis of polioencephalomalacia (cerebrocortical necrosis), one was diagnosed with ketosis, one with pulmonary emphysema, and in four no specific diagnosis was made (Braun et al. 2002).

The differential diagnosis for septicemic listeriosis, particularly when diarrhea is present, includes salmonellosis, yersiniosis, and enterotoxemia. When weakness predominates and diarrhea is absent, milk fever, and pregnancy toxemia should be ruled out. Causes of abortion in which the doe shows clinical signs of illness are discussed in Chapter 13.

Treatment

Early intervention improves the prognosis for recovery. Goats already recumbent rarely respond favorably

to treatment and a poor prognosis should be given for recumbent animals. Penicillins, tetracyclines, and where permitted, chloramphenicol, are effective antibiotics. Adult goats with the septicemic form of disease responded favorably to intramuscular penicillin administered for three consecutive days at a dose of 2.5 g per day, but shorter courses of therapy were less effective (Løken and Grønstøl 1982). In the encephalitic form, intravenous sodium penicillin at a dose of 40,000 IU/kg every six hours until improvement is noted, followed by a seven-day course of intramuscular procaine penicillin at a dose of 20,000 IU/kg twice a day has been recommended (Brewer 1983). Oxytetracycline should be given intravenously at a dose of 10 mg/kg twice a day for at least three days. These high dosage levels are necessary to promote passage of antibiotic across the blood brain barrier and development of high-tissue concentrations in the CNS.

It has been reported that ampicillin or amoxicillin given in conjunction with gentamicin is the treatment regimen of choice in human listeriosis cases. The use of a combination of gentamicin given at a dose of 3 mg/kg bw IV BID and amoxicillin given at a dose of 7 mg/kg bw IM BID was reported in one retrospective case study in small ruminants (Braun et al. 2002). The outcomes for sheep and goats treated with gentamicin/ampicillin were better than those treated with either penicillin or oxytetracycline. However, more of the animals treated with gentamicin/amoxicillin had a favorable prognosis at the onset of therapy because they were not yet recumbent. The use of gentamicin in goats is problematic due to prolonged antibiotic residues in meat and milk.

Dexamethasone given once a day at a dose of 0.1 mg/kg intravenously has also been used in conjunction with antibiotics in the treatment of encephalitic listeriosis with the rationale that steroids may suppress the infiltration of mononuclear cells that lead to microabscesses in the brain stem. The nonsteroidal anti-inflammatory drug flunixin meglumine has been used at a dose of 2.2 mg/kg bw IV SID in the treatment of goats with encephalitic listeriosis but its contribution to a favorable outcome is not documented.

Supportive therapy in the form of fluid and electrolyte administration, supplemental feeding, and management of exposure keratitis associated with lid paralysis may be necessary in severely affected animals. Large amounts of bicarbonate and fluid may be lost when salivation is prolonged and intense so fluid therapy should be tailored to address these deficiencies.

Control

In outbreaks of disease, aborting does should be isolated from the herd, and kids should be raised separately from adults. Aborted fetuses, placentas, and discharges should be handled wearing gloves and face masks, and disposed of carefully. Kids should not receive unpasteurized colostrum or milk from does involved in the outbreak to avoid neonatal septicemia. Feed samples, particularly silage, should be examined and cultured and infected feeds discarded. Even when culture tests are negative, poor quality silage with a pH more than 5 should be suspect, and not fed. Recently introduced animals also should be considered suspect as carriers. Floors and pens should be thoroughly cleaned and disinfected. After an outbreak, herd-wide fecal cultures with culling of fecal shedders has been used to effectively eliminate infection from goat herds (Dijkstra 1984b). Because of the zoonotic potential, no unpasteurized milk should be consumed from goats in a herd with a history of listeriosis since shedding of the organism in the milk of latent carrier animals does occur.

A vaccine has been in use in central Europe and Norway to protect sheep from listeriosis. While case rates in vaccinated and unvaccinated sheep were similar, the severity of disease was less and the response to treatment better in vaccinated animals (Gudding et al. 1985). A vaccination trial in goats in France produced a sharp reduction in new cases that lasted for at least three months when used in known infected herds. No difference was observed in disease rate or host response to vaccination between a live and killed vaccine except for a rare abortion in does vaccinated with the live vaccine in late gestation (Guerrault et al. 1988).

Goat farmers who produce or market milk, cheese, or other dairy products need to be aware of the zoonotic potential of these products if contaminated with *L. monocytogenes*. There should be no sale of raw milk products from herds where the *Listeria* infection status in not known to be negative. Some of the challenges of keeping cheeses free of listeria contamination in small scale cheese making operations and approaches to reducing the risk of contamination of soft goat cheeses have been reported (Theodoridis et al. 2006).

Tetanus

Tetanus is a well known clostridial disease of humans and animals that produces a characteristic syndrome of muscular rigidity, hyperesthesia, and convulsions. Routine prophylaxis against tetanus in goats is recommended.

Etiology and Pathogenesis

The causative agent is *Clostridium tetani*, an anaerobic, Gram-positive, spore-forming rod found widely in soil and animal feces. Spores are very resistant to destruction and can persist in soil for many years. Proliferation of the organism with release of a potent neurotoxin, tetanospasmin, can occur when spores are

subject to a suitable anaerobic environment as can occur in deep puncture wounds or injuries producing necrotic tissue in susceptible hosts. The organism does not disseminate from the site of proliferation, but the neurotoxin ascends the peripheral nerve trunks to the spinal cord where it blocks the inhibitory effect of interneurons on alpha motor neurons. This leads to sustained discharge of motor neurons with resultant signs of tetany. When the toxin reaches the post-synaptic sites where it exerts its effect, it cannot be neutralized by antitoxin and is only removed by gradual degradation. Death is usually caused by respiratory arrest from dysfunction of the tetanic diaphragm. Further explanation of the pathogenesis of tetanus at the cellular and molecular level is available elsewhere (Rings 2004).

Epidemiology

Goats are susceptible to tetanus, and factors that predispose other livestock to the disease also predispose goats. The tetanus organism may be introduced into the goat via puncture wounds; obstetrical interventions; performance of routine procedures such as disbudding, dehorning, tattooing, castration, and hoof trimming; dog bites; fighting by bucks; and penetration of the oral mucosa by fibrous plant awns (King 1980). The use of elastrator bands for castration may be particularly dangerous in establishing conditions for the proliferation of spores. In South Africa, tetanus is frequently encountered in young Angora goats after shearing (Van Tonder 1975). Persistent skin irritation caused by constant rubbing from a metal neck chain (Sinha and Thakur 1978) or a rope tether has been identified as causing tetanus in goats (Figure 5.5).

Spores of *C. tetani* are resident in the intestines of livestock and may be passed in the feces in large numbers, particularly by horses. These spores accumulate in soil, particularly where livestock are kept under intensive management. Goats maintained in barns currently or previously used for horses may be at increased risk of disease.

Clinical Findings

The incubation period varies in tetanus. It can depend in part on the location of the inciting wound or injury and its distance from the CNS as the toxin has to reach the spinal cord before clinical signs are seen. Tetanospasmin moves intra-axonally at a rate of 75 to 250 mm/day (Sanford 1995). Clinical disease has been observed in a one-week-old kid within four days of disbudding and in an adult doe several months after dystocia. In most cases however, the incubation period is ten to twenty days.

Early signs of tetanus include an anxious expression, a stiff gait, and mild bloat. Affected animals adopt a characteristic base-wide, or "sawhorse" stance, and the ears and tail become stiff. There is reluctance to move and difficulty opening the mouth. The animal
Figure 5.5. Young goat with advanced tetanus. Note extensor rigidity and opisthotonos. This goat developed tetanus secondary to abrasions of the neck associated with prolonged tethering with a tight rope. (Courtesy of Educational Media, Cummings School of Veterinary Medicine at Tufts University, Mr. David Wilman, photographer.)

may become constipated. Food may accumulate in the buccal space and salivation may be observed. Prolapse of the third eyelid may occur. Over time, animals become hyperesthetic and respond dramatically to touch or loud noise by stiffening and collapsing to the ground. This may be followed by seizures. Eventually animals are permanently recumbent, with rigid extension of all limbs and opisthotonos. Rumen tympany may be pronounced. Affected animals convulse periodically at the slightest disturbance. Once recumbent, death usually occurs within twenty-four to thirty-six hours.

Clinical Pathology and Necropsy

There are no characteristic laboratory abnormalities in tetanus and no definitive necropsy findings, as the neurologic lesion is functional rather than physical. A thorough history and careful inspection of the carcass may lead to identification of the wound or infection site of bacterial proliferation where the organism might be cultured. Because the organism may be present in tissues without causing disease, this supports but does not confirm the diagnosis.

Diagnosis

The diagnosis of tetanus is based on the rather characteristic clinical syndrome it produces. However, at different points in the development of full blown tetanus, other differential diagnoses must be considered. Laminitis and nutritional muscular dystrophy can produce a stilted or stiff gait as seen in early tetanus, but not bloat or the other signs. Hyperesthesia and trismus are seen in bacterial meningitis but this condition can be differentiated by CSF analysis. In the terminal stages when recumbency, opisthotonos, and convulsions are present, polioencephalomalacia, which is common in goats, must be differentiated. Strychnine poisoning and hypomagnesemic tetany must also be ruled out, but these are less common in goats. Myotonia congenita, as discussed in Chapter 4, can produce tetanic spasms, but these are intermittent and spontaneously resolve.

Treatment

The prognosis is always guarded, but early identification and intervention improve the recovery rate. Therapeutic goals are to inhibit additional toxin production, neutralize existing unbound toxin, ameliorate the effects of bound toxin, and provide whatever supportive care is necessary. Treatment with systemic penicillin inhibits additional bacterial proliferation and toxin release. Procaine penicillin G at a minimum dose of 25,000 IU/kg bw IM BID for two to three days is recommended with a reduction to once a day treatment after that. Other antibiotics with a Gram-positive spectrum such as ampicillin and amoxicillin may also be used at high, frequent doses.

The drug of choice in human medicine is metronidazole and this is now being used for tetanus cases in small animal practice as well (Linnenbrink and McMichael 2006), but no reports of its use or effectiveness in ruminants were found. The use of metronidazole in food animals (including all goats) is forbidden in the United States (Payne et al. 1999). The site of bacterial proliferation should always be searched for and whenever possible, the wound or infection site should be opened to the air, debrided, flushed with hydrogen peroxide, and infiltrated with penicillin. It is suggested that the area be infiltrated with tetanus antitoxin before the wound cleaning process begins to reduce the chance that more pre-existing toxin will be absorbed during tissue manipulations.

Neutralization of existing unbound toxin is accomplished by parenteral administration of tetanus antitoxin at a dose of 10,000 to 15,000 units intravenously every twelve hours for at least the first twenty-four hours and longer if the proliferation site has not been identified and treated. An alternative approach is the one time administration of antitoxin directly into the CSF via the atlanto-occipital space. In a goat, 5 ml of antitoxin has been introduced into the subarachnoid space after removal of an equivalent amount of CSF (Brewer 1983).

Anticonvulsants, tranquilizers, and muscle relaxants can be administered to reduce the clinical effects of bound toxin. Diazepam can be used at a dose range of 0.5 to 1.5 mg/kg intravenously to effect. Acepromazine works well as a tranquilizer in tetanic animals at a dose of 0.2 mg/kg intramuscularly. Methocarbamol is an effective muscle relaxant at a dose of 22 mg/kg intravenously. Guaifenesin, given intravenously to effect as a 5% solution, may also be used to reduce muscle spasms but care must be taken not to overdose the animal, because it acts by blocking nerve transmission at the level of the interneurons (Rings 2004). Other drugs recommended for use as muscle relaxants but not specifically reported for use in goats are dantrolene sodium, mephenesin, and magnesium sulfate (Rings 2004).

Supportive care includes removing the animal to darkened, quiet surroundings. Intravenous fluids containing dextrose and electrolytes are indicated to counter dehydration and lack of feed intake. An enema may relieve constipation and make the animal more comfortable. The position of the animal should be shifted regularly to avoid decubital ulcers. A nasogastric tube can be passed to relieve bloat and provide fluids and feed per rumen. An egg, honey, milk, glycerine, and oatmeal gruel has been recommended (King 1980). Care must be taken not to traumatize the pharynx and esophagus when the tube is passed repeatedly. When valuable animals are severely affected and the

convalescence is expected to be long, surgical creation of a rumen fistula may be indicated to facilitate feeding and bloat control. Any sign of improvement is favorable, but it may take several weeks for complete recovery to occur.

Control

Tetanus can be readily prevented by a combination of improved hygiene and immunoprophylaxis. In general, all wounds should be cleaned promptly and thoroughly. The use of elastrator bands for castration should be avoided. When the immune status of young kids is unknown, routine procedures such as disbudding and castration should be accompanied by injection of 150 to 250 units of antitoxin. When the status of adults is unknown, 500 to 750 units of antitoxin can be administered when treating wounds, dystocias, and other potential sources of tetanus.

It is recommended that routine vaccination for tetanus be incorporated into the herd health program. For small ruminants, tetanus is often included with *Clostridium perfringens* types C and D as a trivalent vaccine which can serve as the foundation for a goat preventive vaccination program. Initially, all goats vaccinated should receive a booster vaccine three to four weeks after their initial vaccination. Then, if pregnant does are vaccinated one month prior to parturition, their kids will be protected by passive colostral antibody for at least several weeks and can be vaccinated for the first time at three to four weeks of age. The kids then should be boostered three to four weeks later, and then revaccinated annually, preferably three to four weeks before kidding. Bucks should also be included in the vaccination protocol.

Botulism

Botulism, a fatal paralysis resulting from the ingestion of the preformed neurotoxin produced by *Clostridium botulinum*, has been reported in goats but is uncommon.

Etiology and Pathogenesis

Clostridium botulinum is an anaerobic, Gram-positive, spore-forming rod found in soil and vegetation and as a normal inhabitant of the intestine of various livestock species including poultry. Seven neurotoxin types (A–G) of *Clostridium botulinum* are known along with different subtypes. As in cattle, botulism in goats is caused principally by types C_β and D. Spores revert to the vegetative state under suitable anaerobic conditions and produce an extremely stable neurotoxin. Bacterial proliferation and toxin production commonly occur in infected, decomposing carcasses and decaying vegetation contaminated with *C. botulinum*. Livestock become ill after consuming preformed toxin. Ingested toxin is absorbed from the intestine and reaches the nervous system via the blood. The toxin acts primarily on lower motor neurons, interfering with the release and function of acetylcholine, the principal neurotransmitter. The result is a general flaccid paralysis that includes the diaphragm and leads to death by asphyxia.

In experimental type C_β botulism in goats, clinical signs usually appeared on day two or three after oral administration of toxin. Doses as small as 0.5 minimum mouse lethal dose (MMLD)/g of bw were fatal and a cumulative toxic effect was observed when small doses were fed over eight days. Goats that grazed pasture or ate silage tolerated higher challenges than goats receiving hay and concentrate, suggesting a protective effect of green forage (Fjøelstad 1973). In another experimental study, goats were given type C botulism toxin subcutaneously in doses ranging from 15.6 to 500 LD/kg bw. Goats given doses of 250 or 500 LD/kg bw died at forty-two to forty-six hours post inoculation. Goats given 31.3, 62.5 or 125 LD/kg bw developed subacute disease, while the goat receiving 15.6 LD/kg developed a chronic form of the disease, indicating that clinical response in goats is dose dependent. Toxin was only detectable by the mouse toxicity test in goat serum at the highest dose administered (Santos et al. 1993).

Epidemiology

There is little information on the incidence of botulism in goats throughout the world. In South Africa, where cattle botulism is considered common and is frequently associated with gnawing on the bones of carrion as a result of phosphorus deficiency, botulism in Angora goats is reported, but is comparatively rare. In contrast to cattle, all reported cases in Angora goats were associated with contaminated feed, either milled lucerne containing rodent carcasses or poultry litter containing dead chickens (Van Tonder 1975). In Senegal, a water-borne outbreak of type D botulism killed fifty goats, one hundred sheep, ten cattle, and five horses. The source of toxin was identified as a dead mammal contaminating the well (Thiongane et al. 1984). In a more recent report from South Africa, type D botulism was confirmed in a mixed flock of sheep and Boer goats via the mouse toxicity test using intestinal contents from one of the affected sheep (van der Lugt et al. 1995). Most affected goats and sheep in that outbreak were found dead without first exhibiting clinical signs, or had a short course of disease lasting two to twelve hours.

Clinical Findings

The duration and severity of disease depends on the dose of toxin ingested and can range from peracute to chronic. In experimental caprine botulism (Fjøelstad 1973), early signs include a hoarse character of the voice, depression, anorexia, difficulty in chewing, sali-

vation, and a reluctance to stand. When forced to stand, goats show trembling of the limb muscles and stiffness in the hindquarters, and lie down immediately when permitted. Some show an abdominal respiratory effort. Hypersensitivity to light may be seen. As the disease progresses, animals are unable to stand due to flaccid paralysis, but remain sternal. This progresses to lateral recumbency and death, sometimes as early as two days after toxin ingestion. Recoveries are possible after a prolonged illness when low doses of toxin are initially ingested.

In the clinical outbreak reported from South Africa, death without clinical signs was the most common presentation. Goats that did show clinical signs initially showed restlessness, reluctance to move, a stiff gait, muscle tremors, grinding of the teeth, salivation, foaming at the mouth, and pupillary dilatation. They then became recumbent, exhibited paddling of the limbs, and died within minutes to a few hours of lying down (van der Lugt et al. 1995).

Clinical Pathology and Necropsy

There are no characteristic clinicopathological laboratory abnormalities in botulism and no specific necropsy findings because the neurologic lesion is functional rather than physical. Grossly affected animals may show a variety of lesions: congestion of the carcass; some ascites, hydrothorax, and hydropericardium; pulmonary congestion and emphysema; and petechiation of the ruminal, abomasal, and duodenal mucosa (van der Lugt et al. 1995). Stomach contents and suspect feedstuffs may be tested for presence of toxin by toxin neutralization assays in laboratory animals, usually mice. However, distribution of toxin in feeds may be patchy, and ingested toxin may already have been absorbed from the gut, so these tests are often unrewarding in addition to being costly and time-consuming. The blood of goats is unlikely to contain sufficient toxin to be a useful sample for animal challenge studies (Santos et al. 1993). Culture of the organism from feeds or the tissues of affected animals may be misleading, because the organism may be present without participating in disease.

Diagnosis

In most cases, the diagnosis of botulism is presumptive based on identification of a feed source contaminated by likely sources of *C. botulinum*, such as rodent and bird carcasses, in conjunction with a characteristic syndrome of rapidly progressing generalized weakness. Several other conditions should be considered in the differential diagnosis. Enzootic muscular dystrophy should be responsive to vitamin E and selenium therapy in the early stages. Milk fever in lactating does should respond to calcium therapy. Tick paralysis may appear similar, but ticks should be identifiable on the affected goat. The paralytic form of rabies should be considered and can be confirmed at necropsy. Skeletal trauma and spinal cord damage can be ruled out by careful physical examination and supported by radiographs or other imaging techniques.

In the reported South African outbreak, sudden death was the predominant presentation, and the necropsy findings suggested that heart failure was contributory to that outcome. Therefore, the differential diagnosis also included plant poisonings caused by cardiac glycoside- and monofluoroacetate-containing plants, gousiekte-inducing shrubs, and ionophore toxicity (van der Lugt et al. 1995). These cardiotoxic agents are discussed further in Chapter 8.

Treatment

The prognosis is grave in botulism. If type-specific or polyvalent antitoxin were available, it might be useful given early on, but there is little documentation for this in the veterinary literature. Animals with slowly progressive disease may recover gradually over many weeks. Supportive care is necessary and includes maintenance of hydration, tube feeding, slinging or frequent shifting to avoid decubital ulcers, and in extraordinary cases, ventilatory support when the diaphragm is paralyzed.

Control

Because the disease appears to be sporadic in goats, control measures are limited. In cattle, it is recommended that grazing animals be provided adequate protein and phosphorus in the diet to reduce osteophagia. At the least, feed and water supplies should be routinely examined to identify the presence of dead rodents and waterfowl and poultry litter should be fed cautiously. Vaccination can be protective, but is not widely practiced. If goats are vaccinated, a bivalent C and D toxoid should be used.

Clostridium perfringens type D Enterotoxemia

Disease due to *Clostridium perfringens* type D is associated mainly with hemorrhagic enteritis and/or sudden death in goats and is discussed in detail in Chapter 10 in the section on Enterotoxemia.

However, clinical signs of neurologic disease, such as opisthotonos and convulsions, are sometimes observed in cases of enterotoxemia, particularly in calves and lambs (Rings 2004). At necropsy, sheep show a characteristic brain lesion, cerebellar microangiopathy, that is considered pathognomonic for the disease in sheep (Buxton et al. 1978). Until recently, neurologic manifestations of enterotoxemia in goats have been poorly documented. Then, Uzal et al. (1997) reported on the histologic findings of cerebellar microangiopathy with perivascular edema in two goats in Australia which died suddenly and were confirmed

with type D enterotoxemia. One goat also demonstrated bilateral symmetrical foci of encephalomalacia in the cerebellar peduncles. Similar histologic findings were subsequently reported from a goat with confirmed enterotoxemia in Brazil (Colodel et al. 2003).

Epsilon toxin of *C. perfringens* type D is not a direct neurotoxin and the pathogenesis of neurologic signs and brain lesions in ruminants with type D enterotoxemia is not fully understood. Experimentally, young goats given high doses of epsilon toxin showed clinical neurologic signs of paddling, opisthotonos, and convulsions, but no brain lesions, while lambs given similar doses showed similar clinical signs and histologic lesions of perivascular edema (Uzal and Kelly 1997). In a related experiment, goat kids were given whole cell cultures of *C. perfringens* type D intraduodenally and these kids did develop characteristic brain lesions, suggesting the possibility that, at least in goats, CNS manifestations of enterotoxemia may be associated with bacterial components other than or in addition to epsilon toxin (Uzal and Kelly 1998).

Meningoencephalitis and Brain Abscesses

Meningoencephalitis in goats can be bacterial or thermal. The latter occurs due to injudicious use of a hot disbudding iron during horn bud removal in the kid. Brain abscesses occur only sporadically in goats.

Etiology and Epidemiology

Bacterial meningoencephalitis is most commonly seen in young kids, occurring as a sequela to neonatal septicemia arising from navel infection. Meningoencephalitis may be the only manifestation of septicemia, or it may be one of a constellation of signs including omphalophlebitis, polyarthritis, pneumonia, diarrhea, and endotoxic shock. Neonatal septicemia is a major cause of kid mortality worldwide but the frequency of CNS involvement is not well established (Sherman 1987). Sporadic cases of meningoencephalitis can also be seen in mature goats.

Multiple factors contribute to the high frequency of bacterial infections in young kids. They include failure of passive transfer of maternal antibodies caused by inadequate colostrum intake by neonates, failure to treat the navel with antiseptics after birth, poor environmental sanitation caused by overcrowding, inadequate drainage or insufficient bedding, and stresses of weather and poor nutrition, among others.

The most commonly involved bacterium in septicemia and subsequent meningoencephalitis is *E. coli*, but other *Enterobacteriaceae* may be isolated as well. In addition, *Streptococcus zooepidemicus* has been identified as the cause of meningoencephalitis in a yearling goat (Gibbs et al. 1981). Cryptococcosis of the CNS has been reported in goats in Brazil (Santa Rosa et al. 1987).

Listeria monocytogenes may occasionally produce a general meningoencephalitis, but is more commonly associated with focal brain stem lesions. *Corynebacterium pseudotuberculosis* and *Arcanobacterium pyogenes* may occasionally cause meningoencephalitis secondary to extension of infection from superficial lymph node and soft tissue abscesses of the head and neck. There is also a single case report of pyogranulomatous meningoencephalitis in a goat due to *Corynebacterium ulcerans* (Morris et al. 2005). Meningitis also may occur during mycoplasma septicemia in goats (East et al. 1983).

A major noninfectious cause of meningoencephalitis in kid goats is the removal of horn buds with a hot, usually electric, disbudding iron. In contrast to calves, the frontal bone of kids is thin and the frontal sinuses are undeveloped. Excessive heat or prolonged application of the disbudding iron to the skin and horn bud can lead to thermal damage of underlying bone, meninges, and brain. Proper techniques for disbudding are discussed in Chapter 18.

It has been stated that cerebral abscesses caused by *Staphylococcus aureus, Fusobacterium necrophorum*, and *Arcanobacterium pyogenes* are common in both sheep and goats (Brewer 1983). However specific studies on the etiology and pathogenesis of brain abscesses in goats are lacking. As in other ruminant species, goats may be predisposed to pituitary abscesses of hematogenous origin by the presence in ruminants of the rete mirabile, a complex mass of capillaries surrounding the pituitary gland. Five such cases are documented in goats (Lomas and Hazell 1983; Pedrizet and Dinsmore 1986).

Pathogenesis

Bacterial infections are most likely to involve the leptomeninges, choroid plexus, and ventricular walls, and not penetrate into the parenchyma, so that any encephalitis that occurs tends to be superficial. It is speculated that in septicemic animals, bacteria become established on these membranous surfaces via transport within blood monocytes destined to develop into CNS macrophages that normally reside on these membrane surfaces (Cordy 1984). Meningoencephalitis can be focal or diffuse. When the spinal meninges are involved, extension of inflammation to the nerve roots can also occur. In thermal meningoencephalitis caused by disbudding, the lesions are usually focal in the frontal region of the cerebrum. Thermal lesions alone can account for the neurologic dysfunction that occurs, but bacterial invasion also can occur secondary to thermal necrosis of skin and bone overlying the brain (Wright et al. 1983) and infection should be considered as a likely sequela when managing thermal necrosis cases associated with hot iron disbudding (Thompson et al. 2005).

Factors leading to the development of cerebral abscesses in goats are not well defined. The behavioral pattern of frequent head butting with the potential for traumatic injury and the common practice of hot iron disbudding of kids are likely contributors to the potential development of abscesses in young goats. Hematogenous spread from focal or generalized infections is also possible, as in the pituitary abscess syndrome. The clinical signs that develop in cases of brain abscess depend on the size and location of the abscess, and are highly variable. In one instance, a cerebellar abscess in a Nubian doe led to rostral transtentorial herniation of the brain (Kornegay et al. 1983). In another case, a pyogranuloma involving the cerebellum, cerebellar peduncles, and pons in a six-year-old goat appeared to have been an extension of a middle ear infection. In that case, the clinical signs were suggestive of vestibular dysfunction and included circling, vertical nystagmus, and head tilt (Morris et al. 2005).

Clinical Findings

Fever is common in bacterial meningoencephalitis and may also occur in the thermal form. Not all possible signs of meningoencephalitis are seen in all cases. Variability depends on whether the lesions are focal or diffuse, and mild or severe. Possible signs include mania or an anxious expression, trismus, cutaneous hyperesthesia, and hypersensitivity to sound. Muscular spasms or rigidity may also be observed or palpated, especially over the neck and back. Recumbent animals may show extensor rigidity of the limbs, opisthotonos, and convulsions.

In goats, depression occurs more often than mania. Incoordination, paraplegia, and coma are common signs. Blindness is also frequently reported in affected kids, and may be accompanied by hypopyon. When hypopyon is not obvious, fundic examination may reveal papilledema and vascular congestion. While mortality is generally high, spontaneous recoveries from thermal meningoencephalitis have been reported (Sanford 1989).

Kids with signs of meningoencephalitis should be examined for other evidence of septicemia, particularly omphalophlebitis; pneumonia; and hot, swollen joints. Frequently animals with thermal meningoencephalitis may show no prodromal signs and die suddenly hours to weeks after disbudding injury is incurred.

Though variable, signs most often associated with brain abscesses include mental depression, clumsiness, head pressing, blindness, and intermittent attacks of motor irritation, including convulsions (Radostits et al. 2007). In pituitary abscess syndrome, dysphagia, blindness, abnormal pupillary responses, and reduced jaw tone are the most common signs (Pedrizet and Dinsmore 1986).

Clinical Pathology and Necropsy

Characteristic changes in the CSF caused by meningoencephalitis include an increase in white blood cells, particularly neutrophils, and an elevation of the total protein. Bacteria may also be present in the CSF. In severe cases, the CSF may be visibly cloudy on collection. Gram stain of the CSF sediment can be helpful in guiding therapy while cultures are pending.

Brain abscesses that may occur deep in the parenchyma of the brain may not induce inflammatory changes in the CSF. The inflammatory response may be reflected in the hemogram in both meningoencephalitis and brain abscesses. Kids with meningoencephalitis are often hypogammaglobulinemic.

Meningoencephalitis is usually detectable grossly at post mortem as thickening, cloudiness, and hemorrhage of the meninges along with hyperemia and congestion of the adjacent brain tissue. In early cases, histologic examination may be necessary to identify active inflammation. Signs of septicemia may be observed in other tissues, such as hemorrhage of serosal surfaces and cloudy joint fluid. Bacterial culture of liver, heart blood, and CSF should be carried out when there is a potential herd problem. In thermal meningoencephalitis, obvious focal, circular, necrotic, fibrinous lesions of the frontal bones (Figure 5.6) and underlying meninges and cerebrum will be observed, representing
Figure 5.6. Circular lesions of the skull associated with excessive heat applied to the head during a thermal disbudding procedure with a hot iron. (From Wright et al. 1983. Reproduced by permission of Veterinary Medicine Publishing Company.)

the points of application of the disbudding iron. Focal abscesses are revealed by systematic serial section of the brain or inspection of the sella turcica.

Diagnosis

The presumptive diagnosis of meningoencephalitis in young kids is based on typical clinical signs in conjunction with a history of recent hot iron disbudding or identification of management factors that predispose to septicemia. Meningoencephalitis and brain abscesses can virtually always be confirmed by post mortem examination, and this is the most common method of diagnosis for the latter.

Treatment

The prognosis is guarded in meningoencephalitis, but early, aggressive intervention can result in some successful outcomes. Antibiotic therapy is indicated in all cases of meningoencephalitis because there is evidence of secondary bacterial invasion even in cases initiated by thermal injury. Resolution of brain abscesses with antibiotic therapy is rarely achieved.

Treatment should be initiated using broad spectrum, bactericidal antibiotics until culture and sensitivity results are available to guide therapy. Several antibiotics have been recommended for use in ruminants with Gram-negative bacterial meningitis (Jamison and Prescott 1988).

Trimethoprim-sulfonamide combinations are recommended for intravenous use at doses of 16 to 24 mg combined/kg at least every twelve hours. Third generation cephalosporins such as cefotaxime or moxalactam can be used intravenously at 50 mg/kg two to four times a day. Gentamicin can be used at a dose of 3 mg/kg intravenously or intramuscularly three times a day either alone or in conjunction with trimethoprim-sulfonamide combinations, cephalosporins, ampicillin, or penicillin.

The recommended dose for sodium ampicillin is 10 to 50 mg/kg intravenously or intramuscularly given four times a day. The dose for sodium penicillin G is 20,000 to 40,000 IU/kg given intravenously four times a day. Penicillin or ampicillin should not be used alone when there is any likelihood of Gram-negative bacterial involvement, but they are usually effective alone in streptococcal infections. The duration of antibiotic therapy depends to a large extent on the clinical response, but should extend for at least forty-eight hours after the goat appears normal.

Antibiotics should be administered in cases of thermal meningoencephalitis associated with hot iron disbudding. In one report from New Zealand, eighteen of 150 kids showed altered mentation two days after hot iron disbudding and were treated with a single dose of long acting oxytetracycline. On the next day, an additional twelve of the 150 disbudded kids were found dead and five that were necropsied had lesions of cerebral infarction beneath the disbudding sites. It was concluded that the eighteen goats treated the day before also had thermal injury but survived because of the antibiotic therapy which had been given (Thompson et al. 2005).

Nonsteroidal anti-inflammatory drugs are also indicated, including phenylbutazone at a dose of 10 mg/kg given once daily or flunixin meglumine given intravenously or intramuscularly at 1 to 2 mg/kg every twelve hours. Aspirin can be given to goats with a developed rumen at a dose of 100 mg/kg orally every twelve hours.

Affected animals should be kept in quiet, dimly lit, well-bedded surroundings. They should be turned frequently if recumbent to minimize decubital ulcers and hypostatic congestion of the lung. If excitatory signs are present, anticonvulsant therapy or sedation may make the animal more comfortable and manageable as described earlier for tetanus.

Control

When bacterial meningitis is confirmed in kids, a careful review of kid rearing techniques with the owner or herdsperson is necessary to identify deficiencies in management. Special attention must be paid to identifying problems of overcrowding and poor sanitation, inadequate disinfection of navels, and failure of transfer of passive immunity, as discussed in Chapter 7. Serious kid losses caused by septicemia and meningitis have been reported in herds in which kids were deprived of colostrum and instead fed commercial products advertised as colostrum supplements (Scroggs 1989; Custer 1990).

Veterinarians should provide information to clients on the risks of hot iron disbudding and the proper techniques for performing it. If thermal meningoencephalitis does occur in a herd, the veterinarian should ask to be present at subsequent disbudding sessions to identify any problems associated with the disbudding iron or its application. Despite the potential problems of thermal meningoencephalitis, hot iron disbudding still remains the most efficient, reliable way to prevent horn growth when done properly. It has been recommended that a dose of broad spectrum antibiotic be given to kids prophylactically at the time of hot iron disbudding, because some of the losses that occur may be due as much to secondary infection of the meninges and brain entering through devitalized tissue as to the thermal lesion itself (Thompson et al. 2005).

PARASITIC DISEASES

Parelaphostrongylosis and Elaphostrongylosis

Infection with the meningeal worm *Parelaphostrongylus tenuis* is subclinical in its only definitive host, the

whitetail deer. In aberrant hosts, including goats, sheep, llamas, and other wild cervids, clinical signs of focal myelitis or encephalomyelitis are produced. The disease is restricted to North America.

In Norway, a similar clinical syndrome of cerebrospinal nematodiasis in goats has been identified. The condition results from infection with *Elaphostrongylus rangiferi*, the elaphostrongyloid nematode of reindeer (Handeland and Sparboe 1991). Though not completely elucidated, the natural history of this disease in goats appears quite similar to parelaphostrongylosis as seen in North America.

More recently, a similar clinical syndrome has been reported in goats in Switzerland associated with *Elaphostrongylus cervi*, the elaphostrongyloid nematode of several species of Eurasian deer, including red deer, roe deer, maral deer, and sika deer.

Etiology and Pathogenesis

Parelaphostrongylus tenuis is a hair-like nematode in the family *Protostrongylidae.* The definitive host is the whitetail deer, *Odocoileus virginianus.* The parasite has an indirect life cycle that involves terrestrial slugs and snails as intermediate hosts. Adult worms reside in the subdural spaces and cranial venous sinuses of the CNS of deer. Eggs laid on the meninges hatch, enter the circulation, and localize in the lungs. Eggs laid in the venous sinuses are carried to the lungs and hatch there. In either case, larvae migrate up the airways, are swallowed, and passed in the deer's feces. They are subsequently ingested by gastropods where they develop into infective larvae over a three- to four-week period. Infective larvae are released from snails and slugs when the gastropods are ingested by grazing mammals. In the deer, larvae penetrate the intestine and migrate to the spinal cord through the peritoneum, reaching the CNS within ten days where they mature in the dorsal horns of spinal gray matter for an additional twenty to thirty days. Adults then travel to the subdural space, migrate to the cranium, and penetrate the dura mater to enter the venous sinuses, thus completing the life cycle.

When infective mollusks are ingested by goats and other aberrant hosts, migration to the spinal cord via the peritoneum also takes place over a ten-day period. However, beyond this point, the normal life cycle goes awry. Maturation of larvae is erratic, and subsequent migrations through the spinal cord are random and unsuccessful in reaching the cranial venous sinuses. Randomly migrating larvae are responsible for the parenchymal destruction and inflammation that leads to clinical neurologic disease in aberrant hosts. The wide variety of neurologic abnormalities observed in clinical cases reflects the frequently multifocal nature and diverse distribution of lesions in the spinal cord or brain. The goat is able to control *P. tenuis* infection in some cases, as recovery has been observed in experimentally challenged animals and in natural outbreaks. In kids experimentally infected orally with 200 or more larvae, severe colitis and peritonitis developed within four to eleven days of infection caused by larval migration through the intestinal wall (Anderson and Strelive 1969). The occurrence of peritonitis in naturally occurring goat cases has not yet been reported.

The life cycles of *E. rangiferi* and *E. cervi* are similar to that of *P. tenuis*, involving gastropods as intermediate hosts. The life cycle of these parasites is completed without damage to the natural hosts, but in goats, as with *P. tenuis*, the life cycle is not completed and aberrant migration through the spinal cord and brain results in clinical disease. Experimental challenges of goats with *E. cervi* did not produce patent infections (Scandrett and Gajadhar 2002)

Epidemiology

Cerebrospinal nematodiasis caused by *P. tenuis* is restricted to North America, reflecting the geographic distribution of the definitive host. The whitetail deer originally was concentrated in the eastern United States and Canada but now has spread throughout much of the two countries and into northern Mexico.

The deer favors forested areas as natural habitat, and commonly grazes pastures and croplands adjacent to woodlands. Goats grazing pastures where deer feed are at increased risk of exposure to *P. tenuis.* Although the intermediate gastropod hosts are terrestrial, there appears to be increased risk of exposure to snails and slugs in low-lying, wet, and poorly drained fields and pastures.

Cool, moist weather is believed to enhance the infectivity of the first stage larvae passed by deer and to promote the activity of intermediate host snails. Pastures in the northern half of North America are most dangerous during late summer to early fall and most cases of clinical disease in goats are seen in fall and early winter. In Texas, clinical disease has been reported in April (Guthery et al. 1979). Additional reports of *P. tenuis* in goats have come from Minnesota, Michigan, and New York (Mayhew et al. 1976; O'Brien et al. 1986; Kopcha et al. 1989). It can be presumed that grazing goats are at risk wherever whitetail deer are found.

In experimental infection of goat kids, clinical signs of neurologic disease appeared between eleven and fifty-two days after introduction of infective larvae into the peritoneum (Anderson and Strelive 1972). In natural infection, onset of clinical signs has been noted as late as nine weeks after removal of goats from pasture. Morbidity rates in affected herds have been reported from 10% to 27%, with mortality rates as high as 65%.

Elaphostrongylus rangiferi is naturally found in reindeer in Scandinavia, and the disease has been well

documented in goats in Norway (Handeland and Sparboe 1991). The parasite was introduced into Canada in the early 1900s with the importation of reindeer into Newfoundland. As a result, native caribou herds and moose in Canada became infected (Lankester and Fong 1979). Therefore, the potential for goat cases exists in North America as well. Clinical and pathological findings of experimental infections of goats with *E. rangiferi* have been reported (Handeland and Skorping 1992, 1992a, 1993).

Elaphostrongylus cervi is naturally found in Europe and western Asia in a number of native cervids but was introduced into New Zealand through the importation of red deer (Mason et al. 1976). There are several well documented case reports of cerebrospinal nematodiasis due to *E. cervi* from Switzerland (Pusterla et al. 1997, 1999, 2001).

Aberrant hosts such as the goat are most commonly exposed to these parasites by grazing on pastures that also have been grazed by infected wild ungulate hosts. Goats grazing on these contaminated pastures ingest gastropods that contain infective larvae. As this occurs most commonly in summer and early fall, clinical cases of disease are seen most commonly in late fall and winter.

Clinical Findings

All breeds, sex, and ages of goats can be affected. Animals usually have been on pasture within the past two months. Observation of deer on pasture can often be elicited in the history. Affected animals can have a variable history regarding duration of signs, ranging from a gradual progression of lameness or paresis over several days to a sudden onset of recumbency since the previous day. Angora goats on range have been found dead, entangled in brush, presumably because of limb weakness and locomotor difficulties associated with spinal lesions.

The most common clinical presentations suggest involvement of the spinal cord. Signs include paresis or paralysis of one or more limbs, ataxia, postural reaction deficits, knuckling, toe dragging, abnormal gait, limb weakness, recumbency in a dog-sitting posture, or inability to rise. Any combination of forelimb and hind limb involvement is possible. Reflex responses, muscle tone, and the presence of muscle atrophy are variable, depending on the degree of upper and lower motor neuron involvement. Affected animals may get progressively worse, remain static, or in some cases improve without therapeutic intervention. In most cases they remain mentally alert and continue to eat and drink normally. Pruritus and linear excoriations of the skin may be noted if the larvae migrate through dorsal nerve roots.

Indications of brain involvement in affected goats include circling and blindness, separation from the flock, abnormal posture, and head tilt. Hypopyon has also been noted.

The duration and severity of clinical signs vary. Animals that remain ambulatory should be given at least one month to demonstrate if they will stabilize or recover. Animals unable to rise have a poorer prognosis.

Clinical Pathology and Necropsy

Affected animals frequently have a moderate increase in total protein and white blood cell counts in the CSF with eosinophils frequently noted. In one study of fourteen cases, CSF protein concentration ranged from 29 to 360 mg/dl with a median of 69.5 mg/dl. The white blood cell counts ranged from 0 to 1,000/mm^3 with a median of 54/mm^3. Eosinophils were present in CSF in 57% of cases (Smith 1982). Hemograms are usually normal. The life cycle of *P. tenuis* is not completed in aberrant hosts. Therefore, first stage larvae are not found in the feces of goats.

No serologic tests are currently available commercially, but the potential for serologic diagnosis exists. In experimental infection of two goat kids, antibodies to *P. tenuis* were detectable in the serum and CSF using ELISA. Serum antibodies were detectable before, during, and after the onset of clinical signs and peaked at eight weeks post infection. CSF antibodies peaked at five to eight weeks post infection (Dew et al. 1992).

There are no gross lesions associated with *P. tenuis* infection except perhaps neurogenic muscle atrophy. After preservation of tissue in formalin, however, focal asymmetrical areas of whitish discoloration may be observed in the spinal cord on cut section. Some of these areas may have a greenish tinge and are the most likely areas to find evidence of the parasite itself (Mayhew et al. 1976). Both L4 and L5 stages of *P. tenuis* have been identified in goat tissues, the latter containing reproductive structures.

Microscopically, lesions are usually confined to the spinal cord and brain stem. There are focal areas of malacia and necrosis, especially in white matter, with evidence of degenerating axons. Adjacent to malacic areas there is perivascular cuffing with lymphocytes, sometimes eosinophils, and occasionally plasma cells. The degree of general inflammation is mild, although focal granuloma formation has been reported (Kopcha et al. 1989). Hemorrhage is sometimes observed and a mononuclear or eosinophilic meningitis may occur.

Diagnosis

No definitive antemortem diagnosis is currently possible. Presumptive diagnosis is based on a history of goats grazing where deer are found, a seasonal occurrence of neurologic disease in goats with diverse

clinical signs, and the presence of eosinophils in CSF when found. Definitive diagnosis depends on identifying the parasite in nervous tissue at time of necropsy.

Treatment

Currently, there is no proven effective therapy for *P. tenuis* or *Elaphostrongylus* spp. in goats and other aberrant hosts. Reports of successful therapy to date must be viewed cautiously because no controlled studies have been reported and spontaneous recoveries are known to occur in untreated animals.

Diethylcarbamazine has been used at doses ranging from 40 to 100 mg/kg for one to three days, on the basis of its reported efficacy in treatment of cerebrospinal nematodiasis caused by *Setaria digitata* in Asia. However, this filarial worm is not a member of the family *Protostrongylidae* and has a different pattern of anthelmintic susceptibility. More recently, ivermectin has been a focus of therapeutic interest. However, studies in whitetail deer indicate no effect against *P. tenuis* once the larvae have entered the CNS, although larvae are killed during the preceding migration period (Kocan 1985). A newer avermectin, moxidectin, has higher lipid solubility and is more hydrophobic than other avermectins and may therefore be better able to cross the blood-brain barrier to reach nematodes already present in the CNS. Benzimidazoles, notably fenbendazole, also are used empirically, though levamisole has shown no efficacy (Nagy 2004). Steroid therapy may have some value in reducing inflammation in nervous tissue, although its effect on subsequent migratory or developmental activity of larvae is unknown. Nonsteroidal anti-inflammatory drugs such as flunixin meglumine have also been used empirically.

Combination of multiple anthelmintics and anti-inflammatory drugs is commonly reported in the treatment of cerebrospinal nematodiasis, perhaps reflecting the uncertainty of what actually is known to be effective (Nagy 2004). For example, there is a report of treatment of goats for clinical *Elaphostrongylus cervi* infections in seventeen goats using flunixin meglumine at 1.1 mg/kg bw IM and oral administration of fenbendazole at 50 mg/kg and ivermectin at 200 µg/kg SQ for five days (Pusterla et al. 1999). Eleven (64.7%) showed an immediate improvement in neurological signs. Three of them had a complete recovery while eight had some persistent ataxia. Six recumbent goats (35.3%) were killed because of a lack of response. It was concluded that the therapy was effective if neurologic deficits were not already severe when treatment was initiated.

Because goats have been known to recover spontaneously from cerebrospinal nematodiasis, affected animals should be allowed time to show signs of improvement when the situation permits. Supportive care is extremely important during that period. Because animals may be recumbent from paresis or paralysis, ample dry bedding is necessary and periodic lifting or slinging may be appropriate.

Control

Control methods are currently limited to reducing deer access to livestock grazing areas and reducing exposure of goats to gastropods and infective larvae. Practical means of reducing deer access are limited by regulations on hunting and the ability of deer to jump fences. It may be helpful to limit goat pasturing to fields without contiguous woodlands and to pastures that are on high ground and well drained. When feasible, goats should be removed from pasture earlier in the grazing season before weather turns wet and cool. No other practical means of snail and slug control have been reported.

Based on knowledge of the life cycle of the parasite and the effectiveness of ivermectin against migrating larvae, control is theoretically possible by anthelmintic prophylaxis every ten to sixteen days while goats are at pasture; this, however, is costly and may be impractical. It would be useful to have larvicidal anthelmintics that can be administered regularly and inexpensively during grazing periods to prevent entry of ingested larvae into the CNS. Benzimidazoles effective against the larval stages of other *Protostrongylidae* such as *Muellerius* that are available as salt or feed additives are potential candidates in non-lactating goats. Pyrantel tartrate has also been recommended for use in this manner because it is formulated to be fed on a daily basis (Rickard 1994). However, the regular use of anthelmintics to control cerebrospinal nematodiasis could contribute negatively to the growing problem of anthelmintic resistance in gastrointestinal nematodes, a far more common and costly problem.

Setariasis

The filarial worm *Setaria digitata* is nonpathogenic in definitive ungulate hosts, but can produce a cerebrospinal nematodiasis in goats, sheep, and other aberrant hosts in Asia. The disease is commonly referred to as lumbar paralysis or kumri. It is clinically similar to the conditions produced by *Parelaphostrongylus tenuis*, *Elaphostrongylus rangiferi*, and *E. cervi*.

Etiology and Pathogenesis

Setaria digitata is a non-pathogenic parasite of the peritoneal cavity of cattle, buffalo, and zebu. It occurs only in Asia. There was some debate whether *S. labiatopapillosa*, found in the peritoneum of cattle, antelope, deer, and giraffe, was a separate or identical species, but phylogenetic analysis now indicates that the two species are distinct (Jayasinghe and Wijesundera 2003). The life cycle of these filarids is not completely

understood, but is known to be indirect. Mosquitoes of various genera, including *Anopheles, Aedes,* and *Armigeres* spp., serve as the intermediate hosts.

In the definitive cattle host, adult worms live in the peritoneal cavity and produce microfilaria that circulate in the blood stream. Mosquitoes ingest the microfilaria along with blood during feeding. Within two weeks these microfilaria mature into infective larvae and enter the salivary glands of the mosquito. During subsequent feedings, they are introduced into the blood stream of new ungulate hosts. In the definitive host these larvae migrate to and mature to adults in the peritoneal cavity to complete the life cycle. In aberrant hosts such as the goat, sheep, and horse, the microfilaria migrate to the CNS, sometimes the eye, and occasionally the fetus of pregnant animals, where they cause mechanical damage and an inflammatory reaction. Clinical signs usually develop one month after infection. The life cycle is rarely completed in aberrant hosts, and microfilaria are not detectable in the blood stream.

Epidemiology

The disease was first suspected in imported goats in Japan in 1927, but the parasitic nature of the disease was not confirmed until much later. It has since been reported in goats in Japan, Korea, and Sri Lanka (Innes et al. 1952); India (Patnaik 1966); China (Wang et al. 1985); Taiwan (Fan et al. 1998); and most recently as a putative outbreak in Saudi Arabia (Mahmoud et al. 2004). The disease occurs as a seasonal epizootic; it is associated with increased numbers of mosquitoes. In Japan, most cases are seen in August and September, in China, June through October, and in India, September through December, after the rains and before winter. Morbidity rates can be high, with as many as 30% to 40% of susceptible animals affected. There appears to be some natural immunity in local animals, with higher morbidity and mortality observed in imported goats. The proximity of large cattle populations infected with *S. digitata* predisposes to infection of aberrant hosts.

The goat is considered an aberrant host for *S. digitata*. Microfilaria are introduced into the goat via the bites of mosquitoes and the parasite generally is considered not to reach maturity in this host. However, patent infections in Saudi goats have now been reported, with adult worms detected in five of forty-eight goats examined at a veterinary diagnostic laboratory. These animals did not show clinical signs of disease, but had male and female *S. digitata* in the abdominal cavities, mostly on the omentum as well as microfilaria in the blood (El-Azazy and Ahmed 1999). It was speculated that the genetic constitution of this local Saudi goat breed may be predisposed to establishment of patent infection.

Clinical Findings

All ages, sex, and breeds of goats may be affected. The appearance of clinical signs may be acute or subacute, and mild to severe. Variable outcomes occur, including acute death, progressive worsening of neurologic signs, stabilization of neurologic deficits, and occasionally spontaneous recovery. Most typically, affected animals show evidence of spinal cord involvement with ataxia, lack of proprioception, paresis, or paralysis. Any or all limbs may be affected, but most often hind limbs are involved. Sensory deficits are minimal. Additional signs suggesting brain involvement include cranial nerve deficits, nystagmus, and circling. In most cases, animals remain mentally alert. Fever is not observed.

Clinical Pathology and Necropsy

As with other parasitic infections of the CNS, eosinophilia of the CSF can occur in caprine setariasis. Gross necropsy lesions are rarely identified and diagnosis depends on thorough microscopic examination of the brain and spinal cord, concentrating especially on those areas that correlate with the clinical neurologic examination. In most cases only a single larva is involved, and rarely more than three. Microscopically, lesions are characterized by a focal malacia that can be identified in serial sections as the migratory tract or channel of the offending parasite. In adjacent areas there may be evidence of axonal degeneration, demyelination, astrocytosis, and perivascular cuffing with mononuclear cells and eosinophils. Hemorrhage is variable. Locating the actual offending larvae in histologic sections is uncommonly achieved.

Diagnosis

Antemortem diagnosis is presumptive based on the seasonal observation of epizootic neurologic disease characterized principally by locomotor dysfunction in countries where setariasis occurs. Definitive diagnosis depends on identification of the parasitic larvae in the CNS of affected animals at time of necropsy.

Treatment

The filaricide diethylcarbamazine can be effective in goats and sheep when animals are treated early in the course of disease. Early signs may represent meningeal irritation or radiculitis caused by the parasite before its entry into the brain or spinal cord and the parasite may still be susceptible to anthelmintic therapy at this stage. Diethylcarbamazine is given orally, suspended in water, once at a dose of 100 mg/kg bw, or at a dose of 40 to 60 mg/kg daily for one to six days (Shoho 1952, 1954). Once the parasite has crossed the meninges, response to therapy is poor. Avermectins may also

show efficacy against some species of microfilaria in other livestock species, but reports on use of ivermectins specifically against *S. digitata* in goats are lacking.

Control

To reduce the incidence of setariasis in aberrant hosts such as goats, the parasite should be controlled in the normal host, cattle, particularly at the beginning of the mosquito season. Because the infection is subclinical in cattle, routine treatment of cattle by farmers may be difficult to effect. When possible, goats should be housed separately from cattle. The use of diethylcarbamazine in sheep at an oral dose of 40 mg/kg given one time every three weeks before and during the mosquito season appeared to reduce the number of clinical cases observed in the field compared with untreated controls (Shoho 1954). Reduction of mosquito populations could also reduce the transmission of the parasite from cattle to goats.

Strongyloidosis

Strongyloides papillosus is a nematode parasite of ruminants normally associated with gastrointestinal parasitism. It is discussed in more detail in Chapter 10 in the section on nematode gastroenteritis. However, there were several outbreaks of mortality recorded in young kids and lambs in Namibia in which *S. papillosus* was identified as the cause. Of note in these outbreaks were the signs of neurologic disease in addition to the characteristic signs of gastrointestinal parasitism. Neurologic signs included gnashing of teeth, aimless wandering, and persistent head pressing against objects. The presence of neurologic signs was so unexpected that experimental challenge studies were undertaken to better characterize the clinical syndrome and the underlying pathology seen in the field and to confirm *S. papillosus* as the etiology (Pienaar et al. 1999).

In the experimental studies, some but not all challenged goats showed signs of CNS involvement in their clinical presentation. Signs included gnashing of teeth, wide based stance, ataxia, stupor, nystagmus, and head pressing ("pushing syndrome"). At necropsy, no gross lesions were seen in the CNS, but histopathologic lesions were found in the brain and spinal cord. These lesions were characterized as status spongiosus with marked vacuolation of the white matter but also in the gray matter and in some nuclei. The most common sites for lesions were the roof nuclear area of the cerebellum, corpus striatum, thalamus, and midbrain and medulla; less common sites included the cerebrum, granular layer of the cerebellum, spinal cord, and optic tracts. The severity of lesions was closely correlated with the presence of neurologic signs in challenged goats.

To date, neurologic signs associated with *S. papillosus* have not been reported elsewhere either under field conditions or in experimental challenge studies. It is not clear why neurologic disease was noted in these Boer cross goats in Namibia. Possible explanations include the intensity of the challenge dose; variations in breed susceptibility; or the presence of other toxic, metabolic, or infectious causes that were not recognized in the field outbreaks or the experimental animals. Further documentation of the occurrence of neurologic disease associated with *S. papillosus* infection is needed. When unexplained head pressing, ataxia, or gnashing of teeth is noted in goats, particularly if signs of gastrointestinal parasitism are present as well, then fecal samples should be checked for *S. papillosus* and goats that die should be necropsied with examination of the brain.

Coenurosis

Coenurosis, also known as gid, sturdy, or staggers, is a metacestodal infection of ungulates, especially sheep and goats. It primarily causes a focal encephalopathy.

Etiology and pathogenesis

The metacestode involved in this disease is the intermediate stage of the tapeworm of carnivores, *Taenia multiceps*, formerly known as *Multiceps multiceps.* The metacestode is identified in sheep as *Coenurus cerebralis* and in goats as either *C. cerebralis* or, historically, as *C. gaigeri.* It was thought that a separate species existed because cysts are frequently located outside the CNS in the goat. However, it is now believed that the difference lies with the host, not the parasite (Soulsby 1982).

T. multiceps is a large intestinal tapeworm of dogs, foxes, coyotes, and jackals. Eggs or gravid tapeworm segments are passed in the feces of the host, contaminate herbage, and are ingested by grazing ruminants. Embryos are released after ingestion and penetrate the small intestine, enter portal vessels, and are distributed widely throughout the tissues via the circulation. In sheep, only larvae that reach the CNS develop into metacestodes; all others die.

In goats, metacestode development occurs primarily in the CNS, but frequently in the skeletal musculature and the heart as well. The muscular form of the disease is discussed in Chapter 4. Cysts also have been found in mesenteric lymph nodes and there is a recent report of metacestode cysts within the eye of a goat (Islam et al. 2006). There is a period of migration through nervous tissue that may result in clinical signs of acute meningoencephalitis if large numbers of larvae are present. In most cases, however, this migratory phase is subclinical. After migration, the stationary phase of metacestode maturation lasts from two to

seven months. The mature metacestodes are cystic structures up to 7 cm in diameter, transparent, thin-walled, and filled with clear fluid. They contain up to several hundred scolices that are visible as white plaques on the clear cyst wall in excised cysts. The majority of mature cysts are located superficially in the parietal or frontal region of the cerebral cortex, but location is variable throughout the CNS and musculature. The life cycle of the tape worm is completed when carnivores ingest mature cysts while feeding on tissues of infected ruminants.

During early growth of cysts, irritation of adjacent nervous tissue occurs and may be reflected in some cases by early excitatory signs. As the metacestode enlarges, pressure on adjacent tissues increases, and neuronal death occurs, leading to signs of neurologic deficit. The pressure that develops is considerable and is reflected in a high incidence of papilledema and rarefaction of cranial bone adjacent to superficial cysts. Cerebrospinal fluid pressure also can be markedly elevated. The clinical signs that develop reflect the location of the cyst or cysts present.

Epidemiology

T. multiceps is present in carnivores worldwide, but coenurosis is not common in goats in most countries. There are numerous clinical reports originating from the Indian subcontinent. Thirty-two caprine cases were recorded in one year at a single veterinary institution in India (Saikia et al. 1987). A slaughterhouse survey in Bangladesh demonstrated a prevalence range of 1.9% to 13.3% for cerebral coenurosis (Ahamed and Ali 1972). Caprine coenurosis is sporadic in Europe and Africa (Harwood 1986). The disease is rare or absent in goats and sheep in North America, Australia, and New Zealand. The status of coenurosis in Africa and Asia has recently been reviewed (Sharma and Chauhan, 2006).

The disease is most commonly reported in young female goats, but this may reflect their disproportionately large presence in goat herds rather than a predilection to disease. Morbidity rates are low but mortality rates are high in untreated cases. The disease is infrequently reported in humans, with most documented cases reported from Africa. The goat is not directly involved in the zoonotic aspect of the disease.

Clinical Findings

Because of the prolonged development phase for coenurosis, cases may be seen anytime of the year. Affected animals may have a history of ill-defined, low-grade neurologic abnormalities for one month or longer. Animals with the neurologic form of the disease may show a variety of signs.

The clinical presentation is variable, but it has been suggested that there are three phases of development (Saikia et al. 1987). In the first stage, animals may be depressed and show intermittent periods of abnormal head carriage, especially head tilt. There may be short, intermittent convulsions or intermittent circling. This phase lasts four to eight days and may be overlooked. In the second phase, which usually begins eight to sixteen days after onset of signs, signs become more consistent. The most common findings are head tilt, unilateral blindness, circling, and loss of balance with a staggering gait. Some animals may show determined forward walking with the head held high and a hypermetric gait followed by head pressing against obstacles instead of circling. Other signs include grinding of the teeth, salivation, exophthalmos, nystagmus, and irregular rumen contractions. The third or terminal phase usually begins twelve to twenty-five days after onset of signs. Animals become recumbent, exhibit extensor rigidity, and paddle frequently with the hind limbs. These stages overlap considerably and the clinical course is frequently one month or longer.

Papilledema and hemorrhage of the optic papilla are common in coenurosis cases, so a fundic examination should be performed. In addition, firm, digital palpation of the head frequently identifies dissymmetry or softened areas of skull, suggestive of underlying superficial cysts. Digital pressure on such spots may exacerbate clinical signs. Cysts deep in the parenchyma are not associated with bony changes.

Recently a case of coenurosis was reported in a seven-month-old goat in Mongolia which presented with bilateral flaccid paralysis of the hind limbs. The goat had been at pasture and had actually been grazing for some time, dragging its hind limbs behind it. At necropsy, the goat had a metacestode cyst occupying the lumbar vertebral canal, extending along three vertebrae. Impingement of the spinal cord by this space occupying cyst accounted for the clinical signs (Welchman and Bekh-Ochir 2006).

Clinical Pathology and Necropsy

Total protein, cell counts, and pressure are often elevated in the CSF. Mean total protein in affected goats has been reported at 80.3 mg/dl, mean cell counts at 85/mm^3, and mean pressure at 262.4 mm water. Eosinophils and degenerative cells may be common on cytologic examination (Sharma and Tyagi 1975). Allergic skin testing has also been used with positive goats having a reaction of more than 1.2 cm.

Radiographs can reveal metacestode-associated rarefaction of the skull when bone softening has not yet reached the point of detection by digital palpation. Cerebral angiography has been used to identify deep parenchymal cysts in goats. The angiograph reveals stagnation of contrast material around the avascular zone of the cyst surrounded by concentric arches of displaced vessels (Sharma et al. 1974).

At necropsy, cysts ranging in size from 1 to 7 cm in diameter can be identified in predilection sites such as brain, spinal cord, and skeletal muscle.

Diagnosis

Though the clinical course is prolonged, it may not always be recognized as such, and animals may present as acute onset of circling, falling, or head pressing. The differential diagnosis should include listeriosis, CAE, polioencephalomalacia, brain abscesses, sinusitis, cerebral hematomas or tumors, cerebrospinal nematodiasis, and rabies. The nose bot, *Oestrus ovis*, may occasionally penetrate the frontal sinuses and produce a clinical syndrome known as false gid because the signs are similar to those seen in coenurosis.

Treatment

There are no known, consistently effective anthelmintic therapies for elimination of the metacestode in clinically affected animals (Sharma and Chauhan 2006). Praziquantel administered orally at dose of 50 mg/kg bw has given unreliable results in sheep. The drug was more reliably effective at a higher dose of 100 mg/kg given orally (Verster and Tustin 1990).

When bone softening is pronounced so the site of the cyst is obvious, aspiration of cyst contents is accomplished via an aseptic needle passed through the softened or perforated bone. Afterward, a mild antiseptic is introduced, such as 0.1% acriflavine solution. Surgical treatment is possible when bone is still firm but lesions are identifiable by radiography or other imaging techniques. The skull is opened over the area of the cyst and the cyst removed by first bluntly dissecting it from underlying brain tissue and then lifting it out either by application of suction or by a forceps. In two separate studies, 90% of thirty goats and 87.5% of sixteen goats survived and showed good recovery after surgery (Sharma and Tyagi 1975; Ahmed and Haque 1975). Either general or local anesthesia is used.

Control

Control methods involve reducing stray dog populations, restricting the feeding of small ruminant carcasses and offal to dogs, and ensuring strict, regular treatment of dogs kept with livestock for control of mature tapeworms. There are no vaccines commercially available, though research efforts suggest that vaccination could be useful in control of this disease.

Tick Paralysis

Ascending paralysis and death can result from the feeding activity of certain species of ticks on domestic animals including goats. The disease has been reported sporadically in goats in parts of Europe, the Middle East, and South America. It is considered a major constraint on small ruminant production in parts of South Africa where the disease is known as Karoo tick paralysis.

Etiology

At least thirty-one hard ticks in the *Ixodidae* family and six soft ticks of the *Argasidae* family can produce tick paralysis in mammals and birds. In goats, the condition has long been associated primarily with *Ixodes rubicundus* in South Africa, and then later with *Rhipicephalus punctatus* as well (Stampa 1959; Fourie et al. 1991). In Israel, Crete, Turkey, and Bulgaria, *Ixodes ricinus* causes the disease in goats (Hadani et al. 1971; Trifonov 1975). In 1983, tick paralysis was reported for the first time in Brazil, associated with *Amblyomma cajennense* (Serra Freire 1983).

Most reports of tick paralysis involve adult ticks rather than larvae or nymphs and when such ticks have a two- or three-year life cycle, disease outbreaks may be seen only every second or third year. In many cases, the immature tick stages show different host feeding preferences. For example, immature forms of *I. rubicundus* are found primarily on hares and shrews. This is not always the case, however; in Brazil, there is experimental evidence that larval and nymphal stages of *A. cajennense* may also produce the disease. Development of disease appears to be less associated with the number of ticks actually feeding than with the stage of engorgement of the ticks present on the host.

Epidemiology

The incidence of tick paralysis is tied to the life cycle and ecology of the offending ticks and conditioned by livestock management and grazing practices. For example, in Israel, the disease is seen only every third year between December and February when adult ticks are active, and only in the more temperate, inland regions of the country. It usually occurs only in flocks or herds grazing on the more densely vegetated, northern slopes of hills and not the barer, southern slopes (Hadani et al. 1971). In South Africa, Karoo tick paralysis is also seen primarily in the winter months (March to August), on the moister, hillier portions of the Karooveld and tick densities vary with different vegetation types (Stampa 1959). The *Rhipicephalus*-associated disease is seen in September through November and again in February in South Africa. In Brazil, naturally occurring cases were observed between June and December.

Morbidity and mortality can be high in epizootics of tick paralysis. For example, fourteen of fifty-one (27%) South African Angora kids younger than one month of age developed paralysis while grazing over a two-week period in September, and 71% of these died even after ticks were removed (Fourie et al. 1988).

Pathogenesis

Though not proven in all cases, it appears that ticks responsible for paralysis produce a salivary neurotoxin that is introduced into the host animal during active feeding, particularly when the tick reaches a certain stage of engorgement. At least in tick paralysis of dogs infested with *Dermacentor* spp., the toxin is known to interfere with acetylcholine liberation at the neuromuscular junction. In all cases there is a resulting flaccid paralysis that first involves the limbs and may progress to involve the diaphragm with animals dying of respiratory compromise.

The author could not find reports of tick paralysis in goats in North America. However, the disease is reported in cattle, sheep, and New World camelids in western Canada and the western United States, in association with *Dermacentor* and *Argas* spp. ticks, so veterinarians in North America should consider the disease a possibility in goats (Schofield and Saunders 1992; Cebra et al. 1996).

Clinical Findings

The disease is seen most often in grazing animals infested with ticks. Ticks are most common around the head and neck, especially in the ears, and around the tail head, but the entire body should be inspected. Affected goats show evidence of lower motor neuron involvement including muscular weakness of the limbs, unsteady gait, knuckling, ataxia, and hypoesthesia. There is no fever, and animals often remain bright and alert and they continue to eat. Frequently the hind limbs are affected first, but all four limbs may be affected simultaneously, especially in Karoo tick paralysis. As the disease progresses the animal becomes laterally recumbent due to flaccid paralysis. In terminal cases, death is caused by respiratory paralysis or aspiration pneumonia. The clinical course is usually one to three days. If ticks are identified and removed early in the course of disease, before recumbency, many but not all animals recover completely within twenty-four hours.

Clinical Pathology and Necropsy

There are no clinical pathological or necropsy findings that support the diagnosis of tick paralysis, save for the presence of offending species of ticks.

Diagnosis

Diagnosis is presumptive on the basis of identification of ticks known to cause tick paralysis on affected goats under circumstances of likely occurrence. The differential diagnoses for progressive limb paralysis in goats include rabies, enzootic ataxia or swayback, CAE, botulism, cerebrospinal nematodiasis, vertebral trauma or abscesses, and congenital spinal abnormalities. Intramuscular injections affecting the sciatic nerves, nutritional muscular dystrophy, and skeletal trauma must also be considered in sudden loss of mobility in the hind limbs.

Treatment and Control

The only known treatment is removal of feeding ticks and supportive care. Knowledge of the ecology of offending ticks may be used to restrict grazing in high-risk areas during seasons of known adult tick activity. When this is not possible, tick control with the use of topical acaricides is indicated during the high-risk seasons.

NUTRITIONAL AND METABOLIC DISEASES

Polioencephalomalacia

Also known as cerebrocortical necrosis, this nutritional/metabolic disease primarily affects ruminants, including goats. The disease in goats is increasingly recognized under intensive management conditions when goats are fed more grain concentrate feed to encourage accelerated growth or increased production.

Etiology and Pathogenesis

Strictly speaking, polioencephalomalacia (PEM) is a descriptive term for a softening of the gray matter of the cerebral cortex, also referred to as cortical necrosis. The term does not inherently ascribe a particular etiologic basis for the occurrence of such a lesion. Yet, over the years, the term has become closely linked in veterinary medicine to a specific syndrome of ruminants believed to be caused by disturbances of thiamine (vitamin B$_1$) metabolism and which occurs most commonly in feedlot cattle on high concentrate rations. In recent years, however, there has been a serious movement away from the use of the term to describe a specific disease associated with alterations in thiamine metabolism, largely because other distinct diseases can cause the same lesion of polioencephalomalacia. These include lead poisoning, sulfur toxicity, and salt poisoning/water deprivation.

There are several reasons for the traditional association of PEM with thiamine. In ruminants, thiamine is produced by the activity of rumen bacteria and dietary sources of the vitamin are not required under normal conditions. PEM is most commonly seen in cattle in feedlots on high grain rations. It is documented that when the pH of the rumen is reduced, as occurs with the feeding of grain rations, rumen bacteria that produce thiamine are reduced in numbers while other bacteria which produce thiaminase, an enzyme that degrades thiamine, are increased. It is also documented that in experimental studies and field cases of PEM, there may be markedly decreased concentrations of

thiamine in body tissues, decreased activity of a thiamine pyrophosphate-dependent enzyme, transketolase, in blood, and increased levels of thiamine-destroying thiaminases in the gastrointestinal tract (Gould 1998).

But perhaps the most compelling argument for the belief that thiamine plays a central role in the pathogenesis of PEM has been that administration of thiamine to clinical cases, particularly early in the course of disease, frequently results in recovery of affected animals. Nevertheless, current thinking suggests that the positive therapeutic effect of thiamine does not prove that thiamine deficiency or inhibition is the underlying etiologic basis for PEM. Rather, it is now thought that thiamine may improve energy metabolism in the impaired brain regardless of the inciting cause of the polioencephalomalacia (Niles et al. 2002).

Thiamine has important physiologic functions. It is part of the coenzyme thiamine pyrophosphate (TPP), which plays numerous roles in carbohydrate and amino acid metabolism. It participates in the tricarboxylic acid cycle as a cofactor in the oxidative decarboxylation of alpha ketoglutarate to succinate and in the conversion of pyruvate to acetyl CoA. In addition, as a coenzyme of transketolase, it participates in the pentose phosphate pathway to create D-glyceraldehyde-3-phosphate.

The pathophysiology of the polioencephalomalacia lesion is not fully understood. It is believed to result from intracellular edema associated with a dysfunction of the adenosine triphosphate (ATP)-dependent sodium potassium pump (Cebra and Cebra 2004). Failure of the pump results in sodium accumulation within cells and a resulting net influx of water, leading to cell swelling and death. Most neuronal ATP is generated through glycolysis via the pentose phosphate pathway; transketolase is the rate limiting enzyme in the pathway and thiamine pyrophosphate serves as an important cofactor to transketolase. Therefore, the administration of thiamine may help maintain cell function and integrity in nerve cells when energy demands of brain tissue are not being met, regardless of the underlying cause. It is noteworthy that administration of thiamine improves the clinical outcome in cases of ruminant lead poisoning, which are not specifically associated with thiamine deficiency (Coppock et al. 1991). This underscores the point that thiamine therapy in PEM, though effective, may not necessarily be linked to a specific etiology of thiamine deficiency.

Another development that has challenged the central role of thiamine in the pathogenesis of PEM is the emergence of sulfur toxicity as a demonstrable cause of PEM. It has been documented in situations such as cattle feedlots, where cases were historically attributed to thiamine deficiency. Elemental sulfur, as well as inorganic and organic sulfur compounds, may be present in water and a wide range of animal feeds including forages, concentrates, and molasses, and overall dietary intake may present potentially toxic levels of sulfur. The rumen contains a range of bacteria that metabolize sulfur in different ways. So-called assimilatory bacteria reduce sulfate for their own metabolic utilization and to make sulfur-containing amino acids. Dissimilatory bacteria also use sulfur for their own metabolic needs but they produce excess amounts of sulfide, which accumulate in the rumen. A third group of bacteria contain cysteine desulfhydrase and liberate additional sulfide by enzymatic reactions with sulfur-containing proteins (Gould 1998).

It is known that reductions in rumen pH, as occur in feedlots in association with concentrate feeding, favor the accumulation of hydrogen sulfide (H_2S) in the rumen gas cap where it can readily diffuse into the portal bloodstream. If absorbed in excessive amounts, it may override the capacity for hepatic detoxification. In addition, if present in high concentration in the rumen gas cap, eructated H_2S may be inhaled into the lungs and pass directly into the circulation across the pulmonary membranes. Though the pathophysiological effects on nervous tissue are not completely understood, it is known that H_2S and free sulfide radicals are potentially toxic. They can interfere with oxidative processes within mitochondria by blocking cytochrome C, leading to depletion of ATP and resulting in cell anoxia and death.

H_2S has a high affinity for brain tissue because of its high lipid content, and therefore may exert its toxic effects most dramatically in the brain, leading to polioencephalomalacia by mechanisms not yet fully elucidated. The toxic effects of H_2S gas on the respiratory tract are well known, as the inhalation of H_2S from manure pits leads to severe pulmonary edema and has been responsible for the deaths of livestock and humans. While it is known that high sulfur diets can lower ruminal thiamine production, the pathophysiology of sulfur-related PEM does not necessarily involve thiamine deficiency. In reports of clinical cases of PEM in feedlot steers, rumen H_2S levels were elevated while blood thiamine levels remained in the normal range (McAllister et al. 1997). Current perspectives on polioencephalomalacia and its causes, with an emphasis on sulfur toxicity, have been reviewed (Gould 1998, 2000; Niles et al. 2002).

Epidemiology

Information is sparse on the worldwide incidence of caprine polioencephalomalacia. Currently the disease is presumed to occur only sporadically in goats. Nevertheless, it has been reported to be the most commonly seen nervous disease of goats in New Zealand (McSporran 1988).

The pattern of disease in goats is not as well established as in cattle or sheep, but as in those species, dietary and management factors that may alter normal rumen flora appear to play a key role. Sudden changes in diet, excessive feeding of concentrates, use of horse feeds high in molasses, feeding of moldy hay, development of rumen acidosis, dietary stress of weaning, and overdosing of amprolium have all been associated with cases of caprine polioencephalomalacia. Given that it is now well documented in cattle and sheep that excess consumption of sulfur in the water and feed can also produce PEM, it is reasonable to assume that this also can occur in goats. However, at the time of this writing, no field cases have been documented in goats with sulfur toxicity as the confirmed etiology.

In North America, an increased occurrence in winter has been noted, when roughage quality and availability are low and grain feeding is increased (Smith 1979). It is known that sulfur and sulfates can be found in high quantities in drinking water, notably in the Plains and intermountain regions of the United States and Canada, and this could contribute to the development of PEM. In India, cases increased between August and December when lush pasture was available (Tanwar 1987). In South Africa, an outbreak was associated with concentrate supplementation during winter grazing (Newsholme and O'Neill 1985).

Poor growth rate has been associated with subclinical thiamine deficiency in lambs. One study demonstrated that normal goats in herds where clinical polioencephalomalacia occurred had more thiaminase activity in feces than normal goats in herds with no history of the disease. This suggests that subclinical thiamine deficiency may occur in goats as well (Thomas et al. 1987).

Clinical Findings

All goats are susceptible to PEM, but most cases involve weanlings and young adults. The history frequently includes a sudden change in feed, increases in concentrate feeding, difficulties in weaning, or a recent bout of digestive disease. The initial presentation is variable with some animals showing a prodromal period of depression, anorexia, and/or diarrhea with gradual expression of neurologic abnormalities over a period of one to seven days. In most cases, however, the presentation is one of acute neurologic dysfunction. Early neurologic signs include excitability, elevation of the head or opisthotonos while standing, staring off into space (stargazing), aimless wandering, circling, ataxia, muscle tremors, and apparent blindness.

As the disease progresses, dorsomedial strabismus, nystagmus, lack of a menace response, extensor rigidity, odontoprisis, recumbency with opisthotonos, and convulsions are observed. Fever is not seen except in association with convulsions. The pupillary reflexes are variable depending on the degree of cerebral edema. Rumen contractions are present in uncomplicated polioencephalomalacia, but they may be absent if the condition was precipitated by a severe rumen acidosis. If there is no therapeutic intervention, goats usually die between twenty-four and seventy-two hours after onset of clinical signs.

Clinical Pathology and Necropsy

Goats with polioencephalomalacia show little or no change in the CSF except for a slight mononuclear pleocytosis. While CSF pressure would be expected to increase, normal CSF pressures are poorly documented in the goat. In one reported case of polioencephalomalacia, the CSF pressure was 220 mm water (deLahunta 1977).

Measurement of transketolase activity of red blood cells offers an indirect measurement of thiamine levels. In one study, the mean transketolase activity in nine normal goats measured as μmoles pentose/hour/10^9 red blood cells was 0.782 with a range of 0.125 to 2.90 compared with levels of 0.099 and 0.068 in two clinically affected goats (Smith 1979). In another study, mean transketolase activity in normal goats was reported as 35 ± 5 IU/l compared with 18 ± 2 in affected goats (Thomas et al. 1987). To have the transketolase assay performed, heparinized blood should be centrifuged for ten minutes at 3,000 g, the plasma discarded, and the red cells frozen at $-4°F$ ($-20°C$) for shipment to the laboratory.

Thiaminase activity can be measured in feces of live animals or rumen content at necropsy. Fresh samples should be submitted frozen to the laboratory and at least 60 grams of rumen content provided. In normal goat feces, thiaminase activity has been measured as 0.2 ± 0.1 mU/g and 0.8 ± 0.3 in clinically affected goats. In normal goats, no rumen fluid thiaminase activity was detected while a mean activity of 0.5 ± 0.3 mU/m was measured in clinically affected goats (Thomas et al. 1987).

The calculated normal reference range for blood thiamine levels in goats has been reported as 66 to 178 nmol/l, but the diagnostic value of such measurements in clinically affected goats remains uncertain. At necropsy decreased tissue thiamine levels support the diagnosis of polioencephalomalacia (Rammell and Hill 1988). Liver and brain samples should be submitted frozen. Mean liver thiamine levels in normal goats have been reported as 1.6 ± 0.3 μg/g wet weight and 0.3 ± 0.4 in affected goats. In brain, the mean for normal goats was 0.7 ± 0.1 and 0.3 ± 0.1 in affected goats (Thomas et al. 1987).

Confirming the presence of high concentrations of H_2S in the rumen gas cap can support the diagnosis of sulfate toxicity as the underlying cause of PEM. A technique for sampling the rumen gas cap through the left

paralumbar fossa using a commercially available H_2S detection tube has been described (Gould et al. 1997). Normal and diagnostic values for the goat have not been specifically reported, but in cattle, steers on a high carbohydrate diet supplemented with sodium sulfate developed PEM and had rumen H_2S gas concentrations forty to sixty times higher than control steers on the same diet without sodium sulfate supplementation. The H_2S concentration in the supplemented steers was 4,850 ppm by the fifth day of feeding, while the concentration in non-supplemented steers never exceeded 75 ppm during the experimental trial (Gould et al. 1997). It is recommended that in field cases the analysis be performed when possible on healthy herd mates of the clinically affected animals because sick animals that are off feed quickly revert to lowered concentrations of H_2S in the rumen and may therefore give false negative results. If quantitative testing cannot be performed, the breath of affected animals should be checked during eructation for the characteristic "rotten egg" odor of H_2S, which can give a qualitative indication that sulfur toxicity may be involved.

Gross necropsy findings are limited to the brain. In the most severe cases, the cerebrum is soft and edematous with a grayish yellow or yellow discoloration. The cerebral gyri appear flattened from pressure and the cerebellum may be partially herniated through the foramen magnum. In less severe cases, examination of the cerebrum in darkness using an ultraviolet lamp (black light) may demonstrate areas of fluorescence in the cortex associated with cerebrocortical necrosis. Histologically, a laminar necrosis is confirmed in affected gyri with evidence of separation of the gray and white matter, and obvious degeneration of neurons with perineuronal vacuolation.

In cases where grain engorgement is a predisposing factor, evidence of rumenitis and other sequelae of lactic acidosis may be observed.

Diagnosis

Early signs of depression or altered mentation and diarrhea are consistent with enterotoxemia caused by *Clostridium perfringens* or pregnancy toxemia. The former disease might respond favorably to antitoxin administration; the latter occurs in pregnant does usually with positive urine ketones. The combination of blindness, opisthotonos, extensor rigidity, nystagmus, and strabismus is strongly suggestive of polioencephalomalacia in goats. These signs, however, may occur successively, simultaneously, or not at all, and definitive diagnosis is not always easy. The differential diagnosis for acute, central blindness is given in Chapter 6.

Opisthotonos and extensor rigidity are also characteristic of tetanus and goats with advanced polioencephalomalacia can easily be mistaken for tetanus cases. When circling or other unilateral signs are seen, listeriosis, brain abscesses, ear infections, cerebral nematodiasis, and CAE must be considered. Listeriosis is associated with changes in the CSF fluid and the other diseases are more slowly progressive. Terminal cases of polioencephalomalacia are often convulsive and therefore, meningitis, rabies, pseudorabies, and a variety of toxicities must be considered in the differential diagnosis. As discussed above, lead poisoning and salt poisoning can produce the brain lesion of PEM and may therefore also produce similar clinical signs.

While laboratory tests can support the diagnosis of polioencephalomalacia, the critical nature of the disease demands swift intervention by the practitioner, usually before such laboratory results are ever available. In practice, polioencephalomalacia is most often diagnosed by a response to therapy with thiamine. In goats, evidence of therapeutic response may be seen as soon as two hours after treatment.

Treatment

Despite questions concerning the role of thiamine metabolism in the pathogenesis of PEM, administration of thiamine remains the treatment of choice (Niles et al. 2002). Response is variable, depending mostly on the severity of the disease at the time treatment is initiated. The dose is 10 mg/kg bw repeated every six hours for twenty-four hours. The initial dose is usually given intravenously, and subsequent doses can be given intravenously, intramuscularly, or subcutaneously. Thiamine hydrochloride is most frequently used. If only multiple B vitamins are available, be sure that they are dosed according to the thiamine content. In early or mild cases, complete cure frequently occurs. In advanced cases, partial cures may occur with permanent residual blindness or abnormal mentation. Severely affected goats may die despite therapy. In other species, intravenous hyperosmotic mannitol at a dose of 1.5 g/kg bw in a 20% solution and parenteral dexamethasone at 1 to 2 mg/kg bw have been used in severe cases to reduce cerebral edema. The diuretic furosemide has also been used empirically for that purpose at a dose of 1 mg/kg bw IV. Diazepam at 0.5 to 1.5 mg/kg or other anticonvulsants may be required when seizures occur.

In addition to thiamine therapy and the management of cerebral edema, any underlying problems that may have predisposed to polioencephalomalacia, such as grain engorgement, should be identified and treated, as should sequelae such as dehydration and metabolic acidosis.

Control

A careful history is required to identify specific predisposing factors in each affected herd. Common control recommendations include an increase in

roughage feeding with a concomitant decrease in concentrate feeding, and avoidance of moldy feeds and those containing large amounts of molasses, such as horse feeds. When weanlings are involved, weaning procedures should be reviewed to ensure that kids obtain adequate roughage before weaning to promote normal rumen development and proper rumen flora. In problem herds, supplementation of the grain ration with thiamine mononitrate or brewer's yeast may be indicated.

New information on sulfur toxicity as a cause of PEM indicates that the total sulfur content of the ration, including the water supply, should be calculated and then reduced if it exceeds requirements. Levels of dietary sulfur able to produce toxicity in goats are not reported. In beef cattle, sulfur content of the total ration is recommended to be between 1,500 to 2,000 ppm (0.15% to 0.20% on a dry matter basis) and to avoid toxicity, should not exceed 4,000 ppm (0.40%) (Niles et al. 2002). The maximum tolerable dietary sulfur level for ruminants is 0.50% when the diet contains at least 40% forage (NRC 2005). Some specific dietary constituents known to have high sulfur content may need to be removed from the ration. These may include cruciferous forages (*Brassica* spp.), molasses, gypsum (calcium sulfate dihydrate), and ammonium sulfate. The latter may be in use in some goat herds as a supplement to acidify urine where urolithiasis is a problem. To avoid the risk of sulfur toxicity, ammonium chloride should be used for that purpose instead of ammonium sulfate.

Enzootic Ataxia and Swayback

Nutritional copper deficiency can lead to neuronal degeneration and secondary demyelination in the CNS and result in progressive paresis of young lambs and kids. The term swayback is applied to the congenital form of this condition, while enzootic ataxia refers to the condition if it develops after birth. Both are discussed here. Some authors consider the terms synonymous.

Etiology

In sheep, nutritional copper deficiency of the ewe during the second half of pregnancy leads to abnormal maturation and subsequent degeneration of neurons and myelin in the developing fetus and the lamb postnatally. The clinical and pathological similarities of enzootic ataxia in kids to the condition in lambs suggests that the cause is similar, if not identical, in both species.

The problem with attributing caprine enzootic ataxia and swayback solely to copper deficiency is that in some reports of naturally occurring disease, serum and tissue copper levels in clinically affected kids and their dams are not always low. In some instances, unaf-

fected control animals have even lower copper levels. Nevertheless, the favorable therapeutic response to copper administration and the cessation of additional cases through copper supplementation in affected goat herds support copper deficiency as playing a central role in the development of the disease in goats. It is very likely that caprine enzootic ataxia and swayback are metabolic diseases of complex origin with conditioned copper deficiency at the core.

Epidemiology

Enzootic ataxia and swayback in goats have been reported from California, New York, Massachusetts, and Louisiana in the United States (Cordy and Knight 1978; Summers et al. 1980; Lofstedt et al. 1988; Banton et al. 1990), Saskatchewan in Canada (Brightling 1983), Argentina (Dubarry et al. 1986; Bedotti and Sanchez Rodriguez 2002), Scotland (Barlow et al. 1962; Owen et al. 1965), the Netherlands (Wouda et al. 1986), Germany (Winter et al. 2002), Switzerland (Beust et al. 1983), Kenya (Hedger et al. 1964), Ethiopia (Roeder 1980), India (Prasad et al. 1982), Australia (O'Sullivan 1977; Seaman and Hartley 1981), and New Zealand (Black 1979).

Copper deficiency in goats can either be primary, caused by low copper levels in soil and forages raised on that soil, or secondary (conditioned), when normal amounts of copper are present in soils and feeds but uptake and absorption are impeded by the presence of copper antagonists such as molybdenum, iron, manganese, cadmium, lead, and sulfates.

A genetic predisposition was postulated in the Netherlands, where dwarf goats were disproportionately represented in a review of twenty-three cases (Wouda et al. 1986). Breed and family line predispositions play a role in the disease in sheep, presumably through differences in intestinal absorption and storage efficiency of copper.

Pathogenesis

Copper plays an essential role in a number of metabolic and developmental functions, serving primarily in tissue oxidation-phosphorylation reactions as part of the cytochrome oxidase system. Copper is specifically involved in myelination, osteogenesis, hematopoiesis, hair pigmentation, and normal growth (Brewer 1987). The role of copper in myelination is believed to involve phospholipid metabolism for production of normal myelin nerve sheaths.

In congenital copper deficiency or swayback, severe, prolonged copper deficiency in the dam affects normal development of myelin throughout the entire CNS of the developing fetus. This form occurs frequently in lambs and is associated with cavitating lesions of the cerebrum. It is rare in kids. Microcytic anemia and fragility of long bones occasionally have been observed

in swayback kids, reflecting the roles of copper in hematopoiesis and osteogenesis, respectively. In contrast to swayback, the postnatal disease enzootic ataxia develops when copper deficiency occurs later in gestation, when the deficiency is less severe, or when the deficiency continues in offspring after birth. Neuronal death and myelin degeneration occur, but are more limited to the spinal cord, brain stem, and sometimes the cerebellum (Cordy and Knight 1978; Wouda et al. 1986).

Clinical Findings

Male and female kids of all breeds can be affected. In congenital copper deficiency (swayback), kids are abnormal at birth. They are weak and most are unable to rise unassisted, but may stand unsteadily if helped to their feet. Muscle tremors and persistent nodding or shaking of the head are characteristic signs. Teeth grinding also occurs variably. Affected kids are able to suckle, vocalize, see, and hear. With intensive nursing care, these kids may live from several days to several weeks.

In the delayed form of the disease, enzootic ataxia, kids are born normally and develop a progressive paresis beginning as early as one week or as late as twenty-eight weeks of age. The mean age of onset is thirteen weeks. The clinical course varies from one to fourteen weeks and at least in the early stages, kids remain bright and alert and continue to eat. Early signs include weakness, fatigue, tremors, difficulty in rising, and incoordination. Symmetrical paresis and ataxia are usually observed first in the hind limbs, but sometimes in the forelimbs first. The signs are never unilateral. Periodic spasmodic contractions of the hind limbs and overstretching of the tarsal joints may occur. Hypermetria has been noted when there is cerebellar involvement. Laryngeal stridor was noted in a kid with involvement of the recurrent laryngeal nerve.

Affected kids may adopt a straddle-legged posture and collapse from weakness after standing a few minutes. Kids with forelimb involvement may drop onto their knees, while kids with hind limb involvement adopt a dog-sitting position and pull themselves along with the forelimbs. Rising becomes progressively more difficult as paresis gives way to paralysis. Permanently recumbent kids show flexor contracture of the forelimbs, spastic extension of the hind limbs, decubital ulcers, and muscle wasting. Diarrhea may occur, but affected kids frequently have concurrent coccidiosis or helminthiasis, so attribution of diarrhea to copper deficiency is problematic. Kids with enzootic ataxia are either euthanized or succumb to secondary problems such as pneumonia.

Signs of copper deficiency in adults in affected herds are not usually noted, but may include ill thrift, diarrhea, anemia, and depigmentation of the hair coat.

Clinical Pathology and Necropsy

Normal blood copper levels in goats are reported to be in the range of 9.4 to 23.6 μmol/l (60 to 150 μg/dl or 0.6 to 1.5 ppm) (Underwood 1981). Blood or serum copper levels less than 8 μmol/l (50 μg/dl or 0.5 ppm) and liver copper levels less than 20 ppm dry weight are reported to be diagnostic for enzootic ataxia in kids (Seaman and Hartley 1981). However, these low levels are not consistently recorded in affected goats, and considerable overlap occurs in blood and tissue copper levels among affected goats, nonaffected goats from the same farm, and control goats from premises with no history of the disease (Owen et al. 1965; Cordy and Knight 1978; Wouda et al. 1986; Bedotti and Sanchez Rodriguez 2002). Numerous animals in suspect herds must be tested to assess the overall copper status in the herd.

A microcytic anemia may be seen in affected kids, and hemoglobin values in the range of 5 to 7.7 g/dl have been reported (Hedger et al. 1964). Analysis of CSF has been performed infrequently and most reported cases of enzootic ataxia had concurrent CAE retroviral infections, so the significance of moderate pleocytosis and elevated protein in the CSF is not clear (Summers et al. 1980). In one uncomplicated case of enzootic ataxia, the CSF was normal (Lofstedt et al. 1988).

At necropsy, the cavitation and gelatinization of the cerebral hemispheres common in lambs with swayback are not seen in affected kids. Neither are gross lesions evident in the CNS of kids with enzootic ataxia. These kids are usually emaciated and show evidence of muscle atrophy.

Microscopic lesions are most common in the brain stem and spinal cord. The lesions are bilaterally symmetrical and are particularly obvious in the dorsolateral tracts of the cervical and thoracic spinal cord. Neuronal degeneration and demyelination are characteristic. Swelling of the neuronal cytoplasm with shrunken nuclei and marked chromatolysis is typical. Wallerian degeneration and loss of myelinated axons with gliosis and phagocytosis are evident. Cerebellar atrophy or hypoplasia may also be noted, with degeneration of Purkinje cells and reduced thickness of molecular and granular cell layers (Cordy and Knight 1978; Wouda et al. 1986).

Diagnosis

Definitive diagnosis is based on determination of low tissue copper levels and characteristic lesions at necropsy. A presumptive diagnosis antemortem is based on the typical clinical presentation, evidence of low copper levels or the presence of copper antagonists in the diet, low tissue copper levels, and a therapeutic response to treatment with copper compounds in mildly affected kids.

For congenital copper deficiency, the differential diagnosis includes hydrocephalus, congenital verte-brospinal abnormalities, caprine beta mannosidosis, border disease, hypoglycemia, and hypothermia. There is also a reported case of granulomatous encephalitis in a newborn kid due to congenital infection with *Neospora caninum*, which produced signs similar to those of congenital copper deficiency (Corbellini et al. 2001). This protozoal parasite is more commonly associated with abortion and is discussed further in Chapter 13.

For delayed copper deficiency, the neurologic form of CAE, vertebral trauma, spinal abscesses, cerebrospi-nal nematodiasis, nutritional muscular dystrophy, floppy kid disease, and listeriosis must be ruled out. In the early stages of disease, ascending paralysis caused by rabies is also a diagnostic consideration. Numerous cases of enzootic ataxia concurrent with CAE have been reported, which complicates the diag-nosis (Summers et al. 1980; Lofstedt et al. 1988).

Treatment

Mildly affected congenital cases, and early cases of enzootic ataxia, may respond favorably to treatment with copper compounds, but complete recovery is uncommon. If desired, blood and liver biopsy speci-mens should be taken before treatment so that inter-pretation of tissue copper levels is not confused. Copper glycinate has been reported as an effective treatment given parenterally to kids as a single total dose of 60 mg (Seaman and Hartley 1981).

Control

Effective control depends on determining the underlying cause of copper deficiency. It may be nec-essary to assay feeds, water, and soils to ascertain if there is a primary copper deficiency or a secondary deficiency conditioned by excess molybdenum, sul-fates, or other copper antagonists. Copper require-ments are not well defined for goats. This is unfortunate because goats appear to metabolize and store copper differently from sheep and extrapolations are proba-bly inaccurate. Nevertheless, for sheep, copper levels in various feeds should be at least 5 ppm and molyb-denum levels should not exceed 5 ppm. The copper to molybdenum ratio in the overall diet should be kept between 5:1 and 10:1 (Rankins et al. 2002). The current dietary copper recommendation for goats, as discussed in Chapter 19, is 10 to 20 ppm. Sulfate levels may be high in water and on pastures and may induce conditioned copper deficiency even when Cu:Mo ratios are within acceptable limits. Sulfate levels in feed should not exceed 3,500 ppm (Black 1979). When soils are copper deficient, annual top-dressing of pasture with copper sulfate at a rate of 2 to 3 kg/ha is recommended.

Enzootic ataxia may be prevented by supplementa-tion of copper. In the face of outbreaks of swayback or enzootic ataxia, pregnant does can be given copper glycinate subcutaneously at a total dose of 150 mg at mid gestation to prevent subsequent copper deficiency in kids. Kids can be given 60 mg of copper glycinate subcutaneously at birth if does were not treated earlier in pregnancy. This should protect them at least through weaning. Oral copper sulfate in the drinking water of does at a dose of 1.5 g per head per week during preg-nancy has also been used successfully, but may cause corrosion problems in metal pipes and troughs.

The most convenient method of control is to ensure that goats always have adequate copper in the diet. Trace mineralized salts containing copper sulfate in the range of 0.5% to 2% can be made available in blocks free choice or incorporated into the concentrate ration. A number of sustained release copper products for oral administration such as copper oxide needles in gelatin capsules have been used successfully in sheep in copper deficient areas, and there is at least one report of their safe use in goats in a herd with a history of swayback, though at fifteen weeks following adminis-tration of 4 g copper oxide needles, copper levels in viscera were no different between treated and untreated goats, suggesting that the intervention may be less effective in goats than in sheep (Inglis et al. 1986).

Hypovitaminosis A

In cattle, vitamin A deficiency is associated with a number of clinical manifestations including lacrima-tion, nasal discharge, coughing, corneal opacity, abor-tion, and weak calves. Signs of neurologic dysfunction include night blindness, total blindness, incoordina-tion, and convulsions. The incoordination and convul-sions are due to increased intracranial pressure resulting from reduced absorption of CSF caused by biochemical and structural alterations of the arachnoid villi associated with vitamin A deficiency.

It has been demonstrated experimentally in adult goats fed vitamin A-deficient diets that decreased absorption of CSF can result, but CSF pressure does not rise significantly and no papilledema of the optic nerve develops (Frier et al. 1974). Convulsions were not observed in either this study or an earlier one involving both adult and young, growing goats (Schmidt 1941). Signs were limited to a loss of appetite and weight, ropy nasal discharge, corneal opacity, and night blindness. Hypovitaminosis A is not a likely cause of convulsions in goats.

PLANT TOXICITIES

Bitterweed Poisoning

Hymenoxys odorata, an annual of the Texas range, is a major cause of economic loss in sheep and also affects

Angora goats. The plant, known as western bitterweed or bitter rubberweed, is most common in southwest Texas, especially on the Edwards Plateau. It is found between December and May, especially January through March, and may be the only succulent range plant available, particularly during times of drought. Goats are much less inclined to eat this plant than sheep unless forced to do so by a severe lack of forage.

A second plant, *Hymenoxys richardsoni*, known as pingue or Colorado rubberweed, can also produce the disease and is found more extensively in the west from Kansas to Mexico. The major toxin, hymenoxon, a sesquiterpine lactone, is a cumulative toxin that inhibits cellular function by alkylating sulfhydril groups of cellular enzymes. The principal signs are gastrointestinal and neurological. In sheep, the LD_{50} of *H. odorata* is just 1.3% of body weight. Goats are reported to be slightly more resistant, requiring 1.8 times more plant material than sheep to produce death (Rowe et al. 1973).

Acute, subacute, and chronic disease states can occur. The acute form is seen mostly under experimental conditions, after a single large ingestion. The clinical course is one to four days and leads to death. Early signs include bloat, anorexia, arching of the back, teeth grinding, and marked depression. Affected animals become increasingly depressed and may show regurgitation, fine muscle tremors, mucous nasal discharge, mild dyspnea, and head pressing. Terminal animals become recumbent with intermittent paddling, tonic convulsions, opisthotonos, tachycardia, severe dyspnea, and regurgitation.

The subacute and chronic forms are more likely under field conditions, usually after approximately one month of low-level exposure to the plant. In the subacute form, animals show only anorexia, a greenish nasal discharge, and possible regurgitation, and die quietly after one to seven days. Chronically affected animals become anorexic, weak, and thin, and die of starvation or dehydration caused by the inability to gather food. At necropsy, gross findings consist of edema and hemorrhage of lungs and epicardium and congestion and hemorrhage of the abomasum and duodenum.

Though there is no specific therapy, a gradual recovery can occur if affected animals are removed from the plant source and fed fresh feed and water. In severe cases, oral administration of activated charcoal may improve chances of recovery. Control of bitterweed poisoning involves avoidance of overgrazing and reduction of bitterweed or pingue by mowing and burning, fencing, or applying herbicides to reduce plant populations.

Coyotillo Poisoning

Karwinskia humboldtiana, or coyotillo, is a woody shrub indigenous to southern Texas and California and northern Mexico. It grows on gravelly hills and ridges and in canyons, gullies, and river valleys. The leaves and fruit are toxic, and spontaneous poisoning has been reported in goats, sheep, cattle, and humans, especially in winter when the plants are heavy with fruit and other forage is scarce. Losses of more than 1,000 goats caused by coyotillo poisoning have been reported on Texas ranches (Sperry et al. 1962). Consumption of whole fruit in quantities as little as 0.3% of the goat's body weight is lethal. The toxicity is due to polyphenolic compounds in the plant which are not fully characterized. The toxic action is primarily on striated muscle cells and Schwann cells leading to cellular degeneration.

Early signs in goats include increased alertness, hypersensitivity to sound and touch, generalized fine tremors, and a humpbacked posture, soon followed by disturbances of gait. The stride becomes shortened and jerky or hypermetric. These abnormalities are aggravated by forced exercise. The jerkiness of the gait gradually gives way to a marked weakness with hypotonia and loss of stretch reflexes. The goat assumes a crouched posture with marked hock and carpal flexion during standing or ambulation. Stumbling is common. Severely affected goats gradually become recumbent. Patellar and gastrocnemius reflexes are lost. Appetite, urination, and defecation remain normal until close to the time of death. Dyspnea is common in the terminal stages. The course of disease may last from several days to several weeks (Charlton et al. 1971).

Gross lesions in coyotillo poisoning of goats are not described. Histologically, lesions of the nervous system are found in the peripheral nerves and the cerebellum. There is extensive Schwann cell degeneration and demyelination and to a lesser extent Wallerian degeneration of axons. Secondary axonal degeneration is most prominent in distal sections of long motor nerves (Charlton and Pierce 1970). Axonal dystrophy of Purkinje cells is also prominent in the cerebellum of affected goats (Charlton et al. 1970). Myodegeneration of heart and skeletal muscle may also be observed as well as fatty degeneration of the liver (Dewan et al. 1965). The muscle lesions are similar to those seen in nutritional muscular dystrophy.

Treatment is nonspecific and involves removal of affected goats from the plant and providing adequate feed and water. Some recoveries can occur. Goats should not be turned into infested areas for grazing when the plant is in fruit.

Astragalus Poisoning (Alpha mannosidosis; Locoism)

Several distinct disease syndromes of differing pathogenesis are associated with livestock consumption of leguminous weeds of the genera *Astragalus* and

Oxytropis. Three of these syndromes produce signs of nervous disease and have been identified in goats. The first, locoism, is a chronic poisoning that results from prolonged consumption of species containing the indolizidine alkaloid, swainsonine. This alkaloid produces an acquired lysosomal storage disease, alpha mannosidosis, by inhibiting lysosomal alpha mannosidase, which leads to vacuolation and degeneration of the CNS.

Other plants also contain swainsonine and can induce acquired alpha mannosidosis in grazing livestock. These include *Swainsona* spp. and *Sphaerophysa* spp. which are, like *Astragalus* and *Oxytropis*, in the family Fabaceae, *Ipomoea* spp. and *Turbina* spp. in the family Convolvulaceae, and *Sida* spp. in the family Malvaceae. Ingestion of *Ipomoea carnea* (Schumaher-Henrique et al. 2003) and *Turbina cordata* (Dantas et al. 2007) are reported to cause acquired alpha mannosidosis in goats in Brazil and *I. carnea* consumption has been associated with the disease in goats in Mozambique as well (Balogh et al. 1999). Ingestion of *Sida carpinifolia* has caused the disease in Brazilian goats (Colodel et al. 2002). A similar acquired lysosomal storage disease in goats has been reported in association with consumption of *I. hieronymi* in Argentina (Rodriguez Armesto et al. 2004). Several *Oxytropis* spp. in China and *Swainsona* spp. in Australia have also been associated with acquired alpha mannosidosis in grazing livestock, but cases specifically in goats, though possible, have not been reported.

The second syndrome is an acute poisoning resulting from short term consumption of plant species possessing nitro-containing glycosides, notably miserotoxin. The third syndrome is blind staggers, or alkali disease, a condition long thought to be due to chronic selenium poisoning associated with consumption of plant species such as *Astragalus* that act as selenium accumulators. The condition has been known in western rangelands of the United States for more than a century, but in recent years the role of selenium in this disease has been called into question and the theory proposed that this condition is actually a manifestation of polioencephalomalacia resulting from excessive sulfur intake (O'Toole et al. 1996).

Species of *Astragalus* and *Oxytropis* that cause locoism are found in temperate regions worldwide but the disease is of particular concern in grazing stock in the western United States, particularly on open plains in winter. The plants are not palatable and livestock eat them initially only during times of limited forage. They quickly become habituated to locoweeds, however, continuing to eat them even when other feeds become available. The poisoning results from chronic ingestion, with signs appearing six to eight weeks after the onset of grazing locoweed and death four to six weeks later.

While reports of spontaneous locoism in goats in the United States are scarce and the economic impact minor, the clinical effects of two Texas locoweeds, *A. earlei* and *A. wootoni*, have been documented (Mathews 1932). Goats ate 335% of their body weight of *A. earlei* over fifty-four days to produce locoism, but refused to eat *A. wootoni.* Early signs include hind limb weakness characterized by inability to extend the hocks and an intermittent, weaving, rear gait. Startled goats may stumble or suddenly collapse onto their hindquarters but remain supported on the forelimbs. Paresis and ataxia are progressive, eventually involving the forelimbs as well. In advanced stages, goats become sternally recumbent with intermittent opisthotonos, nystagmus, and shaking of the head. There is progressive weight loss. Goats may remain bright and alert until just a few days before death. In comparison, sheep almost always show profound depression in locoism. Documentation of abortion in goats caused by locoism, a common problem in sheep, is lacking. At necropsy, gross lesions are limited to emaciation and possibly abomasal ulceration. Histologically there is vacuolation of neurons in the CNS.

Goats may recover from locoism if they are removed from locoweeds early in the course of the disease and then are well fed and watered. However, they may seek out and resume eating locoweed if allowed subsequent access, due to the habituation that occurs.

The acute neurologic form of *Astragalus* poisoning caused by nitro-containing compounds has been reported in cattle and sheep in Texas and reproduced experimentally in goats by feeding *A. emoryanus*, the red-stemmed peavine (Mathews 1940). Young green plants are most toxic and effects are seen when plants are consumed at a rate of 0.7% to 1.8% of body weight. Goats may show profound depression, anorexia, recumbency, weakness, and death within one to two days of initial consumption. In less severe cases, goats develop pronounced ataxia that is particularly evident in the hind limbs and that can persist for as long as one year after the animals are denied access to the plant. Dyspnea, associated with methemoglobinemia, as observed in sheep poisoned by peavine, was not observed in goats. There are no characteristic gross or microscopic lesions.

"Blind staggers" has been reported in goats and sheep in Iran after prolonged grazing of *Astragalus* spp. (Hosseinion et al. 1972). This form of *Astragalus* toxicity has been ascribed to its role as a selenium accumulator. Emaciation, rough hair coat, anorexia, separation from the flock, impaired vision, circling, and a staggering gait were observed as were foamy salivation, lacrimation, severe constipation, and signs of abdominal pain. The mortality rate was approximately 4%. Selenium concentration of the weeds was 500 ppm.

Guajillo Poisoning

Acacia berlanderi, or guajillo, is a perennial shrub of rangeland in southwest Texas and Mexico. The plant is palatable and routine grazing by goats and sheep is generally permitted. However, it may cause toxicity under drought conditions when the diet is monotonous and consumption extends for six months or longer. The toxic principles are sympathomimetic amines, N-methyl-beta-phenylethylamine (Camp and Lyman 1957) and tyramine. Affected animals retain their appetites and remain bright and alert. The predominant clinical sign is a progressive ataxia that eventually leads to recumbency and death secondary to starvation and thirst. The condition is known locally as limberleg or guajillo wobbles. There are no significant lesions found at necropsy. Recoveries can occur if the condition is identified early and animals removed from the plant.

Carpetweed or Caltrops Poisoning

Kallstroemia hirsutissima, known as carpetweed or caltrops, is a low lying, ground hugging weed of disturbed soils in western North America from Kansas south to northern Mexico. Though not palatable, the plant may be consumed by grazing livestock in summer during periods of drought. Natural cases of poisoning in goats are not documented, but experimental poisoning has been reported (Mathews 1944). The toxic principal is unknown. The susceptibility of goats is variable with clinical disease seen in one goat eating the plant at a rate of 11% of body weight, and no signs seen in another eating 177% of its weight in carpetweed. After three days of consumption, the affected goat showed signs of marked paresis, being unable to stand normally, and walking on the carpi in front with the hocks flexed behind. The animal was killed and no gross lesions were observed. Cattle and sheep also showed marked paresis and walked with prominent knuckling of the fetlocks.

Milkweed Poisoning

There are numerous species of milkweeds in the genus *Asclepias* and many are toxic to livestock. Many are distributed widely throughout the United States. These plants are not normally eaten except in times of drought or limited forage. They also may be baled into hay and retain their toxicity when dry. Goats are poisoned by milkweed (Kingsbury 1964). Consumption of various *Asclepias* species in doses from 0.25% to 2% of body weight can be toxic. Clinical signs appear within a few hours of ingestion of a toxic dose and include profound depression, weakness, and a staggering gait. Bloat and dyspnea may also occur. Severely affected animals go down and exhibit intermittent tetanic convulsions. Pupils become dilated, coma ensues, and death usually occurs between one and two days after the onset of signs. The milkweeds contain toxic resins and steroid glycosides, including cardiac glycosides, but the specific mechanism of neurotoxicity is not known. Nonspecific lesions at necropsy include congestion of liver and kidneys and irritation of intestinal mucosa. There is no known treatment and poisoning is controlled by reducing access to milkweed and by maintaining pastures in good condition.

Cycasin Toxicity or Zamia Staggers

Cycasin is a toxic pseudocyanogenic glycoside found in the nuts, leaves, and young shoots of various tropical cycad palms. Poisoning of cattle has been associated with consumption of leaves or young shoots of four genera: *Cycas, Macrozamia, Zamia,* and *Bowenia* in Puerto Rico, the Dominican Republic, Japan, and Australia. The poisoning of goats with *Cycas media* is a serious problem in parts of Australia, notably Groote Eylandt (Hall 1964). Clinical neurologic disease associated with ingestion of the seeds of the King Sago palm tree, *Cycas revoluta*, has been reported in dogs in the southern United States so the potential for goat exposure exists there (Albretsen et al. 1998).

Chronic consumption leads to incoordination characterized by a lack of proprioception, with abnormal placement of feet, knuckling, and stumbling or falling. Pain responses, motor control, and withdrawal reflexes remain intact. Once signs are observed, the condition is irreversible (Baxendell 1988). Goats experimentally poisoned with cycasin extracts also show marked depression, anorexia, weight loss, and anemia. At necropsy, histologic lesions of the spinal cord include axonal swelling and death with demyelination most prominent in the lateral and ventral funiculi. Hepatic necrosis, biliary hyperplasia, and pancreatic atrophy were additional necropsy findings in experimentally poisoned goats (Shimizu et al. 1986).

Miscellaneous Plant Poisonings

Nervous disease in goats associated with plant ingestions have been reported sporadically from various places in the world. *Solanum* spp. have been reported to produce neurologic dysfunction in goats in Australia (Bourke 1997) and Florida (Porter et al. 2003). In Australia, the implicated plant was *S. cinereum* (Nawarra burr) and in Florida, *S. viarum* (tropical soda apple). The clinical presentation was similar in both instances and strongly suggested involvement of the cerebellum, with grazing goats showing signs of head tremor, wide base stance, hypermetria, incoordination, nystagmus, and proprioceptive deficits. At necropsy, CNS lesions were restricted to the cerebellum and were characterized by cytoplasmic vacuolation, degeneration, and loss of Purkinje fibers. The *Solanum* spp. may contain several toxic principles, including the

steroidal glycosides solasonine and solasodine as well as beta-carboline alkaloids. The exact cause of the cerebellar degeneration is not fully clarified.

Albizia is a genus of legumes in the family Mimosaceae. Seed pods of the toxic species in this genus contain 4-methoxy-pyridone, a pyridoxine (vitamin B_6) analog which causes neurologic dysfunction as well as cardiomyopathy and pulmonary edema. An outbreak of *A. versicolor* poisoning of goats and sheep eating ripe, dry, seed pods was reported from Malawi and was confirmed by experimental oral challenge of goats and sheep with dried seed pods (Soldan et al. 1996). Sheep were more susceptible than goats. Signs of intoxication included hyperesthesia, wild running, lateral recumbency with rapid leg movements, nystagmus, and rapid blinking. The condition is reported to be treatable in sheep with 20 to 25 mg/kg pyroxidine hydrochloride/kg bw given twice at an eight-hour interval, even after clinical signs are apparent and well advanced (Gummow et al. 1992).

In Togo, grazing on the shrub *Byrsocarpus coccineus* —especially young shoots—at the beginning of the rainy season in March and April produces toxicity in goats. Clinical signs include anorexia, weight loss, separation from the flock, dizziness, staggering gait, circling, and frantic, aimless flight. In peracute cases, tetanic convulsions are observed. Recovery occurs if goats and sheep are removed to pastures where the shrub is absent (Amégée 1983).

In Tanzania, ingestion of the seeds or leaves of the deciduous shrub *Burttia prunoides* has produced neurologic signs in goats including circling, bleating, lateral recumbency, teeth grinding, convulsions, coma, and death. The disease has been observed naturally and produced experimentally (Msengi et al. 1987). In Sudan, *Azadirachta indica* is reputed to cause toxicity to livestock. Experimentally, continuous feeding of leaves of this plant to goats led to weight loss, weakness, diarrhea, and terminally, ataxia and tremors (Ali 1987).

In Holland, ingestion of fool's parsley (*Aethusa cynapium*) by goats led to signs of ataxia, indigestion, and hyperpnea. Affected goats were treated orally with oak bark, tannalbumin, and purgative salts, and recovered in several days (Swart 1975). This annual weed also occurs in northeastern North America and is found locally in waste places and gardens.

Diplodiosis is a neuromycotoxicosis of cattle and occasionally sheep in South Africa. It occurs when livestock consume maize contaminated with the fungus *Diplodia maydis.* Goats are susceptible based on experimental toxicosis, showing typical signs of ataxia, paresis, and paralysis. The fungus occurs on corn in the United States and Argentina, but poisoning of livestock has not yet been reported from these places (Kellerman et al. 1985).

Larkspurs (*Delphinium* spp.) are an important cause of cattle mortality during spring and early summer grazing in western North America. The plant is readily eaten. Goats are presumed susceptible. Toxic alkaloids in larkspurs block postsynaptic cholinergic receptors. Signs of toxicity include sudden death, or a staggering gait, basewide stance, collapse, difficulty rising, muscle twitching, abdominal pain, constipation, and bloat. Removal from the plant and early treatment with neostigmine at 0.01 to 0.02 mg/kg bw intramuscularly, repeated as needed, may be effective (Knight 1987).

Plant poisonings that produce signs of nervous dysfunction via the mechanism of hepatoencephalopathy secondary to phytogenous hepatosis are discussed in Chapter 11. Plants causing blindness are discussed in Chapter 6.

A number of additional plants have been identified as causing neurologic symptoms in small ruminants (Brewer 1983). While their toxicity in sheep is well established, documentation of goat poisonings is often lacking. These plants include *Solanum esuriale*, the cause of "humpy back" in Australia; *Kochia scoparia*, or Mexican fireweed found in the western United States; and the lupines of the western United States and Australia. In addition, phalaris, paspallum, rye, and dallis grasses have been associated with "grass staggers" in sheep but the condition in goats is not well defined. Periodically, Bermuda grass *(Cynodon dactylon)* has been associated with cattle losses in the southern United States, producing ataxia, tremors, and sometimes death. The toxicity for goats has been demonstrated experimentally (Strain et al. 1982). Convulsive ergotism, well documented in other livestock species, is poorly substantiated in goats.

INORGANIC CHEMICAL NEUROTOXICITIES

Lead Poisoning

Documented cases of naturally occurring lead poisoning in goats are not found in the contemporary veterinary literature. Nevertheless, several reviews of goat diseases identify lead poisoning as a disease of goats producing neurologic signs similar to those seen in affected cattle or sheep. Signs cited include blindness, ataxia, head pressing, circling, hypermetria, grinding of teeth, and diarrhea. However, experimental studies of lead poisoning in goats report either no neurologic dysfunction or nervous signs limited to depression, incoordination, or terminal convulsions. Weight loss, anorexia, abortion, and diarrhea are the more prominent signs in experimental lead poisoning of goats (Dollahite et al. 1975; Davis et al. 1976; Gouda et al. 1985).

Goats are considered resistant to lead poisoning compared to cattle and dogs and have been observed not to become ill under circumstances where compan-

ion cattle show signs of disease. Whether this was caused by innate resistance or an unwillingness to consume sources of lead is not clear (Guss 1977). Certainly they are exposed to lead in certain circumstances such as when they graze near lead-zinc smelters, in which case elevated blood lead levels have been documented along with depressed blood copper and cobalt levels (Swarup et al. 2006). At least experimentally, goats refuse to eat lead-based paint or pure lead acetate despite the sweet taste of the latter (Davis et al. 1976). Susceptibility to lead poisoning varies between individual goats and may be increased by pregnancy (Dollahite et al. 1975).

Diagnosis of lead poisoning in goats depends on a strong history of exposure, identification of the source, and confirmation of increased blood or tissue lead levels. Goats appear to accumulate lead less dramatically than other species. Experimentally poisoned, clinically ill goats had whole blood lead levels as low as 0.2 ppm, liver levels as low as 5.5 ppm, and renal cortex levels as low as 26 ppm. Values higher than these should be considered diagnostic for lead poisoning when evaluating field cases. Liver lead levels in aborted fetuses greater than 1.5 ppm are suggestive of lead-induced abortion. It has also been reported that blood porphyrin levels are reliably elevated in lead poisoning in goats. Goats experimentally administered lead acetate for ninety-one days had progressively increasing mean blood porphyrin levels in the range of 31.7 to 56.9 μg/dl, while control goats had levels in the range of 23.5 to 24.6 μg/dl. Most of the lead-exposed goats also showed a so-called lead line in radiographs of forelimbs, with marked radiopaque bands at the distal metaphysis of the radii, indicating incorporation of lead in bone at the growth plates. The goats were eight to nine months old at the onset of the exposure (Swarup et al. 1990).

Because the occurrence of nervous signs in lead poisoning of goats is not firmly established, veterinarians are strongly encouraged to submit whole blood for lead analysis in all suspect cases and to pursue alternate diagnoses while waiting for test results. When blindness is present in conjunction with other neurologic signs, serious consideration must be given to polioencephalomalacia as an alternate diagnosis and intravenous thiamine therapy at 10 mg/kg should be instituted immediately.

When lead poisoning is the working diagnosis, treatment is similar to that of other species and is targeted primarily at chelation of lead for removal from the body. The chelating agent, calcium disodium versanate, remains the standard treatment in ruminants (Cebra and Cebra 2004). The recommended regimen consists of two treatments given intravenously at a dose of 110 mg/kg bw daily at a six-hour interval for up to three to five days (Radostits et al. 2007).

Experimentally, meso-2,3-dimercaptosuccinic acid has also shown promise as a chelation treatment for lead removal in ruminants (Meldrum et al. 2003). As an adjunct to chelation therapy, administration of thiamine hydrochloride in cattle with lead poisoning improved the clinical response. It resulted in better remission of nervous signs and also appeared to enhance the reduction of blood lead concentration (Coppock et al. 1991). The dose was 2 mg/kg bw thiamine hydrochloride given intramuscularly once daily.

Treatment efficacy may be monitored by repeated blood lead measurements. High blood levels that persist during a course of therapy suggests the presence of a persistent source of lead in the rumen that may require removal by rumenotomy.

Salt Poisoning

Salt poisoning occurs in livestock when there is excessive salt intake from the feed, inadequate water intake in the face of normal salt intake, or when only saline drinking water is available. The condition is most common in swine, but is also reported in cattle and sheep. Documentation of the condition in goats is rare but it is sometimes included in discussions of diseases showing nervous signs (Guss 1977; Baxendell 1988). In a case report from Italy, one of eight affected goats presented with convulsions, opisthotonos, and respiratory distress while the other seven showed weakness and intense thirst. The severely affected goat died and had cerebral edema at necropsy. The others were successfully rehydrated (Buronfosse 2000).

Signs of acute salt intoxication in other species include tremors, blindness, nystagmus, weakness, incoordination, knuckling of the fetlocks, head pressing, opisthotonos, convulsions, coma, and death associated with cerebral edema. When the disease occurs from a large dose of excess salt, signs of gastrointestinal irritation including vomiting, diarrhea, and abdominal pain may also be seen. When neurologic signs are marked, tranquilization with diazepam and reduction of cerebral edema with diuretics and mannitol solutions may be indicated. The condition and its management in other species is reviewed in detail elsewhere (Cebra and Cebra 2004; Radostits et al. 2007).

Bromide Intoxication

Two separate incidents of bromide poisoning of goats have been reported in the United States. One involved contamination of pastures by sodium bromide from an adjacent chemical dump and the other, contamination of oat hay grown on fields initially treated with methyl bromide as a nematocide (Knight and Costner 1977; Liggett et al. 1985). Although the latter source of bromide is organic, toxicity is believed to be caused by release and uptake by plants of bromide ion from the treated soil. The clinical signs were similar in

both cases and developed over a period of days to weeks after exposure. Weakness and locomotor impairment were characteristic, with difficulty standing and turning, stumbling and dragging of the feet while walking. Dribbling of urine; drooping ears, eyelids, and tail; and a progressive somnolence and recumbency were observed. Deaths occurred in both outbreaks.

Measurement of serum bromide can be diagnostic. In the sodium bromide-related outbreak, unexposed, control goats had concentrations less than 0.625 mEq/l, exposed goats with no clinical signs measured 1.6 to 3.2 mEq/l, and clinically affected goats had concentrations more than 21.1 mEq/l. When laboratory measurement of serum chloride is performed using an ion-selective electrode, pseuodhyperchloremia may be recorded in animals with bromide poisoning.

There are no definitive necropsy lesions, although necrosis of the ventral horn of the lumbar spinal cord was noted in one goat. There is no specific therapy reported, but some goats did recover after hospitalization with supportive care for four to fifteen days.

Boron or Borax Intoxication

Borax may be found on the farm for use as a soil sterilant or fly control compound. Goats may be accidentally exposed but are unlikely to voluntarily ingest it unless it was accidentally incorporated into the feed. Clinical signs of intoxication may include diarrhea, dehydration, and convulsions before coma and death (Guss 1977).

The toxicity of boron has been demonstrated experimentally in goats (Sisk et al. 1988). A goat given sodium borate fertilizer orally at a dose of 3.6 g/kg bw exhibited signs of weakness and somnolence, with the chin resting on the floor. It developed muscle tremors and pasty feces, and died quietly eight hours after challenge. A second goat given the fertilizer at a dose of 1.8 g/kg did not become ill. Neurotoxicity is presumed to be involved in boron toxicity, but the mechanism is not fully known. A stimulatory effect on serotonergic and dopaminergic neurons has been proposed based on increased metabolites of serotonin and dopamine in CSF fluid of experimentally challenged goats (Sisk et al. 1990). No specific treatment is reported, but efforts to restore hydration may be helpful.

ORGANIC CHEMICAL NEUROTOXICITIES

Organophosphates and Carbamates

Etiology and epidemiology

Organophosphate and carbamate pesticides are commonly found on farms. They are used to treat livestock for internal and external parasites, and to protect soil and crops from insect pests. Toxicities occur when animals are overdosed either by parenteral or topical administration or when livestock gain accidental access to chemicals that are carelessly stored, accidentally spilled, or inadvertently added to feed or water supplies. Toxic doses of various organophosphate and carbamate compounds administered either orally or topically to goats are given in Table 5.5.

Pathogenesis

Organophosphates and carbamates exert their toxic effects by competitive inhibition of acetylcholinesterase, the enzyme ordinarily responsible for the degradation of the neurotransmitter acetylcholine. This inhibition leads to accumulation of acetylcholine at neuromuscular junctions, autonomic ganglia, and effector cells, and causes an increased, prolonged stimulation of skeletal muscle, the entire parasympathetic nervous system, and the post-ganglionic cholinergic nerves of the sympathetic system. These sustained muscarinic and nicotinic effects are responsible for the clinical signs associated with toxicity.

In sheep, a delayed neurotoxicity caused by the organophosphate anthelmintic haloxon is recognized. The pathogenesis of delayed neurotoxicity is believed to involve an inherited esterase deficiency in Suffolk sheep. A distal axonopathy with dying back of neurons, particularly long axons in the spinal cord, develops several weeks after administration of haloxon. The clinical picture is one of progressive, symmetric, spastic paresis of the hind limbs. This syndrome has been suspected in Angora goats, but no additional documentation has emerged (Wilson et al. 1982).

Clinical Findings

The clinical signs of acute toxicity in goats are similar to those seen in other species, and include restlessness, frothing at the mouth, dyspnea, tremors, frequent urination and defecation, bloat, head pressing, teeth grinding, lacrimation, staggering gait, intermittent convulsions, paresis, and finally, recumbency and death (Mohamed et al. 1989, 1990).

Clinical Pathology and Necropsy

Identifying a marked decrease in acetylcholinesterase activity supports the diagnosis of organophosphate and carbamate poisoning. Whole blood is a suitable sample in goats because 89% of acetylcholinesterase activity in blood is in red blood cells (Osweiler et al. 1984). Heparinized blood samples should be submitted refrigerated but not frozen. When carbamates are suspected, blood must be refrigerated immediately and tested as soon as possible because inhibition of acetylcholinesterase by carbamate is reversible. The laboratory should be notified of your suspicion of carbamates so that test methods that require dilution of the sample are not used.

Table 5.5. Toxicity of some organophosphate, carbamate, and chlorinated hydrocarbon insecticides for goats.

Chemical	Oral dose		Dermal dose (%)	
	Maximum nontoxic dose tested (mg/kg bw)	Minimum toxic dose found (mg/kg bw)	Maximum nontoxic dose tested (% concentration)	Minimum toxic dose found (% concentration)
Organophosphates				
Chlorpyrifos		$LD_{50} = 500$		
Coumaphos			0.25	0.5
Crufomate		100	2.5	
Crotoxyphos			1	
Demeton		$LD_{50} = 8$		
Diazinon	20	30		
Dichlofenthion			0.25	0.5
Dioxathion			0.25	
Disulfoton		$LD_{50} < 15$		
Ethion			0.25	0.5
Fenthion				0.25
Malathion	50	100		
Methyl trithion			0.1	
Monocrotophos		$LD_{50} = 20$		
Parathion		20		
Phosmet			0.5	
Carbamates				
Carbaryl			1	
Landrin		$LD_{50} = 210$		
Propoxur		$LD_{50} > 800$		
Chlorinated hydrocarbons				
Aldrin				4
Chlordane			3	4
DDT	250			8
Dieldrin		$LD_{50} = 100$		
Endrin		$LD_{50} = 25$		
Toxaphene	25	$LD_{50} > 160$		

Traditional test methods determine the change of pH that occurs when acetylcholinesterase hydrolyses acetylcholine or a substitute ester under controlled conditions. The normal range of delta pH for caprine whole blood acetylcholinesterase activity is 0.04 to 0.24, with a mean of 0.14 (Osweiler et al. 1984). In cases of toxicity, delta pH is frequently zero. Titrimetric methods, which do not require sample dilution, report acetylcholinesterase activity as the μmol of substrate hydrolyzed/minute/ml of whole blood or plasma. Normal values in goats using acetylcholine iodide as a substrate have been reported in the range of 4.20 to 5.60 μmol/minute/ml of whole blood and 0.60 to 1 μmol/minute/ml in plasma. Activity was reduced to levels of 20% to 50% of normal after oral administration of toxic doses of diazinon, phosmet, phosphamidon, or trichlorfon, with reported activity ranging from 0.90 to 2.50 μmol/minute/ml in whole blood and 0.27 to 0.32 μmol/minute/ml in plasma (Abdelsalam 1987). Dialkyl phosphates are hydrolytic breakdown products of the phosphate moieties of organophosphate insecticides. Detection of dialkyl phosphates in the urine of goats proved to be a reliable indicator of exposure to diazinon over a range of challenge doses (Mount 1984). The test was more sensitive than measurement of blood cholinesterase activity in goats not showing clinical signs of toxicity.

There are no specific necropsy findings in organophosphate or carbamate poisoning. Chemical analysis of tissues is often unrewarding because organophosphate and carbamate insecticides are rapidly metabolized. Analysis of stomach or rumen content, suspected feeds, or other formulations for insecticide content is preferred.

Diagnosis

Diagnosis is based on the characteristic signs of acute toxicity in conjunction with documentation of decreased or absent acetylcholinesterase activity. In the absence of laboratory support, a favorable clinical response to atropine or oxime therapy supports the diagnosis. Other acute poisonings, such as cyanide, nitrate, and urea toxicity, and anaphylactic reactions must be considered in the differential diagnosis. The pyrethroid insecticide fenvalerate has been shown to produce clinical signs suggestive of organophosphate toxicity when administered orally to Nubian goats at doses more than 112.5 mg/kg (Mohamed and Adam 1990).

Treatment and Control

Treatment can be successful, especially with early intervention. The treatment of choice to counteract signs of toxicity is atropine sulfate given at a dose of 0.6 to 1 mg/kg bw. One-fourth to one-third the total dose should be given intravenously and the remainder subcutaneously or intramuscularly. The higher end of the dose range can be used in severe cases. Repeated dosing may be necessary every four to five hours for as long as two days in severe cases, but dosage should be cut back when possible to avoid serious bloat.

Oximes, such as trimedoxime bromide, 2-pyridine aldoxime methiodide (2-PAM), and pralidoxime chloride, free acetylcholinesterase from organophosphate, but not from carbamate complexes. They are particularly useful in combination with atropine for the treatment of coumaphos, ronnel, dimethoate, and crufomate toxicity, where atropine alone is not always effective (Osweiler et al. 1984). The use of these drugs in goats is not reported. In other ruminants, recommended doses are as follows; 2-PAM, 50 to 100 mg/kg bw; trimedoxime bromide, 10 to 20 mg/kg bw; and pralidoxime chloride, 20 mg/kg bw intravenously.

When poisoning is by the oral route, oral administration of 1 g/kg bw activated charcoal per adult goat by orogastric tube may help to reduce the additional uptake of insecticide. When exposure is dermal, washing animals with soap and water helps to reduce additional absorption. Handlers should wear masks and rubber gloves. Control of these toxicities is difficult because most outbreaks involve accidental exposure. Certainly these chemicals should be treated with respect and used only according to directions. They should be stored securely where animal contact is impossible.

Chlorinated Hydrocarbons

Etiology and Epidemiology

These insecticide compounds, also known as organochlorines, have been used widely in agriculture for treatment of soils, water supplies, crops, seeds, and livestock. Methoxychlor, lindane, DDT, aldrin, dieldrin, chlordane, and toxaphene are common examples. Use of these insecticides directly on livestock is increasingly restricted due to environmental and public health concerns. Nevertheless, accidental exposures or inappropriate use still lead to toxicities in livestock, including goats. Information on toxic doses of various chlorinated hydrocarbons for goats is given in Table 5.5. Because goats are used for both meat and milk production, the potential for relay toxicity to humans from consumption of goat products is similar to cattle. These compounds are noted for persistence in fatty tissues over long periods. Residue levels in goat milk and tissues for various chlorinated hydrocarbons have been reported (Cho et al. 1976).

Pathogenesis

The pathogenesis of toxicity for these compounds is not completely known and may be different for each. At least for chlorophenothane, the compound acts on axonal membranes to prolong the depolarized state by interfering with sodium influx and potassium efflux. Poisoning can occur by single large-dose exposure or chronic lower-dose exposure due to the ability of these insecticides to accumulate in tissues. Absorption of these chemicals can occur through the skin, or by oral ingestion, aspiration, or inhalation. Neurologic signs in all cases are the usual clinical manifestation.

Clinical Findings

Clinical signs are similar in all species. Hypersensitivity, apprehension, and/or aggressiveness are frequent early signs followed by fasciculation of muscles, especially in the head and neck, that extend to muscular spasms over the entire body. Snapping of the eyelids and continuous chewing or teeth grinding are common, sometimes with excessive salivation. Moderate bloating may occur. Loss of coordination with staggering gait, aimless wandering, or circling may be observed. Severe and prolonged convulsions frequently develop. It is not unusual for animals to have a high fever due to seizure activity. Though animals may die during convulsions, death is usually preceded by terminal coma.

The severity of signs is to some extent dose dependent. Experimental poisoning with aldrin at a daily oral dose of 2.5 mg/kg bw led to clinical signs of depression, anorexia, teeth grinding, salivation, staggering gait, and hypersensitivity in one goat after eighteen days of dosing but no signs of toxicity in three others (Singh et al. 1985). Goats given daily aldrin orally at a dose of 20 mg/kg showed signs of hyperexcitability, incoordination of movement, muscle tremors, and convulsions by the ninth day of dosing, and died one to three days later (Omer and Awad Elkarim 1981).

Clinical Pathology and Necropsy

Clinicopathologic data are generally not helpful in the diagnosis before death. There are no specific necropsy findings, although pulmonary congestion and ecchymotic hemorrhages of the heart and other serosal surfaces may be observed. When there have been severe prolonged convulsions with fever, the intestines may have a blanched or cooked appearance.

Diagnosis

Presumptive diagnosis depends on a history of exposure to chlorinated hydrocarbons followed by the development of typical clinical signs. Definitive diagnosis depends on identification of the offending agent by laboratory analysis of hair samples, rumen content, fat biopsies, or milk samples antemortem or in tissue samples post mortem, especially liver, brain, and fat. Concentrations of the various chlorinated hydrocarbons considered diagnostic of toxicity in goat tissue are not well documented. Analyses are complex and costly so there should be some notion of the specific chemical being searched for.

Treatment and Control

Therapy is primarily supportive. When topical poisoning is involved, animals should be washed thoroughly with soap and water. Handlers should wear masks and rubber gloves. In cases of ingestion, gastric lavage may be performed or activated charcoal given at a dose of 1 g/kg bw per adult goat as soon as possible after exposure. Seizures may need to be controlled by use of long-acting barbiturates. Daily oral dosing of recovered animals with small volumes of mineral oil may help to clear chlorinated hydrocarbons from the intestinal tract but will have little or no effect in mobilizing the agents in tissue. Specific guidelines for the safety of meat and milk products from goats recovered from poisoning are not available. Because of the potential harmful effects in humans, the consumption of meat or milk from these recovered animals should be discouraged. Control essentially involves client education concerning the danger, proper usage, and safe storage of chlorinated hydrocarbons.

Miscellaneous Organic Chemical Toxicities

Levamisole, a widely used caprine anthelmintic, is one of the most common potential causes of neurotoxicity in goats. When overdosed, it can produce a clinical syndrome very similar to nicotine poisoning with signs including anxiety, hyperesthesia, increased urination and defecation, muscle tremors, staggering gait, and convulsions. More information on levamisole use and toxicity in goats is given in Chapter 10.

Urea toxicity has been reported in goats. The syndrome is characterized by abdominal pain, bloat, dyspnea, and frothy salivation; neurologic signs include ataxia, tremors, hyperesthesia, and struggling. The condition is discussed in detail in Chapter 19.

Both cyanide and nitrate poisoning can produce signs of nervous dysfunction including excitement, muscle tremors, staggering gait, and dilated pupils secondary to systemic anoxia. These conditions are discussed in detail in Chapter 9.

Diesel fuel poisoning has been reported in goats when the animals drank from a small pond containing fuel from an overturned tank truck (Toofanian et al. 1979). Goats drank the tainted water readily. Clinical signs developed within hours and included anorexia, depression, diarrhea, dyspnea, and a mucopurulent nasal discharge. The breath and the urine smelled strongly of diesel fuel. Affected goats progressively worsened; developed neurologic signs including incoordination, tremors, head pressing, aimless wandering, pica, abnormal vocalization, and recumbency; and died, presumably due to respiratory compromise.

Nitrofurans are a class of antibacterials that were formerly in common use for control of enteric infections in young calves and pigs. Due to public health concerns about their carcinogenicity, the use of nitrofurans in food animals is now severely restricted in many countries, including the United States, where parenteral use was first banned in 1991 and topical use was banned in 2002. The toxicity of furazolidone in Nubian goats has been reported (Ali et al. 1984). At oral daily doses as low as 40 mg/kg for as long as ten days, goats showed signs of anorexia, weight loss, restlessness, incoordination, and hyperexcitability, with constant chewing movements, tail wagging, foot stamping, backward walking, and circling. At daily oral doses of 160 or 320 mg/kg similar signs were more severe and accompanied by frothy salivation, grunting, and bellowing and death within one week of the onset of treatment.

Dinitro compounds such as dinitrophenol and dinitrocresol are used as herbicides and fungicides and are toxic to goats immediately after application to foliage, but not after the residue has dried (Guss 1977). When goats feed on sprayed foliage there may be yellow discoloration of skin and hair around the mouth and nose associated with feeding activity. Clinical signs of toxicity include fever, dyspnea, tachycardia, and convulsions. The clinical course is short and death rapidly ensues. Even with early intervention, the prognosis is guarded. No specific therapies have been reported, but use of antipyretics, anticonvulsants, and supportive care may be of some value.

Pentachlorophenol is commonly used as a wood preservative for lumber. It is toxic to livestock via the mechanism of uncoupling oxidative phosphorylation. It is readily absorbed through the skin, via inhalation, or by ingestion. As a general precaution,

pentachlorophenol-treated wood should not be used in goat buildings because of the well known wood chewing and swallowing behavior of goats. Of particular concern is freshly treated wood that has not yet dried or cured. Clinical signs of toxicity can include muscular weakness and lethargy, fever, sweating, dehydration, tachypnea, collapse, and death with rapid onset of rigor mortis. Convulsions have been reported in goats before death (Guss 1977). There is no specific treatment.

Chlorpromazine and piperazine produce a fatal drug interaction when given to goats. The drug combination resulted in immediate, severe, clonic convulsions, and rapid respiratory arrest when chlorpromazine was given intravenously at a dose of 10 mg/kg after oral administration of piperazine at a dose of 220 mg/kg (Boulos and Davis 1969).

CONGENITAL AND INHERITED DISEASES

Beta Mannosidosis

This heritable, lysosomal storage disease in goats is seen only in newborn kids of Nubian breeding and is characterized by intention tremors and an inability to rise. The condition is transmitted as an autosomal recessive trait. There is no treatment and carrier adults can be identified by blood test.

Epidemiology

The condition was first described as a neurovisceral storage disease with dysmyelinogenesis of unknown cause in newborn Anglo Nubian kids in Australia in 1973 (Hartley and Blakemore 1973). It was later characterized as beta mannosidosis in Nubian kids in Michigan in 1981 (Jones and Laine 1981). It was long thought to occur only in the goat, but is now also recognized in humans (Dorland et al. 1988) and the Salers breed of cattle (Abbitt et al. 1991). The specific molecular defect responsible for caprine beta-mannosidosis has been identified and the associated cDNA coding region has been sequenced and characterized (Leipprandt et al. 1996). It involves a single base pair deletion.

Currently the caprine disease is known only in the Nubian breed or Nubian crossbreds (Shapiro et al. 1985). It has been reported in Australia, New Zealand, Fiji, Canada, and the United States. Heterozygous carriers of the trait can be identified by intermediate plasma levels of beta mannosidase. An Australian survey identified 13.7% of 988 Anglo Nubians as carriers (Sewell and Healy 1985). This suggests a significant potential economic loss for Nubian breeders.

Pathogenesis

The lysosomal storage diseases result from an acquired or inherited deficiency of a catabolic lyso-somal hydrolase. In cells where the hydrolase is missing, the substrate that is ordinarily catabolized accumulates in lysosomes producing marked vacuolation and destruction of cells. In the case of beta mannosidosis, the condition is inherited as an autosomal recessive trait, transmitted with a frequency of 25% by the mating of two heterozygous parents, and the deficient hydrolase is beta mannosidase. The deficiency results in intracellular accumulation of incompletely catabolized oligosaccharides leading to marked vacuolation of cells, the characteristic histologic lesion. These substances, the disaccharide betamannosyl-(1-4)-*N*-acetylglucosamine and the trisaccharide betamannosyl-(1-4)-*N*-acetylglucosaminyl-(1-4)-*N*-acetylglucosamine, are also excreted in the urine.

While vacuolation occurs in a wide variety of cell types, lesions are most severe in the CNS and clinical manifestations of the disease in neonates are essentially neurologic. Vacuolation of neurons is accompanied by marked dysmyelinogenesis in beta mannosidosis, but the exact relationship of these two findings is unresolved. One study has reported that greater accumulation of oligosaccharide at various locations in the CNS is not directly associated with the severity of myelin deficiency at those sites (Boyer et al. 1990).

Clinical Findings

The clinical presentation is consistent (Kumar et al. 1986). Affected kids of either sex are born alive. They are unable to rise, and lie in lateral recumbency or drag themselves along if placed sternally. They have contracted tendons with carpal flexion, hind limb extension, and hyperextension of the pastern joints. Withdrawal reflexes are intact. There is a varying degree of facial dysmorphism including a domed skull, an elongated and narrow muzzle, small, slit-like palpebral fissures, enophthalmos, and a depressed nasal bridge. Most, if not all, affected kids are deaf, though this may be difficult to establish. Bilateral ptosis as part of Horner's syndrome is present. Pendular nystagmus and intention tremors may be observed. The skin is thickened and the muscle mass may be decreased. Affected kids can see, smell, suckle, defecate, and urinate normally and may survive for several weeks with nursing care.

Clinical Pathology and Necropsy

The hemogram and serum chemistry profile are normal. Despite the facial dysmorphism and locomotor difficulties, radiographs of the skull, vertebrae, and long bones are normal. An abnormal electromyogram, with spontaneous potentials resembling positive sharp waves and fibrillation potentials, occurs in some cases.

Techniques for measuring plasma beta mannosidase activity have been developed and can be used as an aid to distinguish normal goats from affected goats and heterozygous carriers (Healy and McCleary 1982; Cavanagh et al. 1983). Using a fluorometric technique, affected kids have markedly reduced or absent activity, with measurements below 0.2 U/l, while the activity of heterozygous carriers is always below 2.4 U/l and frequently below 1.7 U/l (Healy and McCleary 1982). Most normal, adult, noncarrier goats have activity greater than 2.1 U/l, but some may measure as low as 1.7 U/l, giving false positive results. In screening for heterozygous carriers, false positive identification rates as high as 12% can occur in goat populations when 2.1 U/l is used as the discriminate value and 2% when 1.7 U/l is used (Sewell and Healy 1985). Laboratory values for plasma beta mannosidase activity have also been reported for normal kids in the range of 66 to 222 nmol/hour/ml (Cavanagh et al. 1982). Clinically affected homozygous kids have no beta mannosidase activity in plasma and heterozygous carriers have intermediate activity. In one study, heterozygous carriers had activity measurements that averaged 47% of that of normal goats (Sewell and Healy 1985).

While there is conflicting information on the effect of reproductive status and gender on beta mannosidase activity, the activity is known to decrease with increasing age up to but not after sexual maturity (Dunstan et al. 1983; Sewell and Healy 1985). Severe stresses such as transport and shearing can reduce activity into the heterozygous suspect range, so blood samples should not be taken from goats immediately after obvious stressors (Mason 1986).

Affected kids also have the abnormal oligosaccharides betamannosyl-(1-4)-*N*-acetylglucosamine and betamannosyl-(1-4)-*N*-acetylglucosaminyl-(1-4)-*N*-acetylglucosamine present in the urine (Matsuura et al. 1983). Prenatal testing by ultrasound guided aspiration of fetal fluids has been described (Lovell et al. 1995). Abnormal accumulation of oligosaccharides was confirmed in the allantoic fluid, but not in the amniotic fluid. Diagnosis in live kids may be possible by examination of gingival biopsies for the characteristic lesions of Schwann cell vacuolation and axonal dense bodies in peripheral nerve cells (Malachowski and Jones 1983).

At necropsy, muscles appear pale and small. When the contracted tendons are cut, joint motion is unimpaired. The most prominent gross lesions are in the brain. Ventricular dilation is observed in association with a marked diminution of white matter because of a paucity of myelin, especially in the cerebrum. There is also polypoid hypertrophy of the middle ear mucosa (Jones et al. 1983).

Histologically, the disease is characterized by fine to coarse vacuolation of a wide variety of cell types in all tissues. These are lysosomal storage vacuoles. Fibroblasts, macrophages, and endothelial and perithelial cells are most consistently affected in all tissues. In the CNS there is vacuolation of virtually all cell types. In addition, there is marked demyelination, especially in the brain and to a lesser extent in the spinal cord, and axonal spheroids occur throughout the white matter. Mineralization may be seen, especially in the cerebellum and globus pallidus (Lovell and Jones 1983). Ocular lesions have also been described (Render et al. 1989).

Diagnosis

The diagnosis is based on the characteristic presentation in newborn kids of Nubian descent, confirmation of reduced beta mannosidase activity in plasma or abnormal oligosaccharides in urine, and characteristic histology at necropsy. Differential diagnoses include hydrocephalus, congenital spinal malformations or trauma at birth, Akabane disease, border disease, and swayback.

Treatment and Control

There is no treatment for this condition. Control in individual herds depends on diagnosis of the condition in newborn kids and removal of the parents of affected kids from the breeding program. Goat owners purchasing Nubian goats for breeding purposes may want to screen for heterozygous carriers by assaying plasma beta mannosidase activity. More recently, a genetic test has been developed and is available through the Texas Veterinary Medical Diagnostic Laboratory.

Mucopolysaccharidosis IIID

Mucopolysaccharidosis IIID (MPS IIID) is an inherited lysosomal storage disease first described in human beings and later recognized in the Nubian breed of goats (Thompson et al. 1992). In human medicine the condition is also known as Sanfilippo D syndrome and Nubian goats are now used as a model for studying the human disease.

MPS IIID is caused by a deficiency in N-acetylglucosamine 6-sulfatase (G6S) activity in lysosomes that results from a nonsense mutation in the 5′ region of the gene coding for expression of this enzyme. The result of this enzyme deficiency is that the catabolism of glycosaminoglycans (GAG) is disrupted so that *N*-acetylglucosamine 6-sulfate and heparan sulfate accumulate in the tissues and urine of affected individuals. While multiple tissues are affected, the lysosomal accumulation of these GAG in the central nervous system is mostly responsible for the clinical manifestations seen in humans and Nubian goats. The key lesions seen in the CNS of affected goats are primarily the neuronal accumulation of heparan sulfate and the excess storage

of gangliosides in cerebral cortical and spinal cord gray matter as well as dysmyelination (Jones et al. 1998).

The pattern of inheritance for MPS IIID is autosomal recessive with individuals homozygous for the defective gene expressing the disease condition. In a Michigan study of 552 Nubians using a G6S PCR-based mutation test, 25.2% of animals tested were identified as heterozygous carriers and 1.3% were homozygous for the mutation (Hoard et al. 1998).

There is phenotypic variation in MPS IIID disease expression with mild and severe forms recorded in homozygous Nubian goats (Jones et al. 1998). Affected goats may be born with marked neurological deficits. One carefully studied case showed an inability to rise at birth, and a wide based stance and hyperextension of the limbs when lifted to standing. Additional signs included a fine neck tremor and horizontal nystagmus. Though the animal gradually became ambulatory, it remained ataxic and showed delayed and stunted growth. However, six other homozygous individuals in the same study showed no overt clinical signs at birth and continued normally for extended periods of time. One individual, for example, only showed signs beginning at forty-four months of age. These signs included abnormal gait, persistent head tremor, and intermittent hyperextension of the forelimbs. Another homozygous goat began showing aggressive behavior in her second year of life. The one observation common to all six mildly affected goats was growth retardation (Jones et al. 1998). Field reports suggest that mildly affected goats have decreased muscle mass and may be more prone to infection and that overt signs of disease may manifest as animals become older due to progressive accumulation of GAG in CNS and other tissues.

Differential diagnosis for newborn kids should include congenital copper deficiency, congenital skeletal abnormalities such as hemivertebra, hydrocephalus, and beta mannosidosis, the other lysosomal storage disease that occurs only in Nubian goats. Akabane virus infection can also produce kids unable to rise at birth, but these kids have arthrogryposis which is not reported in MPS IIID. When progressive neurological signs appear in adult goats, scrapie must be considered as well as coenurosis where it occurs. The differential diagnosis for animals showing poor growth and decreased muscle mass should include the various nutritional, infectious, and parasitic diseases discussed in Chapter 15 relative to wasting.

Testing for the presence of the G6S mutation can be performed on white blood cells harvested at the laboratory from 1 to 2 ml of blood collected in EDTA. The Texas Veterinary Medical Diagnostic Laboratory currently performs this test in the United States. The condition can be controlled through breeding based on the G6S mutation status of breeding stock determined through testing. There is no treatment for the condition.

Progressive Paresis of Angora Goats

Ataxia, first noted at approximately four months of age, has been seen in Angora goat kids from serial litters of the same parentage in Australia. Kids had normal mental status, cranial nerve function, and reflexes, but exhibited signs of weakness including difficulty in rising, a reluctance to move, and stumbling when forced to do so. Weakness was more apparent in the hind limbs than the forelimbs.

Though clinically similar to enzootic ataxia or caprine arthritis encephalitis, this condition has characteristic pathologic findings. No gross lesions were observed except muscle atrophy. Microscopic lesions were characterized by the occurrence of large cytoplasmic vacuoles in large neurons of the midbrain, brain stem, and ventral horns of the spinal cord. Chromatolysis and pyknosis were also observed. The history of reoccurrence of the condition in kids from serial litters of the same parentage suggested a hereditary basis for the condition, though the pathogenesis of the disease remains unclear (Lancaster et al. 1987).

Spastic Paresis

This condition is well known in cattle and is considered to be inherited in that species. Spastic paresis is characterized by intermittent unilateral or bilateral spastic contracture of the gastrocnemius muscle leading to hyperextension of one or both hind limbs. The hyperextension may be so extreme that the animal is unable to place the foot on the ground and the leg is carried straight behind. The hock is straight and the gastrocnemius muscle is palpably firm or knotted. It has been demonstrated that selective depression of gamma efferent neurons in the spinal cord by epidural administration of dilute procaine alleviates the condition, indicating that the disorder occurs from overstimulation of the myotatic (stretch) reflex (De Ley and De Moor 1980).

Reports of the condition in goats are infrequent. The condition was first reported in Czechoslovakia in 1973 and involved a three-year-old male Saanen (Kral and Hlousek 1973). The goat was reluctant to stand and when forced to do so remained on its carpi with rump in the air, hind limbs overextended with the hocks straight, and the gastrocnemius tendons palpably taut. Though the diagnosis could not be confirmed, tibial neurectomy, as frequently applied in cattle, corrected the condition.

More recently, the condition was reported in two familially related pygmy goats in the United States (Baker et al. 1989). In these cases, the diagnosis was supported by application of a dilute procaine epidural with subsequent alleviation of signs. Despite this evi-

dence of spastic paresis in goats, the diagnosis must be made with caution because of the hereditary implications of the disease, which are not well defined in the caprine species. The author has observed at least two goats with classically described signs of spastic paresis that turned out to be cases of the arthritic form of CAE. The occurrence of joint pain without joint swelling is not uncommon in CAE and could lead to abnormalities of gait and posture that can mimic spastic paresis.

Hydrocephalus and Hydranencephaly

Hydrocephalus occurs sporadically in goats as a developmental anomaly resulting in improper drainage of the CSF. This causes increased intracerebral pressure, with thinning of the cerebral cortices, expansion of the ventricles, and possible distortion of the skull surrounding the brain. Affected kids can be delivered dead or alive. Live kids are usually dull and blind with pronounced muscular weakness; they are unable to stand unassisted or ambulate (Figure 5.7). Obvious doming of the skull is variable and does not have to be present to make a diagnosis of hydrocephalus. Hydranencephaly, which is a normotensive hydrocephalus that results from necrosis or a failure of cell growth, occurs in goats in conjunction with arthrogryposis as a result of fetal Akabane virus infection as discussed in Chapter 4. Kids with hydranencephaly have neurologic deficits similar to those seen in hydrocephalus.

NEOPLASTIC DISEASE

Neoplasms of the CNS in goats are rarely found in large scale surveys of neoplastic disease of livestock. For example, there was one caprine neoplasia, a spongioma, in a report on 400 tumors of the nervous system of domestic animals (Luginbuhl 1963). However, some individual cases have been reported in the literature. In Germany, a fifteen-year-old female goat that suddenly developed a right sided heat tilt that progressed to loss of orientation and ataxia was subsequently euthanized and found to have a choroid plexus carcinoma which manifested as a well circumscribed mass in the left ventricle that compressed the cerebrum and infiltrated the left piriform lobe (Klopfleisch et al. 2006). In a report from North Carolina, glioma was diagnosed in a six-year old castrated male, mixed-breed goat that presented with a one-week history of circling, behavioral change, decreased appetite, and adipsia. A CT scan identified a large cerebral mass which was confirmed at necropsy as a glioma (Marshall et al. 1995). Lymphosarcoma (Craig et al. 1986) and malignant melanoma (Sockett et al. 1984) have also been reported involving the nervous system in goats. A malignant Schwannoma of peripheral nerve

sheaths, manifesting as 0.5 to 2 mm nodules, was recently identified in the diaphragm of a two-year-old female goat at slaughter in Spain (Ramírez et al. 2007).

A goat with cerebral gliomatosis was identified in a survey of small ruminant field cases with clinical presentations of neurologic disease carried out in support of Swiss scrapie surveillance activities. The goat also had hair lice and the combination of pruritus from the lice and neurologic signs from the tumor effectively mimicked clinical scrapie (Maurer et al. 2005). Another case report of cerebral gliomatosis from Switzerland involved a three-year old Appenzell goat buck (Braun et al. 2005). The animal showed depression, generalized ataxia, hypermetria of the forelimbs, generalized hypoesthesia, bilateral mydriasis, and a decreased menace response. At necropsy, there were no gross lesions in the brain, but histologically there was extensive diffuse glial cell hyperplasia in the white matter of the cerebral hemispheres and in the brain stem.

NEUROLOGIC DISEASES OF UNKNOWN ETIOLOGY

Polyradiculoneuritis

Polyradiculoneuritis has been reported as a cause of progressive hind limb ataxia, hyporeflexia, and extensor rigidity in a six-week-old male kid in California (MacLachlan et al. 1982). At necropsy, there were no gross lesions but microscopically there was evidence of mononuclear inflammation and demyelination involving the meninges, nerve roots, and peripheral nerves, but not the brain or spinal cord. Similar conditions are known in man and in dogs and are hypothesized to be caused by an auto-immune reaction.

Caprine Encephalomyelomalacia

Caprine encephalomyelomalacia has been reported from California (Cordy et al. 1984). The condition has been described only in kids between three and a half and four months of age of dairy breeds. There is an acute onset of nervous dysfunction characterized by posterior paresis and incoordination progressing rapidly to paralysis. In some cases tetraparesis is observed. All kids were killed after a clinical course of six to ten days.

There are no gross lesions at necropsy. Microscopic lesions are bilaterally symmetrical and are restricted to the gray matter of the spinal cord, particularly in the cervical and lumbosacral enlargements, and certain brain stem nuclei. Necrosis of neurons is observed.

a
b

Figure 5.7. A two-day-old kid with hydrocephalus. The kid was dull and depressed at birth and could only stand when assisted. It preferred the curled, recumbent position, as shown in Figure 5.7a. Doming of the skull was not prominent, but distension of the ventricular system was evident at time of necropsy (Figure 5.7b). (Courtesy of Dr. T.P. O'Leary.)

6

Ocular System

Although ophthalmologists have in general paid little attention to the goat in their writings, several published reviews are oriented toward caprine ophthalmology (Wyman 1983; Baxendell 1984; Moore and Whitley 1984; Whittaker et al. 1999). Most aspects of anatomy and therapy apply across species lines. Any good ophthalmology text, then, should be useful for the practitioner needing more information than this chapter supplies.

CLINICAL ANATOMY AND EXAMINATION OF THE EYE

The history elicited from the owner may suggest a problem with ocular structures or vision. The goat may have a hesitant gait or refuse to move or pass through a gate. The animal may carry its head abnormally elevated or near the ground. A report of normal vision should be verified by the examiner; visual loss may not be apparent until the goat is placed in unfamiliar surroundings. The eyes should also be examined relative to systemic conditions (i.e., dehydration, anemia, icterus, septicemia, hemorrhagic diseases) and during prepurchase or breeding soundness examinations.

Lids and Lashes

The upper and lower eyelids normally are tightly apposed to the globe. They should neither roll inward (entropion) nor gape outward (ectropion). Lashes should not be in contact with the cornea. The examiner should note the location of any long, tactile hairs before evaluating vision by the menace response. Touching the lids near the medial canthus should evoke the palpebral reflex (blinking and retraction of the globe). This reflex requires function of cranial nerves V (sensory branches of trigeminal nerve) and VII. The third eyelid (nictitating membrane) is normally unobtrusive. It can be seen better if the globe is retropulsed, using digital pressure through the eyelids. Topical anesthesia permits grasping of the third eyelid with smooth forceps so that its posterior surface can be inspected for lesions or foreign bodies. Prolapse of the third eyelid occurs in some cases of tetanus. Passive prolapse of the nictitans occurs in conditions causing enophthalmos, including dehydration or emaciation, as well as in neurologic diseases accompanied by Horner's syndrome (see Chapter 5).

Lacrimal Glands and Ducts

The lacrimal apparatus of the goat has been reviewed by Sinha and Calhoun (1966). Lysozyme has been identified in goat tear samples (Brightman et al. 1991). Plasma cells in the nictitating gland secrete IgA into the tear film (Schlegel et al. 2003). Normally no staining or wetness occurs beneath the goat's eye, neither is there a deep recess filled with exudate near the medial canthus analogous to the infraorbital gland of sheep. The nasolacrimal duct can be catheterized from the ocular puncta (Moore and Whitley 1984).

Ocular Position

The ruminant eye normally maintains a constant position relative to the ground rather than remaining centered between the lids. This can make ocular examination frustrating if the goat's head cannot be restrained in the position required to expose the structures of interest. Abnormal function of the nerves supplying the extraocular muscles (cranial nerves III, IV, VI) affects ocular position. Dorsomedial strabismus, for instance, sometimes occurs in polioencephalomalacia. Mydriasis and strabismus may occur with botulism as a result of paralysis of intrinsic and extrinsic ocular muscles (Wyman 1983). Normal nystagmus (vestibular nystagmus) occurs when the head is slowly turned to one side and has its quick phase in the same direction as the head movement. Normal postrotatory nystagmus (direction opposite the direction of rotation) lasts for less than ten seconds.

Exophthalmos (protrusion of the globe) may be due to a retrobulbar abscess or tumor. Ideally, examination of the orbit by ultrasound or computed tomography, followed by guided aspiration of cells or fluid from the lesion, allows a diagnosis to be made. Enucleation may be required to resolve a retrobulbar abscess. It is unlikely to cure the tumors most likely in this location (lymphosarcoma, enzootic nasal tumor). See Chapter 9 for further discussion of enzootic nasal tumor.

Conjunctiva, Sclera, and Scleral Vessels

Everting the eyelids permits inspection of the conjunctiva (Figure 6.1). Rotating the head upward and to one side exposes bulbar conjunctiva and the deeper sclera and its vessels. A pale white color with almost invisible blood vessels occurs with severe anemia, and yellow sclera is indicative of icterus. A brownish discoloration of this and other mucous membranes occurs with nitrate poisoning, a purplish color with cyanotic conditions, and bright red coloration with cyanide poisoning. Vessels may appear congested with ocular, regional, or systemic inflammatory or toxic diseases.

Cornea

The cornea is normally clear and moist. Oblique lighting and observing the clarity with which the iris

Figure 6.1. The lower lid has been everted to expose the conjunctiva. This goat had a packed cell volume of 21%. (Courtesy Dr. M.C. Smith.)

can be visualized aid in differentiating cloudiness of the cornea from lens opacity. If the cornea is lightly touched with a finger or a wisp of cotton, the corneal reflex results in the same blinking and globe retraction, via the same pathway, as the palpebral reflex.

Iris, Pupil, and Lens

A strong and well-focused light source should be used to evaluate direct and consensual pupillary response (optic nerve and parasympathetic fibers traveling with the oculomotor nerve, midbrain). Pupillary responses may be intact in a blind animal, and they may be almost impossible to elicit in an apprehensive goat. The pupil is oval, becoming more rectangular in bright light, and has granula iridica (corpora nigra) attached to both its dorsal and its ventral rim. Various toxicities may affect the pupil (e.g., mydriasis with chlorinated hydrocarbons [Choudhury and Robinson 1950] or miosis with organophosphates). The anterior chamber, between cornea and iris, should be examined for hyphema, hypopyon, and aqueous flare (cells and protein, often indicative of anterior uveitis).

If a cataract (opacity of the lens or its capsule) is detected, the density of the cataract should be evaluated. If a portion of the retina is clearly visible in a blind animal, any cataract that may be present is not the cause of blindness.

Retina and Ophthalmoscopic Examination

The goat's fundus can usually be examined without resorting to mydriatics. If a detailed examination is desired, and if the examiner is willing to wait fifteen to thirty minutes for its effect, 1% tropicamide may be used to dilate the pupil (Figure 6.2). This should not be done until after pupillary response has been evaluated and diagnostic cultures or scrapings have been performed.

Figure 6.2. The normally rectangular pupil has been dilated with tropicamide to permit a thorough fundus examination. (Courtesy Dr. M.C. Smith)

Figure 6.4. The fundus of a normal Boer goat. (Courtesy Dr. M.C. Smith.)
Figure 6.3. The fundus of a Saanen goat. o.d. = optic disc, a = arteriole, t.n. = tapetum nigrum, o.c. = optic cup, v = venule.

Hyaloid remnants on the optic nerve head and continuing into the vitreous body are commonly found in adult ruminants, including four of ten goats in one study (Schebitz and Reiche 1953). Presence of blood within the hyaloid vessel is also considered normal until eight weeks of age in lambs, although this has not been investigated in kids.

Photographs of the fundus of goats have been published (Rubin 1974; Whittaker et al. 1999; Galan et al. 2006b). A diagram of a goat fundus is provided in Figure 6.3 and a normal Boer goat fundus is illustrated in Figure 6.4. The fundus is usually in focus with a direct ophthalmoscopic setting of –1D to –5D. The optic disc is rather round or oval, whereas in the sheep it is often more kidney-shaped. The optic disc in goats is frequently located totally within the tapetal fundus (tapetum lucidum, yellow to bluish green). In cattle and sheep it is usually situated in the nontapetal fundus (tapetum nigrum, brownish) just beneath the horizontal junctional area of tapetal and nontapetal fundus. The optic disc is grayish pink and sharply demarcated, and has a small funnel-shaped physiologic cup. The broader veins enter the middle of the disc while the thinner, redder arteries originate like rays from a pericentral location (Schmidt 1973). There are more blood vessels than in sheep or cattle. Galan et al. (2006b) report three to six retinal arteries in the goat, often branching from a common artery that emerges from the dorsotemporal portion of the disc. There are many stars of Winslow which are black dots in the tapetum lucidum where choriocapillaris vessels penetrate the tapetum. Fluorescein angiography of the normal goat fundus has been described (Galan et al. 2006a).

Ultrasonography can be used to evaluate the contents of the globe and the retrobulbar area, as is done routinely in companion animal medicine. Ideally, both a 7.5-MHz probe and an offset pad are used. The globe can be imaged through the upper eyelid or directly through the cornea. Tranquilization is followed by application of a local anesthetic to the cornea, and the probe is placed on lubricating jelly on the lid or on a mound of sterile ocular lubricating gel on the cornea. Normal chamber fluid is hypoechoic, while the posterior lens capsule and retina are hyperechoic. Conditions that might be demonstrated by ultrasound include luxated lens, retinal detachment, or a retrobulbar abscess or tumor (Toal 1996).

Cranial Nerves and Evaluation for Blindness

The optic disc is the optic nerve head. It may be swollen with papilledema or with optic neuritis. Unilateral blindness may be detected by covering one eye and observing the goat's behavior in a strange environment. Young kids often visually follow a bottle of milk when other items fail to attract their interest. The complete visual pathway, including optic nerve and cerebral cortex, is also evaluated by the menace response. Fingers are moved vertically or quickly spread apart (to decrease air currents) in front of each eye in turn. Lashes and tactile hairs must not be touched. The palpebral reflex (cranial nerves V and VII) should be checked if the goat does not blink in response to the menacing gesture.

MALFORMATIONS OF THE GLOBE

Various chemical or viral teratogens may interfere with embryologic development of the eyeball.

Cyclopia

Veratrum californicum, if consumed on approximately day four of pregnancy, can cause cyclopia in kids and lambs (Binns et al. 1972). Deformation of the skull ("monkey face"), absence of the pituitary, and other brain malformations may also occur. This problem can be prevented by not allowing the buck access to the females when grazing on the plant might occur. The author has seen cyclopic kids in New York, where *Veratrum californicum* does not grow, and several case reports from India also did not identify a cause of the malformation (Raju and Rao 2001). It is logical that other toxins or tissue insults occurring at the critical stage of embryologic development, when a single optic field is dividing in two, could also result in cyclopia.

Microphthalmia

Microphthalmia and other congenital deformities including lens luxation or aphakia have been reported in lambs when pregnant ewes have grazed on seleniferous pastures. Anophthalmia has been caused by exposure of a pregnant ewe to apholate, an insect chemosterilant (Younger 1965). The effects on caprine ocular structures of these compounds or of in utero viral infections have not been reported.

LID ABNORMALITIES

Lacerations of the eyelids should be repaired using standard techniques. Skin diseases involving the lids (e.g., contagious ecthyma, mange, staphylococcal dermatitis, zinc deficiency) are described in Chapter 2. When skin lesions are restricted to the eyelids, the possibility that they are caused by ocular discharge or rubbing in response to ocular discomfort should be investigated. Injuries to the face may occur because of

blindness. Small palpebral fissures, thickened non-pliable lids, and partial prolapse of the nictitating membrane occur in Nubian kids with inherited beta mannosidosis (Render et al. 1989), which is discussed in Chapter 5.

Entropion

Entropion is the turning inward of the lower lid or both eyelids so that the eyelashes rub on the cornea. The condition is painful and results in tearing and retraction of the eyeball. The lids are partially closed; the lashes may be stuck together with exudate.

Congenital or Primary Entropion

When a kid's eyelids are malformed from birth, the condition is usually recognized within the first few days of life. The longer the entropion remains uncorrected, the more likely that a serious infection or corneal ulceration will result. It is probable, though unproven, that this condition has a hereditary component. Thus, if surgical treatment is required on humane grounds, the identity of the goat should be recorded so that it can be slaughtered for meat or sterilized rather than being permitted to reproduce.

Spastic Entropion

Older animals may develop entropion as the result of prolonged squinting when another painful eye condition is present (Figure 6.5). Typical examples are severe keratoconjunctivitis or the presence of a foreign body in the eye. If one goat continues to suffer from "pinkeye" after the rest of the herd has recovered, a point should be made of examining its eyelids. When the entropion is of spastic origin, surgically altering the eyelids is not always necessary. Instead, the lid position can be corrected by sutures or wound clips long enough for the initial and secondary problems and pain to be resolved.

Other Causes of Secondary Entropion

It is possible for entropion to follow a previous injury to and deformation of the eyelid. A small or collapsed globe also permits the lids to roll inward, as does retraction of a painful eyeball deeper into the orbit. Severe dehydration and emaciation (as from starvation or parasitism) are perhaps the most common causes of secondary entropion.

Corrective Measures

The literature is replete with techniques for correction of entropion in goats and in other species (Rook and Cortese 1981; Wyman 1983; Baxendell 1984; Moore and Whitley 1984; Whittaker et al. 1999). In general, the veterinarian should not rush into a complicated and therefore expensive technique without giving con-

a

Figure 6.5a. Chronic spastic entropion with severe keratitis and hair loss.

b

sideration to one of the more temporary but often effective methods developed by ingenious shepherds and private practitioners.

One such simple but versatile technique is the use of Michel wound clips (Eales et al. 1984) (Miltex Instrument Co., New York, NY) or metal surgical staples, three or four per affected lid, to pinch up a fold of skin adjacent and parallel to the lid margin. No anesthesia is required; it is simple to remove and replace a clip if the effect of its placement is not immediately satisfying, and the clips fall out on their own over time. The owner of a newborn kid may be able to achieve correction simply by drying the area and manually rolling the lid margin outward as often as possible over the course of one or two days. Another version of this approach is to roll superglue onto the skin below the eyelid with a toothpick (which only serves as the applicator), causing the skin to evert and adhere to itself

(Mongini 2007). Tensing of the lid by injection of penicillin in the same site where clips would be placed is also effective. A slightly more traumatic approach is to crush a fold of skin with hemostats; the ensuing swelling everts the lid. Naturally, any additional causes of ocular pain should be identified and treated. An antibiotic ointment is administered for several days, until the eye appears to be comfortable.

Surgical techniques, mostly adapted from canine ophthalmology, include removing an ellipse of skin alone or skin plus orbicularis muscle. Although initially effective, these methods carry the danger of creating an ectropion when the scar contracts. Thus, they should not be used for the treatment of very young kids or of goats with a simple, spastic entropion.

Tumors

A hemangioma of the third eyelid has been reported in a goat in England (Matthews 1992). Tumors of the third eyelid (type not specified) have been observed in Saanen goats in Australia (Baxendell 1984) and other regions where animals are exposed to high intensity sunlight. Conjunctivitis, lacrimation, and even a purulent secretion may result. The tumor is surgically removed with the aid of tranquilization, local anesthesia, and (if available) electrocautery. Eye ointments are used postoperatively. The Angora goat (because of lack of protective pigmentation) is also considered to be predisposed to ocular squamous cell carcinoma.

Warts may involve the eyelids. They are discussed in detail in Chapter 2. Most warts on the face regress spontaneously, but excision may be desirable in select cases. They need to be distinguished from contagious ecthyma lesions, which are also proliferative and self-limiting but have an important zoonotic potential. Almost any lesion on the eyelid, including warts and other tumors, can become secondarily infected with staphylococci.

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS

Infectious keratoconjunctivitis is known to the layperson as "pinkeye." A number of etiologic agents have been incriminated. When only one or two animals are affected, it becomes more difficult to distinguish between an infectious and an irritant cause. In fact, many sources of irritation, such as bright sunlight, dusty hay, and dust blown into the eyes by wind or transport in an open vehicle, can predispose the goat to development of an infection. Flies and hay or grass contaminated by ocular secretions can spread the agents to other goats. A herd outbreak may follow introduction of a carrier animal or attendance at a show.

Another common source of irritation to conjunctiva and cornea is entropion. Entropion should be suspected in young kids with tearing; its management is

discussed above. In an older animal with sudden occurrence of entropion, the possibility that a foreign body remains in the conjunctival sac or beneath the third eyelid must be considered and investigated by thorough examination.

Infectious Keratoconjunctivitis

Etiology

Mycoplasma and *Chlamydophila* are currently believed to be the most common causes of keratoconjunctivitis in goats in the United States. Numerous other agents are rarely involved or are exotic to North America.

Mycoplasma

Mycoplasma conjunctivae has been isolated from naturally occurring cases of pinkeye in goats and in sheep and has induced the disease in experimental studies (Barile et al. 1972; Baas et al. 1977; Trotter et al. 1977). It also can exist in a carrier state in the conjunctival sac of clinically healthy eyes. Mild forms of the disease are self-limiting and last approximately ten days, although clinical signs have been reported as persisting as long as twelve weeks. Other mycoplasma species isolated from goats with keratoconjunctivitis include *Mycoplasma agalactia*, *M. mycoides* subsp. *mycoides*, large colony type (McCauley et al. 1971; Bar-Moshe and Rapapport 1981), *M. capricolum* (Taoudi et al. 1988), and *Acholeplasma oculi* (Al-Aubaidi et al. 1973). Because these agents can be associated with mastitis, pleuropneumonia, or arthritis, it may be easier to demonstrate the organism in other disease processes in the same goat. A report of *M. mycoides* var. *capri* from the United States (Jones and Barber 1969) probably represents a misidentification of *M. mycoides* subsp. *mycoides* (DaMassa et al. 1984). *Chlamydophila* remains an important differential, especially if arthritis or pneumonia is concurrent.

Chlamydophila

Chlamydial conjunctivitis has been recorded as a contagious disease of young goats and adults (Baas 1976; Eugster et al. 1977). In sheep, recurrence of chlamydial keratoconjunctivitis within a few weeks after clinical remission and an outbreak duration of several months have been recorded (Andrews et al. 1987). Lymphoid follicles are reported to develop in the conjunctiva early in the course of the disease. The current name applied to the chlamydial species causing conjunctivitis in small ruminants is *Chlamydophila pecorum* (Nietfeld 2001).

Rickettsia

Colesiota (*Rickettsia*) *conjunctivae* has been proposed as an etiologic agent for pinkeye in goats and sheep (Rizvi 1950). Most reports were based on cytology and predated the knowledge that chlamydia and mycoplasma are commonly involved, and thus rickettsia have fallen out of favor as being involved in the syndrome (Jones et al. 1976). The reported clinical signs, including occasional prolonged outbreaks, are indistinguishable from the disease produced by the other agents. However, experimental subconjunctival injection of the Q fever agent (*Coxiella burnetii*) has produced severe keratoconjunctivitis in goats, with rickettsia demonstrable in scrapings (Caminopetros 1948).

Other Possible Agents

The isolation of a bacterium from the conjunctival sac of a goat with keratoconjunctivitis is not adequate proof of causality. It is possible that *Moraxella (Branhamella)* (*Neisseria*) *ovis* is sometimes involved in the pathogenesis (Bulgin and Dubose 1982). Conjunctivitis but not severe keratitis has been reproduced experimentally in goats using a strain of *Moraxella (Branhamella) ovis* isolated from an outbreak of keratoconjunctivitis (Bankemper et al. 1990), but this same organism appears to be common in normal eyes of goats, at least in some herds (Pitman and Reuter 1988). *Staphylococcus aureus* has also been isolated from ocular swabs of healthy goats (Adegoke and Ojo 1982). In cattle and sheep, *Listeria monocytogenes* has been associated with a keratitis resulting from direct inoculation of contaminated silage into the eye (Evans et al. 2004).

Moraxella bovis, an important cause of pinkeye in cattle, is rarely involved in caprine keratoconjunctivitis. The organism is rod-shaped, whereas *Moraxella (Branhamella) ovis* is a coccus. Commercial *Moraxella* vaccines have no place in caprine medicine. A very closely related species, *Moraxella caprae*, is also a rod and has been isolated from normal goats (Kodjo et al. 1995). The significance of this organism as a potential cause of keratoconjunctivitis is unknown.

Infectious bovine rhinotracheitis (IBR) virus has been isolated from a goat that developed severe keratoconjunctivitis after five days of treatment with an antibiotic preparation containing corticosteroid for respiratory disease (Mohanty et al. 1972). Most experimental inoculations of goats with the IBR virus have produced seroconversion but only mild clinical signs in addition to fever.

Borna disease is an infectious meningoencephalomyelitis of viral origin that affects horses and sheep in middle and eastern Europe and may be transmitted by ticks. Conjunctivitis and epiphora have been reported as ocular signs. Central nervous system involvement can lead to blindness as well as other neurologic signs. Antibodies have been found in goats, but spontaneous cases of the disease have rarely been reported in this species (see Chapter 5).

The rinderpest and peste des petits ruminants paramyxoviruses cause high fever and erosive lesions in the alimentary tract of ruminants. Ocular signs may include increased lacrimation and a serous conjunctivitis that turns mucopurulent. Gray, elevated fibrinonecrotic lesions in the conjunctiva may eventually slough, leaving an ulcer (Williams and Gelatt 1981).

Goats with capripox infections sometimes develop oculonasal discharge, conjunctivitis, and keratitis, in addition to fever and anorexia (Patnaik 1986). The typical skin lesions caused by the virus are discussed in Chapter 2.

Thelazia spp., the eyeworms, can cause conjunctivitis or keratitis in sheep, and probably in goats. *Thelazia rhodesii* occurs in goats as well as cattle, sheep, and other species, and is cosmopolitan in Europe, Asia, and Africa. *Thelazia californiensis* is widely distributed in the United States, but goats are not mentioned as harboring the parasite (Soulsby 1982). The nematodes are small (7 to 18 mm) and slender. They may be found in the conjunctival cul-de-sacs, behind the third eyelid, or swimming across the surface of the cornea. Sometimes they invade the nasolacrimal duct. A topical anesthetic is applied and the eye is irrigated with sterile saline to remove the worms (Wyman 1983). Alternatively, topical application of an avermectin, such as a drop or two of 1% moxidectin for injection, kills the parasite (Lia et al. 2004). Systemic levamisole or avermectins should also kill the worms (Whittaker et al. 1999). Control of nonbiting flies, which serve as vectors (Otranto and Traversa 2005), is desirable.

A single *Setaria cervi* worm longer than 1 inch was found in the aqueous humor of a goat in India. The goat exhibited continuous unilateral lacrimation. The worm was successfully removed under local anesthesia (Emaduddin 1954).

Migrating larvae of *Gedoelstia hassleri* (nasal botfly) cause keratoconjunctivitis and panophthalmitis in goats and other species in endemic areas of South Africa (Basson 1962). *Trypanosoma brucei* and *T. rhodesiense* cause blepharoconjunctivitis and keratitis in goats (Losos and Ikede 1972). In many tropical and subtropical countries, screwworm larvae may invade fresh wounds on the head or ocular tissues infected with keratoconjunctivitis. A foul odor and brownish exudate are produced. Other opportunistic fly larvae may then infest the lesions.

Besnoitiosis is a parasitic disease of goats as well as cattle and horses in southeastern Europe, Africa, and New Zealand. The causative agent in goats is a *Besnoitia* species, possibly different from *B. besnoiti* of cattle (Njenga et al.1993). Cats that eat cysts in infected tissues develop an intestinal infection and excrete infective forms in their feces. Clinical signs in goats include dermatitis, alopecia, and infertility. Ocular cysts (white, elevated, sand-like foci) on the scleral conjunctiva are useful for field diagnosis of the infection (Bwangamoi et al. 1989).

Mycotic keratitis, although relatively common in horses, seems to be rare in ruminants (Wyman 1983) and specific reports in goats are lacking. Isolation and identification of the fungus are required before the diagnosis can be made. A chronic keratitis, plaque-like growths on the cornea, or severe keratomalacia might prompt attempts to culture a fungus, especially if there is a history of treatment with antibiotics and corticosteroids together. Therapy is difficult and expensive. The practitioner should consult with an ophthalmologist.

Clinical Signs

Early or mild keratoconjunctivitis results in lacrimation; the side of the face is wet below the eye. The conjunctiva is also red and swollen (chemosis) (Figure 6.6). Over several days, hyperemia of the conjunctiva increases, follicle formation occurs, and neovascularization of the cornea may develop. The cornea may be slightly hazy at the limbus or entirely opaque (Baxendell 1984). A few animals develop a corneal ulcer that can be demonstrated with fluorescein stain (Figure 6.7), and that ulcer may perforate. The eye is painful and held partially closed; blinking is frequent. If both eyes are opaque or ulceration occurs, the goat will lose body condition because it does not forage well. Totally blind animals on range may die (Eugster et al. 1977).

Diagnostic Techniques

The various etiologic diagnoses for infectious keratoconjunctivitis cannot be distinguished on the basis of clinical signs; laboratory assistance is required. Mydriatics, topical anesthetics, or vital stains should not be used until after diagnostic samples have been taken.

Figure 6.6. Early keratoconjunctivitis with chemosis and slight ocular discharge. (Courtesy Dr. M.C. Smith.)

Figure 6.7. A corneal ulcer is green from uptake of fluorescein stain. Marked neovascularization of the cornea indicates chronicity. (Courtesy Dr. M.C. Smith.)

CULTURES. A premoistened sterile polyester or calcium alginate swab is rubbed briskly across the conjunctiva and placed in transport media (such as Amies). If possible, personnel at the diagnostic laboratory should be consulted regarding media, because chlamydia and mycoplasma can be difficult to isolate. If the laboratory does a polymerase chain reaction test for chlamydia, use of transport media may dilute the sample too much for good results. Dry cotton swabs are less desirable for fastidious organisms. It is also important to take samples from early lesions; secondary bacteria, leukocytes, and various products of immune mechanisms interfere with isolation efforts.

SCRAPINGS FOR IMMUNOFLUORESCENCE TESTING. Scrapings from the palpebral conjunctiva (especially lymphoid follicles) can be made with a wooden spatula designed for obtaining Pap smears, the butt end of a disposable scalpel blade, or with the bevel of a sterile, disposable 20-gauge needle. The tissue thus obtained is spread on several microscope slides. Many laboratories consider fluorescent antibody testing for chlamydia to be easier than culturing this agent in embryonated eggs or tissue culture cells.

EXFOLIATIVE CYTOLOGY. Interpretation of cytological preparations from conjunctival scrapings can be very difficult, even for trained people. Practitioners should consider preparing duplicate slides to simplify later consultation with an ophthalmologist or diagnostic laboratory. Superficial cells can be harvested with minimal distortion by rolling a dry swab across the conjunctiva and then across the slide, as is done for canine vaginal smears. Deeper scrapings are obtained with a blade or small spatula. New methylene blue, Wright, Giemsa, Dif-Quik, or Gram stain is typically used. Large basophilic, Gram-negative cytoplasmic inclusion bodies in epithelial cells occur with chlamydial conjunctivitis but are difficult to find after the first week (Wyman 1983). Smaller basophilic coccobacillary (McCauley et al. 1971) and signet-shaped bodies are found attached to or within epithelial cells in mycoplasmal infections. *Moraxella* (*Branhamella*) *ovis* organisms are larger than mycoplasma and more uniform in shape, and stain more intensely (Dagnall 1994). Rickettsia are described as small, Gram-negative, highly pleomorphic bodies that may be both intracytoplasmic and free (Beveridge 1942; Rizvi 1950). Pigment granules or stain precipitates can be confusing, and visible evidence of an etiologic agent may be lacking, even when cultures are positive.

Treatment

The intensity of treatment varies according to the number of infected goats and the concern of the owner. What follows is most appropriate for single pets or valuable animals. The eye should be irrigated with physiologic saline, sterile saline for contact lens wearers, or clean (preferably previously boiled) water to remove exudates and dust or other foreign matter. Although antibiotic drops are theoretically better than ointments, it is inconvenient for the owner to apply drops every two hours. Ointments are generally effective if given at least twice (or better, three to four times) a day. Several antibiotics have been clinically effective, but it must be remembered that many animals heal uneventfully without treatment. Given the spectrum of agents associated with keratoconjunctivitis, a tetracycline eye ointment is a reasonable choice. In countries where its use is permitted, chloramphenicol ointment might be effective, although systemic chloramphenicol was not effective in treating sheep with keratoconjunctivitis (König 1983). It is illegal to administer chloramphenicol to goats in the United States, because all goats are assumed to be food-producing animals despite the owner's plans for the individual.

Powders and aerosols are irritating to the eyes and ideally should not be used, but they have been reported to give good results. When economics become an important consideration, as when many goats are affected or the whole herd is being treated simultaneously to try to end a prolonged epizootic, it may not be possible to use ophthalmic ointments. Experimentation may identify a nonirritant mastitis ointment containing a suitable antibiotic that is better than no treatment at all. Under similar circumstances, intramuscular injections of long-lasting tetracycline have prevented relapses in sheep affected with *Mycoplasma conjunctivae* and other agents (König 1983; Hosie 1988). Intramuscular tylosin (200 mg/goat/day) has afforded good results in goats treated early in the course of chlamydial keratoconjunctivitis (Eugster et al. 1977). Subcutaneous administration of these antibiotics would also be effective and less painful. A newer macrolide antibiotic, tulathromycin, has not yet been evaluated in small ruminants but is effective in treating

keratoconjunctivitis in beef cattle (Lane et al. 2006). Milk contamination makes systemic antibiotic treatment unjustifiable in most dairy herds. In fact, the possibility of milk contamination from eye ointments has apparently not been investigated.

Corticosteroids are available in many different topical and injectable preparations of varying anti-inflammatory effect and penetrating ability (Bistner 1986). Corticosteroids are not necessary and are contraindicated if an ulcer is present. A subconjunctival injection of a depot form of corticosteroid may be helpful to control neovascularization after extensive keratitis. The eye must be "quiet" and the cornea free of ulcers, as demonstrated by fluorescein staining, before such a treatment is performed. In general, it is best to dispense an ointment without steroids because the owner is likely to use whatever product is on hand to treat undiagnosed eye problems of goats or other animals at a later date.

Ulcerated eyes should be observed several times a day for descemetocele formation. If perforation of the cornea appears imminent, a conjunctival flap, third eyelid flap, or tarsorrhaphy is indicated to protect and support the cornea. The third eyelid flap is probably easiest. Local anesthesia with an ophthalmic anesthetic, paralysis of the eyelids with 1 or 2 ml of injectable anesthetic (diluted if the goat is small) over the auriculopalpebral nerve (on the lateral surface of the zygomatic arch), and light tranquilization with xylazine are employed. Mattress sutures of 00 chromic gut that pass through the full thickness of the upper lid but do not penetrate the bulbar aspect of the third eyelid pull the cartilaginous portion up to the upper lid (Moore and Whitley 1984); small buttons or pieces of tubing on the outside of the lid prevent pressure necrosis of the skin. Follow-up care includes continued therapy with antibiotic ointment and close observation for loosening of the sutures. Misplaced sutures abrade the cornea. Absorbable sutures dissolve in two to three weeks, and nonabsorbable sutures should be removed at this time.

As a simpler alternative to surgery for severe corneal ulcers, the author has seen excellent response to topical 5% silver nitrate, a few drops applied once a day for five days in conjunction with systemic oxytetracycline. This solution is not available commercially but can be approximated by dissolving the material coated onto one Grafco® silver nitrate applicator stick (Atlanta, GA) in 1 ml of sterile water. The totally opaque soft cornea is firm and shiny again in a few days, although total clearing of the cornea can be expected to require more than a week (Figure 6.8). Because the silver nitrate appears to sting, pretreatment with a topical anesthetic is advised. In human medicine, both 1% silver nitrate solution and 2.5% povidone iodine solution have been effective in killing microorganisms in

a

Figure 6.8a. A totally opaque and softened cornea from severe bilateral keratoconjunctivitis.
b

Figure 6.8b. The same cornea, five days after initiation of treatment with systemic oxytetracycline and topical 5% silver nitrate. The cornea is firm, shiny, and clearing. (Courtesy Dr. M.C. Smith.)

the eye for prophylaxis of ophthalmia neonatorum (Isenberg et al. 1994).

Noninfectious Keratitis

Not all cases of keratitis begin as infectious conjunctivitis.

Abrasions

Foreign bodies (in addition to eyelashes) may abrade or penetrate the cornea. The eye is painful, and fluorescein staining reveals a defect in the corneal epithelium. Treatment for shallow abrasions is with an antibiotic ointment after careful search for a foreign body in the fornix or behind the third eyelid. If the injury has reached the level of Descemet's membrane, and the inner layer of the cornea bulges outward, a conjunctival or third eyelid flap is indicated. A corneal stromal ulcer with lysis (melting) as a result of collagenase production may appear soft and

gelatinous or may resemble a deep abrasion. When any doubt exists as to the origin of the lesion, anticollagenase drugs (Mucomyst® [Bristol-Myers Squibb, Princeton, NJ] topically) and aspirin (100 mg/kg twice daily orally) should accompany placement of a conjunctival flap. If the full thickness of the cornea has been perforated but iris has plugged the hole, consultation with or referral to an ophthalmologist is desirable. A collapsed eyeball is generally best enucleated.

Exposure Secondary to Facial Nerve Deficit

Listeria organisms often enter the brain stem along a cranial nerve. If the facial nerve is thus involved, unilateral paresis or paralysis of the eyelids may occur before any signs of central nervous system disturbance are recognized. The goat that can no longer blink may incur a shallow abrasion to the cornea, which the owner recognizes because of lacrimation, conjunctival injection, corneal clouding, and photophobia. It is very important for the veterinarian to evaluate ipsilateral tonus of lids, ear, and lip. Although it may be impossible to distinguish a facial nerve paralysis of traumatic origin or secondary to otitis media from early listeriosis, treatment with penicillin or tetracycline for one week is justified because the prognosis for an animal with listeriosis is so much worse when the signs are unequivocal.

The cornea dries out and becomes opaque in more advanced listeriosis or other long-standing facial nerve paralysis. A lid-splitting suture pattern to hold the lids in apposition over the cornea prevents additional damage and decreases the frequency with which application of ointments is required during the prolonged recovery period, until nerve function returns. In general, local therapy for exposure keratitis should include antibiotics to prevent secondary infection and atropine for cycloplegia (Rebhun and deLahunta 1982). Uveitis and even hypopyon can be expected in severely affected goats.

Vitamin A Deficiency

Bilateral corneal opacity, lacrimation, and diarrhea were observed in kids born in a goat herd experiencing severe vitamin A deficiency due to six months on dry pasture. All signs disappeared after improvement of the diet (Caldas 1961). Night blindness, lacrimation, and corneal ulceration were reported in adult goats kept on an experimental vitamin A deficient diet for periods as long as two years (Schmidt 1941; Majumdar and Gupta 1960; Dutt and Majumdar 1969).

Toxins

Phenothiazine was once commonly used as an anthelmintic. If metabolism is not complete, phenothiazine sulfoxide reaches the aqueous humor and is a primary photosensitizing agent; it induces uveitis, corneal endothelial damage with subsequent edema, and keratitis (Enzie and Whitmore 1953). Young goats should be kept out of direct sunshine for three days after receiving this drug.

Keratoconjunctivitis sicca, or dry eye, is one of the signs associated with locoweed poisoning (*Astragalus* spp). Drying out of the eyes may be caused by inadequate blinking and failure of neurologic stimulation to the lacrimal glands or by reduced tear production capabilities of the glands.

The imported fire ant (*Solenopsis invicta*) is present in the south central United States. Ants occasionally attack weak or debilitated animals, injecting a necrotoxic venom into the victim. Necrotic ulceration of conjunctiva and cornea has been observed in a goat stung by these ants (Joyce 1983).

Caprine Mucopolysaccharidosis-IIID

A recessive genetic defect (G6S) of Nubian goats which causes a deficiency of *N*-acetylglucosamine-6-sulfatase results in the accumulation of glycosaminoglycans in lysosomes. Growth retardation has been reported clinically. One severely affected kid was ataxic and developed mild, nonprogressive corneal clouding; histologically there was vacuolation of cells in the cornea as well as in the brain (Jones et al. 1998). A survey of 552 purebred Nubian goats in Michigan revealed that 25% of the animals were heterozygous for the mutation and 1.3% were homozygous (Hoard et al. 1998).

ANTERIOR UVEITIS, CATARACTS, AND GLAUCOMA

Anterior uveitis (inflammation of the iris and ciliary body) produces a variety of changes within the eye. These include decreased production of aqueous humor (decreased intraocular pressure), increased protein content of aqueous humor (flare), and accumulation of leukocytes (hypopyon) or erythrocytes (hyphema). Constriction of the pupil is an important diagnostic sign, as is photophobia because of painful inflammation of the ciliary muscle. Organophosphate toxicity, which is also accompanied by miosis, is an important differential. Miosis has also been reported with urea poisoning (Schmidt 1973). Adhesions may form between the swollen iris and the lens or cornea. Retinal detachment and glaucoma are other potential sequelae.

Causes of Anterior Uveitis

Septicemia

Hypopyon, deep neovascularization of the cornea, and other signs of anterior uveitis sometimes accompany neonatal septicemia. The posterior segment of the eye or the brain may also be infected. Appropriate

systemic antibiotic therapy is critical to survival of the animal. If the infectious agent is resistant to the antibiotic chosen, the corticosteroids used to treat the secondary anterior uveitis may exacerbate the primary infection.

Toxemia

Constriction of the pupil and anterior uveitis may be noted in goats with severe toxic mastitis or metritis.

Deep Keratitis

Severe keratitis resulting from infectious keratoconjunctivitis or exposure keratitis may extend to or cause reflex inflammation of deeper portions of the globe. *Mycoplasma* spp. infections can also reach the uveal tract by the systemic route during septicemia (Whitley and Albert 1984).

Retroviral Infections

A nonsuppurative chorio-iridocyclitis, sometimes accompanied by granuloma formation, has been documented in the eyes of goats with chronic neurologic disease believed in retrospect to be caused by retroviral infection (Stavrou et al. 1969; Dahme et al. 1973). Clinical signs directly related to the ocular system included corneal opacity, nystagmus, and blindness (usually unilateral). The prevalence of anterior uveitis in goats with caprine arthritis encephalitis or related virus infections (see Chapter 5) is unknown. Clinical blindness could be the result of a brain lesion rather than an eye lesion and few studies have reported histology of the eye. In one group of naturally infected goats where optic nerves and eyes were examined, no histologic lesions were found in these tissues (Sundquist et al. 1981).

Toxoplasmosis

At least in other species, toxoplasmosis can lead to iridocyclitis and necrotizing granulomas on the retina and ciliary body. In one study including sheep (but no goats), granulomatous ocular lesions were demonstrated in eyes from twelve of eighteen sheep with experimental toxoplasmosis (Piper et al. 1970). Systemic therapy with sulfonamides and pyrimethamine and topical treatment with atropine, steroids, and 10% sulfacetamide ophthalmic ointment have been recommended. The possible occurrence of ocular lesions in kids congenitally infected with toxoplasmosis needs to be investigated.

Trauma

Blunt trauma to the head may induce hyphema or an anterior uveitis. This might explain the occasional occurrence of fibrin tags attached to the iris of goats with central blindness because of polioencephalomalacia (Smith 1979). In general, it is wiser to administer thiamine whenever blindness is accompanied by any other neurologic signs rather than to exclude from consideration a common disease based on the presence of an unusual sign.

Treatment of Anterior Uveitis

Even though the exact cause is rarely determined, in the absence of fluorescein uptake by the cornea, treatment of the eyeball showing such signs should include corticosteroids and atropine. The corticosteroids are generally given by bulbar subconjunctival injection with a tuberculin syringe and a 25-gauge needle. The atropine might be given by injection, but more commonly, ointment or drops are instilled every few hours until the pupil dilates, then once or twice a day. Both painful spasm of the ciliary muscle and the danger of adhesion formation are decreased by using atropine. The animal should be allowed access to a darkened stall until the ability to constrict the pupil is regained after discontinuation of therapy. Antiprostaglandin therapy also results in dilation of the pupil.

Cataracts

Cataracts are opacities of the lens or its capsule. Uveal pigment may be deposited on the anterior lens capsule. Fluid accumulation within the lens or denaturation of lens protein may hinder light transmission. A cataract can occur as a sequela to any severe anterior uveitis if not vigorously treated. Congenital cataracts have apparently not been reported in goats (Wyman 1983). Referral to a specialist should precede any surgical attempt at cataract extraction.

Glaucoma

Secondary glaucoma has been reported as occurring after severe anterior uveitis induced by *Mycoplasma agalactia* (Moore and Whitley 1986). The intraocular pressure rises because the iridocorneal angle is closed by the inflammatory process. Both the anterior uveitis and the glaucoma may contribute to corneal edema, as does anterior lens luxation if it occurs. Buphthalmia (enlargement of the globe) may initially protect the retina. When intraocular pressure becomes high enough to damage the retina, permanent blindness occurs. Proper use of mydriatics and corticosteroids to prevent secondary glaucoma is paramount.

Tonometry

The only method available to most large animal practitioners for estimating intraocular pressure is digital tonometry. The index and middle fingers of one hand are used to slightly flatten the globe by applying pressure through the upper lid. The other hand simultaneously evaluates the second eye of the patient. At least until experience is gained, comparison with a normal goat is helpful.

The Schiotz tonometer, although previously available in many small animal practices, is not practical for use in goats. The goat must be in dorsal recumbency for the cornea to be accessible when the tonometer is held vertically. A topical anesthetic is required. Struggling or compression of the jugular veins might artificially elevate the intraocular pressure. By contrast, Tono-Pen tonometers are easy to use on goats. Although a normal range for the goat using this device has not been reported, values from the patient could be compared with intraocular pressure measurements from several normal goats.

Treatment

It is unlikely that glaucoma will be diagnosed in an affected goat until the cornea is "steamy" and the globe is enlarging. In most instances, medical management is impractical. Prompt referral to an ophthalmic surgeon may be appropriate for certain valuable animals. Otherwise, the practitioner should plan to enucleate the glaucomatous eye when the goat appears to be in persistent pain or when the eyelids can no longer cover the enlarged globe well enough to prevent drying of the central cornea. An alternative to enucleation might be an injection of gentamicin plus corticosteroid into the vitreous to destroy the ciliary body.

RETINAL CHANGES

A number of lesions may be recognized in the course of a thorough ophthalmoscopic examination of the retina. Cellular infiltration may appear focal or diffuse or it may follow blood vessels. Infiltrations are white or gray. Edema has a similar appearance but may be better demarcated. Hemorrhages have different shapes depending on the layer of the retina where they are located. Thus, focal or round hemorrhages are deep within the retina, linear lesions (flame hemorrhages) are in the nerve fiber layer, and crescent shaped (keel) hemorrhages are preretinal (beneath the vitreous).

Papilledema

Papilledema is a noninflammatory swelling of the optic disc. It is an important sign of increased intracranial pressure. Causes in ruminants include hypovitaminosis A, acquired and congenital hydrocephalus, space-occupying brain lesions, meningitis, encephalitis, coenurosis, and hexachlorophene toxicity (Whittaker et al. 1999). Papilledema is usually bilateral. The arterioles are more thread-like (and more red) than the congested retinal venules. Hemorrhages may be present on the disc or retina.

Chorioretinitis

Retinitis has been described in association with elaeophorosis in sheep. Trypanosomosis of sheep has caused severe uveitis, chorioretinitis, and optic neuritis. Natural infection with bluetongue or use of an attenuated vaccine in ewes in the first half of pregnancy has caused necrotizing retinopathy in lambs, according to Wyman (1983). Toxoplasmosis, as discussed under anterior uveitis, can cause a granulomatous chorioretinitis in ruminants. These conditions apparently have not been reported in goats.

Chorioretinopathy

This term suggests that active inflammation is not (or is no longer) present. One example would be scars from an earlier septicemia. Retinopathy is manifested by tapetal hyper-reflectivity and pale depigmented areas in the nontapetal fundus. Retinal atrophy has been reported after congenital infection with Akabane virus. A spontaneous retinopathy possibly caused by rod-cone dysplasia has been reported in a young Toggenburg goat (Buyukmihci 1980). Four other closely related Toggenburg kids in Canada were blind from birth and showed a similar tapetal hyperreflectivity and marked retinal vessel attenuation; an inherited disorder was suspected (Wolfer and Grahn 1991). Other causes of retinal degeneration in ruminants, even if unreported in goats, are mentioned below for completeness.

Scrapie

Scrapie, at least in sheep, can cause a central blindness. However, multifocal retinal elevations have also been described. These are blister-like, hyperreflective, with a dark edge, and scattered in the tapetal fundus. They vary from one-fourth to three-fourths the size of the optic disc (Barnett and Palmer 1971).

Border Disease

Because of parallels with lesions identified in cattle affected in utero with bovine virus diarrhea (BVD) virus, border disease might be expected occasionally to be accompanied by retinal changes. Abnormalities reported in cattle include grayness of the optic disc, vascular attenuation, hyperreflective areas of the tapetal fundus, unusual admixtures of tapetal colors, and multifocal depigmentation of the nontapetal fundus. Cataracts may occur and normal pupillary light reflexes may be absent. Such findings have not yet been reported in sheep or goats.

Bright Blindness

Sheep consuming bracken fern (*Pteridium* spp.) (Barnett and Watson 1970) for many months may develop progressive bilateral blindness. The tapetum develops increased reflectivity, and the neuroepithelium degenerates. The pupils become circular and react poorly to light. The arteries and veins of the

retina appear narrower than normal. The shepherd notices the blindness when a sheep becomes separated from the flock and runs around with elevated head and a high-stepping gait.

Blind Grass

Stypandra imbricata, or blind grass, is a plant found in western Australia. Goats and sheep that survive acute exposure become permanently blind, with degeneration of photoreceptor cells, optic nerves, and optic tracts. Clinical examination several weeks after blindness develops reveals foci of pigment epithelium hypertrophy, especially prominent in the nontapetal fundus near the optic disc. Pupillary light reflexes are absent (Main et al. 1981). A related Australian plant, *Stypandra glauca* (nodding blue lily), has been associated with blindness in goats consuming the plant during its flowering stage. Acute cerebral edema with subsequent compression of the optic nerve within the optic canal may be important to pathogenesis (Whittington et al. 1988).

Other Plant Toxicities

Helichrysum argyrosphaerum toxicity has caused papilledema and retinal changes in sheep and cattle in Namibia, with spongiform lesions occurring in brain and optic fasciculi as well (Kellerman et al. 2005). Goats appear to be resistant (Basson et al. 1975) but in one blind goat with cerebral and brainstem vacuolation, a slight increase in tapetal reflectivity and pigmented foci in the nontapetal fundus were noted (Van der Lugt et al. 1996).

Some species of *Astragalus* (locoweed) cause a retinal degeneration, at least in cattle and sheep. Many cells in the body are vacuolated, including neurons in the brain and inner ganglionic layer of the retina and secretory cells in the lacrimal gland. The eye appears dull and vision is impaired (Van Kampen and James 1971). *Swainsona* (darling pea) in Australia causes similar signs. Both plants contain substances that inhibit lysosomal mannosidase, thereby producing a storage disease. Similar vacuolation of retinal cells has been seen in goat kids with hereditary beta mannosidosis (Render et al. 1989). *Astragalus* species have also caused blindness, ataxia, and weight loss (blind staggers) caused by high concentrations of selenium (Hosseinion et al. 1972), although it has been speculated that some cases of blind staggers were actually sulfur-related polioencephalomalacia (Whittaker et al. 1999). This condition is discussed in Chapter 5.

Dryopteris filix-mas (male fern) ingestion in cattle causes acute retrobulbar neuropathy that may progress to optic atrophy. Hemorrhages on or around the optic disc and papilledema are noted acutely. Chronic lesions include optic nerve atrophy and reduced retinal vasculature; these animals are blind.

Retinal Detachment

Detachment occurs when transudates or exudates accumulate between the retinal pigment epithelium and the receptor layers. A total detachment results in blindness and is recognized by the presence of a billowing structure containing blood vessels in the vitreous. Case reports in goats are lacking.

AMAUROSIS

Amaurosis is blindness without any externally detectable defect in the visual system. The cornea, lens, and uveal tract appear to be normal. If the lesion is limited to the cerebral cortex and optic nerve and nuclei are intact, the pupillary reflexes are also normal. Blindness becomes apparent because of abnormal behavior or failure to respond to visual stimuli.

Blindness versus Failure to Blink

It is common but inaccurate to equate the ability to blink in response to a menacing hand gesture with the ability to see; this is because the entire visual pathway, from the retina to the cerebral cortex, must be intact for the reflex to function (deLahunta 1983). Because it is a learned response, very young kids may not menace even though they have no trouble seeing and following a moving bottle or other item of interest. A goat with normal vision also fails to blink if facial nerve paralysis is present. This possibility is investigated by actually touching the medial or lateral canthus. Even a blind animal should then blink, unless either sensory or motor function is disturbed.

Blindness versus Severe Depression or Toxemia

Severely obtunded or semi-comatose goats respond minimally to stimuli routinely applied to evaluate cranial nerve function. If the animal is severely depressed, a metabolic disease (hypoglycemia, hypocalcemia, pregnancy toxemia, rumen acidosis), liver disease (see Chapter 11), or terminal septicemic or toxemic (Boermans et al. 1988) condition, rather than a lesion specifically involving visual pathways or cerebral cortex, may be present. It is inappropriate, then, to limit diagnostic consideration to those diseases with blindness as a leading sign.

Polioencephalomalacia

Blindness is almost always present in advanced cases of polioencephalomalacia. Thus, thiamine administration, as discussed in Chapter 5, is indicated (at least initially) for every goat with amaurosis.

Enterotoxemia

Blindness is one sign of focal symmetrical encephalomalacia, an uncommon disease reportedly caused by exotoxins of *Clostridium perfringens*, in sheep. The

condition has been reported only rarely in goats (see Chapter 5).

Lead Poisoning

Although blindness is a prominent sign of lead poisoning in cattle, this is not the case in goats. Anorexia and diarrhea, not blindness and convulsions, are reported with experimental lead poisoning in goats (Davis et al. 1976).

Hydrocephalus

A young kid that has a good suckle reflex and a normal gait may become separated from its dam or stuck in corners. Hydrocephalus or other congenital malformation of the brain may be responsible for this abnormal behavior associated with blindness. Sometimes the skull is domed, which increases the suspicion of hydrocephalus. Other kids have no outward conformational changes even though very little brain is in fact present.

Vitamin A Deficiency

Maternal deficiency of vitamin A produces atrophy of the optic nerves in calves. This is because the optic canals have not grown to accommodate the optic nerves, resulting in pressure atrophy and demyelination of the nerves. In the case of acquired avitaminosis A in cattle, there is an initial, often reversible night blindness caused by deficient formation of rhodopsin. If the deficiency continues, the retina degenerates and eventually constriction of the optic nerve can occur in growing calves. Papilledema is an important sign of vitamin A deficiency and is secondary to increased cerebrospinal fluid (CSF) pressure. Vascular congestion and focal superficial hemorrhages also occur. The intraocular pressure is not elevated. Specific reports of this condition in goats are lacking, and in one experimental study adult goats fed a vitamin A depletion ration failed to develop papilledema or increased CSF pressure (Frier et al. 1974).

Severe vitamin A deficiency, as occurs during the dry season or droughts in semiarid regions, causes night blindness that is not always accompanied by corneal opacity and ulceration. These ocular problems are documented in sheep (Eveleth et al. 1949, Ghanem and Farid 1982) and have been reproduced experimentally in goats (Schmidt 1941).

Coenurosis

Coenurus cerebralis is the larval stage of the tapeworm *Taenia multiceps*. It can form a cyst in the cerebral hemispheres or median fissure. A common clinical sign is partial or total blindness in one eye (Sharma 1965; Tirgari et al. 1987; Nooruddin et al. 1996). The head is held in the direction away from the blind eye and the animal circles in that direction, that is, toward

the cerebral lesion. Pupillary reflexes generally remain normal, but papilledema may be noted because of increased intracranial pressure (Sharma and Tyagi 1975). In some cases, the skull overlying the cyst is softened and deformed, and pressure on the affected bone elicits signs of pain (loud bleating). Vision usually returns within one day after surgical removal of the cyst. The disease has not been reported in recent years in the United States (Kimberling 1988).

Miscellaneous Causes of Central Blindness

Several other diseases may cause blindness in sheep, and perhaps in goats. Melioidosis is a fatal septicemic disease caused by *Burkholderia* (*Pseudomonas*) *pseudomallei* and occurs mainly in Southeast Asia and Australia. A central blindness can accompany other neurologic signs. Likewise, scrapie can cause blindness but will probably be recognized by other neurologic signs. Caprine arthritis encephalitis can cause a variety of central neurologic signs, including blindness.

Chronic poisoning with some forms of arsenic, in some species, can cause blindness. Acute blindness in cattle and sheep has been associated with consumption of rape (*Brassica napus*), but documentation is meager. In some instances of poisoning with *Brassica* spp., the actual cause of blindness may be polioencephalomalacia (Wikse et al. 1987). Ironwood (*Erythrophloeum chlorostachys*), a tree from tropical Australia, has been reported to poison goats and cause, among other signs, a staring-eyed demeanor with vision apparently affected (Hall 1964). Overdosage with hexachlorophene, rafoxanide, and closantel can cause degeneration of the optic nerve, optic tract, or retina (Button et al. 1987). The pathologic changes (Gill et al. 1999) resemble those caused by *Stypandra* spp, but pigment epithelium hypertrophy has not been described.

Residual Blindness

Blindness may persist for days, weeks, or even the life of a goat that did not receive thiamine early in the course of polioencephalomalacia. Other traumatic or metabolic insults to the cerebral cortex (prolonged application of a disbudding iron, pregnancy toxemia) could also result in amaurosis. Usually there is a history of partial recovery from a previous severe illness.

ENUCLEATION

Enucleation is indicated if the eyeball has collapsed because of trauma or the perforation of an ulcer resulting from infectious keratoconjunctivitis, or whenever a chronic painful eye condition cannot be resolved. Whether local or general anesthesia is used depends on the facilities available to the veterinarian. If necessary, tranquilization with xylazine and infiltration of 1% lidocaine subcutaneously around the eye and in the depth of the orbit can be used. Thus, in a large animal

practice, enucleation in a goat can be performed on the farm. The lids are clipped and disinfected; irritating solutions should be kept out of the unaffected eye, and they should not be allowed to pool on the surgery table near the down eye. The lid margins, conjunctival sac, and ocular muscles are dissected free from the orbit with curved scissors. A tight ligature around the optic nerve and accompanying blood vessels should control hemorrhage, although a hematoma may form in the orbit. An everting mattress suture is often chosen to close the skin, and penicillin may be instilled into the cavity created by enucleation.

Blood, Lymph, and Immune Systems

Caprine hematology has received considerable attention in the past thirty years. A range of discrepant normal values and hematologic responses have been reported. These discrepancies result from variations in age, breed, and health status of the goats evaluated and from differences in environment, climate, methodology, and sample size. Despite inconsistencies, sufficient data exists for reasonable standardization of normal caprine hematologic values and kinetics (Jain 1986; Kramer 2000). In contrast, information on the organization of the caprine immune system and the immune response is limited. Newer information that is available derives from studies of specific diseases. The most notable is caprine arthritis encephalitis (CAE), which emerged as an animal model for study of acquired immunodeficiency syndrome (AIDS) in humans because of the relatedness of the CAE and human immunodeficiency (HIV) lentiviruses (Cheevers et al. 1997; Sharmila et al. 2002; Fluri et al. 2006; Bouzar et al. 2007) as well as paratuberculosis (Storset et al. 2000, 2001) and others.

BASIC CAPRINE HEMATOLOGY

Anatomic Considerations

The principal organ of hematopoiesis in the goat is the bone marrow. The spleen of the goat is located in the left craniodorsal abdomen between the diaphragm and the dorsal sac of the rumen. The anomaly of two distinct spleens in the left abdomen of a goat has been reported (Ramakrishna et al. 1981). As in other ruminants, goats possess a hemal node system. These nodes contain lymphoid tissue and may also participate in blood storage by hemoconcentration. There are five to twelve hemal nodes in a goat, located along the course of the aorta in the abdominal and thoracic cavities (Ezeasor and Singh 1988). The distribution of the lymph nodes is discussed in more detail in Chapter 3.

Bone Marrow

The myeloid to erythroid (M:E) ratio of the bone marrow of the goat has been reported as 0.69,

indicating more active erythrocyte than granulocyte production. The proportions of cell types found in normal caprine marrow is reported as follows: myeloblasts, 0.58%; promyelocytes, 0.79%; neutrophilic myelocytes, 2.69%; metamyelocytes, 8.25%; band neutrophils, 8.88%; segmented neutrophils, 9.98%; eosinophils, 1.79%; basophils, 0.06%; monocytes, 0.02%; lymphocytes, 7.49%; and nucleated erythrocytes, 56.33% (Coles 1986). Megakaryocytes were not included in the differential count.

Bone marrow collection procedures should be performed aseptically. Bone marrow biopsies and aspirates can be conveniently obtained from the iliac crest. In addition, an aspirate can be obtained from the dorsal 5 to 10 cm of ribs 10 to 13 using sturdy, 3.8-cm, 16- or 18-gauge styletted needles (Weber 1969). Care must be taken to place the needle on the midline of the narrow goat rib. Marrow aspiration from the third or fourth sternebrae also has been reported (Whitelaw 1985). Because goats are prone to developing chronic abscesses in the sternal region, the sternal site should be used as a last resort.

Blood and Plasma Parameters

Mean blood volume as a percentage of body weight is approximately 7% with a range of 5.7% to 9% (Fletcher et al. 1964; Brooks et al. 1984), or 70 to 85.9 ml/kg of bw (Jain 1986). Blood volume increases in response to increased altitude (Bianca 1969). The mean specific gravity of whole blood is 1.042 with a range of 1.036 to 1.050 (Fletcher et al. 1964; Brooks et al. 1984). The osmotic pressure of serum colloids is 300 mm H_2O.

Mean plasma volumes range from 4.2% to 7.5% of body weight, or 53 to 60.2 ml/kg of bw (Jain 1986). Mean plasma specific gravity is 1.022, with a range of 1.018 to 1.026.

Erythrocyte Parameters

Erythrocyte parameters in the goat are labile, changing markedly over the goat's lifetime (Holman and Dew 1964, 1965; Edjtehadi 1978). So-called normal or average values from the clinical laboratory, then, must be interpreted in the context of the animal's age. The decreases in hemoglobin (Hb) and packed cell volume (PCV) that occur during the first month of life may be due to iron deficiency anemia associated with a milk diet. The decrease can be prevented in kids by administering 150 mg of iron as iron dextran at birth (Holman and Dew 1966). Other age-related variations seen in erythrocyte parameters are shown in Table 7.1.

Seasonal changes are also noted in erythrocyte parameters, with greater red blood cell (RBC), Hb, and PCV values in late summer and fall than in winter and spring. Male goats tend to have higher RBC counts than females. Pregnancy has little effect on erythrocyte parameters, but PCV can decrease during the first five months of lactation.

The goat has the smallest erythrocyte of the domestic mammals, with a diameter of 3.2 to 4.2 microns. As a result, standard methods of determining the PCV may overestimate it by as much as 10% to 15% because of inadequate centrifugation time. For the microhematocrit method, centrifugation for a minimum of ten minutes at 14,000 G is recommended for accurate results. The standard Wintrobe method cannot generate sufficient relative centrifugal force to completely pack goat RBCs, even when centrifugation time is extended. As much as 20% of plasma can be trapped with the erythrocytes (Jain 1986). The standard erythrocyte sedimentation rate (ESR) is not applicable to the goat because there is no settling of goat RBCs within the one-hour interval prescribed for the Wintrobe method. However, a decrease of 2 to 2.5 mm can be observed in normal goat blood held for twenty-four hours.

The small size of the goat RBC is also associated with the highest osmotic fragility among the domestic species. When exposed to hypotonic saline solutions, RBC hemolysis begins at concentrations of 0.62% to 0.74% and complete hemolysis occurs in saline concentrations of 0.48% to 0.60%. Pygmy goat erythrocytes are more fragile than those of Toggenburg goats on the basis of susceptibility to osmotic lysis, possibly because of differences in membrane composition (Fairley et al. 1988).

Goat RBCs have only slight biconcavity. In blood smears, they lack a zone of central pallor and do not exhibit rouleaux formation, except perhaps at the edge of a thick smear. Normal cell shape is quite variable and poikilocytosis is common, with triangular, rod-shaped, pear-shaped, and elliptical cells frequently seen, especially in goats younger than three months of age. Sickle cells can occur in Angora goats similar to those seen in deer (Jain et al. 1980). This morphologic change is associated with filamentous polymerization of hemoglobin and is considered innocuous.

Nucleated RBCs may be seen in newborn goats as old as six weeks of age, but are uncommon afterwards. Reticulocytes are always absent or rare in health. Basophilic stippling of goat erythrocytes has been reported in experimental lead poisoning (Davis et al. 1976). The normal life span of circulating RBCs in the domestic goat, *Capra hircus*, is an average of 125 days, but as long as 165 days in a wild goat, the Himalayan Tahr *(Hemitragus jemlaicus)* (Kaneko and Cornelius 1962).

Hemoglobin

The goat has one embryonic Hb type that occurs very early in fetal development in erythroid precursors. A single distinct fetal Hb (HbF) that comprises alpha and gamma globin chains is present by approxi-

Table 7.1. Erythrocyte parameters in the normal goat from selected reports worldwide.

Country	Goat description	RBC count (× 10⁶ ul)	PCV (%)	Hb (g/dl)	MCV (fl)	MCH (pg)	MCHC (%)	References

RBC = red blood cell, PCV = packed cell volume, Hb = hemoglobin, MCV = mean corpuscular volume, MCH = mean corpuscular hemoglobin, MCHC = mean corpuscular hemoglobin concentration.

mately forty days of fetal life and persists through birth, diminishing to zero by approximately fifty days of age. Replacing HbF in the young growing goat is HbC, a Hb type peculiar to sheep, goats, and other members of the Caprini family, including the aoudad, Barbary sheep, and the mouflon. In the goat, by fifty days of age, from 80% to 100% of Hb is the HbC type. Hemoglobin C demonstrates decreased oxygen affinity compared with HbF. It is postulated that HbC is a physiologic adaptation that allows the relatively fast-growing kid to satisfactorily oxygenate tissues during rapid growth (Huisman et al. 1969). The marked poikilocytosis commonly observed in kids between one and three months of age may be associated with the switch to HbC during this period.

By 120 days, the final adult types of Hb, comprised of alpha globin chains together with beta globin chains, have largely replaced HbC. However, 5% to 10% of adult Hb may normally persist in the HbC form. In addition to its regular occurrence in growing kids, and its mild persistence in normal adults, Hb switching to HbC also occurs extensively in adult goats during erythropoiesis in response to naturally occurring and experimentally induced anemias and at high altitudes.

Erythropoietin is the direct stimulus for Hb switching and the increased production of HbC by developing erythrocytes in the bone marrow (Garrick 1983).

In addition to small amounts of HbC, three adult hemoglobins are commonly recognized and identified as A, B, and D, although a later publication identified the three adult hemoglobins as A, D, and E (Garrick and Garrick 1983). Adult hemoglobins are comprised of both alpha and beta chains and globin chain production is controlled by at least five structural genes. Polymorphism of goat Hb occurs from variation in either beta or alpha chains. Phenotypic variation occurs in the goat with phenotypes AA, AB, BB, and AD previously reported as most common (Huisman 1974). Another Hb type, HbD$_{malta}$ has been identified in high frequency in goats on Malta (Bannister et al. 1979). An association between certain Hb phenotypes and disease resistance has been observed in the goat in relation to helminthiasis (Buvanendran et al. 1981). In a Finnish study of milking goats, increased hemoglobin concentration correlated with increased milk yields and decreased somatic cell counts, though there was no direct explanation for the relationship (Atroshi et al. 1986).

Response to Anemia

The goat demonstrates only a mild to moderate reticulocyte response to anemia. Red cell parameters have been measured after experimental induction of hemorrhagic anemia via controlled venisection that reduced mean RBC counts more than 50% (Dorr et al. 1986). Reticulocyte counts before bleeding were between 0% and 0.5%. Maximum reticulocyte counts occurred six to eight days after bleeding, and ranged from 3.2% to 7.7%. A second reticulocyte peak was seen between eleven and nineteen days with maximum counts between 2.9% and 6.3%. Anisocytosis and persistence of macrocytes for four weeks after bleeding were more dramatic indicators of regeneration than reticulocytosis. The large size of newly released erythrocytes was reflected in a progressive increase in the mean corpuscular volume (MCV), which was highest from twenty-five to twenty-nine days after bleeding, but did not always exceed the normal range of MCV reported for the species. Therefore, the MCV must be interpreted carefully in establishing the presence of regenerative anemia. Hemoglobin and PCV levels returned to before-bleeding levels by five weeks.

Jain et al. (1980) reported a marked poikilocytosis in response to experimentally induced hemorrhagic anemia in normal Angora goats exhibiting increased percentages of erythrocyte sickling. The percentage of fusiform (sickle) cells decreased as new distinct poikilocytic forms developed. Poikilocytosis was maximal between eight and thirteen weeks after bleeding. The change in erythrocyte morphology was attributed to the presence of HbC in regenerative cells.

Blood Types

Currently, most references to the caprine blood grouping system compare it to the sheep system but specific similarities and differences are not always clear. Seven blood groups are known to exist in the sheep, identified as R-O, A, B, C, D, M, and X. The antigens of the R-O group are soluble substances, and naturally occurring anti-R antibodies may be found in R-negative sheep. The M system in the sheep is associated with variation in intracellular RBC potassium concentration, with animals homozygous for the Ma allele having greater intracellular potassium levels. High potassium and low potassium red cell types have also been recorded in goats, but no clear association with the M blood group system has been established despite attempts to do so (Ellory and Tucker 1983). The B system is most complex, with at least fifty-two alleles involved in expression of B-group antigens. Using sheep reagents, at least five of the seven sheep blood groups have been confirmed in goats; B, C, M, R-O, and X. Multiple phenogroups occurred in the B system, similar to sheep (Nguyen 1977).

As with other ruminant species, hemolytic testing is preferred to agglutination testing for blood typing work because of the inherent inagglutinability of erythrocytes in some individuals (Andresen 1984). Neonatal isoerythrolysis is not known in goats. However, hemolytic disease has been reported in one-week-old kids that had received bovine colostrum at birth (Perrin et al. 1988).

In 1992, the American Dairy Goat Association (ADGA) instituted a voluntary blood typing program to assist in indentification and parentage verification of registered goats. In 1998, ADGA replaced identification of individual goats and parentage by blood typing with DNA typing because of the superiority of DNA technology and the limited availability of antisera available for blood typing (Bowen 2007).

Transfusions

In sheep, it has been advised that R-positive blood not be used for transfusion to avoid early donor RBC destruction by isoantibodies (Andresen 1984). In practice, however, cross-matching of goat or sheep blood before single transfusions is not usually performed (Bennett 1983). Nevertheless, naturally occurring antibodies to RBCs can be present in goats and cross matching may be advisable. Transfusion reaction rates of 2% to 3% have been reported (Fletcher et al. 1964). Cross matching is indicated whenever multiple transfusions are anticipated.

Autologously transfused RBCs have a half survival time of eight days while homologously transfused cells have a half survival time of only 2.4 to 5.1 days (Gulliani et al. 1975). Sheep RBCs transfused into goats had a maximum average life span of 4.6 days (Clark and Kiesel 1963). Cross species transfusions in clinical practice are not advised.

Goats are considered to be a "large-spleened" domestic species. As such, the healthy goat can accommodate a blood loss of up to 25% of the red cell mass acutely, and up to a 50% loss over a twenty-four-hour period. In such cases, fluid replacement is of more concern than RBC replacement. In chronic blood loss, as often occurs with parasitic diseases, the PCV may reach levels as low as 9% without overt clinical manifestations of anemia, as long as the animal is not decompensated by stress, activity, or concurrent disease. Treatment of the underlying cause of anemia may be sufficient therapy without the need for blood transfusion. If the anemia is accompanied by profound hypoproteinemia with clinical signs of edema and ascites, plasma transfusions may be indicated.

For transfusions, the safe volume of blood that can be collected from a healthy goat has been reported as low as 6 ml/kg (Mitruka and Rawnsley 1981) to as high as 15 ml/kg bw (Bennett 1983). In practice, 10 ml/kg of bw is a reasonable volume. A 4% solution of

sodium citrate is a suitable anticoagulant for blood collection, using 50 to 100 ml per 400 ml of blood collected. Collection bags or bottles should be swirled continuously during blood collection, and blood administered through a filtered system to remove possible clots. Blood can be safely given to recipients in volumes of 10 to 20 ml/kg bw.

Leukocyte Parameters

The mean white blood cell (WBC) count of the goat is generally reported to be 9,000 cells/ul with a range of 4,000 to 14,000. However, total WBC counts and differential cell counts may vary significantly with age as shown in Table 7.2. This is also true of the neutrophil to lymphocyte (N:L) ratio. The following mean N:L ratios have been reported for normal goats at different ages: one day old, 1.6:1; one week old, 0.8:1; one month old, 0.6:1; three months old, 0.3:1; two years of age, 1.1:1; and three years of age and older, 1.0:1 (Holman and Dew 1965a). These changes are partially due to a lower neutrophil count at birth that peaks at one month of age and then returns to and remains at birth levels after three months of age.

More significant is the dramatic two- to three-fold increase in lymphocyte numbers that occurs from birth to three months of age. Lymphocyte numbers begin to decline again and remain roughly equivalent to neutrophil numbers throughout adulthood. Eosinophils, basophils, and monocyte counts did not change notably with age in this study (Holman and Dew 1965a). However, in a field study with samplings of 1,000 goats in Mexico, eosinophil counts in kids younger than seven weeks of age averaged 0.5% of the WBC count, but 4.3% in adults (Earl and Carranza 1980).

Band neutrophils may represent up to 2.5% of the neutrophils in neonates as old as six weeks of age, but are rare or absent in health after this time. Lymphocytes in goats exhibit three distinct sizes: small, medium, and large. Young goats may exhibit two and a half times more small lymphocytes than large. It is postulated that the small lymphocytes represent thymocytes and that small lymphocyte numbers decrease as thymic involution progresses (Earl and Carranza 1980). Morphologically, large lymphocytes may be confused with monocytes. The large lymphocyte is distinguished by a nuclear chromatin that is condensed in large, irregularly shaped clumps, as compared with the looser, stringier chromatin pattern of monocytes.

Interpretation of Leukogram

Guidelines for interpretation of caprine leukograms have been suggested (Coles 1986). A WBC count more

WBC = white blood cell.

than 13,000/ul constitutes leukocytosis and a count less than 4,000/ul, leukopenia. A neutrophil count greater than 7,200/ul represents neutrophilia and a count less than 1,200/ul, neutropenia. More than 100 band neutrophils/ul constitutes a left shift. Lympho-cytosis is interpreted as a lymphocyte count greater than 9,000/ul and lymphopenia by a count less than 2,000/ul. Monocytosis is represented by a monocyte count more than 550/ul and eosinophilia by an eosino-phil count more than 650/ul. Inflammatory responses in the goat often produce a neutrophilia with total WBC counts in the range of 22,000 to 27,000/ul. The maximum WBC count reported in a goat is 36,300/ul observed in association with a kidney abscess (Jain 1986).

A mature neutrophilia is often seen that in associa-tion with stress and chronic infections, particularly when abscesses develop as in caseous lymphadenitis or mastitis. Acute bacterial infections can produce a moderate to severe neutrophilia with some degree of left shift. Acute, severe coccidiosis in young kids is a frequent cause of marked neutrophilia and left shift.

Leukopenia is a common finding in infectious con-ditions of goats associated with the release of endo-toxin. Transient leukopenia has been reported with experimental administration of staphylococcal entero-toxin B and *E. coli* endotoxin (Van miert et al. 1986). Leukopenia also occurs in theileriosis and tick-borne fever. Infection of WBCs is a fundamental part of the pathogenesis of these diseases. In theileriosis, lysis of lymphocytes occurs when protozoal merozoites are released into the bloodstream and lymphopenia may be observed. In tick-borne fever, *Ehrlichia phagocyto-phila* invade the cytoplasm of granulocytes and mono-cytes, producing a marked leukopenia. Persistent leukopenia also has been reported in experimental heartwater disease (cowdriosis) (Illemobade and Blotkamp 1978) and as a result of plant poisoning with *Ipomoea carnea* in goats in the Sudan (Tartour et al. 1974).

Neoplastic transformation of lymphocytes may occur in caprine lymphosarcoma. This condition is not common in goats, and leukemia is a rare clinical pre-sentation when the disease does occur. Peripheral lymphadenopathy is the clinical presentation most likely to suggest the diagnosis of lymphosarcoma in goats.

Platelet Parameters

The mean platelet count in the goat is generally considered to be 500,000/ul, with a range of 340,000 to 600,000/ul (Lewis 1976; Mitruka and Rawnsley 1981). One disparate study identified considerably lower counts in goats, with an average count of 116,000/ul

during the first two weeks of life, decreasing to 28,000/ul by 1.5 years of age and stabilizing at an average of 62,550/ul by two years of age (Holman and Dew 1965a). These findings have not been duplicated by others. Platelets appear in the peripheral blood, usually in clusters of varying size. The platelets themselves also vary in size and shape, but all contain prominent azurophilic granules that are evenly distributed throughout the cytoplasm.

Coagulation Parameters

Two studies of coagulation parameters in the goat have been reported (Breukink et al. 1972; Lewis 1976). Both general coagulation tests and specific coagulation factor assays were conducted. Reported values are summarized in Table 7.3.

BASIC CAPRINE IMMUNOLOGY

The area of veterinary immunology has made con-siderable advances in recent years, but specific infor-mation on the caprine immune system remains relatively difficult to find in comparison to other domestic animal species. The purpose of this section is to highlight what is specifically known about the caprine immune system. A broader view of veterinary immunology is available from textbooks on the subject (Tizard and Schubot 2004)

There are no reported inherited immunodeficiencies in goats. Acquired immune-mediated diseases are uncommon and those that occur, such as the pemphi-gus complex, are discussed in the chapters relating to the organ system most affected. The most important immunological disease of goats is that shared with other ruminant species, namely, failure of passive transfer of immunologloglobulins to the newborn via the dam's colostrum. Failure of passive transfer (FPT) is discussed in detail later in this chapter.

Immunoglobulins

The structure and function of ruminant immuno-globulins have been reviewed and the categories and distribution of caprine immunoglobulins fit the general ruminant pattern (Butler 1986). The major classes of immunoglobulin identified in the goat are IgG, IgA, and IgM. As in cattle and sheep, there are two distinct IgG subclasses, IgG_1 and IgG_2 (Gray et al. 1969). The major immunoglobulin in goat colostrum is IgG_1, and it is transported preferentially over IgG_2 into the mammary gland from serum (Micusan and Borduas 1976). This is presumably because of a higher affinity of IgG_1 for Fc receptors on mammary epithelial cells. IgG_1 is also the predominant circulating serum anti-body produced in response to infection (Micusan and Borduas 1977). Local IgG_1 production has also been

Table 7.3. Coagulation parameters reported from normal goats.

demonstrated in synovial fluid, specifically in response to caprine arthritis encephalitis (CAE) virus infection (Johnson et al. 1983).

Very little is recorded about caprine IgM, possibly because little difference has been observed in the structure and function of IgM between ruminant species (Aalund 1972; Butler 1986). Caprine IgA has been isolated from serum, colostrum, milk, saliva, and urine. A distinct secretory component occurs in secretions, either in the free state or associated with IgA. The small amount of IgA found in serum is rarely associated with secretory component (Pahud and Mach 1970). IgA is considered the primary immunoglobulin of mucosal surfaces. In all the ruminants, including goats, immunoglobulins with biologic activities typical of IgE have been identified. IgE has become recognized as a useful marker for the development of parasite resistance in ruminant animals and efforts are underway to develop tests for the measurement of IgE to detect resistance. Partial DNA sequencing of caprine IgE has been reported as part of this overall effort (Griot-Wenk et al. 2000). Concentrations of caprine immunoglobulins in serum and various secretions are presented in Table 7.4.

Other Serum Proteins

The range of mean total serum protein concentrations reported in goats is from 6.75 to 7.53 gm/dl with concentrations in individual goats ranging from 5.9 to 8.3 gm/dl (Fletcher et al. 1964; Melby and Altman 1976; Mitruka and Rawnsley 1981). Concentrations for various serum proteins reported in goats are summarized in Table 7.5.

The normal range of plasma fibrinogen levels in goats, 0.1 to 0.4 gm/dl, is less than that of cows. Hyperfibrinogenemia frequently occurs in conjunction with neutrophilia in inflammatory responses. The maximum goat plasma fibrinogen recorded during inflammation is 1.1 gm/dl (Jain 1986).

Reports of complement component concentrations in goats are limited. However, one study demonstrates hemolytic, conglutinating, and bactericidal complement activity and indicates that complement activity is significantly less in kids younger than six months of age than in adults (Bhatnagar et al. 1988).

Cell-mediated Immune System

The induction of the host immune response begins at mucosal surfaces where immune cells in mucosa-associated lymphoid tissue (MALT) come into contact with and process antigens for subsequent transport to regional lymph nodes. The structure, function, and distribution of the caprine MALT system has been reviewed (Liebler-Tenorio and Pabst 2006).

Distinct populations of B and T lymphocytes have been identified in goats (Sulochana et al. 1982) and subpopulations of T lymphocytes also have been identified on the basis of reactivity and nonreactivity to

peanut agglutinin (PNA) (Banks and Greenlee 1982). The percentages of B cells and PNA-positive T cells among peripheral blood lymphocytes have been reported, respectively, as 14% and 69% (Banks and Greenlee 1982; Hedden et al. 1986).

There are several reports on optimization, kinetics, and application of the *in vitro* lymphocyte transformation or blastogenesis assay for the measurement of lymphocyte responses using standard mitogens (Staples et al. 1981; Greenlee and Banks 1985), specific antigens, such as CAE virus (DeMartini et al. 1983), steroids (Staples et al. 1983), and allogeneic lymphocytes (van Dam et al. 1978).

Normal caprine neutrophil function has been evaluated in female goats using a variety of indices including migration, chemotaxis, bacterial ingestion, cytochrome C reduction, and antibody-dependent, cell-mediated cytotoxicity (Maddux and Keeton 1987). The effect of dexamethasone and levamisole on neutrophil functions has also been reported (Maddux and Keeton 1987a). Selenium deficiency in goats has been shown to have adverse effects on caprine neutrophil function (Aziz et al. 1984). There is very little informa-tion on characterization and function of caprine macrophages and nonneutrophil leukocytes.

Cytokines

Cytokines are proteins that play a central role as immune mediators during host responses against foreign pathogens. The role of cytokines in veterinary medicine has received considerable attention and a recent text on the subject has chapters on cattle, sheep, pigs, horses, dogs, cats, and birds, but alas, not on goats (Schijns and Horzinek 1997). Though knowledge on goat cytokines has not been comprehensively reviewed, information is available in various research reports.

Interleukin 1 (IL-1, endogenous pyrogen) occurs in the plasma of goats during bacterial-induced febrile episodes (Verheijden et al. 1983). Other studies have demonstrated the existence and activity of neutrophil chemotactic factor, leukocyte migration inhibition factor, and interleukin 2 (IL-2) in goats (Aziz and Klesius 1985, 1986). Caprine macrophages stimulated *in vitro* with lipopolysaccharide expressed tumor necrosis factor (TNF) and interleukin 6 (IL-6) (Adeyemo

et al. 1997). Interleukin 8 (IL-8) and monocyte chemoattractant protein 1 (MCP-1) were expressed by CAE-infected caprine macrophages *in vitro* (Lechner et al. 1997) and interleukin 16 (IL-16) was expressed at higher levels from peripheral blood mononuclear cells and synovial membrane cells of goats infected with CAE than from cells from control goats (Sharmila et al. 2002). Goats with caseous lymphadenitis produced greater interferon gamma (IFN-γ) responses than uninfected goats when cells in whole blood were stimulated *in vitro* with either *Corynebacterium* *pseudotuberculosis*-secreted antigen alone or with pokeweed mitogen (Meyer et al. 2005).

Major Histocompatibility Complex (MHC)

The MHC of goats is called the goat lymphocyte antigen (GLA) system. Both serologically defined (SD) class I and lymphocyte defined (LD) class II antigens have been identified. Three distinct gene clusters appear to be involved in expression of the GLA: an SD$_1$, an SD$_2$, and an LD, producing five, four, and four antigenic specificities respectively (van Dam et al.

1979, 1980, 1981). A more recent report suggests as many as twenty-seven class I antigen specificities (Ruff and Lazary 1987). Cross-matching for GLA antigens prolongs skin graft survival time (van Dam et al. 1978a). Also, the degree of humoral immune response has been associated with GLA type. Increased antibody responses to tetanus toxoid were demonstrated in goats with GLA-SD$_{1-2}$ and SD$_{1-4}$ specificities (van Dam and van Kooten 1980). Additional information on the caprine MHC is available elsewhere (Obexer-Ruff et al. 1996).

DIAGNOSIS OF HEMIC-LYMPHATIC DISEASES BY PRESENTING SIGN

Bleeding Disorders

Indications of bleeding disorders include petechial or ecchymotic hemorrhages of mucous membranes, prolonged bleeding from venipuncture sites or surgical wounds, passage of blood from body orifices, or development of subcutaneous or periarticular swellings. Such signs can result from vasculitis, platelet disorders, or coagulopathies. These categories of disease have received limited attention in goats.

Inherited afibrinogenemia has been reported in a family of Saanen goats (Breukink et al. 1972). The inheritance pattern is incomplete autosomal dominant. There is complete absence of circulating fibrinogen in homozygous individuals, and goats thus affected do not live past the kid stage. Unchecked umbilical hemorrhage at birth is the most common presentation, but recurrent hemarthroses and subcutaneous and mucosal hemorrhage can also be seen. Clotting time, thrombin time, stage 1 prothrombin, and partial thromboplastin times are all prolonged in afibrinogenemia. Fibrinogen concentration, as measured by bioassay of thrombin-clottable protein, is always under 0.15 gm/dl and is usually zero. Acquired coagulation disorders presumably occur in the goat at a rate similar to other species, but the literature on specific causes or cases of coagulopathy in the goat is sparse. Bleeding from the orifices of a dead goat is suggestive of anthrax.

Thrombocytopenia is reported as a consistent finding in African trypanosomosis in all affected species, including goats (Davis 1982). The degree of thrombocytopenia and the development of subsequent hemorrhage are directly correlated to the degree of parasitemia that develops.

Bracken fern *(Pteridium aquilinum)* ingestion by cattle can lead to a syndrome of pancytopenia with leukopenia, thrombocytopenia, and anemia. Melena, epistaxis, and widespread petechial and ecchymotic hemorrhage are major clinical findings. While the morbidity rate may be low, the mortality rate is high. There is one report of naturally occurring bracken fern toxic-

ity in goats, but no signs of hemorrhage were observed (Tomlinson 1983).

Hemorrhagic diathesis is considered to be a clinical manifestation of severe, diffuse liver disease in other farm animal species (Radostits et al. 2007). However, a review of liver diseases of sheep and goats did not identify coagulopathy as a clinical outcome of hepatic disease (Fetcher 1983). The only report documenting decreased clotting activity in goats in association with liver disease involved experimental dosing with carbon tetrachloride (Jones and Shah 1982).

Anemia

Anemia is suggested clinically by pale or white mucous membranes (Figure 7.1), exercise intolerance, tachypnea, tachycardia, possible systolic murmurs, weakness, and (in extreme cases) collapse. When anemia is a result of intravascular hemolysis, then jaundice and hemoglobinuria are also important clinical signs. Signs of anemia are frequently accompanied by signs of hypoproteinemia, particularly intermandibular edema, ascites, and weight loss. Anemia is a common and important clinical presentation in goats.

Causes of Hemolytic Anemia

Important, established causes of hemolytic anemia in goats include the hemoparasitic diseases anaplasmosis, babesiosis, eperythrozoonosis, and theileriosis; nutritional disorders including copper toxicity, kale ingestion, and consumption of other, regional poisonous plants; and an infectious cause, leptospirosis.

Other suspected causes of hemolytic anemia in goats include infections due to *Clostridium novyi* type D *(C. hemolyticum)* and *Clostridium perfringens* type A,
Figure 7.1. White-colored conjunctiva characteristic of a goat with marked anemia. In normal goats, the color is pink to red. (Courtesy of Dr. M.C. Smith.)

as reported in sheep. Experimental poisoning with oak tannins caused marked hemolytic anemia in goats, but naturally occurring oak poisoning is uncommon in this species (Begovic et al. 1978). Experimental infections of sarcocystosis (sarcosporidiosis) produce hemolytic anemia (Dubey et al. 1981), but almost all known naturally occurring infections in goats are subclinical, producing muscle cysts seen at slaughter or necropsy, as discussed further in Chapter 4.

Two reports suggest hypophosphatemia as the cause of hemolytic anemia and hemoglobinuria in female goats, but in two of the three reported cases, serum inorganic phosphorus levels were in the normal range (Setty and Narayana 1975; Samad and Ali 1984). In cattle with post-parturient hemoglobinuria, serum inorganic phosphorus levels are well below the normal range.

Causes of Blood Loss Anemia

Anemia due to loss of blood is of major clinical significance in goats. The condition is most often associated with some form of parasitism. Important causes of blood loss anemia include infestations by *Haemonchus* spp., and liver flukes, especially *Fasciola hepatica*. External parasitic causes include sucking lice, ticks, and fleas (Schillhorn van Veen and Mohammed 1975). Predation may be another important cause of blood loss. While wild predators can be expected to kill goats outright unless interrupted, domesticated dogs often maim goats without killing them. Severe hemorrhagic trauma often results.

Causes of Anemia Due to Impaired Erythropoiesis

Anemias of this type occur infrequently or are overshadowed by other concurrent and more prominent clinical signs. Nutritional causes include cobalt, copper, and iron deficiencies. Toxic causes include fluorosis and possibly bracken fern ingestion. Anemia of chronic infection also occurs in goats (e.g., in paratuberculosis).

Iron deficiency is associated with prolonged feeding of doe's milk to kids without mineral supplementation or access to forage. Copper deficiency manifests primarily as a neurologic disease in young kids. In experimentally induced cobalt deficiency in goats, a macrocytic, normochromic anemia was observed in addition to weight loss (Mgongo et al. 1981). In naturally occurring cases of cobalt deficiency, ill thrift is a consistent finding, but the presence of anemia is variable (Brain 1983; Black et al. 1988). Nonregenerative anemia has been documented in chronic fluorosis of goats grazing near a superphosphate factory in Egypt (Karram et al. 1984). One incident of bracken fern poisoning has been reported goats. Anemia was present, but may have been due to concurrent parasitism (Tomlinson 1983).

Documented causes of anemia in goats are summarized in Table 7.6. The table emphasizes concurrent clinical and laboratory findings, such as hypoproteinemia and hemoglobinuria that can aid in the differential diagnosis of anemia. All of the hemoparasitic diseases, leptospirosis, copper poisoning, phosphorus

Table 7.6. Anemia in goats: Aids for differential diagnosis.

Cause of anemia	Pathogenesis and morphologic type	Role of anemia in disease	Total serum protein	Icterus	Hemoglobinuria	Other clinical signs	Comments
Anaplasmosis	Hemoparasitic; extravascular hemolysis; regenerative	Major	Normal	Likely	No	Few; abortions can occur, concurrent disease common	Often subclinical
Babesiosis	Hemoparasitic; intravascular hemolysis	Major	Normal	Likely	Likely	Fever, diarrhea, abortion	Poorly described in goats
Theileriosis	Hemoparasitic; pathogenesis of anemia unclear	Minor	Normal	Variable	Transient	Fever, swollen lymph nodes, lacrimation	Primarily a parasite of white cells
Trypanosomosis	Hemoparasitic; mainly extravascular hemolysis	Major	Normal to low	Unlikely	Unlikely	Fever, edema, lymphadenopathy, weight loss	Seen primarily in Africa
Eperythrozoonosis	Hemoparasitic; mainly extravascular hemolysis	Major	Normal	Likely	No	None, but concurrent disease common	Poorly described in goats

Table 7.6. *Continued*

Cause of anemia	Pathogenesis and morphologic type	Role of anemia in disease	Total serum protein	Icterus	Hemoglobinuria	Other clinical signs	Comments
Leptospirosis	Septicemia; intravascular hemolysis	Major	Normal	Yes	Yes	Fever, abortion	Uncommon in goats
Copper poisoning	Nutritional; intravascular hemolysis	Major	Normal	Yes	Yes	Acute death	Goats more resistant than sheep
Haemonchus spp.	Gastric parasite; blood loss anemia	Major	Low	No	No	Weight loss, edema	Major cause of anemia in goats
Coccidiosis	Intestinal parasite; blood loss anemia	Major	Low	No	No	Diarrhea or dysentery; dehydration	Especially young goats affected
Liver flukes	Liver parasite; blood loss anemia	Major	Low	Likely	No	Weight loss, edema, ascites, eosinophilia	
Schistosomosis	Vascular parasite; blood loss anemia	Major	Low	No	No	Weight loss, diarrhea, ascites	Numerous spp. affect the goat
External parasites (ticks, fleas, lice)	Skin parasites; blood loss anemia	Usually minor	Normal to low	No	No	Pruritus, rough hair coat	Sucking lice and fleas may cause severe anemia
Trauma/predation	Blood loss anemia	Minor	Normal to low	No	No	Shock, musculoskeletal	Predation a serious problem
Cobalt deficiency	Nutritional; RBC multiplication reduced; macrocytic anemia	Minor	Normal to low	No	No	Weight loss, diarrhea, lacrimation, weakness	Mimics gastrointestinal parasitism
Copper deficiency	Nutritional; reduced heme synthesis; microcytic anemia	Minor	Normal	No	No	Enzootic ataxia, or "swayback"	Primarily neurologic; mostly in young goats
Iron deficiency	Nutritional; reduced heme synthesis; microcytic anemia	Minor	Normal	No	No	None	Uncommon; seen in milk-fed kids
Phosphorus deficiency	Nutritional; hemolytic anemia	Major	Normal	Yes	Yes	None	Some cases reported from India
Chronic diseases (e.g., paratubercuosis)	Anemia of chronic disease, nonregenerative	Minor	High to low	No	No	Weight loss, possible edema	
Kale poisoning	Plant toxicity; Heinz body anemia; regenerative	Major	Normal	Likely	No	None	Goats more resistant than cattle

RBC = red blood cell.

deficiency, kale ingestion, and other poisonous plants causing anemia are discussed in detail later in this chapter. Other diseases associated with anemia are discussed elsewhere in the text because other clinical signs predominate.

Lymphadenopathy

Transient swelling of select regional lymph nodes can be expected in common, localized infections such as mastitis, or subsequent to vaccinations. Persistent lymphadenopathy, however, is a major clinical finding in many important caprine diseases including caseous lymphadenitis, theileriosis, trypanosomosis, melioidosis, tuberculosis, nocardiosis, and lymphosarcoma. Theileriosis and trypanosomosis are discussed in detail in this chapter because of the significant role of anemia in these diseases. The remainder of the diseases are discussed in Chapter 3.

SPECIFIC DISEASES OF THE HEMIC-LYMPHATIC SYSTEM

RICKETTSIAL DISEASES

Anaplasmosis

Anaplasmosis is an arthropod-borne, rickettsial, hemoparasitic disease of ruminant animals that causes hemolysis. It is usually a subclinical disease in goats and sheep, with goats more likely to manifest clinical signs.

Etiology

In goats, the causative agent is *Anaplasma ovis*. In sheep it is *A. ovis* and a species described in Europe as *A. mesaeterum*, but not listed in the 1980 Approved Lists (Euzéby 2003); in cattle, *A. marginale* and *A. centrale*; and in wild ruminants, *A. marginale* and *A. ovis*. Goats may be transiently infected with *A. marginale* and *A. mesaeterum*, but do not become clinically ill, and are unlikely to be a reservoir of infection for cattle (Maas and Buening 1981). The discussion here is limited to *Anaplasma* organisms that produce erythrocytic anaplasmosis. Some rickettsial organisms that infect white blood cells have been transferred to the genus *Anaplasma* (Dumler et al. 2001) as discussed further in this chapter in the section on tick-borne fever.

Epidemiology

Caprine anaplasmosis has been reported widely in Africa, India, the Mediterranean countries, and the former USSR. In the United States it occurs in sheep but natural infection of goats has not been reported. Because of the largely subclinical nature of the disease in goats, it is often considered to be of minor economic importance (Akerejola et al. 1979). However, clinical disease due to *A. ovis* has been reported sporadically

from Nigeria, India, and Iraq (Kuil and Folkers 1966; Mallick et al. 1979; Yousif et al. 1983). More recently, *A. ovis* infection has been implicated in abortion outbreaks in Boer goats in South Africa, and the economic impact of the disease may be more than previously imagined (Barry and van Niekerk 1987).

The disease is spread by a variety of ticks, particularly *Rhipicephalus* and *Dermacentor* spp., while *Haemaphysalis* and *Ornithodoros* spp. have also been incriminated. Ticks become infected by feeding on infected animals; transmission is probably transstadial and intrastadial, as it is in bovine anaplasmosis. The role of other insects, contaminated syringes, and other veterinary equipment in the mechanical transmission of *A. ovis* in goats has not been investigated although such transmission is known in bovine anaplasmosis. *In utero* transmission of *A. ovis* has been established in sheep, and also confirmed in goats (Barry and van Niekerk 1987a).

The severity of clinical disease in cattle increases with advancing age. In experimental infection of goats with *A. ovis*, no correlation of disease severity with age was discernible although older animals did have a greater reduction in red cell mass (Splitter et al. 1956). A carrier state develops with *A. ovis* in goats although sterile protective immunity may occur. Recrudescence of clinical disease is possible when the carrier is sufficiently stressed.

Pathogenesis

The disease produced by *A. ovis* is primarily an anemia. Parasitized RBCs are destroyed in the spleen and bone marrow and the severity of anemia generally correlates with the percentage of parasitized cells. However, immune-mediated destruction of nonparasitized cells may also contribute to the degree of anemia. In experimentally infected goats, the prepatent period was eight to twenty-three days, with parasitized erythrocytes first evident at an average of fifteen days post inoculation. Maximum parasitemia occurred fifteen to thirty days post inoculation and the lowest RBC counts occurred from twenty-three to thirty-four days after inoculation. On average, RBC count, PCV, and Hb decreased more than 50%. Complement fixing antibody began to appear anywhere from eight days before to one week after the appearance of parasitized erythrocytes and remained detectable in carrier animals for as long as one year (Splitter et al. 1956).

Clinical Findings

While *A. ovis* infection is often subclinical in the goat, concurrent disease problems, malnutrition, and other stressors may precipitate clinical anaplasmosis. The most consistent clinical finding may be exercise intolerance, but other signs may be observed including a fever up to 107.5°F (41.9°C), anorexia, depression,

weakness, pallor of mucous membranes, dyspnea, and increased heart rate. If anemia is extreme, icterus may be present, but hemoglobinuria is an uncommon event. Subclinically infected animals may show only pallor. Diagnosis of anaplasmosis requires laboratory confirmation.

Clinical Pathology and Necropsy

Unless there is concurrent disease, the leukogram is likely to be unchanged. Erythrocyte parameters are reduced during clinical and, to a lesser extent, subclinical disease. A mean RBC count of 7.45×10^6/ml, mean PCV of 23.4%, and mean Hb of 6.8 gm/dl have been reported in cases with clinical signs of jaundice, weakness, and ill thrift (Yousif et al. 1983). In terminal cases, RBC counts, PCV, and Hb as low as 2.92 10^6/ml, 10%, and 2.8 gm/dl, respectively, have been observed (Mallick et al. 1979). Staining of peripheral blood smears with Wright's or Giemsa stain reveals the organisms in the erythrocytes. Like *A. marginale,* some 60% to 70% of *A. ovis* organisms are found on the periphery of the red blood cell, while as many as 40% of *A. ovis* are submarginal or central in location. The organism is most evident during active parasitemia and may be difficult or impossible to find during the prepatent period or during the carrier state. Even during parasitemia, only a maximum of 6.8% of red cells were observed to be parasitized during experimental subclinical infection, and only 2.7% in naturally occurring clinical disease. Therefore, careful examination of the smear is advisable. Increased MCV, anisocytosis, and polychromasia may be observed during convalescence.

To confirm infection during the carrier state, serologic testing may be necessary. Complement fixing antibody titers are highest during and immediately after active parasitemia but persist with variable intensity during the subsequent carrier state. False-negative tests can occur in some carriers. The most definitive test for establishing the carrier state is the inoculation of a splenectomized goat with blood of the suspected carrier. Other serologic tests include a capillary tube agglutination test, a rapid card agglutination test, a fluorescent antibody test, and an enzyme-linked immunoabsorbent assay test. The capillary tube agglutination test has been reported to be reliable in the diagnosis of caprine anaplasmosis (Mallick et al. 1979).

Necropsy may reveal thin, watery blood, pallor, and jaundice of tissues. The liver may be enlarged and orange in color.

Diagnosis

Anaplasmosis occurs in regions where other caprine hemoparasitic diseases also occur, including babesiosis, eperythrozoonosis, cowdriosis, and theileriosis. In fact, it is not unusual for some of these conditions to occur simultaneously in the same animal, and laboratory confirmation of anaplasmosis is essential to establish infection. Clinically, the absence of hemoglobinuria distinguishes anaplasmosis from babesiosis, leptospirosis, copper toxicity, and other causes of intravascular hemolysis.

Treatment

Treatment is most effective during the parasitemic phase of disease and is directed at reducing the rate of erythrocyte infection. The stress of handling ill animals for repeated therapy may be fatal when anemia is severe. Treatment administered during the prepatent period slows but does not prevent the onset of parasitemia. Oxytetracycline and tetracycline hydrochloride have been used successfully to treat clinically affected goats at an intramuscular dose of 10 mg/kg bw given once a day for one or two days. However, this dose given once a day for three to five days will not eliminate the carrier state. In cattle, the use of long-acting tetracycline preparations at a dose of 20 mg/kg given once a week for two to four weeks has been effective in this regard. Imidocarb diproprionate may be useful in caprine anaplasmosis but information on dosage and treatment schedules for goats is limited.

Control

In general, efforts to control the spread of anaplasmosis by controlling the biologic vectors are not practical except on a local basis through repeated dipping or spraying. There is no evidence that available *A. marginale* bovine vaccines offer any protection against *A. ovis* infection in small ruminants, and no specific vaccine for *A. ovis* is currently available. In lieu of vaccination, prophylactic antibiotic administration might be used to prevent the spread of infection in the case of an outbreak. In exposed cattle, oxytetracycline is administered at a dose of 1 to 2 mg/kg bw daily for ten days to prevent infection. The cost benefit of this program is difficult to evaluate in goats because uncomplicated caprine anaplasmosis is most often a subclinical disease.

Eperythrozoonosis

This hemoparasitic disease of goats is of little clinical and economic significance and is caused by the organism *Eperythrozoon ovis*. This organism, formerly classified in the *Rickettsiales,* is now known to belong to the *Mycoplasmatales* (Neimark et al. 2004), but the differences with classical *Mycoplasma* spp. do not warrant fusion of the two genera (Uilenberg et al. 2006).

Epidemiology

While *E. ovis* infection of sheep is known to occur widely in Europe, Africa, Australia, North America, and the Middle East, reports of infection in goats have

come only from Pakistan, South Africa, Australia, and most recently, Cuba (Joa et al. 1987). Transmission is probably by biting insects, contaminated needles, and surgical instruments. In Tasmania, a serologic survey indicated widespread infection in sheep with *E. ovis*, but virtually no infection in goats, suggesting the possibility of different vectors for the two animal species, or a difference in host susceptibility to chronic infection (Mason et al. 1989).

Etiology and Pathogenesis

The same organism, *E. ovis*, is infective for both sheep and goats, though a dimorphism has been noted. On Giemsa-stained smears, the organism on sheep erythrocytes demonstrates a large ring form, while in goats smaller ring and coccoid forms predominate (Daddow 1979, 1979a). In both small ruminant species, subclinical or latent infection is the rule; when clinical disease appears, it is often triggered by concurrent problems such as malnutrition or gastrointestinal parasitism. In experimental infection the prepatent period is six days for both species but the degree and length of parasitemia is shorter in the goat, lasting four weeks compared with six in the sheep. A carrier state developed in goats, with blood infective as long as fourteen months after infection (Daddow 1979).

Clinical Signs

Clinical disease is rarely observed in goats. The disease is characterized in sheep by weakness, unthriftiness, anemia, and mild icterus. Staggering and stiffness of the hindquarters have also been reported in sheep.

Diagnosis

The organism can be found on erythrocytes in Giemsa-stained blood smears during the parasitemia. However, clinical signs of anemia may not be recognizable until the waning stages of parasitemia. Antibody may also be detected with the CF test for up to three weeks after clinical signs are observed. However, false-negative results may occur (Daddow 1977). Low levels of antibody may also be intermittently detectable during subsequent carrier states. It is recommended that the CF test be used on a herd basis rather than for individual diagnosis. Differential diagnoses include other hemoparasites, especially anaplasmosis, malnutrition, gastrointestinal parasitism, and cobalt deficiency.

Treatment and Control

Treatment may alleviate clinical disease, but may not clear the carrier state. Single-dose therapy with either neoarsphenamine at a dose of 30 mg/kg, antimosan at 6 mg/kg, or oxytetracycline at 6.6 mg/kg have been recommended for sheep. No specific therapeutic evaluations have been reported in goats. Control involves good preventive medicine programs to avoid predisposing conditions as well as the single animal use of needles and surgical equipment.

Tick-borne Fever

Tick-borne fever is a tick-transmitted rickettsial disease of goats, sheep, and cattle caused by the organism *Anaplasma phagocytophilum*, formerly classified in the genus *Ehrlichia (E. phagocytophila)*. There are several strains of this organism which differ in host pathogenicity—the zoonotic HGE agent that causes human granulocytic ehrlichiosis (or human anaplasmosis), strains formerly called *E. equi* that cause equine ehrlichiosis (or equine anaplasmosis), and others more adapted to cattle and/or small ruminants that cause pasture fever or tick-borne fever. Dogs can also be infected. The condition is characterized in all ruminant species by fever and leukopenia. Abortions commonly occur in affected sheep and cattle, but not goats. Tick-borne fever in endemic areas causes noticeable losses in goats because of decreased milk production and secondary infections resulting from impaired immune responses.

Epidemiology

The disease occurs in cattle and sheep throughout Europe, wherever its tick vector, *Ixodes ricinus*, occurs. *I. persulcatus* in eastern Europe is also a vector. A similar organism has also been reported from India. Strains causing human and equine ehrlichiosis (or anaplasmosis) in the United States are transmitted by *I. scapularis.* Reports of naturally occurring tick-borne fever in goats have come only from Scotland and Norway (Melby and Grønstøl 1984; Gray et al. 1988). It is reasonable to assume, however, that where the disease occurs in sheep, goats are susceptible. In Europe, the tick vector *Ixodes ricinus* favors wet, cool, woodland pastures, and forest. In Scotland, the infection has been identified in feral goats, which are considered a wildlife reservoir along with the red, roe, and fallow deer (Foster and Greig 1969). The incidence of disease increases in spring and autumn, with increased tick activity.

Etiology and Pathogenesis

The causative agent of tick-borne fever in cattle and small ruminants is *Anaplasma (Ehrlichia) phagocytophilum*, but bovine and ovine strains are recognized. Strains isolated from sheep readily produce the disease experimentally in goats and vice versa. The infectivity of the bovine strains can be less in small ruminants than cattle. Cross immunity between strains is not always complete. Related organisms, with other tick vectors, are *Anaplasma* or *Ehrlichia bovis* in cattle and *Ehrlichia ovina* in sheep.

Infected ticks introduce the organism into host animals in their saliva during blood feeding. Because the organism is passed transstadially and not transovarially in the tick, only nymphal and adult stage ticks can transmit the infection to ruminants. When entering the host's bloodstream, the organism invades neutrophilic granulocytes, and to a lesser extent macrophages, where it replicates. In experimental infection of goats, high fever and granulocyte inclusions are seen by day three after infection. By day seven after infection, the total WBC count may drop to 27% of the level before infection. There is a transient lymphopenia and a persistent neutropenia, with no left shift. A transient eosinophilia is also observed around day five after infection (Van Miert et al. 1984).

It is believed that the invasion of leukocytes stimulates interleukin-1 (endogenous pyrogen) release that accounts for the high fever, rumen stasis, and other signs seen in clinical disease. The transient lymphopenia and neutropenia may impair immune defenses and predispose affected animals to serious secondary infections and increased risk of mortality.

There is limited information on morbidity and mortality rates in goats. In a report from Scotland, twenty-five goats were at risk. Thirteen had detectable antibody responses to tick-borne fever, seven showed clinical signs of disease, and one died (Gray et al. 1988). In a Norwegian report, fifty of 103 goats in a dairy herd were affected by tick-borne fever, including all goats younger than one year of age (Melby and Grønstøl 1984). While a low level of immunity develops after infection, the organism has been reported to persist in the blood stream of infected sheep for as long as two years.

Clinical Signs

Clinical signs reported in goats include a fever often higher than 106°F (41°C) that persists for three to six days accompanied by dullness, anorexia, decreased rumen motility, tachycardia, tachypnea, occasional shivering, and coughing. In lactating does, there is a significant drop in milk production. Animals should be examined for ticks. In contrast to sheep and cattle, abortion and secondary bacterial infections have not played a significant part in reported outbreaks of caprine tick-borne fever. Complete recovery may take several weeks.

Clinical Pathology and Necropsy

By day three of infection, the organism should be readily apparent in neutrophils in peripheral blood smears stained with methylene blue. The organism is located within vacuoles in the cell cytoplasm. Leukopenia is marked, with white blood cell counts commonly less than 3,500 by day seven. Initially there is a reversal of the neutrophil-to-lymphocyte ratio because

of a transient lymphopenia. Subsequently, lymphocyte numbers return toward normal and neutrophil numbers continue to decrease. A decrease in serum alkaline phosphatase has been observed in the acute phase of tick-borne fever in goats, but the cause is unclear. There are no remarkable necropsy findings.

Diagnosis

A presentation of high fever in tick-infested goats should suggest tick-borne fever in endemic areas. In the acute phase of disease, identification of the organism in neutrophils in peripheral blood smears is diagnostic. Serologic evidence of infection may be obtained by complement fixation test or counter immunoelectrophoresis (Webster and Mitchell 1988), as well as an indirect immunofluorescent test (Jongejan et al. 1989). Louping-ill, a viral disease, is also transmitted by *Ixodes ricinus* and can produce fever. The two diseases can occur concurrently in endemic areas. Louping-ill produces neurologic signs, and serologic evidence of infection can be obtained.

Treatment and Control

Several drugs have been evaluated for treatment of goats (Anika et al. 1986, 1986a). A single intravenous injection of oxytetracycline at a dose of 10 mg/kg resulted in a return to normal body temperature in six hours and killing of intracellular organisms. A single intravenous dose of trimethoprim (20 mg/kg) in combination with sulphamethylphenazole (50 mg/kg) and sulphadimidine (50 mg/kg) was also effective, as is chloramphenicol in a single intravenous dose of 50 mg/kg, where its use is permitted. Spiramycin and ampicillin were not effective against tick-borne fever.

Control of tick-borne fever involves controlling exposure of goats to ticks. Pasturing young goats in tick-infested areas during seasons of low tick activity may promote immunity and reduce the severity of disease that develops during periods of increased exposure. The use of acaricides during seasons of high tick activity may also be beneficial.

BACTERIAL DISEASES

Leptospirosis

Leptospirosis is a contagious, zoonotic disease caused by various serovars of the spirochete *Leptospira interrogans.* Goats and sheep are less susceptible to leptospirosis than cattle, swine, dogs, and man, and the disease is uncommon in small ruminants. Most leptospiral infections of goats are probably subclinical, although epizootics of abortion have been reported, as have outbreaks of acute septicemia with hemolytic jaundice. The two syndromes can occur simultaneously. Numerous serologic prevalence surveys of

caprine leptospirosis have been done, but descriptions of clinical disease are limited.

Etiology

Several serovars of *L. interrogans* have been identified in clinical caprine leptospirosis, most notably *L. pomona, L. grippotyphosa, L. icterohemorrhagiae*, and *L. serjoe.* Additional serovars identified infrequently in apparently healthy goats on serologic survey include *L. autumnalis, L. australis, L. balcanica, L. ballum, L. bataviae, L. bratislava, L. canicola, L. hardjo, L. hyos, L. panama, L. pyrogenes*, and *L. wolfii.*

Epidemiology

Leptospiral infection of goats has been reported from Brazil, Israel, Iran, India, Kenya, Nigeria, Turkey, Spain, Italy, Portugal, the former USSR, Jamaica, Grenada, New Zealand, and the United States. Serious outbreaks of disease with high morbidity and mortality rates in goats have been reported from Iran and Israel. In both countries, *L. grippotyphosa* was involved. In the Iranian epizootic, morbidity was between 90% and 100% for both sheep and goats, but goats showed a mortality rate of 42%, compared with 18% in sheep (Amjadi and Ahourai 1975). In Israel, the morbidity rate was also higher in affected goats than sheep, and goat mortality was also as high as 44% in some herds (Van der Hoeden 1953). In Nigeria, abortions in a university herd of west African dwarf goats were diagnosed as due to leptospirosis. Affected animals also showed diarrhea and jaundice. The predominant serovar was *L. pomona*, but antibodies to *L. grippotyphosa* and *L. icterohemorrhagiae* were also identified in some individuals (Agunloye et al. 1996).

In southern Spain, the seroprevalence was reported as 16.1% in goats and leptospirosis, primarily *L. pomona*, accounted for 2.6% of 262 caprine abortion outbreaks investigated over a fifteen-year period (Leon-Vizcaino et al. 1987). In a Jamaican survey, 35% of 1,545 goats tested were seropositive (Oliveira 1987). In one Brazilian study, the seroprevalence was 0.9% in confined or semiconfined dairy herds, but 6.7% among goats kept under subsistence conditions (Silva et al. 1984). In a more recent study from Brazil, seroprevalence was higher in goats that grazed more than two hours per day as compared to those that grazed less, suggesting a greater risk of exposure to leptospires through grazing. Seroprevalence was also greater in goats in tropical climatic settings than in temperate settings, suggesting that heat stress and rainfall contributed to infection (Lilenbaum et al. 2008). The predominant serovar in the survey was *L. hardjo*

The goat is most likely exposed to infection from wild rodents or other infected livestock shedding the organism in urine, and is not itself considered a persistent reservoir of infection (Schollum and Blackmore 1981). However, goats can shed the organism in urine for at least one month after an acute infection and should be considered as potential sources of new infections during that time.

Leptospires most commonly gain entrance to the host through skin or mucosal abrasions. They are readily killed by drying, but thrive under warm, moist conditions and will persist in contaminated, standing water for long periods. In the Iranian epizootic, the outbreak was attributed to a period of frequent rain, flooding, and warm weather that favored the environmental survival and spread of leptospires. In the Israeli report, the incidence of clinical cases fell off rapidly when the wet winter season ended and dry spring weather began. In Brazil, as well, the occurrence of leptospirosis in goats is associated with increased rainfall (Alves et al. 1996)

Pathogenesis

Infection leads to a septicemic leptospiremia, followed by clearance of the blood as antibody response develops, and subsequent localization of the organism in the kidney with leptospiruria. Death may occur during the septicemic phase. Hemolytic anemia may develop as a result of hemolysin production by certain serovars of *L. interrogans.* In sheep, at least, leptospirosis can also produce immune mediated hemolytic anemia. Abortion results from transplacental passage of leptospires during the septicemic phase with death of the fetus. This is more likely to occur in the second half of pregnancy. In animals that survive acute infection, a strong immunity develops against the inciting serovar, but cross immunity does not occur.

Clinical Signs

In acute leptospirosis goats may show a fever of 104°F to 106.7°F (40°F to 41.5°C), marked depression, and inappetence after an incubation period of four to eight days. Heart rate is elevated and the animals are dyspneic. Icterus of mucous membranes is a prominent finding, and petechial hemorrhages of the conjunctivae may be observed. Reddish brown urine indicative of hemoglobinuria is evident. Pregnant animals often abort. In untreated animals, death can occur within two to three days. Subclinical infections commonly occur in seemingly unaffected herd mates.

Clinical Pathology and Necropsy

A moderate to severe hemolytic anemia develops concurrently with the onset of clinical signs, and hemoglobinuria is present. In animals that do not die, there is soon evidence of a regenerative erythroid response. Leukopenia occurs during the acute phase of disease in cattle, but has not been reported in goats. Thrombocytopenia can occur in all affected species,

with or without evidence of concurrent disseminated intravascular coagulation.

At necropsy, icterus is pronounced and extensive in acute leptospirosis (Amjadi and Ahourai 1975). Edema and ecchymosis of the subcutis and serous membranes occur. Lungs may be pale and edematous with widening of the interlobular septa with yellow serous fluid. The liver may be enlarged and friable with extensive subcapsular hemorrhage. The kidneys are swollen, dark brown, and have a rough surface. Grayish streaks may be noted in the renal cortex. Histologic examination indicates renal tubular degeneration and a marked interstitial nephritis. Silver stains reveal spirochetal organisms in the renal tubules.

Diagnosis

Definitive diagnosis depends on isolation of the organism and identification of the serovar. During the leptospiremic phase, the organism may be isolated from blood, but only with difficulty. The potential for isolation from the urine during the leptospiruric phase is somewhat better. It is advised to initiate cultures from fresh specimens right at the farm by inoculating a suitable transport medium, or by injecting urine into guinea pigs or hamsters. In abortion cases, fetal kidney, lung, and pleural fluid should be examined microscopically for leptospires using silver stains or immunofluorescence techniques.

The most practical diagnostic approach is the identification of rising antibody titers in acute and convalescent serum samples taken seven to ten days apart in clinically affected animals. The microscopic agglutination test (MAT) is most commonly used. The MAT measures both IgM and IgG antibody and is more useful in the diagnosis of acute disease than chronic disease. The range of positive titers observed in goats during outbreaks of abortion was 1:200 to 1:12,800 using the MAT (Leon-Vizcaino et al. 1987). In Israel, titers of 1:100 were commonly encountered in animals with no history of clinical leptospirosis. Therefore, titers of 1:300 or more were considered as evidence of active infection. A titer of 1:30,000 was reported as early as day four of illness in a goat (Van der Hoeden 1953). Other serologic tests, including indirect ELISA and antibody-capture ELISA, are also now being used in cattle, but reports of their use in goats are limited.

Where both diseases occur, babesiosis must be ruled out because of the similar presentation of hemolytic anemia, fever, and possible abortion. Identification of characteristic piroplasms in RBCs would confirm babesiosis. Anaplasmosis may also produce fever, anemia, and abortion, but icterus and hemoglobinuria are uncommon. Other differential diagnoses for hemolytic anemia with hemoglobinuria include copper toxicity and plant intoxications, especially kale poisoning.

Treatment

Goats with acute leptospirosis have been reported to respond to a combination of streptomycin and penicillin (Amjadi and Ahourai 1975). In other species, streptomycin used at an intramuscular dose of 12 mg/kg twice a day for three days controls the septicemia. A single intramuscular injection of 25 mg/kg of streptomycin may clear leptospires from the kidney in the subsequent leptospiruric phase. A single intramuscular injection of long acting oxytetracycline at a dose of 20 mg/kg bw may be effective where the use of streptomycin in food animals is prohibited. Tetracyclines administered in the feed at a dose of 3 mg/kg for one week before and two weeks after exposure to leptospirosis has prevented clinical signs in calves, though infection did occur.

Supportive therapy must be considered in acute leptospirosis because anemia can be severe and the potential for renal failure is high due to primary interstitial nephritis and secondary hemoglobinuria with cast formation. Continuous intravenous fluid therapy is indicated to maintain renal output, and blood transfusions may be considered when the degree of anemia appears life-threatening.

Control

Early recognition and initiation of streptomycin or tetracycline therapy may reduce the number of clinical cases. Concurrent use of vaccination with the appropriate serotype vaccine in the face of an outbreak has been shown to reduce the incidence of new cases and abortions in cattle. Active and recovered cases should be isolated because of the possibility of organisms continuing to be shed in the urine. Always remember that leptospirosis is a potential zoonosis.

Prevention is based on environmental hygiene measures such as rodent control, elimination of standing water, and avoidance of damp bedding; screening or prophylactic treatment of newly acquired animals for elimination of the carrier state; and vaccination. Little or no protective cross immunity occurs among the various serovars of *L. interrogans*, so vaccination should be based on serologic evaluation of prevailing serovars. Multivalent vaccines suitable for use in goats are available. All animals older than three months of age should be vaccinated. Kids of vaccinated dams nursing colostrum should be protected by passive antibody up to three months of age. Annual or semi-annual revaccination is practiced in cattle. While the duration of protective immunity in goats has not been reported, semi-annual revaccination of goats has been suggested.

When considering vaccination, bear in mind that leptospirosis in goats is uncommon, and the cost-to-benefit ratio of routine vaccination for leptospirosis in

goats is not known. In an American study undertaken to evaluate health status of goats in relation to management practices in forty-three herds, no cases of leptospirosis were reported in any of the herds, regardless of whether they were vaccinated (Hagstad et al. 1984). The prevalence of leptospirosis in the practice area should be assessed in consideration of vaccination programs. Farmers, herders, veterinarians, milkers, and slaughterhouse workers have an increased occupational risk of exposure to this zoonotic disease and should exercise appropriate hygienic precautions to prevent infection.

Anthrax

Anthrax is a well known, infectious disease of livestock with zoonotic potential. The disease in goats is very similar to that in other ruminant species. This septicemic condition is characterized by a failure of the blood to clot. This is commonly noted at death by a bloody discharge from the nose and mouth.

Etiology and epidemiology

Bacillus anthracis is the cause of anthrax in herbivores and humans. The organism is characterized by the ability to produce spores, on exposure to air, that are capable of persisting for longer than fifty years. Anthrax is endemic in many tropical and subtropical regions of the world. The major route of transmission in animals is ingestion of spores residing in soil during periods of grazing. The disease has a seasonal occurrence, and is predisposed by environmental temperatures exceeding 59°F (15°C), periods of drought, or heavy rains. Goats are susceptible to anthrax, but reports of the condition in goats are uncommon, perhaps because they are not ground grazing animals by nature. Outbreaks in goats have been reported from Nigeria (Okoh 1981), Texas (Whitford 1982), China (ProMED-mail 2006), and Ethiopia (Shiferaw, 2004), and are possible wherever anthrax is endemic in other species. Grazing is not an absolute prerequisite for exposure to anthrax. Zero-grazed goats in Texas that were fed hay and a pelleted feed were confirmed with anthrax (ProMED-mail 2008). It is presumed that one or more of the provided feeds was contaminated with anthrax spores. Additional information on the epidemiology of anthrax is available elsewhere (Radostits et al. 2007).

Clinical Findings and Diagnosis

The disease is characterized most commonly by a peracute, fatal course, with most affected animals found dead, the result of bacteremia and toxemia. In acute cases, goats may be noted to be salivating and extremely depressed with the head hanging down. Over a period of one to two days they become recumbent and moribund, and die. Observation of bleeding from the nostrils and mouth of dead animals is characteristic of anthrax. Carcasses of suspect animals should not be opened at the site of death because this will release spores that will contaminate the environment. If movement of the carcass is not possible, then carefully aspirated blood samples and superficial lymph node aspirates can be taken and submitted for bacterial culture. If necropsy is performed, the blood is unclotted and the spleen is dramatically enlarged. Hemorrhages on serosal surfaces suggestive of septicemia are observed. The organism can be cultured from tissue. The differential diagnosis must include all potential causes of sudden death as discussed in Chapter 16.

Treatment and Control

Antiserum and/or antibiotics including tetracyclines, streptomycin, and penicillin may be effective therapies in early cases in the face of an outbreak. In endemic areas, effective vaccines are usually given annually and can be used safely and effectively in goats.

Anthrax is an important zoonotic disease. Transmission is usually by direct handling of hair, wool, skins, or carcasses of infected or contaminated animals. The disease can also be spread by inhalation of spores. A textile mill worker in North Carolina was diagnosed with anthrax that was traced to handling cashmere goat hair imported from endemic regions of western Asia (Briggs et al. 1988). Cases of cutaneous and inhalation anthrax in humans have been reported in the United States in association with the handling of goat skins imported from Africa for drum making (Kaplan 2007). There are numerous reports from developing countries of human cases of anthrax occurring among villagers who eat meat from livestock that have died of anthrax, including goat meat (Boutin et al. 1985; ProMED-mail 2006). Gloves and masks should be worn when handling carcasses or animal products suspected of being contaminated with anthrax. Animals dying of unknown causes or of suspected anthrax should not be eaten. Carcasses should be burned or buried deeply to avoid dissemination and persistence of spores in the environment.

PROTOZOAL DISEASES

Babesiosis

Babesiosis is a tick-borne protozoan hemoparasitic disease of goats. In those regions where it occurs, the economic losses associated with caprine babesiosis may be significant, particularly around the Mediterranean and in the Middle East and India.

Etiology

Two main species of *Babesia* infect sheep, *B. motasi* and *B. ovis*, but in goats *B. motasi* infection

predominates. *B. motasi* is classified as a large *Babesia* sp. with a length of 2.5 to 4 microns while *B. ovis* is a small *Babesia* sp. with a length of 1 to 2.5 microns. Another large species, *B. crassa*, has been found in Iran and a few other countries, including Turkey. It is reported to be infective, but probably nonpathogenic, for goats. Another small species, *B. taylori*, infective for goats has been reported from India but the current status of this species is unclear. The agents causing bovine babesiosis are not pathogenic for goats although inapparent infections of goats with *B. bigemina* have been observed. Ticks serve as biological vectors but mechanical transmission is also possible.

Epidemiology

B. motasi infection of small ruminants has been reported from much of Europe, the Middle East, the former USSR, India, southeast Asia, and parts of Africa (Purnell 1981). The primary biological vector for *B. motasi* is the tick *Haemaphysalis punctata*, although it is also likely to be transmitted by other species in the genus *Haemaphysalis*. Reports of transmission by *Dermacentor silvarum* and *Rhipicephalus bursa* are probably erroneous (Uilenberg et al. 1980). Transovarial and transstadial tick transmission occurs.

Several strains of *B. motasi* exist, with variable infectivity and pathogenicity for goats (Purnell 1981a). An outbreak of naturally occurring disease in both sheep and goats caused by *B. motasi* has been reported from India (Jagannath et al. 1974). A strain of *B. motasi* isolated from sheep in Wales produced fever and anemia in a splenectomized goat, but pathogenicity for intact goats was not evaluated (Lewis et al. 1981). Babesiosis was the cause of debilitating disease in sheep and goats in southwest Nigeria but caused death only in goats (Adeoye 1985).

B. ovis is transmitted primarily by *Rhipicephalus bursa*. The geographic distribution of *B. ovis* coincides in part with that of *B. motasi*, but is associated primarily with disease in sheep where it occurs. Natural infection of goats with *B. ovis* has been reported only from Somalia, and the infection was subclinical (Edelsten 1975).

The pathogenicity of *Babesia* spp. in goats and sheep may be intensified by concurrent infections, particularly other hemoparasites. No cross immunity develops after infection with either *B. motasi* or *B. ovis.*

Pathogenesis

Merozoites introduced by feeding ticks invade erythrocytes. Asexual reproduction of the protozoa occurs within the red blood cells to form a pair of trophozoites that are released and re-invade other red blood cells. The release of trophozoites from parasitized red cells results in intravascular hemolysis. The degree of anemia does not always correlate with the degree of parasitemia, and immune-mediated hemolysis may also be occurring. In other species, infection may lead to the development of neurologic signs from cerebral thrombosis, hypotension from activation of plasma kallikrein, and disseminated intravascular coagulation. These syndromes have not yet been reported in the goat. Antibodies are produced in response to infection. A protective immunity develops in nonfatal infections. It does not completely prevent reinfection, but does inhibit recurrence of clinical disease with the same-infecting strain. The development of a carrier state in goats is not addressed in the literature.

Clinical Signs

Affected goats may have fevers as high as 107°F (41.7°C) and show anorexia, weakness, and signs of anemia, including dyspnea and tachycardia. Sheep consistently show icterus and hemoglobinuria, with coffee-colored urine. These signs occur less consistently in goats, but aid in diagnosis when present (Jagannath et al. 1974). Additional signs of coughing and diarrhea have been reported but may be because of other concurrent infections. Affected goats may harbor ticks, though infective ticks may have dropped off before clinical signs develop. Morbidity and mortality rates can be high. Death can occur within forty-eight hours of the onset of signs. Chronic infections may occur, with anemia and ill thrift the prominent findings.

Clinical Pathology and Necropsy

Giemsa-stained blood smears should be examined for evidence of piroplasms. Thin smears are usually adequate at the height of parasitemia, but in chronic cases or when parasitemia is low, thick blood smears prepared from ear vein blood are preferred. Blood from several animals in a suspect group should be examined to avoid missing the diagnosis. *B. motasi* is a large piroplasm and occurs in single and double pear-shaped forms. *B. ovis* is a smaller piroplasm and often assumes a round form near the periphery of the erythrocyte. The *Babesia* piroplasms must be distinguished from *Theileria* piroplasms that can also affect goats and have a similar geographic distribution.

An indirect fluorescent antibody test can be used for the serodiagnosis of *B. motasi* infection, with titers of 1:640 or more considered as evidence of infection (Lewis et al. 1981).

At time of necropsy, the predominant findings are splenomegaly, lymphadenopathy, and enlarged liver. Icterus and hemoglobinuria are variable. Peripheral blood should be examined for piroplasms.

Diagnosis

The diagnosis of caprine babesiosis is suggested by signs of anemia, hemoglobinuria, and acute collapse in

animals where babesiosis is known to occur. Definitive diagnosis depends on the identification of the organism in blood smears. Theileriosis can be differentiated by the morphology of piroplasms and a more prominent lymph node enlargement. Anaplasmosis does not normally produce hemoglobinuria. When hemoglobinuria is present, plant poisonings, copper toxicity, anthrax, and leptospirosis must also be considered.

Treatment

A single dose of prescribed treatments is often satisfactory. The diamidine derivatives diminazene and imidocarb diprorionate are effective at doses of 3 mg/kg and 1 to 2 mg/kg, respectively. Diminazene in intramuscular doses as high as 12 mg/kg have been used in goats without adverse effect (Bannerjee et al. 1987). Most of the earlier drugs used for treatment, such as the quinuronium sulfate compounds, are no longer commercially available.

Control

No specific recommendations for control of caprine babesiosis have been made. In cattle and sheep, control efforts are directed at vaccination and reduction of tick infestations using acaricides. Vaccination protocols include vaccination with live protozoa in conjunction with imidocarb chemoprophylaxis, or chemoprophylaxis alone, leading to a controlled natural exposure and self-immunization. Inoculation with indigenous strains of *Babesia* in conjunction with chemoprophylaxis (infection and treatment) may be essential for survival of exotic breeds of goats imported into areas where babesiosis is enzootic.

Theileriosis

Theileriosis is a tick-borne protozoal disease of ruminants affecting primarily the hemic-lymphatic system.

Etiology and Epidemiology

Theileriosis has received little direct attention in goats and much has been inferred from the disease in sheep. As a result, discrepancies occur in the literature concerning pathogenicity for goats. Pathogenic *Theileria* spp. infecting goats and sheep include *T. lestoquardi* (earlier known as *T. hirci*) and two species described recently in China. There is some confusion about the nomenclature of these Chinese species; they have been designated as *Theileria* sp. (China 1) and *Theileria* sp. (China 2) (Ahmed et al. 2006). They have also been named *T. luwenshuni* and *T. uilenbergi* (Yin et al. 2004), but it may not be quite clear to which of the two species each of these names refers.

There are also several nonpathogenic species in small ruminants causing benign theileriosis, which may confuse the picture. *T. ovis* is distributed widely throughout Europe, Asia, and Africa. In Africa, it may be confused with another species, *T. separata*, and in Europe with one or two other species, as yet unnamed.

T. lestoquardi is most often associated with high morbidity and mortality rates and infection with *T. lestoquardi* is known as malignant small ruminant theileriosis. It has produced serious losses in sheep and goats in northern Africa, including the Sudan, Asia, the Middle East, southern Europe, and the southern former USSR. In a report from Iraq, however, a strain of *T. lestoquardi*, responsible for 100% morbidity and 89.7% mortality rates in a flock of sheep, produced no clinical disease when inoculated in a goat (Hooshmand-Rad and Hawa 1973). Similarly, in an Indian study, the infection was transmitted to sheep but not goats (Sisodia and Gautam 1983), and in the Sudan infection of goats with *T. lestoquardi* appears to be rare. Species of *Theileria* highly pathogenic for cattle do not cause disease in small ruminants.

Infections in goats with nonpathogenic small ruminant species of *Theileria* are also much less common than in sheep, and goats may be refractory to some species infective for sheep.

T. lestoquardi is transmitted by *Hyalomma anatolicum* in Asia, while the recently described species in China are transmitted by *Haemaphysalis quinghaiensis*. The tick vectors of *T. ovis* in sub-Saharan Africa are unknown. Transmission of *T. ovis* reported in South Africa by *Rhipicephalus evertsi* in fact involved *T. separata*. *Rhipicephalus bursa* is reported as a vector in the former USSR, north Africa, and Asia. *Haemaphysalis punctata* is the vector in Great Britain of a nonpathogenic species.

Pathogenesis

Sporozoites enter the host by the bite of infected ticks. The parasites are initially located in the spleen and lymph nodes, where they invade lymphocytes and produce schizonts. These schizonts, which early in the infection contain large nuclei, and later small ones, are readily identifiable in Giemsa-stained smears of lymph node aspirates or biopsies, and are referred to as Koch's Blue Bodies. After lysis of lymphocytes, micromerozoites enter the blood stream as piroplasms and invade erythrocytes. The piroplasm is polymorphic in red blood cells, exhibiting ring, oval, comma-shaped, or rod forms. Additional replication occurs in the red blood cells, and the sexual stages of the life cycle occur in the tick. The anemia of theileriosis is less severe than that seen in babesiosis, the other piroplasm of goats.

Clinical Signs

In malignant theileriosis (*T. lestoquardi* infection), clinical signs initially include fever, increased heart

and respiratory rates, anorexia, dullness, and depression. Lymph nodes are markedly swollen. Serous nasal discharge and lacrimation develop, and the conjunctivae are congested. The clinical course may last from two to three weeks; during that time, the animal may experience a decrease in milk production, coughing, rough hair coat, emaciation, weakness, recumbency, and death. A mild to moderate anemia may be observed and, in sheep, icterus has been inconsistently reported. In benign theileriosis, transient fever and mild lymph node swelling may occur and be overlooked under field conditions.

Clinical Pathology and Necropsy

Anemia and lymphopenia may be noted in the hemogram. Koch's Blue Bodies may be identified in Giemsa-stained smears of lymph nodes or characteristic piroplasms seen in circulating red blood cells. On examination after death, lymph nodes, spleen, and liver are all enlarged. The liver is yellow and the kidneys may show patchy hemorrhagic infarcts. Necrotizing ulcers ringed by hemorrhage may be seen in the abomasum and intestine.

Diagnosis

Diagnosis is based on identification of Koch's Blue Bodies in lymph nodes or piroplasms in erythrocytes. The piroplasms must be distinguished from those of *Babesia* spp. Molecular methods, comparing selected sequences of nucleotides in DNA, have become important research tools for species identification and phylogenetic studies.

Treatment and Control

Specific information on the treatment of caprine theileriosis is lacking. In cattle, high doses of long-acting oxytetracycline, 20 mg/kg of the 200 mg/ml formulation given intramuscularly, have been therapeutically effective against *T. parva* and *T. annulata*, only when administered very early in the incubation period. A napthoquinone, parvaquone, at 10 mg/kg intramuscularly, given twice to cattle is curative as late as four days into the clinical disease, and a related drug, buparvaquone, is even more effective. An anticoccidial compound, halofuginone, with a single oral dose of 1.2 mg/kg has also been effective against bovine theileriosis. However, even slight overdosing may produce severe adverse effects, so extrapolation to goats is inadvisable without additional evaluation. Control of caprine theileriosis involves control of the tick vectors primarily through dipping programs. Vaccine development is progressing for control of bovine theileriosis, including the use of attenuated schizonts of *T. annulata* in cell culture, but little activity has been reported with small ruminant species of *Theileria*. However, because schizonts of *T. lestoquardi* can

be grown in cell culture, attenuation should be attempted.

Trypanosomosis

Trypanosomosis is a major constraint on ruminant livestock production in Africa, including goat production. The impact of South American trypanosomosis on goats is largely unexplored and is only briefly discussed. Salient characteristics of the important animal and human trypanosomes and their pathogenicity for goats are summarized in Table 7.7. Though often referred to as trypanosomosis, the preferred name for disease caused by trypanosome infections is trypanosomosis (Kassai et al. 1988).

Etiology

The trypanosomes are flagellate protozoa characterized by a kinetoplast and an undulating membrane. Most trypanosomes require two hosts to complete their life cycle, a hematogenous insect vector and a vertebrate host. In sub-Saharan Africa, cyclic transmission of the parasite to mammalian hosts occurs via numerous species of tsetse flies (*Glossina* spp.) during feeding by the flies. Elsewhere in the world, mechanical transmission by other species of biting flies is the primary mode of infection. A recent, detailed and informative review of African animal trypanosomes and the diseases they cause is available elsewhere (Connor and van den Bossche 2004).

T. congolense is the most common trypanosome of goats in Africa. *T. vivax* is the second most common. Natural infection of goats with *T. brucei* is also sporadically reported. Goats are susceptible to *T. uniforme*, a trypanosome of the vivax group in Uganda and Zaire, but only mild infections occur. *T. simiae*, a trypanosome of swine and camels, is transmissible to goats by either *Glossina* spp. or biting flies but causes mostly mild or subclinical disease.

Goats and other domestic animals are relatively resistant to *T. gambiense*, the cause of West African human sleeping sickness. When infection does occur, the clinical course is chronic. *T. rhodesiense*, the cause of East African sleeping sickness in humans, is an uncommon cause of caprine disease. A nonpathogenic trypanosome, *T. theodori*, is found incidentally in goats in Israel. It is transmitted by a hippoboscid fly, *Lipoptena caprina*. This organism is morphologically similar to the common, nonpathogenic sheep trypanosome *T. melophagium*.

Information on the pathogenicity of the trypanosomes that occur outside of sub-Saharan Africa, primarily in South and Central America, as well as in Asia, is limited. *T. cruzi* is cyclically transmitted by reduviid bugs in South and Central America, while *T. evansi* and *T. equiperdum* are mechanically or sexually transmitted, respectively, in Africa, South and

Table 7.7. Trypanosomosis in various hosts with the emphasis on goats.

Species	Morphologic features	Major species affected	Geographic distribution	Vectors involved	Natural infection in goats	Experimental infection in goats	Clinical manifestations in goats
Cyclically transmitted							
T. vivax	20–27 µm long; monomorphic; short, free flagellum	Domestic ruminants, camels, horses, antelope	Widespread in tropical Africa	*Glossina* spp.	Common	Readily	Acute and chronic forms; usually mild
T. congolense	9–18 µm long; monomorphic; no free flagellum; undulating membrane not seen	All common livestock species and dogs; many wild game species	Widespread in tropical Africa	*Glossina* spp.	Common	Readily	Acute, subacute, and chronic forms; mild to fatal outcome
T. brucei	15–35 µm long; polymorphic; undulating membrane always seen	Domestic ruminants, horses, dogs, and cats	Widespread in tropical Africa	*Glossina* spp.	Common, but with strain variation	Yes, with strain variation	Acute, rapidly fatal outcomes or chronic infections
T. simiae	10–24 µm long; polymorphic; variable undulating membrane	Domestic pigs, camels, wild warthogs	Widespread in tropical Africa	*Glossina* spp. and *Stomoxys, Tabanus* flies	Uncommon	Not reported	Mainly subclinical or mild clinical disease
T. gambiense (West African sleeping sickness)	Same as *T. brucei*; slender, intermediate stumpy forms	Humans	Tropical West and Central Africa	*Glossina* spp. and various biting flies	Uncommon; goats very resistant	Very difficult	Noninfective or a chronic form leading to death or spontaneous recovery
T. rhodesiense (East African sleeping sickness)	Same as *T. brucei* and *T. gambiense*	Humans, in addition to species affected by *T. brucei*	East and Southern Africa	*Glossina* spp.	Uncommon	Yes	Experimental infections subacute and fatal
T. cruzi (Chagas disease)	16–20 µm long; in blood forms undulating membrane and free flagellum moderately well developed; tissue forms resemble *Leishmania*	Humans	South and Central America; sporadic in United States	Reduviid blood-sucking bugs	Not reported	Yes	No

Table 7.7. *Continued*

Species	Morphologic features	Major species affected	Geographic distribution	Vectors involved	Natural infection in goats	Experimental infection in goats	Clinical manifestations in goats
T. uniforme	12–20 μm long; monomorphic; flagellum is free, shorter than *T. vivax*	Domestic ruminants; antelope	Zaire, Uganda	*Glossina* spp.	Yes	Not reported	Nonpathogenic or subclinical infection
T. theodori	50–60 μm long; well defined undulating membrane and free flagellum	Goats	Israel	*Lipoptena caprina*, a hippoboscid fly	Yes	Not reported	Nonpathogenic
Mechanically transmitted							
T. vivax viennei	15–25 μm long; monomorphic; similar to *T. vivax*	Cattle, water buffalo	North, South, and Central America	Various biting flies	Uncommon but reported	Not reported	Not reported
T. evansi (Surra)	15–34 μm long; usually monomorphic; same as slender form of *T. brucei*; occasional stumpy form	Camels, equines, dogs, water buffalo	India, Far East, Near East, Philippines, North Africa, South and Central America	Various biting flies	Yes	Not reported	Not reported
T. equiperdum (Dourine)	15–34 μm long; same as *T. evansi*	Horses	Northern and South Africa, Central and South America, Mexico, Middle East, Italy, former USSR	Venereal transmission	Not reported	Not reported	Not reported

Central America, and Asia. These trypanosomes cause disease in various species. *T. cruzi* is primarily of importance for humans; *T. evansi* for camels, horses, cattle, and Asian buffalo, and *T. equiperdum* for horses. Their infectivity for goats is presumed to be low. Kids infected experimentally with *T. cruzi* showed no clinical signs of disease and carried the infection for thirty-eight days (Diamond and Rubin 1958).

The goat is a natural host for *T. evansi*, but reports of the disease, surra, in goats are rare. Recently, surra was reported to be occurring in goats in Mindanao in the Philippines, but field confirmation has been difficult. It is believed that the cases may involve a particularly virulent strain of *T. evansi*. Experimental challenge of goats with an equine strain of *T. evansi* from Mindanao produced clinical and pathological changes consistent with surra (Dargantes et al. 2005, 2005a).

Epidemiology

The distribution and intensity of animal trypanosomosis in sub-Saharan Africa follow the distribution and intensity of the various species of the tsetse fly.

Approximately 10 million km^2 or 37% of the African continent is tsetse-infested. This area includes thirty-eight countries. Various estimates suggest that the live-stock-carrying capacity of such areas in West and Central Africa could be increased five- to seven-fold by eliminating or controlling animal trypanosomosis (Griffin 1978).

There are more than 200 million goats in Africa with 50 million or more in the tsetse-infested regions of the continent. Natural infections with *T. congolense, T. vivax*, or *T. brucei* resulting in clinical disease have been known in African goats since the early twentieth century. Until recently, however, the perception has persisted that goats are highly resistant to infection, that caprine trypanosomosis is only sporadic, and that the disease in goats is of little economic consequence (Griffin 1978). This opinion is currently undergoing a critical reappraisal. Regional differences do exist in the prevalence of caprine trypanosomosis, but it can be high in some areas (Kramer 1966; Griffin and Allonby 1979). In general, caprine trypanosomosis is more common in East than West Africa. This is attributed to differences in feeding preferences between riverine species of *Glossina* and savannah species; the latter are more inclined to feed on goats. A report from Zambia identified *T. brucei, T. congolense*, and/or *T. vivax* infections in goats naturally transmitted by *Glossina morsitans morsitans* and *G. pallidipes* (Bealby et al. 1996).

Goats may serve as a reservoir of trypanosome infection for other species. In the Sudan, goats infected with *T. congolense* developed a chronic form of disease from which many spontaneously recovered. When the organism was passaged from goats into calves however, acute fatal bovine trypanosomosis occurred (Mahmoud and Elmalik 1977). Goats also have been implicated as a reservoir of *T. rhodesiense*, a nosodeme of *T. brucei* transmissible to man (Robson and Rickman 1973).

The economic impact of trypanosomosis on goat production is beginning to be studied. A Kenyan analysis demonstrated that goats receiving monthly chemoprophylaxis against trypanosomosis had significantly decreased mortality rates, increased weight gains, and improved reproductive performance compared to untreated control goats. Differences in performance were also noted between breeds in the study, with indigenous breeds performing better than nonindigenous breeds or cross breeds (Kanyari et al. 1983).

The existence of inherent trypanotolerance in certain goat breeds has been controversial. It is generally accepted that trypanotolerant breeds of cattle exist, notably the N'dama of West Africa and the West African Shorthorn, and that trypanotolerance is measured by the ability to control trypanosome numbers and resist the effects of the disease, independent of pre-existing immune experience. This inherent ability to control parasitemia and minimize disease is not as great in specific goat breeds, despite the general observation that some breeds of goats readily survive in tsetse infested areas. Dwarf West African goats may, to some extent, be inherently trypanotolerant, yet they can be readily infected experimentally (Murray et al. 1982). While earlier studies suggested that indigenous goat breeds of East Africa may show inherent trypanotolerance, no evidence of genetic resistance was observed in a subsequent study with either natural or experimental challenge in East African, Galla, or East African goats cross bred with Toggenburg, Nubian, or Galla breeds (Whitelaw et al. 1985). One factor contributing to the perceived trypanotolerance of various goat breeds under field conditions may be the feeding preferences of *Glossina* spp. Flies may select other livestock over goats when mixed animal populations are present (Murray et al. 1984). The existence of true trypanotolerance in goats deserves additional careful investigation.

Pathogenesis

Trypanosomes fall into two groups regarding their ability to produce disease. The hematic group, which includes *T. congolense* and *T. vivax*, remains confined to the circulation after introduction into the bloodstream by feeding *Glossina* spp. The disease produced in these infections is characterized by anemia. The humoral group, which includes *T. brucei*, is more invasive, with trypanosomes found in intercellular tissue and body cavity fluids after initial infection. Anemia in these cases is overshadowed by marked inflammatory, degenerative, and necrotic changes.

Anemia in trypanosomosis may be due to extravascular hemolysis and erythrophagocytosis, as well as decreased erythropoiesis in chronic infections (Kaaya et al. 1977). The destruction of red blood cells may result from both non-immune and immune mediated mechanisms. Hemorrhage secondary to disseminated intravascular coagulation (DIC) may also contribute to anemia. Thrombocytopenia, microthrombus formation, and hemorrhage suggestive of DIC have been observed in caprine trypanosomosis due to *T. vivax* (Van den Ingh et al. 1976; Veenendaal et al. 1976). Anemia may be exaggerated by hemodilution because of expansion of blood and plasma volumes, which increased, respectively, 29% and 44% in goats with subacute *T. vivax* infection (Anosa and Isoun 1976).

The pathogenesis of inflammation and tissue damage by humoral trypanosomes such as *T. brucei* is complex and is reviewed elsewhere (Soulsby 1982; Connor and van den Bossche 2004). Immunosuppression can occur in trypanosomosis. *T. vivax* and *T. brucei* infection of goats resulted in depressed responses to mitogen stimulation in lymphocyte transformation tests (van Dam et al. 1981a; Diesing et al. 1983) and

goats experimentally infected with *T. congolense* produced a weaker antibody response to vaccination with *Brucella melitensis* vaccine than uninfected controls (Griffin et al. 1980). Impaired immune function may aggravate the severity of concurrent infections. This was suggested by evidence of higher mortality rates and parasite loads in goats concurrently infected with *T. congolense* and *Haemonchus contortus* than in goats infected with only one parasite or the other (Griffin et al. 1981a, 1981b). Under field conditions, goats with chronic trypanosomosis are more susceptible to helminthiasis and carry heavier helminth burdens, probably as a result of immunosuppression.

Trypanosome infection is associated with ovarian dysfunction and irregular estrus cycles (Llewellyn et al. 1987; Mutayoba et al. 1988). Gross testicular atrophy has been reported in bucks with *T. congolense* infection (Kaaya and Odour-Okelo 1980). There is also a variety of endocrine abnormalities reported following inoculation of trypanosomes into the bloodstream of goats, including depression of circulating thyroxine, testosterone, and cortisol levels (Connor and van den Bossche 2004).

One of the most notable features of trypanosomosis is the successive waves of parasitemia that occur every few days in animals that survive initial infection. Each wave of parasitemia is followed by an increase in circulating antibody that temporarily reduces the parasitemia. The effect is only temporary, however, because cyclically transmitted trypanosomes are capable of repeatedly altering their surface antigens and thereby evade the host immune system sufficiently to avoid total elimination of infection. These variant antigens are surface coat glycoproteins. It is the occurrence of variable antigens that has been the major obstacle in the development of effective vaccines.

Clinical Signs

Clinical syndromes produced by the three major tsetse-transmitted trypanosomes are presented separately below. In the early stage of the disease, a prominent skin chancre may be noted at the site of tsetse fly feeding

T. Vivax. Acute, subacute, and chronic forms of disease can occur. Acute disease usually results in recovery or death within four weeks. Subacute disease, with a decreased level of parasitemia, may persist for ten to twelve weeks, and chronic disease for seventeen weeks or longer. The chronic form of the disease is most common. Parasitemia is evident on blood smear within six to seven days after infection and peaks at approximately ten days, but identification of the parasite on blood smears in subacute and chronic cases is less reliable. Successive waves of parasitemia occur at four- to seven-day intervals, accompanied by fluctuating fevers as high as 108°F (42.2°C). Anemia

develops rapidly, coinciding with the first wave of parasitemia.

Clinical signs may include depression, anorexia, lack of rumen motility, enlarged lymph nodes, and weight loss. Anemia can become severe with signs including pallor, increased heart rate and respiration, exercise intolerance, and marked listlessness. Jaundice and hemoglobinuria are uncommon findings. Severe emaciation is evident in chronic disease, although surviving animals may begin to gain weight again and the severity of anemia diminish as the level of recurrent parasitemia is brought under control.

T. Congolense. Acute, subacute, and chronic forms of disease also have been described for *T. congolense* infection of goats (Griffin and Allonby 1979a). The acute phase results in death or recovery within six weeks. Fluctuating temperatures up to 106°F (41.1°C) occur and in fatal cases anemia is severe. Weight loss is variable, depending on the duration of disease. In recovered animals, fever and a milder anemia may occur with the initial parasitemia, but PCV returns rapidly to normal. In subacute cases, animals die or recover within six to twelve weeks after infection. In fatal cases, cyclic parasitemia persists and fluctuating fever, progressive emaciation, weakness, lethargy, and pallor are evident clinically. Recovering animals begin to gain weight and strength as fever and anemia subside. Chronic infections, lasting twelve weeks or longer, are almost always fatal. Cyclic fever and parasitemia persist, as does the anemia. Animals become emaciated, hair coat becomes rough, superficial lymph nodes are palpably enlarged, and intermandibular and facial edema develop. Animals become recumbent, then comatose, and die.

T. Brucei. Because *T. brucei* is a humoral trypanosome, clinical signs may be more severe, although pathogenicity varies with the strain. In addition to anemia, fever, and emaciation, keratitis and signs of encephalitis may occur, including head pressing, circling, and opisthotonos. Lymphadenopathy is a consistent finding and may be more pronounced than with *T. vivax* or *T. congolense* infection. The typical course of disease is three to five months, and is usually fatal. Anemia is not as pronounced as it is in infection with the hematic trypanosomes. Parasitemia is also less severe, and detection of trypanosomes on blood smears is more difficult. Examination of lymph node smears may be more rewarding.

Clinical Pathology and Necropsy

In all forms of the disease, the most significant laboratory findings relate to anemia (Edwards et al. 1956). Moderate to severe decreases in PCV, Hb, and RBC numbers can be seen. In the early stages, anemia is macrocytic, while in chronic and terminal cases, a normocytic anemia is more common. This is reflected in

the bone marrow, which is often hyperplastic in acute disease and normoplastic or hypoplastic in chronic disease. In experimental infection of goats, all species of trypanosomes produced a significant thrombocytopenia with platelet counts 65% to 82% less than the normal mean (Davis 1982). No consistent changes in the leukogram have been noted in caprine trypanosomosis. In cattle, a transient leukopenia and rebound leukocytosis can occur during the acute phase of disease. Serum chemistry values remain normal. Animals with acute trypanosomosis may show laboratory evidence of DIC.

There are no pathognomonic lesions in trypanosomosis. In acute cases, necropsy findings include an anemic carcass, general lymph node enlargement, marked splenomegaly, serosal and mucosal petechial hemorrhage, and hydropericardium. Microscopically, lymphoid hyperplasia is pronounced and microthrombi may be evident in vessels of numerous organs. In the hematic forms of disease, trypanosomes is present only in vascular spaces, while with *T. brucei* extravascular parasites may be seen in tissues such as the cornea and cerebrospinal fluid. In chronic cases, severe emaciation, with serous atrophy of fat, and muscle degeneration may be observed in addition to petechiation, lymphadenopathy, and splenomegaly (Losos and Ikede 1972).

Diagnosis

Anemia and emaciation in goats from tsetse endemic areas suggest the diagnosis of trypanosomosis. Definitive diagnosis is based on identification of trypanosomes in blood smears or tissues. However, chronic infections in goats are common and trypanosomes may be difficult to find in the blood. In live animals, parasites may be more readily detected in blood samples taken from an ear vein rather than the jugular vein. Thick blood smears examined after lysis of red cells and staining with Romanowsky stain may reveal the presence of parasites, but morphologic identification is better performed on thin smears. Microhematocrital centrifugation of blood and examination of a wet mount of the plasma-buffy coat interface can improve detection. For confirmation of *T. brucei* infection, examination of smears of lymph node aspirates, and mouse inoculation are preferred methods of diagnosis. Because parasitemia is cyclical, examining smears from numerous animals in a suspect group may improve the chances of diagnosis.

Serologic tests employed in the diagnosis of trypanosomosis include an indirect hemagglutination test, a complement fixation test, an indirect fluorescent antibody test, and an enzyme linked immunosorbent assay. Information on interpretation of serologic responses in goats is limited. At present, molecular tools, such as PCR, are commonly employed, but demand well-equipped laboratories and do not replace classical methods in the field.

The differential diagnosis for trypanosomosis should include helminthiasis, malnutrition, and other hemoparasites, notably anaplasmosis, babesiosis, and theilerosis, which occur in trypanosomosis endemic areas.

Treatment

A variety of trypanocidal compounds are available for treatment, but no new drugs have been marketed for quite some time. Subsequently, drug resistance has become a significant problem. Compounds and dosages are formulated for single-dose use and treatment is usually on a herd wide basis because serial treatments on individual animals are difficult to carry out in the semi-nomadic livestock farming systems prevalent in endemic areas. Several of the drugs are locally irritating, so subcutaneous injections should be given in areas of loose skin, and intramuscular injections given deeply, avoiding vessels and nerves. Curative doses used in cattle are also appropriate for goats and sheep on a mg/kg body weight basis (Ilemobade 1986). Treatment is reviewed by Uilenberg (1998).

Diminazene aceturate is given intramuscularly as a 7% cold water solution at a dose of 3.5 mg/kg and is considered effective against the three major trypanosomes. Quinapyramine dimethyl sulfate is little used nowadays, except for treating *T. evansi* in camels and horses, because of toxicity and drug resistance problems. It is given subcutaneously as a 10% cold water solution at a dose of 5 mg/kg. Relapse of infection has been reported in goats treated with diminazene aceturate, presumably because of re-emergence of trypanosomes from the central nervous system where they were inaccessible to the drug during earlier treatment (Whitelaw et al. 1985a).

Homidium chloride (soluble in cold water) or homidium bromide (soluble in hot water) are given in a 2.5% water solution at a dose of 1 mg/kg intramuscularly and are effective against *T. vivax* and *T. congolense*. Isometamidium chloride is currently the most commonly used drug in ruminants. It is effective against the hematic trypanosomes when given at a dose of 0.25 to 0.75 mg/kg intramuscularly as a 1% or 2% solution in water. This drug was shown to produce signs of shock or death in goats if given intravenously at doses greater than or equal to 0.5 mg/kg (Schillinger et al. 1985). All drugs of the phenanthridinium group (homidium and isometamidium compounds) are potentially carcinogenic and should be handled as such.

Control

There are numerous constraints on control, including reservoirs of infection in wild animal populations,

the ability of trypanosomes to continuously alter their antigenic character and thus confounding the development of suitable vaccines, a limited availability of effective drugs, the development of resistance to existing trypanocidal drugs, the difficult logistics of widespread tsetse control, lack of economic resources, poorly developed animal disease control programs, limited technical training programs, lack of international cooperation, and political instability (Doyle et al. 1984; Murray and Gray 1984).

Currently, the major fronts in trypanosomosis control in sub-Saharan Africa are reduction or elimination of tsetse populations and chemoprophylaxis of livestock. Tsetse fly control is accomplished by several methods, alone or in combination, including ground or aerial application of insecticides such as chlorinated hydrocarbons and synthetic pyrethroids; tsetse trapping with odor baited, insecticide impregnated traps; and gamma-irradiated sterile fly release. Aerial spraying of insecticides is now less commonly employed for environmental reasons, and trapping has emerged as a viable alternative, albeit for more restricted areas of control.

Isometamidium chloride protects against infection with the three major goat trypanosomes for two to four months. The prophylactic dose of isometamidium is 0.5 to 1 mg/kg bw administered intramuscularly in a 1% or 2% cold water solution. Earlier chemoprophylactic drugs (pyrithidium and quinapyramine chloride) have been discontinued.

Despite intensive research, no effective vaccine is likely in the future because of the continuing problem of antigenic variation in trypanosomes and antigenic strain differences. Given the obstacles to vaccination, there is a keen interest in identifying and promoting trypanotolerant breeds of livestock in endemic areas, as discussed above in the section on epidemiology.

TOXICOLOGICAL DISEASES

Copper Poisoning

Primary copper poisoning has been reported in the goat, but is not common. It can produce a severe hemolytic anemia with hemoglobinuria and death as occurs in the more commonly affected ruminants—sheep and young cattle.

Epidemiology

There is a marked difference in susceptibility between sheep and goats regarding chronic copper poisoning. The condition is harder to produce experimentally in goats than in sheep (Søli and Nafstad 1978; Solaiman et al. 2001), and published reports of naturally occurring caprine copper poisoning are rare. In sheep, several naturally occurring forms of the disease

are recognized, including acute copper poisoning, primary chronic copper poisoning, secondary phytogenous copper poisoning, and secondary hepatogenous copper poisoning. Only the acute and primary chronic forms of copper poisoning have been reported to occur naturally in goats. The acute form was reported from Israel (Shlosberg et al. 1978) and involved the oral administration of copper sulfate solution to goats as an anthelmintic. Chronic cases have been reported from New Zealand and the UK, and involved young, hand-reared Angora goats exposed to a variety of copper-containing feeds and supplements (Belford and Raven 1986; Humphries et al. 1987). More recently, primary chronic copper poisoning was reported in dairy goats in the United States (Cornish et al. 2007).

Etiology and Pathogenesis

Acute copper poisoning is sporadic in occurrence and results from an accidental or unintentional ingestion of abnormally high doses of inorganic copper over a short period. Sources of copper include copper sulfate foot baths, improperly mixed feedstuffs or mineral supplements, or inappropriate administration of copper salts for therapeutic purposes. In acute copper ingestions, direct irritation of the gastrointestinal mucosa causes many of the clinical signs observed, including abdominal pain, vomiting, and shock. Death may precede the development of hemolytic anemia. Animals that survive the initial gastrointestinal insult subsequently absorb sufficient copper to initiate hemolysis.

Acute copper poisoning can be induced in sheep and young calves with a single oral dose of copper in the range of 20 to 110 mg/kg bw. The dose is similar in goats, with acute copper toxicity observed after an oral dose of approximately 60 mg/kg of copper sulfate (Shlosberg et al. 1978). Experimentally, acute toxicosis was produced in goats within three to four days by three daily intravenous injections of $CuSO_4 \cdot 5H_2O$ at a total daily dose of 50 mg (Wasfi and Adam 1976).

In all forms of chronic copper toxicity, the ultimate pathway for clinical disease is thought to be the same. Ingested copper accumulates in the liver over time until maximum hepatic levels are reached, at which point there is a sudden release of the accumulated copper into the blood, initiating an acute hemolytic crisis (Radostits et al. 2007). However, this notion may require reconsideration as a recent, well documented herd outbreak of primary chronic copper toxicosis in a dairy goat herd did not involve hemolysis as part of the clinical presentation in affected goats (Cornish et al. 2007).

In primary chronic copper poisoning, copper is ingested continuously as part of the regular ration. The level of copper may be, but need not be, abnormally high, because the uptake of copper from the rumen and subsequent accumulation in the liver are condi-

tioned by the concentrations of other minerals present in the ration. Low dietary levels of molybdenum, zinc, calcium, and sulfates can permit excessive uptake and accumulation of otherwise normal dietary levels of copper.

In secondary phytogenous chronic copper poisoning, grazing of specific pasture plants, notably subterranean clover *(Trifolium subterraneum)*, promotes the accumulation of copper in liver although the plants themselves are relatively low in copper and do not produce any liver damage. The mechanism behind this phenomenon is not known, but British breeds of sheep and Merino crosses seem more susceptible. This syndrome has not been reported in goats. In hepatogenous chronic copper poisoning, hepatotoxic plants are ingested and produce liver damage that increases hepatocyte affinity for copper accumulation. This can accelerate the development of hemolytic crisis even when dietary levels of copper are within normal limits. Plants most often involved are *Heliotropium europaeum* and other pyrrolizidine alkaloid containing species, including *Senecio* spp. and *Echium plantagineum*. This syndrome has not been reported in goats. In fact, goats are relatively resistant to the effects of *Senecio*, and the use of goats has been proposed to clear rangelands of the plant to make them suitable for grazing by cattle (Dollahite 1972).

Primary chronic copper poisoning can be induced in sheep with daily oral doses as low as 3.5 mg/kg bw, but goats require more aggressive challenge. In one study, oral administration of $CuSO_4 \cdot 5H_2O$ twice daily at a dose of 20 mg/kg of bw for fifty-six days produced hemolytic crisis in only one of three Norwegian breed goats. At necropsy, liver copper levels were 1,168 ppm wet weight and kidney levels were 635 ppm wet weight. There were no hemolytic crises in the two other goats killed after seventy-three and 113 days of daily dosing. Liver copper levels of 314 and 384 ppm wet weight and kidney levels of 3 and 4.5 ppm, respectively, were recorded (Søli and Nafstad 1978). In contrast, sheep are reported to experience hemolytic crises when liver copper levels exceed 150 ppm wet weight (Sanders 1983).

In another study with Nubian goats, neither of two goats given $CuSO_4 \cdot 5H_2O$ daily at 20 mg/kg/bw developed hemolytic anemia, while one of two given 40 mg/kg/day and one of two given 80 mg/kg/day did (Adam et al. 1977). In a more recent experimental study, Nubian goats were fed supplemental copper at increasing levels from 100 mg/head/day up to 1,200 mg/head/day for up to thirty-five weeks. Only individuals receiving 600 mg/head/day or higher showed a clinical effect, with signs of thirst, diarrhea, dehydration, lethargy, and weight loss. However, none experienced hemolytic anemia. The authors report that daily doses of copper of 100 mg/head/day are suffi-

cient to produce clinical toxicity in sheep and conclude that goats are more resistant to copper toxicity than sheep (Solaiman et al. 2001). It has been postulated that the difference in susceptibility of sheep and goats to copper poisoning is a function of differences in the distribution of copper- and zinc-binding soluble hepatic proteins (Mjor-Grimsrud et al. 1979).

In goats, as in sheep, development of copper toxicity may be conditioned by influences of other elements. Goats pretreated with vitamin E and selenium injections developed hemolytic crisis after fifty days of oral dosing with 15 mg/kg of copper as copper sulfate, while animals receiving the same copper dose with no vitamin E or selenium pretreatment showed no clinical signs after the same period. Goats with evidence of hemolytic crisis had decreased liver levels of reduced glutathione and higher glutathione disulfide levels (Hussein et al. 1985).

Clinical Signs

Acute copper poisoning in goats resulting from oral ingestion of copper produces signs of gastrointestinal irritation including evidence of abdominal pain, grinding of the teeth, frothing at the mouth, vomiting, and diarrhea. Additional signs include labored breathing, muscle fasciculation, tachycardia, and increased amplitude of heart sounds. Within six hours, severely affected animals may collapse and die. Morbidity and mortality rates are dose-dependent. Mortality rates as high as 53% have been reported in goats given oral copper sulfate at a dose of 60 mg/kg.

In cases of chronic copper toxicity and acute toxicity associated with parenteral administration of copper, dullness, anorexia, thirst, dehydration, and elevated heart and respiratory rates are early signs. Diarrhea may also be present. If hemolytic anemia is part of the clinical syndrome, then icterus will be noted on mucous membranes, serum will be pink, and urine red-brown. Dyspnea may develop as a result of severe anemia, and death may occur in twenty-four to forty-eight hours after the onset of signs. In untreated animals surviving longer, anuria and uremia may develop as a result of hemoglobinuric nephrosis.

However, in the most recent report of chronic copper toxicosis in a dairy goat herd (Cornish et al. 2007), none of the affected animals showed indications of hemolytic anemia. Only lactating does were clinically affected though young goats had laboratory evidence of copper levels consistent with intoxication. Clinical signs in lactating does included anorexia, agalactia, dullness, dehydration, teeth grinding, and drooling. Affected does progressed to recumbency and showed neurologic abnormalities such as paddling and vocalization followed by death. Signs associated with hemolytic anemia such as icterus or hemolyzed plasma were absent (Cornish et al. 2007).

Clinical Pathology and Necropsy

During the acute hemolytic crisis, PCV may fall below 10%, and RBC and Hb levels drop correspondingly. Heinz bodies can be seen in RBCs and there may also be methemoglobinemia. Serum bilirubin is markedly elevated and the urine is strongly positive for hemoglobin. Alterations in clinical chemistry are consistent with liver damage, and elevations of aspartate aminotransferase (AST), gamma glutamyl transferase (GGT), sorbitol dehydrogenase (SDH), and blood ammonia are reported in the goat, though the magnitude of increase is highly variable. Elevation in liver enzymes may precede the acute hemolytic crisis by several weeks and this may be helpful for screening animals in a herd not yet showing clinical disease. None of these changes are diagnostic for copper poisoning and it is important to establish the presence of abnormally elevated copper levels in blood, liver, kidney, or other tissues to confirm the diagnosis.

In a recent report of field cases of primary chronic copper toxicity, it was noted that in clinically affected goats there was no clear association between the magnitude of increase of serum hepatic enzymes and the concentrations of copper in the serum or liver. In clinically unaffected, younger does in the same herd, there was no consistent relationship between serum hepatic enzyme activities, serum copper concentration, and liver copper concentration. It was concluded that serum liver enzymes and serum copper levels are insensitive markers of liver copper concentration and the definitive method for diagnosis antemortem is to measure copper concentrations in liver samples obtained by biopsy (Cornish et al. 2007). Another study confirmed the reliability of liver as the optimal sample for establishing copper toxicosis and pointed out that hair samples did not reflect the copper status of animals (Solaiman et al 2001).

Normal liver copper levels are reported in the range of 0.188 to 1.805 μmol/g (12 to 115 ppm) (Mjor-Grimsrud et al. 1979). The normal kidney copper level in goats has been reported as 0.1 μmol/g (6.4 ppm). Normal serum copper levels in goats are reported to be in the range of 9.4 to 23.6 μmol/L (60 to 150 μg/dl, or 0.6 to 1.5 ppm) (Underwood 1981).

In field cases of chronic copper toxicity in goats in New Zealand, plasma copper levels of 34.6 μmol/l (219.8 μg/dl or 2.2 ppm) and red blood cell copper levels of 95.8 μmol/l (608.6 μg/dl or 6.1 ppm) were observed during acute hemolytic crisis. Liver copper levels were as high as 21.4 μmol/g dry matter (1359 ppm), and kidney levels as high as 6.4 μmol/g dry matter (406 ppm) (Humphries et al. 1987).

In experimental chronic copper intoxication in goats, animals with hemolytic crises had liver copper levels more than 900 ppm and kidney copper levels more than 170 ppm. Goats that were fed excessive copper but did not develop hemoglobinuria had liver copper levels between 300 and 1,100 ppm and kidney levels between 3 and 150 ppm while a control goat not fed copper had liver copper levels of 18.5 ppm and kidney levels of 6.7 ppm (Adam et al. 1977; Søli and Nafstad 1978).

In acute copper toxicity of goats, animals dying shortly after ingestion had normal liver and kidney levels of copper, but the copper contents of rumen ingesta and feces were elevated to 225 ppm and 1,060 ppm, respectively.

Findings at necropsy may include thin, watery blood and general icterus. The liver is enlarged, friable, and yellow. The kidneys are swollen, dark brown to black, metallic, and softened. Hemorrhages on the epicardium and endocardium and congestion of the lungs and spleen may be noted. In acute oral intoxication, marked inflammation of the abomasal and intestinal mucosae is evident. Histologically, the liver lesion is characterized by hemosiderin deposits, centrilobular necrosis and fatty degeneration, and biliary hyperplasia. The kidney exhibits lesions of nephrosis with casts present in tubules. One experimental study of chronic copper poisoning in the goat resulted in liver lesions atypical for the disease and it was suggested that the pathogenesis of chronic copper poisoning in the goat may differ from that in the sheep (Søli and Nafstad 1978). Others have consistently described lesions found in the goat to be similar to those found in sheep.

Diagnosis

When signs of abdominal pain are prominent—as in acute copper toxicosis—intestinal accidents, urethral obstruction, and early infectious enteritis must be considered. When hemolytic anemia is present, the differential diagnosis for chronic copper toxicity in the goat includes the hemoparasites babesiosis and trypanosomosis, where they occur, and several plant poisonings that could lead to hemolytic anemia, particularly kale, which also can produce Heinz bodies. Other intoxications must be ruled out in acute copper toxicity, including arsenic ingestion, organophosphate toxicity, cyanide poisoning, and nitrate poisoning. The recent report of goats with chronic copper toxicosis which had no evidence of hemolytic anemia but did have elevated liver enzymes and neurological signs suggests that various causes of hepatic encephalopathy may have to be considered in the differential diagnosis of chronic copper toxicity.

Treatment

Treatment is directed at the clearance and elimination of copper from the blood and tissues through the use of chelating agents. Until recently, the only treatment reported specifically in goats was ammonium tetrathiomolybdate, administered intravenously at a

dose of 1.7 mg/kg for three treatments on alternate days (Humphries et al. 1987). In lambs, a daily oral total dose of 100 mg of ammonium molybdate in combination with 1 g of sodium sulfate given for as long as three weeks has been effective in reducing tissue copper concentrations, and may prevent or ameliorate hemolytic crisis. Other chelating agents also have been used, including oral D-penicillamine at a dose of 52 mg/kg daily for six days. A recent report describes the successful use of penicillamine, ammonium molybdate, and sodium thiosulfate in the treatment of adult goats with primary chronic copper toxicosis (Cornish et al. 2007). Penicillamine was given orally at a dose of 50 mg/kg bw every twenty-four hours for seven days, ammonium molybdenate orally at a total dose of 300 mg every twenty-four hours for three weeks, sodium thiosulfate orally at a total dose of 300 mg every twenty-four hours for three weeks. Vitamin E was also given orally at a total dose of 2,000 U every twenty-four hours for three weeks as an anti-oxidant.

Penicillamine is expensive and, though effective, its use may be limited in commercial herds by cost considerations.

Therapeutic consideration should also be given to management of anemia when present as well as management of potential nephrosis in severely affected individuals. Blood transfusion might be indicated in exceptional cases when PCV is perilously decreased. Continuous intravenous administration of balanced electrolyte solutions helps maintain urine outflow and reduce the potential for irreversible hemoglobinuric nephrosis.

Control

Control of acute copper poisoning in the goat depends on common sense to avoid accidental exposure to and ingestion of high doses of copper. Because chronic copper poisoning in goats is rare, aggressive control methods such as fertilization of crop and grazing lands with molybdenum and molybdenum supplementation of feed are probably unnecessary. However, some caution should be exercised in using feedstuffs formulated for cattle, especially calf milk replacers used in kids. Nutritional requirements for copper in goats are discussed in Chapter 19.

Kale Anemia (*Brassica* Poisoning)

The use of kale *(Brassica oleracea)* as a feedstuff for ruminants may lead to the development of Heinz body anemia with possible mortality. Cattle are most susceptible, and sheep least susceptible. Goats have an intermediate position.

Epidemiology

Clinical outbreaks of Heinz body anemia have occurred in ruminants when kale has a predominant role in feeding programs. This has been a notable problem in Great Britain and Germany. Consumption of large amounts for extended periods increases the likelihood of disease, and anemia rarely develops until animals have been consuming kale for one to three weeks. Mature plants and plants with secondary growth are more toxic. The consumption of plants that have been frosted or frozen also increases the likelihood of disease. Certain varieties of kale are more toxic than others, but heating or ensilage destroys the toxic principle.

The condition is reproducible experimentally in goats (Greenlagh et al. 1969, 1970; Smith 1980). It has been reported as a cause of mortality in Angora goats in New Zealand (Anonymous 1988). Affected goats had been grazing the kale for less than two weeks, while lambs that had preceded kids in grazing were unaffected. It was suspected that kids, already anemic from haemonchosis, were more severely affected by kale toxicity.

Etiology and Pathogenesis

Kale contains high levels of S-methyl cysteine sulfoxide that is converted by rumen bacteria to dimethyl disulfide. This is then absorbed from the rumen and induces Heinz body anemia via the oxidation of hemoglobin in circulating red blood cells. Mature red blood cells are more susceptible to oxidation than young cells so that the anemia may become temporarily self-limiting as the regenerative response increases the relative proportion of young cells to old. As these cells mature, the anemia may worsen again if kale continues to be fed. This phenomenon is associated with higher levels of glutathione reductase in young cells that are protective against oxidation of hemoglobin (Smith 1980).

Clinical Findings

After one to three weeks of kale ingestion, goats develop a marked anemia. Sudden death may be the first reported sign in an affected herd or flock. Closer inspection may identify additional animals that hang back from the flock, appear weak, and have pale mucous membranes. Additional signs include inappetence, tachypnea, and tachycardia. Red-brown urine may be noted because of hemoglobinuria.

Clinical Pathology and Necropsy

Anemia may be pronounced, as hemoglobin levels can decrease below 6 g/dl and sometimes as low as 3 g/dl, with a concomitant decline in RBCs counts and PCV. The appearance of Heinz bodies in RBCs in the peripheral blood may precede the decrease in Hb by as much as a week. Methemoglobinemia, sometimes observed in cattle, is rare in goats. The anemia is

regenerative, and reticulocytes and an increase in MCV can be noted.

Necropsy findings specific for the goat have not been reported. In other species, post mortem lesions include pallor, hemoglobinuria, thin, watery blood, dark kidneys, and congestion of the liver with moderate hepatic necrosis. Jaundice, especially of the subcutaneous fat, is pronounced.

Diagnosis

Diagnosis is presumptive based on the presence of Heinz body anemia in conjunction with a history of kale feeding. In other ruminants, rape *(Brassica napus)*, wild onion *(Allium validum)*, cultivated onion, and stubble turnip consumption also produce Heinz body anemia. When widespread jaundice is noted at necropsy, chronic copper toxicity and leptospirosis must be considered in the differential diagnosis.

Treatment and Control

Therapy is limited to supportive care and the possibility of blood transfusion. Removal of kale from the diet results in a return of normal Hb levels within two to three weeks. Affected goats should not be subjected to stress or vigorous exercise during the recovery.

Other Plant-related Anemias

Several reports identify plants toxic to goats with anemia as a clinical manifestation. *Acanthospermum hispidum*, a weed of the Compositae family, has been associated with livestock poisoning in the Sudan, and its toxicity for goats has been confirmed experimentally. Animals fed the plant at a dose of 5 g/kg bw daily showed anorexia, jaundice, and diarrhea within one week, followed by dullness, dyspnea, weakness of the hind end, and terminal neurologic signs, probably because of hepatoencephalopathy. Clinical pathology indicated acute liver dysfunction and development of a marked hemolytic anemia during the course of disease (Ali and Adam 1978).

Ipomoea carnea, in the family Convolvulacae, is a tropical plant with strong drought-resistant properties; it may be an abundant source of browse for goats during adverse climatic periods. Toxicity in goats because of *Ipomoea* spp. has been presumed or documented in India, Brazil, and the Sudan (Tirkey et al. 1987; Dobereiner et al. 1987; Damir et al. 1987). Experimentally, daily repeated doses of fresh leaves of *Ipomoea carnea* as low as 5 g/kg of bw can produce a clinical syndrome of inappetence, depression, pallor, weakness of the hindquarters, dyspnea, weight loss, and death within three weeks, although there is individual variation in response, and some goats survived for longer than three months. A moderate, normocytic, normochromic, occasionally hypochromic anemia is observed in severely affected goats. Packed cell volumes as low as 15% occur, with Hb as low as 5 g/dl. In acute cases, the anemia is nonregenerative, but in animals that survived for longer periods, a macrocytic response was observed. Serum chemistry analysis suggested liver dysfunction with elevated AST and ammonia and hypoproteinemia (Tartour et al. 1974; Damir et al. 1987). Toxicity from *Ipomoea carnea* is dose dependent. In an Indian study, no clinical signs or laboratory abnormalities occurred in goats fed an aqueous extract of the plant at a dose of 160 mg/kg, considered to be one-fifth the LD_{50} dose (Tirkey et al. 1987).

Anemia also has been reported as an incidental finding in several plant poisonings in the Sudan, including *Capparis tomentosa* (Ahmed and Adam 1980), *Tephrosia apollinea* (Suliman et al. 1982), and experimentally, *Solanum dubium.* The latter plant is not routinely eaten by goats but may be consumed during periods of drought (Barri et al. 1983).

Bracken fern *(Pteridium aquilinum)* ingestion has been associated with a number of clinical syndromes in cattle and sheep, including depression of bone marrow activity leading to aplastic anemia, leukopenia with secondary bacterial infections, and ecchymoses secondary to thrombocytopenia, as well as ruminal papillomatosis, progressive retinal degeneration, and enzootic hematuria. There is only one clinical report associating exposure to bracken fern with disease in goats (Tomlinson 1983). Affected goats showed a marked anemia and high fevers that responded to antibiotic therapy, suggestive of secondary bacterial infections. Leukocyte counts and bone marrow evaluations were not performed. The goats concurrently experienced severe gastrointestinal helminthiasis and the contribution of bracken fern ingestion to the anemia and infections was not well established. Currently goats should be considered potentially susceptible to bracken fern toxicity. A report from Venezuela states that bracken fern can cause permanent blindness in goats (Alonso-Amelot 1999).

A number of plants have been associated with hemoglobinuria in sheep, including privet (*Ligustrum* spp.), broom (*Cytisus* spp.), hellebore (*Helleborus* spp.), *Ranunculus* spp., *Colchicum* spp., and frosted turnips (Kimberling and Arnold 1983). Currently, there are no reports of toxicity with these plants in goats, but it is reasonable to assume that a toxic potential exists.

DISEASES OF THE IMMUNE SYSTEM

Thymoma

Neoplasia is comparatively uncommon in goats, but thymoma is one of the two most commonly recognized

caprine tumors. It occurs more frequently in goats than in other domestic species. The other common tumor is the adrenal cortical adenoma seen in castrated male goats, as discussed in Chapter 13.

Epidemiology

Thymoma is rarely seen in goats younger than two years of age. There is no sex predilection. Because thymomas rarely produce clinical disease, recognition of thymoma in goats has come mostly from slaughterhouse surveys and as an incidental finding in necropsy studies. The highest prevalence has been reported in a group of Saanen goats used for slow virus research studies. Seventeen of ninety-two goats (18.5%) had thymomas at necropsy, with a prevalence of 25.3% in goats older than two years of age (Hadlow 1978). Slaughterhouse surveys indicate a lesser prevalence in general goat populations, with eight cases per 100,000 goats in one study and fourteen of 2,600 adult Angora goats in another, but this is still more than the prevalence of thymoma in other livestock species (Streett et al. 1968; Migaki 1969).

Clinical Findings

Most occurrences of thymoma are subclinical, but occasionally thymomas have been associated with clinical disease. Congestive heart failure secondary to thymoma was recorded in two aged Nubian goats (Rostkowski et al. 1985). These cases are discussed in more detail in Chapter 8. There is also a case of megaesophagus in an eight-year-old Saanen doe secondary to a thymoma and an associated hematoma which put pressure on the thoracic esophagus. The goat presented with a history of recurrent tympany and regurgitation after eating (Parish et al. 1996).

Occasionally, the thymoma may produce a pronounced subcutaneous swelling visible at the base of the neck. Normal thymic tissue is commonly found near the thyroids and at the base of the neck in healthy goat kids, as discussed in Chapter 3. In other species, notably the dog, thymoma has been associated with myasthenia gravis and polymyositis.

Clinical Pathology and Necropsy

The majority of thymomas occur in the cranial mediastinal cavity and occasionally at the thoracic inlet. Tumor size is variable, with some weighing up to 600 g. The tumors are encapsulated, firm, and grayish-white, and the larger ones tend to be lobulated. On cut surfaces they can contain areas of hemorrhage, cysts, and focal yellow areas of necrosis, sometimes associated with calcification. Metastases are rare, but adhesions to adjacent structures, especially lungs, do occur. In one report, pulmonary metastases from a thymoma were identified in an eight-year-old castrated male French Alpine goat with a history of progressive weight loss, exercise intolerance, and anorexia (Olchowy et al. 1996).

Diagnosis

Lymphosarcoma involving the thymus occurs rarely in goats and must be differentiated from thymoma. In thymoma, the principle neoplastic cell is a polymorphic epithelial cell that is often spindle-shaped, but can be round or ovoid. Lymphocytes are present in thymomas, and may predominate, but they do not exhibit characteristics of neoplastic transformation. The neoplastic cell in lymphosarcoma is the lymphocyte. Because it often produces peripheral lymphadenopathy, lymphosarcoma is discussed in more detail in Chapter 3.

Treatment and Control

Currently there are no methods of control. The reported high incidence of thymoma in Saanen goats used in slow virus research suggests that either genetic or viral factors may play a role in the development of caprine thymoma. This merits additional investigation, particularly because the retroviral disease CAE is now recognized to be widespread in goats.

Failure of Passive Transfer (FPT) of Maternal Immunity

Newborn goats, like the young of other livestock species, depend on the ingestion of antibody-rich colostrum shortly after birth to provide passive immunologic protection until they can actively produce their own array of protective antibodies. The failure to absorb adequate antibodies in the immediate post partum period predisposes young goats to serious infectious disease problems and high mortality rates.

Epidemiology

Unacceptably high levels of death loss in young goats are recognized as a major constraint on goat production wherever goats are raised. The factors contributing to kid death in various goat-producing regions of the world have been reviewed (Sherman 1987; Morand-Fehr 1987). In extensive management systems, kid losses have been reported in the range of 10% to 60% and, in intensive management systems, from 8% to 17%. These deaths most frequently occur in the first few days of life. Numerous factors contribute to this bias toward early death, including low birth weight, premature delivery, large litter size, poor mothering ability, and environmental and weather conditions at the time of kidding. However, the failure to suckle adequate colostrum at birth contributes significantly to the preponderance of early kid deaths, most likely through the mechanism of failure of passive

transfer of humoral immunity, as discussed below under pathogenesis. In a French survey, 92% of colostrum-deprived kids that died did so within two days of birth (Morand-Fehr et al. 1984). In an Indian study, serum immunoglobulin (Ig) levels were measured in newborn kids eighteen hours after ingestion of colostrum and the mean serum Ig concentration of these kids was determined to be 735 mg/dl. In the next two months, mortality rates of kids with serum Ig levels less than the mean was 44% but was only 3.8% for those with serum Ig levels more than the mean (Nandakumar and Rajagopalaraja 1983).

In addition to providing immunity against infectious disease and reducing neonatal mortality, there are indications that consumption of adequate colostrum by the neonate is associated with other long term benefits. There are positive correlations between serum IgG concentration at twenty-four hours of age (sIgG-24) and weaning weight in beef calves as well as positive correlations with first lactation milk production and milk fat content in dairy heifers. In goats, a significant correlation is reported between sIgG-24 and average daily weight gain in preweaned dairy goat kids measured up to thirty days of age (Massimini et al. 2007).

Etiology and Pathogenesis

The syndesmochorial (epitheliochorial) placentation of the goat does not permit the transfer of Ig from the maternal circulation to the fetus during gestation. Therefore, the kid is born in an agammaglobulinemic state, and though immunocompetent, is highly susceptible to infection because of the immediate lack of circulating humoral antibody. Passive immunization of the newborn kid depends on early oral ingestion of colostrum containing maternally produced Ig. The doe experiences an increase in antibody production, notably of the IgG_1 class, in the weeks preceding parturition, and IgG_1 antibodies are preferentially transported into the colostrum, aided by the affinity of the Fc fragment of IgG_1 for receptors on mammary epithelial cells. The mean concentrations for IgG_1 and IgG_2 in doe serum are reported as 10.9 and 9.1 mg/ml, respectively, while in colostrum the relative mean concentrations are 50.8 mg/ml for IgG_1 and 2.3 mg/ml for IgG_2 (Micusan and Borduas 1977).

The newborn kid, upon ingesting colostrum, is capable of transporting intact Ig molecules out of the intestinal lumen and into the blood circulation. Survival of intact antibody molecules in the gut lumen probably depends on the presence of trypsin inhibitors present in colostrum. The mechanism of transintestinal transport is pinocytosis through the original neonatal intestinal epithelial cells. It is presumed that as these cells are sloughed and replaced in the normal process by new epithelial cells, the capacity for additional pinocytosis and additional intestinal absorption of Ig is lost. In the calf and lamb, maximal absorptive capacity is believed to persist for six hours after birth, with all absorptive capacity absent by twenty-four hours of age, although this is conditioned to some extent by extrinsic factors such as the time of first suckling. In contrast, the kid may be able to effectively absorb antibody for a longer period, perhaps as long as four days. In one study, kids fed milk only at birth and not given colostrum until seventy-two hours old demonstrated increased serum antibody levels after colostrum administration. The level achieved, however, was not as much as that observed in kids receiving colostrum at birth, and mortality rates were higher (Vihan and Sahni 1982). Therefore, the potentially longer period for intestinal absorption of colostral antibodies in kids is no reason for delaying the ingestion of colostrum. The fact that the concentration of antibody in colostrum decreases rapidly after the first six to twelve hours also underscores the importance of early ingestion.

A number of factors influence the ultimate level of Ig reaching the serum of the kid and the immunity derived from it. Most of these considerations have been elucidated specifically for the lamb but are also considered applicable to the kid (Levieux 1984). These include the ability of the kid to suckle early after birth, volume of colostrum available, absorptive potential of the kid, concentration of antibody in the colostrum, and diversity and activity of the antibody. Small kids, especially if weakened by dystocia, may be unable to rise and therefore experience delayed suckling. Severe weather, disturbance of the doe and kid after birth, and competition by litter mates may also delay suckling or reduce the amount of colostrum available. Normal kids should stand and suckle within approximately one-half hour after birth.

The ability of kids to absorb Ig after ingestion of colostrum depends primarily on the time of colostrum ingestion, with earlier ingestion promoting better absorption. Birth weight and length of gestation are reported to be negatively correlated with absorption of Ig. However, there are apparently other unknown factors that affect the intrinsic ability of individual kids to absorb Ig. When newborn kids were administered colostrum from a common source on a per weight basis at the same time interval after birth, serum antibody levels subsequently varied by as much as a factor of eight. In addition to kid factors, maternal factors affect absorption. The concentration and character of Ig in does can also vary. Older does are likely to have a wider immunologic experience than young does and provide a more diverse spectrum of protective antibodies to kids. Breed variation has been observed in both ewes and does (Nandakumar and Rajagopalaraja 1983a; Levieux 1984). In the dairy breeds, where colos-

trum is produced well in excess of that required by offspring, IgG concentrations in the colostrum and subsequently in the kids' serum can be present in levels considerably higher than those reported for non-dairy breeds.

The majority of ingested antibody, primarily IgG_1, is absorbed across the intestinal tract to become circulating humoral antibody. Therefore, the key protective role of colostral antibody is prevention of general infection, and the most common cause of death in colostrum-deprived kids is colisepticemia. Doe colostrum also contains small amounts of IgA and IgM, 1.7 mg/ml and 3.8 mg/ml, respectively, but the role of colostral antibody in protecting against local, mucosal infection, particularly in the gut, is rather limited.

While absorbed antibody is clearly beneficial to the kid in terms of immediate disease protection, passive antibody can have a retarding effect on the development of the kid's own active immunity. Experimental evidence demonstrates that in colostrum-deprived kids, circulating IgG_2 appears earlier in the serum than in colostrum-fed kids and that by twelve weeks of age, circulating levels of both IgG_1 and IgG_2 are higher in colostrum-deprived kids than colostrum-fed kids (Micusan et al. 1976).

Based on studies of the disappearance of antibodies specific for *Corynebacterium pseudotuberculosis* from kid serum after colostrum ingestion, the half-life of passively acquired antibody is approximately twelve days, with some antibody still detectable in most kids between five and six weeks of age (Lund et al. 1982). Persistent antibodies may inhibit active immunization with homologous vaccines. When colostrum-fed kids were immunized with human gamma globulin, a protein with which their dams had been previously immunized, they showed no measurable antibody response to immunizations at birth and four weeks of age and responded only at eight weeks of age when passive antibody levels to the protein had diminished (Micusan et al. 1976). These observations are of practical concern when planning vaccination schedules for young goats.

Clinical Findings

There are no specific clinical signs of FPT per se. The condition is suggested by kid deaths occurring within forty-eight hours of birth, in association with clinical signs of septicemia. These include acute collapse, very high or subnormal body temperature, cold extremities, congested mucous membranes, rapid heart rate and thready pulses, and dehydration. Evidence of navel infection, diarrhea, or swollen joints may also be suggestive of septicemia, but many kids die before these signs are observable. Hyperesthesia, seizure activity, or ophistotonos may be observed because of bacterial invasion of the central nervous system or concomitant

acidosis. Pneumonia, enteritis, or a pneumoenteritis complex occurring in kids during the first few weeks of life is also suggestive of FPT.

A careful history should be taken to determine if the affected kids were observed to suckle, the time of suckling, whether the caretaker provided colostrum by bottle, and whether navels were disinfected after birth. Examination of the kidding and housing areas for evidence of poor sanitation and lapses in good management technique may suggest that septicemia secondary to FPT is involved.

Clinical Pathology and Necropsy

The most direct method for determining if FPT is involved in death losses is to measure circulating Ig levels in the serum or plasma of kids. The optimal time for obtaining serum samples from kids is between twenty-four and forty-eight hours of life, because maximum antibody absorption from the gut will have occurred during that time. Methods reported specifically for determination of serum Ig in kids are limited compared with other livestock species.

Documented tests include a quantitative zinc sulfate turbidity test and a qualitative glutaraldehyde coagulation test (Vihan 1989; Sherman et al. 1990). Using the zinc sulfate turbidity test, kids receiving 480 ml of heat-treated goat colostrum in the first twenty-four hours of life had mean Ig levels of 1.5 gm/dl when tested twenty-four hours after the last colostrum feeding. Using the glutaraldehyde coagulation test, serum from kids with Ig levels less than 1 gram/dl did not clot after sixty minutes incubation with 10% glutaraldehyde solution. Recently, the use of total protein determination by refractometry and a sodium sulfite precipitation test have been described for deriving reliable estimates of Ig levels in kids under field conditions (O'Brien and Sherman. 1993). When FPT was defined as a serum IgG < 1,200 mg/dl, all cases of FPT were indirectly identified using total protein determination by refractometry when the cutoff for total protein was set at 5.4 g/dl. Currently, commercial test kits are also available for direct measurement of IgG in goat serum using radial immunodiffusion (Massimini et al. 2007).

Studies correlating antibody level to morbidity and mortality in kids are scarce compared with similar work for calves, lambs, and foals, so minimal acceptable levels of circulating Ig for kids under different systems and conditions of management are not established. In a recent prospective study of kid survival in relation to circulating Ig levels in intensively managed dairy goat kids in New England, in the United States, a serum Ig level of 1,200 mg/dl appeared to be protective (O'Brien and Sherman 1993a).

An indirect method for evaluating Ig absorption by measurement of serum gamma glutamyl transferase

(GGT) levels in kid serum has been reported. The mean serum GGT levels in pre-suckling newborn kids was 19 U/l, with a maximum recorded measurement of 28 U/l. At twenty-four hours after colostrum ingestion, serum GGT levels were on average six and a half times greater than pre-suckle levels, with a mean of 127 U/l and a minimum reported value of 43 U/l. The mean GGT level fell rapidly after twenty-four hours, so timing appeared critical in the evaluation of the test results (Braun et al. 1984).

Goats with septicemia secondary to failure of passive transfer are likely to be severely leukopenic and may show hyperfibrinogenemia. Necropsy results are nonspecific, but bacterial culture results of heart blood and various other organs can establish the presence of septicemia.

Diagnosis

Decreased serum Ig levels in newborn kids twenty-four hours of age or older confirms the presence of FPT. The contribution of this condition to concurrent disease problems can only be inferred. In kids dead before twenty-four hours, FPT may be contributory, but this is more difficult to establish. Hypothermia and hypoglycemia must always be considered in the differential diagnosis of septicemia secondary to FPT. Hypoglycemia may be presumed in the live animal by measurement of blood glucose, although blood glucose is also likely to be decreased in active septicemia. The absence of an inflammatory hemogram supports primary hypoglycemia, as does the absence of a milk clot in the abomasum or ingesta in the small intestine, indicating lack of feed intake. A diagnosis of hypothermia is supported by low body temperature in conjunction with environmental conditions that would promote chilling such as outdoor kidding, cold temperatures, wet weather, and drafts. In individual kids, congenital abnormalities must also be considered as a cause of early death. Under conditions of extremely poor management and with sufficiently virulent organisms, septicemias can occur even when adequate colostrum has been ingested shortly after birth.

Treatment

In most cases, FPT first comes to the veterinarian's attention because of a primary complaint of early deaths or signs of shock suggesting the presence of septicemia. Immediate attention must be given to the management of the infection. Animals should be moved to a warm, dry environment. Intravenous fluid therapy including glucose and sodium bicarbonate should be initiated to counter the hypoglycemia and circulatory effects associated with septic shock. Parenteral nonsteroidal anti-inflammatory drugs such as flunixin meglumine may be helpful. Antibiotic therapy is essential. Choice of drugs ideally should depend on blood culture, but therapy should be initiated immediately with broad spectrum antibiotics, especially those with efficacy against Gram-negative species. Trimethoprim-sulfa combinations or gentamicin combined with ampicillin can be effective. Aminoglycoside drugs must be used cautiously to avoid serious renal damage, particularly if fluid therapy is not used concurrently. Chloramphenicol, where permitted, is also effective in septicemia.

Correction of the hypogammaglobulinemia requires transfusion of plasma or whole blood. The volume required to replace the Ig deficit depends on the known level of circulating Ig in the sick kid and the average or known level of Ig in the blood of the donor goat. The average circulating serum Ig level of does is approximately 20 mg/ml. Although the minimum level of acceptable circulating immunoglobulin required by the kid has not been established, in most cases an initial transfusion of at least 250 ml of plasma is required for an average-sized kid. Repeated evaluation of zinc sulfate turbidity test results after plasma administration can aid in determining the need for additional transfusions.

Prevention

All goat caretakers should be aware of the potential economic losses associated with failure of passive transfer of antibody to newborn kids and educated on aspects of neonatal management related to colostrum administration. Careful observation of goats at kidding time may be necessary to identify individual kids that do not effectively suckle by six hours of age. These kids should be bottle fed or tubed with colostrum at a rate of 50 ml of colostrum per kg bw for each of three feedings over the first twelve to twenty-four hours of life. In intensive management systems, caretakers responsible for kid rearing can be encouraged to electively administer colostrum to all kids routinely within six hours of birth rather than wait for it to occur naturally.

The maintenance of a frozen colostrum bank ensures that all kids have colostrum available regardless of the status of their dams. In preparing frozen colostrum, only that taken from does during the first twelve hours after kidding should be kept for freezing, because the concentration of Ig in colostrum falls off rapidly and dramatically after the first stripping. It is reported that Ig concentration of caprine colostrum shows a strong positive correlation to its specific gravity, so that colostrum quality can be screened using a colostrometer. Colostrum with a specific gravity more than 1.029 is preferred (Ubertalle et al. 1987). Bovine colostrum, either fresh or frozen, has been used successfully as a substitute for ewe colostrum in rearing lambs. This has also gained popularity in goat rearing in an attempt to limit the colostral transmission of CAE virus in kids.

Serum antibody levels achieved in kids suckling bovine colostrum are equivalent to those obtained with caprine colostrum (Sherman et al. 1990). However, this practice must be viewed with caution; in France, a hemolytic syndrome has been reported in some kids at one week of age after consumption of bovine colostrum. It was demonstrated *in vitro* that bovine antibodies were directed against some caprine erythrocytes (Perrin et al. 1988).

Concerns have arisen regarding the impact of heat treatment techniques on immunoglobulin content of goat colostrum used in caprine arthritis encephalitis (CAE) control programs. The original heat treatment protocol of 56°C (132.8°F) for sixty minutes was developed to avoid the denaturing effect on antibody associated with the higher temperatures of pasteurization, while still inactivating the CAE virus (Adams et al. 1983). However, more recent studies demonstrate *in vitro* that heat treatment of colostrum at 56°C for sixty minutes reduces measurable IgG in colostrum by approximately 37% (Argüello et al. 2002). Nevertheless, if the initial concentrations of the colostrum that is heat treated are sufficiently high, successful passive transfer of antibody may still be achieved.

In recent years, a number of commercial products have become available that have been promoted as colostrum supplements for calves, lambs, and kids but have been used by goat owners as colostrum substitutes in part to avoid the need for heat treating colostrum for CAE control, which can be cumbersome and time consuming. These products are usually in the form of soluble powders or boluses. In one study, two of these products were evaluated in kids. There was virtually no detectable increase in circulating serum Ig levels in colostrum-deprived kids receiving these oral products within twelve hours of birth. Therefore, the value of these products as sources of protective Ig must be viewed skeptically (Sherman et al. 1990). Other reports have corroborated the inadequacy of certain colostrum substitutes in achieving adequate immunoglobulin levels in kids receiving the products (Constant et al. 1994).

Cardiovascular System

The occurrence of clinically recognized cardiovascular disease in goats is very low. As a result, goats have been the least studied of the domestic species regarding normal cardiovascular function and pathophysiology. In recent years, however, goats have received more attention as a suitable animal model for the study of human cardiovascular disease and its management. In particular, goats have been used in studies of the pathophysiology and treatment of atrial fibrillation (Neuberger et al. 2006), chronic heart failure (Tessier et al. 2003), the development of skeletal muscle ventricles (Guldner et al. 2002), the development and testing of artificial heart valves (Björk and Kaminsky 1992), and the use of total artificial hearts (Abe et al. 2007). As reported in 2007, the world record for survival of an animal with a total artificial heart belongs to a goat outfitted with a paracorporeal total artificial heart that survived for 532 days (Abe et al. 2007).

BACKGROUND INFORMATION OF CLINICAL IMPORTANCE

Anatomy and Physiology

Structure of the Heart and Vessels

The heart of the goat extends from the third to the sixth rib and may contact the diaphragm at its caudal edge. The position and orientation within the thorax is similar to that of other ruminants. The adult heart may contain two small cardiac bones, the right and left *os cordis* located around the aortic ring (Aretz 1981). However, a more recent study reported that in a series of fifty goats examined, only a right *os cordis* was present, located beneath the septal cusp of the tricuspid valve near the junction of the interatrial and interventricular septae and that it was only present in 44% of the hearts examined (Mohammadpour and Arabi, 2007). Purkinje fibers extend deep into the myocardium of the goat heart, as in other ruminants, which has clinical implications regarding the diagnostic value of electrocardiography as discussed later in this chapter.

Anomalies of the heart reported in goats include ventricular septal defects (VSD) in the lower, middle, and upper ventricular septum (Parry et al. 1982), and ectopia cordis, with the heart exposed to the outside through a fissured sternum (Narasimha Rao et al. 1980). Kids with ectopia cordis may be born alive and survive for hours or days (Upadhye and Dhoot 2001) or they may be born dead with structural abnormalities of the externalized heart such as a single ventricle (Dadich 2000).

There are no major differences in the structure and distribution of the great vessels of goats compared with other ruminants. Anomalies of the great vessels are uncommon, but persistence of the left cranial vena cava (Waibl 1973), dextroposition of the aorta (Parry et al. 1982), and aortic stenosis (Scarratt et al. 1984) have been reported.

Parameters of Blood Flow

Information on cardiac output, stroke volume, systolic and diastolic arterial pressures, pulmonary arterial pressure, pulmonary arterial flow rates, and central venous pressure has been published, but the numbers of animals involved in the various studies have been

limited (Jha et al. 1961; Hoversland et al. 1965; Foex and Prys-Roberts 1972; Ivankovich et al. 1974; Vesal and Karimi 2006).

Mean cardiac outputs in goats of various breeds, age, and sex have been reported in the range of 2.8 ± 0.7 l/minute to 4.8 ± 1.4 l/minute (Hoversland et al. 1965; Foex and Prys-Roberts 1972; Ivankovich et al. 1974; Olsson et al. 2001). More recently, significant differences in cardiac output were confirmed in dairy goats during pregnancy (6.73 ± 0.72) as compared to lactation (6.12 ± 0.52) and the dry period (4.39 ± 0.27) in the same individuals (Olsson et al. 2001).

Mean stroke volumes derived from a measurement of cardiac output and heart rate or measured directly by dye dilution technique have been reported in the range of 20.3 ± 3.1 ml to 46.9 ± 23 ml (Foex and Prys-Roberts 1972; Ivankovich et al. 1974). Mean systolic arterial pressure recorded from goats of varying breeds, age, and sex ranged from 122 to 124.9 mm Hg, while mean diastolic pressures in the same goats ranged from 85 to 97.8 mm Hg (Jha et al. 1961; Hoversland et al. 1965). Mean central venous pressure in goats of both sexes was reported as 1.25 ± 0.14 cm H_2O but there was a statistically significant difference between males (0.80 ± 0.11) and females (1.9 ± 0.26). There was no difference noted, however, between standing goats and those in lateral recumbency (Vesal and Karimi 2006).

Normal Heart Rate and Rhythm

The heart is heard most audibly over the left thoracic wall at the fourth intercostal space. Heart rate varies considerably in goats with age and level of activity. Mean heart rates for small numbers of goats at different ages have been reported from India (Upadhyay and Sud 1977). Barbari goat kids from birth to fifteen days of age had mean heart rates of 255 ± 15 bpm, and 209 ± 6 bpm from sixteen days to one month of age. By one to six months of age, mean heart rates had decreased to 142 ± 6 bpm and to 125 ± 9 bpm between six and twelve months. Goats one to three years of age had heart rates of 126 ± 5 bpm, and goats three to five years of age, 126 ± 7 bpm. In one American study of one hundred male goats one to one and a half years of age, the mean heart rate was 96 bpm with a range of 70 to 120 (Szabuniewicz and Clark 1967). In a second American study of eight adult females of mixed breed, the mean was 105 bpm with a range of 90 to 150 (Jha et al. 1961). While it is generally presumed that fear and distress increase the heart rate in goats, a study involving goat responses to unfamiliar human contact could not demonstrate a significant elevation in heart rate (Lyons and Price 1987).

Using telemetric recording of heart rate, investigators demonstrated a significant increase in heart rate of normal young goats during physical examination (116 ± 11.7 bpm) compared with before (92.2 ± 6.3 bpm) and a significantly higher rate when eating (114.1 ± 2.1 bpm) as compared to standing (84.2 ± 0.9 bpm) or lying down (76.5 ± 1.1 bpm) (Vesal et al. 2000). Other investigators have reported significant differences in heart rates in goats of different breeds kept under similar conditions (Medeiros et al. 2001) and elevated heart rates in pregnant does as compared to the same does when lactating and when non-pregnant and non-lactating (Olsson et al. 2001)

Two heart sounds are normally heard in the goat, S_1 and S_2. A normal respiratory sinus arrhythmia is common, with acceleration occurring in late inspiration. It is more pronounced in younger goats. Second degree A-V block, though uncommon, has been recorded in a normal goat (Szabuniewicz and Clark 1967).

Diagnostic Methods

Electrocardiography

The electrocardiogram (ECG) has been applied relatively infrequently in caprine medicine. Nevertheless, some parameters for the ECG tests in normal goats have been established using standard and augmented limb leads (Szabuniewicz and Clark 1967; Upadhyay and Sud 1977). The goat may be evaluated while standing or in left or right lateral recumbency with little effect on the ECG. Limb leads should be placed on the anteriolateral aspect just above the elbow joint in the forelimb, and just above the stifle joint in the hind limb. Electrocardiography has also been performed with the leads in a sagittal plane between the ears, on the sacrum, and on the sternum (Schultz and Pretorius 1972).

Interval durations, in seconds, have been reported for the P-wave, P-R interval, QRS complex, Q-T interval, and T-wave (Jha et al. 1961; Szabuniewicz and Clark 1967; Schultz and Pretorius 1972; Upadhyay and Sud 1977; Ogburn et al. 1977). Minimal differences occur between various leads (Szabuniewicz and Clark 1967). The amplitudes of ECG deflections are small in the goat. Mean amplitudes for various leads as measured in one hundred goats have been reported (Szabuniewicz and Clark 1967). Duration and amplitude measurements reported for the commonly used lead II are given in Table 8.1.

The P-wave is most often peaked in standard and augmented leads, but is occasionally flat or rounded. Biphasic P-waves are rarely seen. The P-wave is usually positive in the standard leads and the augmented leads, except for aVR. Changes in the shape of P-waves may be observed sometimes in normal goats, representing wandering of the pacemaker in the sinoatrial node.

Table 8.1. Electrocardiographic parameters for lead II reported in normal goats.

Parameter	P-wave amplitude (mv)	P-wave duration (sec)	P-R interval duration (sec)	QRS complex amplitude (mv)	QRS complex duration (sec)	Q-T interval duration (sec)	T-wave amplitude (mv)	T-Wave duration (sec)
Mean values	0.080	0.04	0.09–0.13	0.258	0.039–0.045	0.295–0.334	0.200	0.07
Range	0.02–0.15	0.02–0.06	0.06–0.16	0.10–0.70	0.03–0.08	0.22–0.38	0.05–0.50	0.04–0.10

QRS = principal deflection in an electrocardiogram.

The shape of the QRS complex is quite variable within and between the different leads. It is usually mono- or diphasic and infrequently triphasic. In lead I, a QS pattern dominates. In lead II, QS or Qr patterns are most often recorded. In lead III, no single pattern is predominant, and the Qr, qR, R, RS, and Rs patterns commonly occur. Q waves are rarely observed in the aVR lead, and the R and Rs patterns predominate. In the aVL lead, the QS pattern is most common, followed in frequency by the rS pattern. In lead aVF, either the Qr or the QS patterns may predominate, with the R, RS, Rs, and rS patterns also common. Because of the variability of the QRS complex in particular, it is generally considered that there is no typical morphologic pattern that is characteristic for the ECG test results of the goat using the common lead systems.

The T-wave occurs most commonly in the peaked form. Flat, round, or diphasic T-waves are uncommon. In most cases, the T-wave is of opposite polarity or deflection to the accompanying QRS deflection, although concurrent positive deflections occur in lead III and concurrent negative deflections in lead aVL.

Vectorcardiography is of limited clinical value in goats. As is the case with other ruminants, Purkinje fibers fully penetrate the ventricular wall with extensive ramification. This permits rapid excitation of both ventricles, resulting in near cancellation of potentials within the wall. As a result, subtle changes in vector orientation or QRS wave structure resulting from cardiac derangements are difficult to distinguish. The occurrence of rapid, simultaneous activation of both ventricles in a period of approximately 10 milliseconds has been well documented in the goat. The pattern of depolarization observed is virtually identical to that of the calf (Hamlin and Scher 1961). In an experimental model of right ventricular hypertrophy, no significant alteration of the QRS complex or vector orientation was identifiable in affected goats. The Q-T interval shortened in goats with right ventricular hypertrophy, but this was attributed to the increased heart rate that occurred (Ogburn et al. 1977). Nevertheless, detailed studies of three goats with naturally occurring ventricular septal defects indicate that prolongation of P-R intervals and P-, QRS, and T-wave intervals and amplitudes may suggest cardiac enlargement (Parry et al. 1982).

Radiography

The radiographic anatomy of the caprine thorax has been described (Singh et al. 1983). In dorsoventral radiographs, the normal heart lies between the second or third intercostal space and the sixth or seventh space, with the base centered over the midline and the apex shifted to the left of midline.

While not universally accepted, measurement of contact area of the heart with the sternum has been used to evaluate cardiac enlargement secondary to ventricular septal defect in the goat. Normal hearts had a mean contact area of 3.3 sternebrae; abnormal hearts had a mean contact area of 6 (Parry et al. 1982).

Echocardiography

While M-mode, two dimensional (B-mode), and Doppler echocardiography are being applied more frequently to the diagnosis of suspected heart disease in goats, published information on normal echocardiographic parameters in the goat remains limited. In one study, mitral, aortic, and tricuspid valves were identified at the right third and fourth intercostal spaces slightly dorsal to the olecranon. The pulmonic valve was identified at the same location on the left (Yamaga and Too 1984). In a more recent study, technical difficulties were noted with regard to echocardiographic examination of the goat. The cranial location of the heart partly covered by the olecranon and the caudal brachial muscles, along with the narrow intercostal spaces, made it difficult to position the ultrasound transducer and limited the acoustic window (Olsson et al. 2001). Nevertheless, echocardiographic and Doppler measurements were obtained in eight normal Swedish domestic goats during pregnancy, lactation, and the dry period. These measurements are presented in Table 8.2. A separate study of eight normal goats in the Philippines also reports normal caprine cardiac parameters measured by B-mode and M-mode ultrasonography (Acorda et al. 2005).

Table 8.2. Echocardiographic and Doppler measurements and calculated stroke volume and cardiac output during pregnancy, lactation, and dry period in the same eight goats (*Capra hircus*).

	Reproductive periods		
Measurements	*Pregnancy*	*Lactation*	*Dry period*
HR (M-mode; beats min^{-1})	148 ± 4***†	123 ± 5	107 ± 9

HR = heart rate; AO = aortic root; LA = left atrium; LVEDD and LVESD = left ventricular end-diastolic and end-systolic diameter, respectively; LVWd and LVWs = left ventricular wall thickness in diastole and systole, respectively; FS = fractional shortening of the left ventricle; VTI = velocity trace integral; V$_{max}$ = maximal aortic flow. Values are means ± S.E.M. ***P* < 0.01 and ****P* < 0.001 vs. dry period; †*P* < 0.05 *vs.* lactation. (From Olsson, K., et al., A serial study of heart function during pregnancy, lactation and the dry period in dairy goats using echocardiography. Experim. Physiol., 86(1):93–99, 2001. Used with permission of Wiley-Blackewll Publishing.)

There is one published case report on the use of echocardiography for the diagnosis of heart disease in a goat (Gardner et al. 1992). In that report, a three-year-old pygmy buck was evaluated for a systolic murmur. Echocardiography revealed an enlarged right atrium and ventricle, an atrial septal defect, and a dysplastic tricuspid valve, while color-flow Doppler echocardiography revealed severe tricuspid regurgitation and a right to left shunt through the atrial septal defect. A diagnosis of Ebstein's anomaly of the tricuspid valve was made, the first such report in goats. Ultrasonography has also been used to identify cardiac and pulmonic abnormalities associated with enzootic calcinosis in goats (Gufler et al. 1999)

Pericardiocentesis

Indications for pericardiocentesis in the goat are limited. Traumatic reticuloperitonitis, which is a well known condition in cattle, is rarely reported in goats in the veterinary literature. Pericardial effusions may occur in caprine heartwater (cowdriosis), but the fluid is not useful for diagnostic purposes. Pericarditis also occurs in conjunction with systemic mycoplasmosis but the organism is more easily isolated from other sites. If attempted, pericardiocentesis is best performed at the right fourth intercostal space low on the chest wall to avoid lung and coronary arteries. The animal can be standing or in lateral recumbency. Chemical restraint such as diazepam is advisable. Surgical access to the pericardium can be accomplished by resection of the left fourth rib.

Computed Tomography

Computed tomography of the caprine thorax has been described (Smallwood and Healey 1982). The heart is visible in cross-section beginning at the caudal aspect of thoracic vertebra T1 and ending at the middle of T5. The right side of the heart is more visible in the anterior cross sections and the left side in the posterior sections. At the level of the caudal aspect of T2, the heart silhouette is in contact with both the right and left thoracic walls.

Angiography

Left ventricular angiocardiograms in goats have been reported for the diagnosis of VSD. Passage of a catheter was performed via the left and right carotid arteries to acquire angiographic and hemodynamic data (Parry et al 1982; Scarratt et al. 1984). Arteriography and ultrasonography also have been applied to studies of the carotid artery diameter and blood flow velocity in goats (Lee et al. 1990).

Clinical Chemistry

The reported use of clinical chemistry in the diagnosis of caprine heart disease is limited. Myocardial damage or necrosis can lead to release of various enzymes into the circulation, including aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatine kinase (CK). However, skeletal muscle damage can also result in measurable increases in serum concentrations of these enzymes. In the case of LDH and CK, measurement of cardiac specific isoenzymes might confirm the involvement of heart muscle, but the cardiac specificity and reference values for caprine isoenzymes of LDH and CK are not well documented.

In recent years, measurement of the myofibrillar contractile protein, troponin, in plasma has become the accepted standard biomarker for acute myocardial infarction in human patients and it is also increased in patients with decreased left ventricular function without acute myocardial infarction (Ammann et al. 2003). Reference values for measurement of troponin (cTNI) in plasma of healthy dogs have been recently published, with a median value of 0.03 ng/mL and a range of 0.01 to 0.15 ng/mL (Oyama and Sisson 2004). Goats have intermediate levels of troponin (cTNT) relative to other domestic species and it has been demonstrated that a second generation immunoassay can detect cardiac muscle troponin cTNT in blood (O'Brien et al. 1998).

DIAGNOSIS OF CARDIOVASCULAR DISEASE BY PRESENTING SIGN

Heart disease is not common in goats and the world literature on caprine cardiovascular disease is sparse. One Indian study on the prevalence of gross cardiac abnormalities in slaughtered goats found approximately 3.5% of 2,720 hearts examined to be abnormal (Chattopadhyay and Sharma 1972). A slaughterhouse survey of 29,687 goats in Zimbabwe identified 525 (1.6%) instances of pericarditis (Chambers 1990). Nevertheless, in routine clinical examination, some physical findings may suggest cardiovascular disease in goats, and these findings should be pursued. The differential diagnoses for clinical signs suggesting cardiovascular disease are given below.

Sudden Death

Attribution of sudden death to cardiac disease must be approached cautiously in goats. The presence of gross or microscopic lesions in the heart at necropsy does not always mean that heart disease contributed to the clinical picture. Some changes may be artifactual, related to autolysis, blanching of the heart muscle during rigor mortis, or uneven staining of histologic sections (Newsholme and Coetzer 1984). In addition, a number of abnormalities may be noted in the heart, pericardium, or great vessels that represent subclinical conditions unrelated to the cause of death. These are discussed below in the section on subclinical cardiovascular conditions.

Peripheral evidence of cardiac dysfunction may be a better indicator of heart involvement than abnormalities of the heart itself. These include passive congestion, lung edema, and fluid accumulation in the thorax, pericardium, or abdomen. Histologic evaluation in all cases of the heart should be performed to identify definitive changes when present. The following cardiac causes of sudden death must be considered.

Nutritional Muscular Dystrophy

Nutritional muscular dystrophy or white muscle disease can affect the heart muscle and skeletal muscle and may be responsible for sudden death caused by cardiac failure, particularly in young kids. The disease is discussed in detail in Chapter 4.

Cardiotoxic Plants

A number of plants may cause heart failure and sudden death in goats. In North America, potentially cardiotoxic plants include the ornamental plants oleander *(Nerium oleander),* foxglove *(Digitalis purpurea),* lily of the valley *(Convallaria majalis),* and yew (*Taxus* spp.). Other weeds and shrubs include Indian hemp *(Apocynum cannabinum),* false hellebore (*Veratrum* spp.), and milkweed (*Asclepias* spp.) (Fowler 1986). Yew and false hellebore contain toxic alkaloids, while the other plants contain cardiac glycosides. In all cases, such poisonings would be sporadic and require careful documentation of exposure. Rumen contents should be examined for identifiable plant parts. The outcomes of these cases often depend on the level of exposure. If nonlethal doses are consumed, clinical signs may persist for several days, because the half-life of most cardiac glycosides is between twenty-four and thirty-six hours.

Successful management of yew toxicity in goats has been reported. Two goats died within twenty-four hours of ingesting the ornamental shrub and three remaining goats showed signs of bradycardia, hypothermia, depression, and weakness. Rumenotomies were performed on these goats to remove ingested plants, and mineral oil, electrolytes, and activated charcoal were added to the rumen. All three survived (Casteel and Cook 1985).

In South Africa, gousiekte, or "quick disease" occurs commonly enough to produce serious economic loss in livestock, including goats. It is caused by six different plants in the family Rubiaceae: *Pachystigma pygmaeum, P. thamnus, P. latifolium, Pavetta schumanniana, P. harborii,* and *Fadogia homblei.* It is a cumulative

poisoning and usually requires several weeks of ingestion of these plants before clinical disease occurs. Goats are more susceptible than sheep (Hurter et al. 1972). The toxic principle in these plants has been isolated. It is a water soluble, heat stable, cationic polyamine that has been termed pavetamine (Fourie et al, 1995). The toxin has been shown to inhibit the synthesis of new myosin during the turnover of myocardial proteins (Schultz et al. 2004). Under range conditions, the disease is perceived as one that causes sudden death after a latent period of three to six weeks following ingestion of the offending plants. However, if animals are carefully observed, prodromal signs of lagging behind the flock, lying down with head and neck extended, dyspnea, and coughing may be noted during this latent period (Pretorius and Terblanche 1967). At necropsy, there is gross evidence of heart failure including general congestion, pulmonary edema, ascites, hydrothorax, and hydropericardium. Histologically, the most consistent finding is hypertrophy of myocardial fibers in the subendocardial region (Prozesky et al. 2005).

Other South African plants that can result in sudden death include *Cotyledon orbiculata* and *Dichapetalum cymosum.* The succulent plant *C. orbiculata* contains bufadeniolides, which are cardiac glycosides. When large amounts of the plant are consumed by goats over a short period of time, sudden death from heart failure can occur (Tustin et al. 1984). This may be preceded by signs of weakness, prostration, tachycardia, and pupillary constriction.

The toxic principle in *D. cymosum,* a plant known as gifblaar, is monofluoroacetic acid. Death occurs within a few hours of ingestion. Peritoneal, pericardial, and thoracic effusions may be observed at necropsy, and histological examination of the heart may demonstrate multiple small foci of myocardial necrosis, with lymphocytic infiltration. However, these are not consistent findings (Newsholme and Coetzer 1984). A related species, *D. barteri*, has been identified as a cause of sudden death in goats eating branches of the tree in Nigeria (Adaudi 1975; Nwude et al. 1977).

Sudden death in South African goats has also been reported three days after ingestion of avocado leaves *(Persea americana),* presumably because of heart failure (Grant et al. 1988). The cardiotoxicity of avocado leaves has since been confirmed experimentally in two goats (Sani et al. 1991). One died suddenly without showing clinical signs while the second developed muffled heart sounds, tachycardia, and tachypnea before dying two days after challenge. At necropsy, there was pleural and pericardial effusion, pulmonary edema, ascites, hepatic congestion, and a pale, flabby heart with widespread degeneration of myocardial fibers seen microscopically. Avocado, oleander, caltrops *(Calotropis procera),* and red cotton *(Asclepias curassavica)* have

also been reported as causes of cardiotoxicity in goats in Australia (Seawright 1984).

In the Sudan, a commonly grazed annual shrub, *Cassia occidentalis,* has been demonstrated to produce a toxic myodegeneration of cardiac muscle in goats (Suliman and Shommein 1986). *C. occidentalis* is also found in the southwestern United States and is known as coffee weed, senna, or coffee senna. It has been associated with death in grazing cattle because of skeletal and cardiac myodegeneration, so goats must be considered at risk.

In all cases of sudden death, when plant toxicity is suspected, additional animals at risk should be removed from the potential source and given activated charcoal orally at a minimum dose of 2 g/kg bw.

Heartwater

Heartwater (cowdriosis), discussed in detail later in this chapter, occurs principally in Africa as well as in some Caribbean islands and can cause peracute death in goats. Lesions observed after death are similar to those described for gousiekte. Where both diseases occur, they must be differentiated by examination of brain tissue for the presence of the rickettsial organisms that cause heartwater.

Foot and Mouth Disease

Foot and mouth disease (FMD) is usually a subclinical infection in goats or it produces mild to moderate signs of lameness in adults. However, very young kids in infected herds may die suddenly of associated viral, lympho-histiocytic myocarditis which can produce a gross lesion of either diffuse gray spots or more organized "tiger" stripes, mainly in the left ventricle and interventricular septum (Kitching and Hughes 2002). FMD is discussed in more detail in Chapter 4.

Other Cardiotoxic Agents

Iatrogenic cardiotoxicity is possible in goats because of overdosage with at least two commonly used substances, calcium salts and ionophore coccidiostats. However, confirmation of sudden death in goats because of these substances is lacking. When treating milk fever (hypocalcemia), it is always advisable to administer intravenous calcium slowly and monitor the heart sounds for arrhythmia, increased rate, or heart block. Goats that are below average weight, have concurrent diseases, or have already been treated by the owner are more likely to experience cardiac irregularities or arrest.

Ionophore toxicity is known to occur in small ruminants. Ionophore antibiotics are used in livestock production as coccidiostats for cattle, sheep, goats, and poultry and the ionophore monensin is also used as a growth promotant that improves feed efficiency and weight gain in beef cattle. Monensin has caused

sudden death in sheep fed three or more times the recommended dose of 15 to 22 ppm. The affected sheep readily consumed feed containing this amount, contrary to the general assumption that feed refusal occurs when the level is more than twice the recommended dose. Sudden death occurred in 20% to 40% of affected sheep and microscopic cardiac lesions ranging from focal necrosis with perivascular lymphocytic cuffing to necrotizing myocarditis were present (Bastianello 1988).

Monensin is approved for oral use in confined goats in the United States as a coccidiostat at a dose of 20 g/ ton of feed (22 ppm). Goats experimentally given monensin orally at the rate of 55 ppm in feed for three weeks showed anorexia, diarrhea, and an increase in serum sorbitol dehydrogenase, indicating some hepatotoxicity (Dalvi and Sawant 1990). There are no published reports of field cases of monensin toxicity in goats but experimental data indicate that the single dose oral LD_{50} for monensin in goats is 26.4 mg/kg bw (12 mg/lb)(Beasley 1999).

There is however, a report of fatal overdose of goats with the ionophore salinomycin. Angora goats in Turkey were fed salinomycin in their ration at a rate of 680 ppm/kg of feed due to a mechanical mixing malfunction during feed preparation. Thirteen of 70 exposed goats died. Among those for which there was an opportunity for clinical examination before death, signs included listlessness, inappetence, incoordination, dehydration, fluid stool, tachycardia, muscle weakness, salivation, panting, and prostration, and death occurring within fifteen to twenty-four hours. At necropsy there was excessive fluid in the abdomen, thorax, and pericardium. The heart showed petechiation in the ventricles and endocardium and microscopically there was prominent myocardial hemorrhage (Agaoglu et al. 2002). The recommended dose of salinomycin for use in goats as a coccidiostat is 100 ppm of concentrate fed.

Sudden death also has been reported in goats fed excessive amounts of vitamin D. At necropsy, calcification of the coronary arteries and aorta were noted (Neumann et al. 1973).

Trauma

It has been suggested that goats, due to their generally low pain threshold, can die of cardiac failure resulting from neurogenic or catecholamine-induced ventricular dysrhythmias when subjected to painful procedures such as dehorning without appropriate analgesia or anesthesia (Gray and McDonell 1986).

Aortic Rupture

In tropical regions, nematode infections of the aorta with *Spirocerca lupi* and/or *Onchocerca armillata* have been reported in goats (Chowdhury and Chakraborty

1973). These infections may be subclinical or identified at necropsy or slaughter by thickening, nodularity, or calcification of the aorta. However, *S. lupi* in the goat aorta can lead to slow bleeding with anemia and emaciation or to aortic rupture and sudden death (Chhabra and Singh 1972).

Neoplasia

There is one reported case of a three-year-old pregnant female goat that died suddenly when being chased around its pen to be medicated for undiagnosed chronic respiratory disease of about one month duration. On necropsy the goat had ovine pulmonary adenomatosis (jaagsiekte) with tumor in both lungs that had also metastasized to the kidneys and heart. Death was attributed to heart failure secondary to tumor infiltration of the myocardium of the left ventricle (Al-Dubaib 2005). Jaagsiekte is uncommon in goats and is discussed further in Chapter 9.

Abnormal Heart Sounds

Documentation of abnormal heart sounds in goats is limited.

Murmurs

In cases of VSD, grade IV or V out of VI holosystolic murmurs over both the right and left heart base with palpable thrills on both sides have been reported (Scarratt et al. 1984). An audible S4 sound was heard to precede S1 in one case of VSD (Parry et al. 1982). Systolic murmurs can be heard during the prodromal phase of gousiekte (Pretorius and Terblanche 1967).

Reports of abnormal heart sounds associated with valvular abnormalities are rare. A single case of endocarditis has been reported in a Pygmy goat that presented clinically with a continuous rasping cardiac murmur, increased heart rate, dyspnea, inappetence, fever, and depression. It was determined after death to have traumatic peri- and endocarditis because of heart penetration with a sewing needle (Waldman and Woicke 1984). Two additional cases of vegetative endocarditis in goats have been identified only as incidental post mortem findings (Geisel 1973; Krishna et al. 1976). A grade III/V plateau pansystolic murmur was auscultated over the tricuspid valve area and a grade II/V plateau pansystolic murmur was auscultated over the left heart base in a three-year-old male pygmy goat with Ebstein's anomaly of the tricuspid valve (Gardner et al. 1992).

Systolic murmurs of variable character have been reported in cases of enzootic calcinosis in goats in Austria (Gufler et al. 1999) and Switzerland (Braun et al. 2000) in association with the consumption of golden oat grass (*Trisetum flavescens*). Enzootic calcinosis is known to occur in ruminants and horses in various countries around the world where animals consume plants with high concentrations of 1,25

dihdroxycholecalciferol (calcitrol) glycoside or substances that mimic its action. Chronic consumption of such plants leads to excessive absorption of calcium and results in calcification of soft tissues, primarily the cardiovascular system, but also lungs, kidneys, and tendons.

Affected goats show loss of appetite, emaciation, dyspnea, and abnormalities of carriage and gait, including increased recumbency, difficulty rising, kneeling after rising, stilted gait, arched back, shifting weight from leg to leg, and intermittently carrying a limb off the ground. These locomotor signs are associated with calcification of the flexor tendons and blood vessels of the limbs. Calcification of cardiac structures including the heart valves and the great vessels also occurs in enzootic calcinosis. As a result, physical examination and ancillary diagnostic testing may reveal tachycardia, a variety of murmurs, possible arrhythmias, pericardial effusions, pleural effusions, ascites, and abnormalities in the ECG and echocardiogram, including evidence of pericarditis, thickening of the aortic orifice, and calcification of the heart valves. Calcification of the aorta is especially remarkable and may be noted in plain radiographs. There is no treatment for enzootic calcinosis, but the condition can be controlled by eliminating or reducing access to the offending plants in the ration. The calcinogenicity of yellow oat grass is reduced if it is made into hay when mature rather than grazed as fresh young grass.

Muffled Sounds

The principle cause of muffled heart sounds in the goat is hydropericardium resulting from the appropriately named disease heartwater, or cowdriosis. In addition, some of the African poisonous plants cited above may produce pericardial effusions. Lymphosarcoma and traumatic reticulopericarditis, the two most common causes of pericardial effusion in cattle, are rare in goats (Sharma and Ranka 1978; Waldman and Woicke 1984; Craig et al. 1986; Reddi and Surendran 1988). In one reported case of thymoma, the heart was heard over an increased area of the left thorax, and the palpable cardiac impulse was displaced dorsally by the thoracic mass (Rostkowski et al. 1985).

Friction Rubs

Infectious pericarditis, the most likely cause of friction rubs synchronous with the heartbeat, is infrequently reported in goats (Chattopadhyay and Sharma 1972; Hein and Cargill 1981). When it does occur, it is most often associated with general mycoplasmal infections. The pericarditis is often an extension of the pleuropneumonia commonly associated with mycoplasmal infections, notably *M. mycoides* subspecies *mycoides* and *M. ovipneumoniae* (Masiga and Rurangirwa 1979; East et al. 1983; Rodriguez et al. 1995; Williamson et al.

2007). Friction rubs may be heard either in association with the heartbeat or respiration or both. Exudative pericarditis can also occur in caprine tuberculosis (Savey 1984).

Arrhythmias

Arrhythmias are infrequently documented. They have been reported in association with the cardiac form of tuberculosis, in cardiotoxicity resulting from cardiac glycoside-containing plants, and in a case of enzootic calcinosis. Atrial fibrillation has been reported with congestive heart failure and pneumonia (Gay and Richards 1983). Gallop rhythms, tachycardia, splitting of the first heart sound, and arrhythmias occur during the prodromal phase of gousiekte (Pretorius and Terblanche 1967).

Congestive Heart Failure

The clinical signs of congestive heart failure are similar to those seen in other species. They include increased jugular pulse, jugular distension, moist cough, tachycardia, submandibular edema, ascites, exercise intolerance, chronic weight loss, and possibly diarrhea. Not all signs are seen in all cases. Findings in dead goats that are consistent with heart failure include hydrothorax, hydropericardium, hydroperitoneum, pulmonary edema, heart enlargement, and ventricular dilation.

Congestive heart failure in the goat has been attributed to *cor pulmonale* secondary to pneumonia (Gay and Richards 1983), mediastinal thymoma (Rostkowski et al. 1985), and VSD (Parry et al. 1982). Krimpsiekte and gousiekte, usually recognized as sudden death, may show evidence of congestive heart failure at necropsy. Waterpens, another poisonous plant disease of goats and sheep in South Africa caused by *Galenia africana*, produces a marked abdominal ascites and death (van der Lugt et al. 1988). The intoxication results in both hepatic and cardiac lesions. Experimental challenge studies with plant extracts indicate that *G. africana* is primarily hepatotoxic with myocardial involvement occurring only in the terminal stages of the intoxication (van der Lugt et al. 1992). Nutritional muscular dystrophy (white muscle disease) may lead to congestive heart failure when heart muscle damage is not severe enough to produce sudden death.

The differential diagnosis for goats with signs suggesting congestive heart failure should include gastrointestinal helminthiasis and liver fluke disease. These parasitisms can produce edema, ascites, and exercise intolerance secondary to hypoproteinemia and anemia.

Marked jugular distension commonly occurs in goats whose neck chains or collars have been fastened too tightly. This should be differentiated from heart disease.

Reports on therapy for congestive heart failure in goats are limited (Gay and Richards 1983). The

principles of therapy and the drugs commonly reported in the dog can be used reasonably as a first approximation in goats. These include reduction of preload with furosemide or other diuretics; reduction of afterload with captopril, hydralazine, or other vasodilators; improvement of contractility with digoxin or dobutamine; and restoration of rate and rhythm with lidocaine, quinidine, procainamide, or other appropriate antiarrhythmic drugs (Kittleson 1985; Wilcke 1985).

SUBCLINICAL CARDIOVASCULAR CONDITIONS

Lesions involving the heart and vasculature are sometimes observed at necropsy in goats when no signs of heart disease have been recognized during the clinical examination. This occurs when other clinical signs overshadow cardiovascular disease, when cardiovascular disease is subclinical, or when lesions observed are non-pathogenic.

Pericardial effusions or pericarditis may be seen in mycoplasmosis, viral goat dermatitis (Patnaik 1986), false blackleg (malignant edema), and enterotoxemia due to *Clostridium perfringens* type D. A nonpathogenic lymphoreticular hyperplasia of the epicardium and pericardium has also been seen histologically from slaughter surveys (Chattopadhyay and Sharma 1972). Hydropericardium has also been reported at necropsy in goats poisoned by consumption of the seed pods of the tree *Albizia versicolor* in Malawi. The predominant clinical picture was one of neurologic disease (Soldan et al. 1996).

Incidental and subclinical myocardial lesions may include gray white foci of necrosis in the ventricles presumed to be caused by earlier plant or bacterial toxic insults, metaplastic cartilage development with or without calcification, focal lymphocytic infiltration of the myocardial interstitium, granulomatous myocarditis, and parasitic myocarditis. Causes of parasitic myocarditis include sarcosporidiosis, hydatid cysts, and metacestodes of other taeniid cestodes including *Cysticercus* and *Coenurus* (Bhalla and Nagi 1962; Chattopadhyay and Sharma 1972; Hein and Cargill 1981).

Aortic abnormalities occur in goats, though in general they contribute little to clinical disease. These include aneurysm, aortitis media, melanosis, intimal fat deposits and intimal fibrosis, cartilaginous and osseous metaplasia, and calcification (Prasad et al. 1972; Geisel 1973). Migratory tracts, nodules, corrugations, aneurysms, and thickening of the aortic wall may be seen in association with onchocerciasis (Kaul and Prasad, 1989). Focal aortic necrosis and calcification in goats is a frequent lesion in caprine paratuberculosis (Majeed and Goudswaard 1971). Calcification of the aorta as well as other great vessels is seen in goats with enzootic calcinosis due to consumption of yellow oat grass (*Trisetum flavescens)*, as described above.

SPECIFIC DISEASES OF THE CARDIOVASCULAR SYSTEM

Heartwater

Heartwater, also known as cowdriosis, is an infectious, non-contagious, tick-borne rickettsial disease of domestic ruminants. Historically restricted to sub-Saharan Africa, heartwater has more recently also been identified in the Caribbean. There is considerable concern about the possible spread of heartwater and its vector to tropical and subtropical regions of North, South, and Central America where, moreover, other suitable tick vectors exist.

Etiology

The causative agent is the rickettsia *Ehrlichia* (previously *Cowdria*) *ruminantium.* It is Gram-negative and stains reddish purple to blue in smears with Giemsa stain. Pleomorphism is common. Smaller organisms are usually coccoid while larger ones may be horseshoe, ring, or rod shaped. In mammalian hosts, the organism has a predilection for vascular endothelial cells. In the tick vector, it is found in intestinal epithelial cells and in cells of the salivary glands.

Historically, efforts to perform *in vitro* cultures of *E. ruminantium* have failed, but successful cultivation of several strains of the organism on endothelial cell lines as well as tick cell lines is now possible (Bezuidenhout et al. 1985; Bell-Sakyi et al. 2000). Live organisms in whole blood or tissue homogenates from infected animals may be stored for extended periods by quick freezing in liquid nitrogen using a suitable cryopreservative, for example, dimethyl sulfoxide.

Various strains of the organism exist. Cross-protective immunity may develop after infection with various field strains (Van Winkelhoff and Uilenberg 1981; Uilenberg 1983), but strains are often not or only partially cross-protective when used to challenge ruminants (Uilenberg 1983; Jongejan et al. 1988; Du Plessis et al. 1989), and antigenic diversity is an important feature of *E. ruminantium*. Field isolates often consist of more than one strain. Strains also vary in virulence, and there are isolates, indistinguishable from *E. ruminantium* using molecular methods, that do not cause clinical disease at all (Allsopp et al. 2007), and one of these has even been detected in a goat in the United States (Loftis et al. 2006).

Epidemiology

Heartwater is indigenous to sub-Saharan Africa. It was first recognized in South Africa in 1838 and is still considered a major obstacle to expansion and development of livestock enterprises on the continent. Imported cattle, sheep, and goats in particular are very susceptible to severe infection with high mortality rates.

Heartwater is also found on islands near Africa, including Madagascar, Mauritius, Reunion, the Comoros and São Tome.

The occurrence of heartwater in the Western hemisphere causes concern. The disease was reported on the island of Guadeloupe in 1980. Since that time, its occurrence on other Caribbean islands including Antigua and Marie Galante has been confirmed. The tick vector *Amblyomma variegatum,* originally introduced into the region with an importation of cattle from Senegal in the nineteenth or possibly even in the eighteenth century, has also been found on Puerto Rico, Vieques, St. Croix, St. Martin, Anguilla, St. Kitts, Nevis, La Desirade, Martinique, St. Lucia, St. Vincent, and Barbados, but *E. ruminantium* has not yet been identified on these islands (Camus et al. 1984). An international campaign for the eradication of *A. variegatum* from the Western Hemisphere, operational from 1994 to 2006, has succeeded on some of these islands, but failed in its ultimate objective (ICTTD 2006).

The distribution of heartwater reflects the geographic distribution of the tick vectors of the genus *Amblyomma* that transmit the disease to domestic and wild ruminants. *Amblyomma* spp. are three-host ticks that feed on a wide variety of mammals and birds. The most widespread vector for heartwater in Africa and the Caribbean is *A. variegatum*, also known as the tropical bont tick. Other natural African vectors include *A. hebraeum* in southern Africa, *A. pomposum* in south-central Africa, and *A. gemma* and *A. lepidum* in east and northeastern Africa. Several other African *Amblyomma* spp. may carry the organism but mainly feed on wild animals. At least two ticks found in North and South America, *A. maculatum,* the Gulf Coast tick, and *A. cajennense,* the cayenne tick, are capable of transmitting *E. ruminantium* to domestic ruminants, the former quite effectively (Uilenberg et al. 1984).

In general, *Amblyomma* ticks can passage *E. ruminantium* transstadially but not transovarially, though there is one report of transovarial transfer. Consecutive passage from larval to nymphal stage, nymphal to adult stage, and larval to nymphal to adult stage occurs. Ticks therefore can remain infected for periods as long as several years. The organism resides in the intestinal epithelium of ticks and is thought to be transmitted with the saliva (Kocan and Bezuidenhout 1987).

The hosts for *E. ruminantium* appear to be essentially members of the family Bovidae including both domestic and wild ruminants in Africa. Cervidae are also susceptible. Wild ruminants may serve as a reservoir for infection, but a wildlife reservoir is not necessary to sustain infection. Prolonged survival of *E. ruminantium* in ticks maintains the disease, and the carrier state in ruminants also occurs (Andrew and Norval, 1989).

An age-related resistance to disease occurs in young domestic ruminants, independent of maternally derived passive immunity. The period of resistance in calves and lambs gradually wanes after approximately the first three weeks of life. The period in kids is not well studied but may be even shorter. Young animals exposed during this period are unlikely to develop clinical disease and are resistant to subsequent homologous reinfection. Because the period of host resistance is short and the infection rate and/or number of the tick vectors may be low, the opportunity to develop an immune host population is limited, and serious disease losses can continue to occur in endemic areas.

Goats are the most susceptible natural hosts based on epidemiologic observations and experimental challenge studies. Indigenous goats in endemic areas are more resistant than imported ones, but serious incidents of acute heartwater in local goats do occur in Africa (Aklaku 1980; Gueye et al. 1984). Very young, resistant goats may not be exposed to feeding ticks during their resistant period because of local variations in tick populations, preferential feeding by ticks on cattle over goats, or confinement of kids to villages to avoid theft and predation (Ilemobade 1977). A seroprevalence survey of heartwater in Red Maasai sheep and Small East African goats conducted at three sites in Narok District of Kenya using the MAP1-B ELISA found 62% to 82.5% of sheep and 42.5% to 52% of goats to be seropositive (Wesonga et al. 2006).

Evidence for differences in breed susceptibility is suggested by epidemiologic and experimental observations. In South Africa, Angora goats and Boer goats are quite susceptible to heartwater compared with other indigenous or exotic breeds (Van de Pypekamp and Prozesky 1987). Breed differences in susceptibility have also been reported in Guadeloupe, with native Creole goats showing greater resistance than European breeds of goats. However, differences are also observed between different populations within a given breed based on their history of exposure to cowdriosis. It is presumed that genetic resistance increases over time by natural selection in the face of continued challenge by *E. ruminantium* and that such resistance may be a recessive sex-linked trait (Matheron et al. 1987).

Pathogenesis

E. ruminantium is introduced into the mammalian host by an infected tick while feeding. The early development of infection is not well clarified. It has been suggested that initial replication occurs in regional lymph nodes within macrophages and other reticulo-endothelial cells. This is followed by a rickettsemic phase lasting one to four days accompanied by fever. The organism can be demonstrated to occur in the blood plasma as well as in neutrophils (Logan et al. 1987). Subsequently, the organism invades and

multiplies in vascular endothelium throughout the body, particularly in the cortex of the brain. The ensuing vasculitis results in fluid and protein loss through capillaries with local edema and hemorrhage that, depending on the location and severity, accounts for the varied clinical and post mortem findings. The incubation period in goats after experimental intravenous inoculation is seven to fourteen days, or even shorter after a massive infective dose.

Clinical Findings

The incubation period to fever after natural tick-transmitted infection is usually from about two to as much as four weeks. There are four clinical forms of heartwater: peracute, acute, subacute, and subclinical. Their development depends on host susceptibility and virulence of the infective strain. Sporadic cases or epizootic outbreaks may occur. Goats most often experience peracute and acute infections.

In peracute disease, affected goats develop a high fever and then suddenly collapse without warning followed by a period of convulsions or paddling lasting from minutes to several hours. The acute form may last from two to five days. The first signs are depression, anorexia, and high fever up to 105.8°F (41°C) accompanied by rapid, labored breathing and cessation of rumination. Auscultation of the chest may suggest pulmonary edema and muffled heart sounds due to hydropericardium. This is followed by nervous signs including bleating, hyperesthesia, muscle twitching, teeth grinding, excessive blinking of the eyelids, nystagmus, frequent urination and defecation, circling, and finally terminal convulsions. Ocular congestion and diarrhea may precede or accompany the nervous signs. Mortality in goats may reach more than 90%.

Signs of subacute disease may be limited to fever, watery eyes, mucous nasal discharge, coughing, dyspnea, and possibly diarrhea and mild nervous signs. Subacute disease is most likely in previously exposed or naturally resistant animals. Subclinical infection, manifested by a transient fever, is uncommonly recognized in goats.

Clinical Pathology and Necropsy

A decrease in packed cell volume, hemoglobin, total plasma protein, and serum albumin are common findings in heartwater. The leukocyte response is variable in goats with either neutropenia and lymphopenia or lymphocytic leukocytosis reported (Ilemobade and Blotkamp 1978; Abdel Rahim and Shommein 1978). Hyperglycemia and lactic acidosis may be recorded terminally. Orange-yellow serum has been reported as a consistent finding in Angora goats affected with heartwater, but the observation has not been repeated in other breeds of goats.

Gross post mortem findings in goats include hydropericardium, variable degrees of hydrothorax, and pulmonary edema. Other possible signs are ascites, edema of lymph nodes, serosal hemorrhage, particularly of the heart, mucosal congestion of the gastrointestinal tract, and swollen kidneys. Splenomegaly, a common sign in other species, was not observed in experimentally infected goats (Ilemobade and Blotkamp 1978). Severe nephrosis is reported in Angora goats (Prozesky and Du Plessis 1985).

Histologically, the disease is characterized by the presence of clusters of *E. ruminantium* in the vascular endothelium of virtually all tissues examined; brain cortex is the most reliable source and liver the least reliable.

For rapid post mortem field diagnosis, squash preparations of Giemsa-stained cerebrocortical gray matter reveal blue- to purple-stained clusters of *E. ruminantium* in vascular endothelium. If removing the entire brain is problematic, cerebellar cortex obtained via the foramen magnum with a spatula or spoon is a suitable sample for examination, or cerebral cortex may be obtained after drilling a hole in the skull, even simply with a good-sized nail and a hammer. Proper precautions in rabies-enzootic countries should of course be taken.

Diagnosis

Diagnosis is presumptive, based on the clinical history and signs, the presence of *Amblyomma* ticks in the region and on the animal, and the demonstration of organisms in vascular endothelium on smears or histologic examinations as described above. Differential diagnosis for the peracute form of disease includes virtually all causes of sudden death in goats, discussed in Chapter 16. The acute or neurologic form of heartwater must be distinguished from tetanus, rabies, pseudorabies, organophosphate toxicity, and various plant poisonings. In particular, one leguminous tree, *Albizia versicolor*, occurs in areas of southern Africa where heartwater is endemic. Consumption of the seed pods by goats can produce both neurologic signs and hydropericardium, which are suggestive of heartwater (Soldan et al. 1996). When diarrhea and fever precede neurologic signs, peste des petits ruminants, rinderpest, and salmonellosis should be ruled out.

Confirmation of heartwater in live animals has long been difficult because the organism cannot be cultured routinely. Intravenous inoculation of 5 to 10 ml of whole blood from suspected cases into known healthy, susceptible goats or sheep with subsequent necropsy of the ill test animal confirms the diagnosis. A technique for cerebral biopsy to examine brain smears from goats for *E. ruminantium* has been described (Synge 1978). It is most diagnostic three to six days after onset of fever (Camus and Barre 1987). At present

the infection can be confirmed by molecular methods, specific DNA probes (Waghela et al. 1991), and PCR, which considerably increases sensitivity (Martinez et al. 2004).

There are presently several serological tests for detecting antibodies to *E. ruminantium*, but all suffer to some extent from lack of specificity, as there are cross reactions with some other *Ehrlichia* species or unknown agents. This has partly been overcome by using more specific recombinant antigens instead of crude antigens for enzyme-linked immunosorbent assays (Van Vliet 1995, Katz et al. 1997; Kakono et al. 2003). A direct fluorescent antibody test is capable of detecting E. *ruminantium* in macrophage and buffy coat cultures of infected goats, sheep, and cattle (Sahu 1986). Challenges and advances in the laboratory and field diagnosis of heartwater have been recently reviewed (Mahan 2006).

Treatment

Successful therapy depends on early initiation of antibiotic therapy. Animals treated during the febrile stage of acute heartwater respond favorably to tetracycline, 5 to 10 mg/kg bw intravenously or intramuscularly administered at the first sign of fever and repeated one additional time either one or two days later. Long-acting oxytetracycline given one time intramuscularly at the onset of fever at a dose of 20 mg/kg is also effective. Therapy initiated after the onset of neurologic signs is almost always ineffective. Delaying treatment until after day two may result in poorer success because of development of severe nephrosis secondary to renal ischemia (Prozesky and Du Plessis 1985).

Control

Attempts to control heartwater by controlling tick populations in Africa have been somewhat successful, though eradication of the disease by vector control seems unlikely, and even the attempt at vector eradication from the Caribbean islands has failed

A combination of controlled exposure and treatment has been used to vaccinate exotic livestock in Africa with some success. Infective materials used as vaccines are prepared by snap freezing of blood (or tissue preparations) derived from artificially infected livestock (or ticks). Because these are rather crude preparations, anaphylactic reactions can and do occur in a small percentage of vaccinates, and other pathogens may unintentionally be transmitted. For vaccination these substances are administered by the intravenous route. At the first sign of fever, vaccinated animals are treated with oxytetracycline (10 mg/kg intramuscularly or intravenously) to diminish the signs of disease and impart an immunity to reinfection.

Kids vaccinated during their period of natural resistance may not show a febrile response (Van der Merwe 1987). Because of the logistical difficulty of determining the onset of fever in individual animals, arbitrarily timed treatments after vaccination have been recommended. However, the time of onset of the febrile response depends on the strain and preparation of the vaccine. When Angora goats were monitored after vaccination with a frozen Ball 3 strain vaccine, 97% were in the febrile phase between day ten and day fourteen, while only 76% of goats given a fresh Ball 3 strain vaccine were febrile during that period (Erasmus 1976). Because successful vaccination depends on proper timing of treatment, the mean incubation period for the vaccine to be used should be known in advance if such block treatment is to be used. It may be several days shorter when tick filtrate vaccines are used. Temperatures in goats should reach 103.1°F (39.5°C) before treatment.

The duration of immunity in goats is not well known but may be as short as two months. Field exposure to antigenically different strains may be responsible for a seemingly short duration of immunity, and homologous immunity is likely to be longer. Vaccination should be timed to precede periods of peak tick feeding activity in wet seasons. Vaccination procedures for cowdriosis have been reviewed (Van der Merwe 1987). At present there are ongoing studies on improving and standardizing the classical method of infection and treatment by using infective material obtained in cell culture, which would also largely solve the problem of spreading other pathogens. Other studies concern inactivated as well as attenuated vaccines. Advances in the development of new vaccines and vaccine methodologies for control of heartwater have recently been reviewed (Mahan 2006).

Efforts to control tick populations on goats may help control cowdriosis. However, dipping of Angora goats during pregnancy or cold weather should be avoided because stress-related abortion and hypothermia are common in this breed (Gruss 1987).

Schistosomosis

Schistosomes are trematode parasites of the vascular system. Different species reside in the vasculature of different organs, and can produce a variety of clinical manifestations including rhinitis, enteritis, hepatitis, or pneumonia. All clinical forms occur in goats in endemic regions of the world.

Etiology

In the family Schistosomatidae are two genera that can cause clinical disease in goats: the *Schistosoma* and the *Orientobilharzia.* Numerous species use goats as a definitive host. These are identified in Table 8.3 along with their geographic distribution, intermediate and

Table 8.3. Schistosomes reported to infect goats.

Species	Geographic distribution	Intermediate snail host	Definitive hosts	Sites of localization	Clinical effects
Schistosoma bovis	Central, East, and West Africa; Mediterranean, Middle East	Various *Bulinus* spp.	Ruminants, equines, camels, rodents, humans	Portal and mesenteric veins	Diarrhea, dysentery, anemia, emaciation, death
S. japonicum	Far East	Various *Oncomeliana* spp.	Ruminants, equines, humans, pigs, dog, cats, rodents	Hepatic, portal, and mesenteric veins	Diarrhea, dysentery, anemia, emaciation, death
S. mattheei	Central, South, and East Africa	Various *Bulinus* spp.	Ruminants, equines, humans, baboons, rodents	Portal, mesenteric, urogenital, and stomach veins	Pneumonia, diarrhea, dysentery, anemia, emaciation, death
S. spindale	Indian subcontinent and Far East	Various *Planorbis, Lymnaea,* and *Indoplanorbis* spp.	Ruminants, rodents, and dogs	Mesenteric veins	Diarrhea, dysentery, anemia, emaciation, death
S. indicum	Indian subcontinent	*Indoplanorbis* spp.	Ruminants, equines, camels	Hepatic, portal, mesenteric, pancreatic, and pulmonary veins	Diarrhea, dysentery, anemia, dyspnea, emaciation, death
S. mansoni	Africa, South America, Middle East	Various *Biomphalaria* spp.	Most important in humans; various rodents, wild mammals, including goats	Mesenteric veins	Diarrhea, anemia, dyspnea, emaciation, death
S. nasale	Indian subcontinent	*Indoplanorbis* and *Lymnea* spp.	Goats, cattle, buffalo, sheep, horses	Nasal mucosal veins	Coryza, sneezing, dyspnea
S. incognitum	Indian subcontinent	*Lymnea* spp.	Pigs, dogs, one report in goats	—	Not reported; found at slaughter
S. curassoni	West Africa	Various *Bulinus* spp.	goats, sheep, cattle	Portal and mesenteric veins	Diarrhea, dysentery, anemia, emaciation, death
Orientobilharzia turkestanicum	Mongolia, Iraq, France, Russia	*Lymnaea euphratica*	Ruminants, camels, cats, equines	Mesenteric veins	Chronic debilitation

definitive hosts, and the site of localization within the goat. There is one report of finding *Schistosoma incognitum* in goats in a slaughterhouse survey in Jabalpur, India (Agrawal and Sahasrabudhe 1982), though this species is usually associated with swine. Experimental patent infection of goats with *S. incognitum* was later demonstrated (Gupta and Agrawal 2005). *Schistosoma curassoni,* previously thought to be synonymous with *S. bovis,* is now considered a distinct species infecting goats, sheep, and cattle (Verycruysse et al. 1984), though hybridization is known to occur between the two species (Rollinson et al. 1990). Ongoing phylogenetic studies are helping to clarify the relationships and classification of the pathogenic species of

Schistosomatidae (Snyder and Loker 2000; Webster et al. 2006).

The schistosomes are elongated trematodes with distinct male and female forms that are found together in the host as mating pairs. The life cycle of schistosomes is indirect and involves aquatic snails as intermediate hosts. Though there are species variations in life cycle, the general pattern is as follows (Soulsby 1982). Adult schistosomes reside in the vasculature of the target organ of their definitive hosts. These organs are usually the liver, intestine, nasal mucosa, or urinary bladder. Gravid females lay eggs that pass through the vessel walls and gain entrance to the gut lumen, bladder lumen, or nasal passage. These eggs, which

may already contain live miracidia, hatch when passed into water. The miracidia are released and infect the appropriate species of aquatic snail, which serves as the intermediate host. Subsequent development in the snail occurs over a variable time period of thirty-eight to 126 days based on environmental factors. Two generations of sporocysts occur in the snail, leading to the formation of cercariae that are released from the snail back into water. When definitive hosts stand in or drink contaminated water, they are infected by the cercariae, either by penetration of the skin or the rumen wall.

After entry into the definitive host, cercariae transform into schistosomula and are carried to the lungs and then the liver via the bloodstream over a period of one week. Schistosomula are usually present in the portal veins by day eight. Mating occurs in the portal vein and adults then migrate to the mesenteric veins where maturation and egg laying occur. When hyperinfection occurs, adult schistosomes may mature in the pulmonary vessels and lay eggs in the lung. Pulmonary schistosomosis due to *S. indicum* has been reported in goats in India (Sharma and Dwivedi 1976). In the case of *S. nasale,* maturation and egg laying occur in the vessels of the nasal mucosa and eggs are passed in nasal discharge. The prepatent period for *S. bovis* infection in goats was recorded as forty-seven to forty-eight days (Massoud 1973).

Epidemiology

Schistosomes infect humans and animals mainly in Asia, Africa, the Middle East, South and Central America, and the Mediterranean region. Schistosomosis, or bilharzia, is an important human disease in Africa, Asia, and South America, caused principally by *S. haematobium, S. japonicum,* or *S. mansoni.* Livestock, including goats, can serve as a reservoir for *Schistosoma* spp. infective for humans (Adam and Magzoub 1977).

The intestinal form of schistosomosis in goats is reported most frequently from Asia and Africa. The nasal form, caused by *S. nasale,* is restricted to the Indian subcontinent. Economic losses because of schistosomosis in goats result from poor growth and performance, treatment costs, mortality, and condemnations, especially of livers, at slaughter (Singh Nara and Nayak 1972; Seydi and Gueye 1982).

The occurrence of schistosomosis is closely tied to the ecology of the intermediate snail hosts. The snails thrive in stagnant or slowly moving water such as is found in irrigation ditches, rice paddies, watering tanks or troughs, shallow ponds or puddles, and ditches during seasons of heavy rain. As such, the occurrence of schistosomosis may be continuous or seasonal depending on the nature of the contaminated water source. Where occurrence is seasonal, snails persist through periods of decreased water habitat,

mostly through a strategy of prolificacy. Livestock are infected when they drink from, stand in, or wallow in such water sources. Additional factors contributing to an increased prevalence are poor grazing, limited water supplies, and overcrowding (Hurter and Potgieter 1967).

The prevalence of schistosomosis in various livestock is largely dictated by their behavior relative to water. Pigs and buffalo, the wallowing species, have a high prevalence of infection; cattle, an intermediate prevalence; and sheep and goats, a low prevalence (Agrawal 1981). Goats show a distinct aversion to immersion in water, and even avoid walking through it. This may reduce their potential for exposure (Kassuku 1983). In abattoir surveys, prevalence of schistosomosis in goats is consistently much lower than in buffalo and cattle (Islam 1975; Kassuku et al. 1986). Nevertheless, serious losses of goats can occur, such as reported from China, where summer rains produce marked increases in intermediate host snail populations (Li 1987).

It is fortunate that the goat is less frequently exposed to infection because when cattle, sheep, and goats are experimentally challenged with *S. bovis* or *S. japonicum* cercariae, the intensity and severity of infection is most profound in goats (Massoud 1973; Chiu and Lu 1974).

Pathogenesis

The intestinal form of the disease occurs approximately two months after infection, when adults begin to lay eggs in the mesenteric veins and the spined eggs pass through the intestinal mucosa. This results in injury to all layers of the intestinal wall with hemorrhage and edema, and the formation of microabscesses, granulomas, and progressive fibrosis. These changes lead to diarrhea and dysentery and probably malabsorption, as hypoproteinemia is common. The adult parasites cause phlebitis in the mesenteric vessels and are sometimes also found in vessels of the urinary bladder and the pulmonary arteries. As many as 1,000 pairs of adults have been counted from the mesenteric veins of goats dying with *S. mattheei* infection (Hurter and Potgieter 1967).

The hepatic form of the disease is considered to reflect a severe cell-mediated immune response to *Schistosoma* eggs refluxed back into the portal circulation. Soluble egg antigens induce a marked eosinophilic, granulomatous reaction leading to extensive damage to the portal vasculature and subsequently severe fibrosis of the portal triads (Soulsby 1982). In humans, especially, this results in portal hypertension with development of varices and possibly congestive heart failure. In ruminants, these cardiovascular effects are not expressed clinically and liver involvement is usually detected only at necropsy. It is reported that

O. turkestanicum infection in goats and sheep leads to chronic debility secondary to hepatic cirrhosis and intestinal granuloma formation (Soulsby 1982). Anemia occurs in schistosomosis as a result of hemorrhagic lesions in the intestinal wall from migration of eggs and from blood feeding by adults in the vessels.

The nasal form of the disease represents an inflammatory reaction to the passage of eggs through the nasal mucosa and, to a lesser extent, the presence of adult schistosomes in the nasal vessels. The result is nasal congestion, copious nasal discharge, granuloma formation, and dyspnea.

Pulmonary schistosomosis occurs when the host is challenged with large numbers of cercariae. Maturation of excessive numbers of schistosomes in the liver leads to spread of parasitic emboli back to the lungs. Adult schistosomes lay eggs in the lung vessels and produce multiple, diffuse, nodular granulomata throughout the lung parenchyma. Emaciation and respiratory distress result (Sharma and Dwivedi 1976).

Clinical Findings

All ages, breeds, and sex of goats are affected. Clinical disease occurs in association with the onset of egg excretion. In the intestinal form, diarrhea, anemia, and emaciation are the cardinal signs. The diarrhea is usually watery, but can be mucoid and/or bloody. Anorexia, dehydration, and edema are common accompanying findings. The clinical course is usually weeks to months and can result in death, chronic ill thrift, or sometimes spontaneous recovery. Clinically, the presentation may be indistinguishable from gastrointestinal nematodiasis.

In the nasal form of the disease due to *S. nasale,* there may be weight loss, snoring, sneezing, copious mucoid or foul-smelling purulent nasal discharge, and dyspnea. In pulmonary schistosomosis, emaciation, and dyspnea can occur. The hepatic form of the disease is usually not recognized clinically; it is overshadowed by the enteric or pulmonary forms.

Clinical Pathology and Necropsy

Anemia and sometimes eosinophilia may be noted in the hemogram. Hypoproteinemia, hypoalbuminemia, and hypergammaglobulinemia may also be present (Pandey et al. 1976). In experimental *S. mansoni* infection of goats, there were elevations in serum arginase, AST, and bilirubin, and a depletion of liver glycogen (Adam and Magzoub 1977).

To date, serological tests are generally unreliable for confirmation of individual cases or for prevalence studies, mainly because of cross reactions with other trematodes, notably *Fasciola* spp. and the amphistomes (rumen flukes), which are likely to be present in the same situations as schistosomes. Experimental infec-

tions of goats with *S. japonicum* have been confirmed serologically during the prepatent period using ELISA and immunofluorescent antibody techniques (Schumann et al. 1984). A dot ELISA test has recently been evaluated in experimentally and naturally infected goats in India (Vohra et al. 2006). Adjustments necessary to improve specificity of the test resulted in reduced sensitivity, but nevertheless, the test was considered to be potentially useful in the field for conducting prevalence studies in locations where infection status is unknown.

In the field, confirmation requires identification of schistosome eggs in nasal secretions, nasal scrapings, feces, rectal scrapings, or possibly urine. Diagnosis by liver biopsy was also reported to be 100% reliable in goats, whereas fecal examination yielded many false negative results (Agrawal and Sahasrabudhe 1982a). Schistosome eggs are generally larger than nematode eggs. They are elongated and spindle shaped and possess a characteristic terminal spine. Direct smears or sedimentation techniques are preferred to flotation methods for finding these trematode eggs. Microscopic examination of squash preps of rectal mucosa obtained with a bowel forceps was 100% effective in diagnosing schistosomosis in a group of acutely affected sheep and goats (Hurter and Potgieter 1967). In chronic cases, egg shedding may be reduced and diagnosis may depend on identification of adult schistosomes in vessels at necropsy. For the diagnosis of caprine hepatic schistosomosis, it has been reported that egg hatching techniques are more sensitive for detection of eggs in the feces of affected goats than either the formal ether sedimentation technique or the alkaline digestion technique (Vohra and Agrawal 2006a).

At necropsy, the carcass is usually emaciated. Adult schistosomes up to 30 mm in length are most frequently found in mesenteric, portal, intestinal submucosal and subserosal veins. They may also be found in pulmonary veins and veins of the urinary bladder. The liver may have a grayish discoloration and an uneven surface. The lungs may be enlarged, heavy, brown-black, and rubbery with multiple grayish nodular foci on the pleura and on cut surface when pulmonary schistosomosis is present (Sharma and Dwivedi 1984). A catarrhal enteritis is usually present and granulomatous swellings of the mucosa may be noted as well as areas of petechial or ecchymotic hemorrhage with accumulation of blood in the intestinal lumen. In the nasal form, large granulomas protruding from the nasal mucosa may be noted on cut section of the nasal passages.

Histologically, lesions are associated primarily with eggs rather than adult schistosomes. Eggs in the liver, lung, intestinal wall, and nasal mucosa induce a marked inflammatory response with infiltration of eosinophils, lymphocytes, and macrophages.

Granuloma formation around schistosome eggs is common. The liver lesion is characterized by fibrosis in the region of the portal triads in advanced cases.

Diagnosis

The definitive antemortem diagnosis of schistosomosis depends on identification of eggs in excretions or by biopsy. The intestinal form of the disease must be distinguished from other causes of diarrhea in association with anemia and emaciation, notably gastrointestinal nematodiasis, coccidiosis, and fascioliasis. The nasal form of the disease must be differentiated from other causes of rhinitis as presented in Chapter 9. At necropsy, the diagnosis is confirmed by identification of adult schistosomes in the vasculature, or characteristic histologic lesions.

Treatment

In the past, the few drugs available to treat schistosomosis, such as antimony compounds, had narrow margins of safety and frequently produced toxic effects in goats and sheep. Haloxon was also reported to be effective in goats at a dose of 300 mg/kg against the intestinal schistosome *S. mattheei* with no noted side effects (Hurter and Potgieter 1967). Currently, praziquantel is being recommended for ruminants at an oral dose of 25 mg/kg bw repeated one time three to five weeks later. However, a single oral dose of 60 mg/kg was reported to effectively eliminate *S. nasale* infection from a goat with no toxic side effects noted (Anandan and Raja 1987).

Control

Efforts at control are directed at reduction of snail intermediate hosts and exposure of livestock to infective cercariae. When possible, stagnant water sources should be eliminated or fenced off and piped or running water provided instead. Water tanks and troughs should be emptied and cleaned periodically. When ponds or other stagnant water sources must be used, then snail control by application of molluscicides such as copper sulfate or niclosamide have been employed.

To minimize effects on livestock, goats should be treated with praziquantel timed to peaks of likely incidence, such as two months after heavy rains. Currently there are no vaccines against schistosomosis.

Respiratory System

ANATOMY

The structure of the lungs of the goat is illustrated in Figure 9.1. The lung is divided into bilateral cranial lobes (each with a cranial and a caudal part), a middle (cardiac) lobe on the right side, an accessory lobe of the right lung that extends ventrally on the midline, and bilateral caudal (diaphragmatic) lobes (Constanti-

nescu 2001). The right cranial lobe is supplied by a separate tracheal bronchus which originates before the bifurcation of the trachea. This lobe wraps around anterior to the heart and actually reaches the left side of the thorax. Subpleural lymph nodes 1 to 30 mm in diameter have been reported in the lungs of Angora and feral goats in New Zealand (Valero et al. 1993).

Figure 9.1. Normal goat lung with trachea opened to demonstrate the tracheal bronchus supplying the right cranial lobe. (Courtesy of Dr. M.C. Smith.)

CLINICAL EXAMINATION OF THE RESPIRATORY TRACT

Either a well-taken case history or basic physical exam may suggest the presence of respiratory disease. Signs noted might include increased respiratory rate, labored breathing, rapid tiring (especially with exercise), cyanosis, abnormal sounds associated with breathing, nasal discharge, coughing, or fever. Table 9.1 lists some of these signs and possible etiologies.

If a respiratory disease is suspected, additional herd history is helpful in directing the diagnostic efforts. The owner should always be questioned concerning recent purchase or boarding of animals or attendance at shows, relative to possible introduction of infectious diseases. Do the goats get out of the barn, at least during part of the year? If not, lungworms and nasal bots are less probable. Is the herd known to be infected with or believed to be free of caprine arthritis encephalitis (CAE) virus, caseous lymphadenitis, and mycoplasma mastitis? Are housing and ventilation acceptable? The veterinarian should not accept the owner's answer to this last question without personally inspecting the premises. Is the region selenium-deficient, and is the ration supplemented with vitamin E and selenium? Has the animal been overdosed with injectable selenium, so that it is dyspneic because of heart failure?

It is often impossible to obtain an exact and unquestionable etiologic diagnosis, at least in the living goat. This frustrates recent graduates whose education has suggested that the clever clinician always gets the right answer. On the other hand, more "experienced" practitioners may prescribe their favorite antibiotic for pneumonia rather than determine the cause of the clinical signs observed.

Table 9.1. Some signs suggestive of respiratory disease and possible causes.

Signs	Possible Causes
Dyspnea or Tachypnea	Anemia
	Pregnancy toxemia, ketosis
	Rumen acidosis
	Bloat
	Heatstroke
	Urolithiasis
	Nasal obstruction (tumor or foreign body)
	Progressive interstitial retroviral pneumonia (CAEV)
	Peste des petits ruminants
	Contagious caprine pleuropneumonia
	Pasteurellosis
	Septicemia
	Internal caseous lymphadenitis
	Tuberculosis
	Lungworms (*Dictyocaulus*)
	Nutritional muscular dystrophy
	Inhalation pneumonia
	Congenital heart malformation
	Cyanide poisoning
	Nitrate poisoning
	Other assorted toxicities
Cough	Tight collar
	Tracheal stenosis
	Dusty or moldy hay
	Ammonia and other fumes
	Dysphagia (nutritional muscular dystrophy, neurologic disease)
	Contagious caprine pleuropneumonia
	Chronic progressive pneumonia (CAEV)
	Parainfluenza virus (PI3)
	Abscessed retropharyngeal lymph node

Not every goat that breathes rapidly or "harshly" has respiratory disease. A complete physical examination always helps avoid embarrassing misdiagnoses. If the mucous membranes are white, think first of anemia, not pneumonia. Do not waste the owner's money on tracheal washes and expensive antibiotics if the kid has an obvious heart murmur, at least not without explaining the seriousness of the underlying heart disease.

Common pulmonary function tests have been adapted to the goat and normal values published (Bakima et al. 1988, 1990). This information should be useful to researchers evaluating respiratory disorders in goats or using goats as models in the study of respiratory physiology.

Respiratory Rate

The normal respiratory rate at rest is approximately ten to thirty breaths per minute (kids twenty to forty per minute). Few goats are "at rest" in the presence of an odoriferous stranger or after a long ride to the clinic in the back of a compact car. In addition, many normal goats pant; a respiratory rate of 270 per minute has been reported for goats held at 104°F (40°C). A goat with a long winter coat will certainly breathe rapidly if brought into a warm and humid room. A curious goat, continually sniffing the examiner, makes just the counting of the respiratory rate frustrating or even meaningless. The movements of the chest and abdominal wall should be observed from a distance, before the patient is disturbed. This is also the best time to note normal costo-abdominal respiration, abdominal pumping, or very shallow and painful chest movements (as with pleuritis).

Many seriously ill goats have an increased respiratory rate because of fever, metabolic disturbances, or pain. Pregnancy toxemia, lactational ketosis, rumen acidosis, or diarrhea can all lead to metabolic acidosis. As part of the respiratory compensation mechanism, goats breathe faster to release carbon dioxide and thereby remove H^+ (along with HCO_3^-) ions from the blood. Goats with listeriosis or other brain stem disease, on the other hand, may have an altered respiratory rate because of acidosis from loss of saliva or lesions in the respiratory centers of the brain. Metabolic alkalosis, which may be accompanied by very slow respiration, is less common in goats than in cattle, because most conditions associated with abomasal stasis (e.g., impaction, displacement, torsion, ulceration) are relatively rare.

Dyspnea

It is helpful to differentiate difficulty in breathing into inspiratory, expiratory, or mixed dyspnea. Strong outward movements of the thorax and longer inspiration are associated with inspiratory dyspnea. Narrowed upper airway passages or bronchopneumonia with reduced respiratory surface in the lungs causes such a pattern. A distended head and neck and dilated nostrils accompany severe inspiratory dyspnea, and audible stenotic sounds may make location of an obstruction possible. With expiratory dyspnea, breathing out is impeded and is accentuated by strong and prolonged expiratory movements of the abdomen. This is less common in goats than in cattle because the caprine lung is not predisposed to interstitial emphysema. Cheek blowing or open mouth breathing with an extended tongue might accompany expiratory dyspnea. Logically, a mixed dyspnea occurs when there is difficulty in both inhaling and exhaling.

Whenever the dyspnea is accompanied by cyanosis, the examiner should proceed cautiously to limit additional stress to the goat. If an upper airway obstruction is suspected, an emergency tracheostomy may become necessary. The heart must also be examined closely, because the cause of dyspnea may reside in the circulatory rather than respiratory system.

Externally Audible Sounds

Sneezing, a brief and powerful expulsion of air through the nose, occurs when the nasal mucosa is irritated by accumulations of secretions, exudates, or foreign matter. Stenotic sounds are caused by constriction in the upper respiratory tract. Snuffling sounds of nasal origin are usually loudest on inspiration. Alternate occlusion of one nostril and then the other helps to determine if the stenosis is unilateral or bilateral. That is, with a unilateral lesion, blocking the nostril on the affected side should decrease the sound while blocking the other nostril should increase the sound by forcing more air through the stenotic nasal passage. Sounds of pharyngeal origin are loudest on expiration, whereas laryngeal stenosis sounds are usually more pronounced on inspiration. Manual compression of the pharynx increases the loudness of pharyngeal sounds while decreasing laryngeal stridor. Sounds originating from a stenotic larynx are accentuated by additional compression of the larynx. If the stenosis is in the trachea, occlusion of one nostril or compression of pharynx or larynx decreases the air flow and the loudness of the stridor. Auscultation along the accessible portion of the trachea may permit localization of the lesion. The character of any stenotic sound (i.e., whistling, hissing, sawing) may be affected by the presence or absence of exudate in the airways.

Coughing

A cough may simply indicate irritation from fumes or dusty feed or compression of the trachea during attempts to reach something theoretically out of reach, such as the neighbor's feed. If irritation lies in the upper respiratory tract, the cough is typically dry and

powerful. If the goat has a deep-seated bronchopneu-monia, the cough may be moist and feeble. Coughing can be elicited by first briefly preventing respiration. This is done by holding a moist towel or similar object over the nostrils until the goat becomes distressed. When the nose is released, the number and nature of coughs are noted and the lungs are auscultated for abnormal respiratory sounds often accentuated by this procedure.

Nasal Discharge

Possible causes of a nasal discharge are listed in Table 9.1 or discussed under the topic of rhinitis below. Figure 9.2 shows a goat with a mucopurulent nasal discharge during a herd outbreak of infectious kerato-conjunctivitis, possibly due to *Mycoplasma conjunctivae* (see Chapter 6). A purulent secretion is more signifi-cant than a serous discharge. A clear scanty bilateral nasal discharge is not unusual in adult goats in appar-ent good health. Clinically normal goats also harbor a wide variety of aerobic bacteria in their nasal passages, including *Pasteurella multocida*, *Mannheimia haemolytica*, and *Streptococcus* spp. (Ngatia et al. 1985).

Closer Examination of the Upper Respiratory Tract

It is useful to smell the breath; rotten odors may suggest the presence of infection or tumor in a sinus or along the airways. Compare with the smell of the open mouth. Some clinicians have the ability to detect ketone bodies on the breath; those who do not should keep a container handy to catch urine because the goat typically urinates on arising or after the stress or insult of close physical examination. If asymmetry in

Figure 9.2. Feed particles adhering to a mucopurulent nasal discharge. (Courtesy of Dr. M.C. Smith.)

airflow from the two nostrils is detected while smell-ing the breath or by holding the palm of the hand before each nostril, a tumor or foreign body may be present.

The frontal and paranasal sinuses should be exter-nally palpated and percussed. If the goat is hornless, the time and method of dehorning should be ascer-tained. If the goat does not eat hay and chew its cud freely, a tooth root abscess rather than a problem in the respiratory tract may be the source of a bad odor. Radi-ography may be helpful for diagnosing infections or tumors of the sinuses.

When lesions in the pharynx or larynx are sus-pected, direct visualization is desirable. Light sedation with xylazine permits a good view of the back of the throat and the teeth. Manual exploration without seda-tion is hazardous at best. Naturally, in regions where rabies occurs, great care should be taken in all aspects of the physical examination.

Do not neglect to palpate very carefully for the ret-ropharyngeal lymph nodes. Their enlargement may occur with nonspecific local infections, but is more common with caseous lymphadenitis. A progressive dyspnea occurs because of external compression of airway (Jones and Schumacher 1990). Capripox infection can cause a similar obstructive lymph node enlargement in countries where this disease exists (Kitching 2004). Great care should be taken to avoid extending the neck during restraint for physical exami-nation or diagnostic procedures; the increased com-promise of the airway may be rapidly fatal.

Endoscopic examination of the nasal passages, pharynx, larynx, and trachea has been performed in awake untranquilized adult goats using a 4-mm flexi-ble endoscope and illustrations of findings in normal animals published (Stierschneider et al. 2007). The normal goat's trachea may be drop shaped, round, or U-shaped in cross section.

The trachea of a goat may be partially obstructed by a mass protruding into the lumen or by tracheal col-lapse. Coughing, stridor, and exercise intolerance are to be expected. Refrain from diagnosing a hypoplastic trachea without close comparison with healthy goats of the same age and size. That the caprine trachea is relatively small in diameter is well substantiated by the size of endotracheal tube typically required (see Chapter 17). Radiographic evaluation should be helpful in confirming stenotic tracheal lesions or com-pression from enlarged lymph nodes (Jones and Schumacher 1990). If localization of the problem is possible, excision of a mass or even placement of pros-thetic tracheal rings may be attempted (Jackson et al. 1986).

In confined groups of animals, a head tilt, some-times accompanied by facial nerve paralysis, suggests the possibility of bacterial pneumonia. This is

because organisms responsible for pneumonia can also ascend the eustachian tube and cause an otitis media/interna.

Auscultation of the Lungs

Much disagreement exists in the literature regarding terminology for normal and abnormal lung sounds. In addition, harsh inspiratory sounds may be heard over the entire lung field of a goat, especially a thin one, whether the lungs are normal or extensively altered by disease processes. The duration of expiration is also audible in goats, as in sheep. Special efforts should be made to auscultate well forward under the elbow, where cranioventral pneumonias are localized.

Normal breath sounds are loudest on inspiration and are loudest over the trachea and base of the lungs. They are bronchial sounds; the velocity of airflow in alveoli is too low to generate audible sounds, and thus the terms "bronchovesicular" and "alveolar sounds" are inappropriate (Curtis et al. 1986). Increased breath sounds are heard in normal animals with increased rate and depth of respiration (i.e., excitement, exercise, high environmental temperature) or in goats with fever, acidosis, or pulmonary congestion.

"Increased bronchial sounds" are heard on both inspiration and expiration. They occur in disease processes when the bronchial lumen remains open but the surrounding lung tissue transmits sound better because of being consolidated. This is true of most pneumonias of goats. There is no sharp line of demarcation between increased breath sounds and increased bronchial sounds. Crackles are clicking, popping, or bubbling sounds produced by fluid in the airways or by dry airways suddenly popping open. The term "crackles" can be used in preference to "moist rales" because it does not erroneously imply anything about the amount of fluid in the airways. Wheezes (also called rhonchi or dry rales) are whistling or squeaking sounds typically caused by the passage of air through a narrowed airway. Bronchospasm, abscesses, and tenacious exudate are possible causes of wheezes. Both crackles and wheezes may stop or move to another location, as when coughing dislodges fluid or exudate. Stridors (loud wheezing type sounds loudest over the trachea or larynx) may be referred to the lung fields, but they result from stenosis in the upper respiratory tract and are commonly audible without a stethoscope.

Pleuritic friction rubs, described as "sandpaper-like sounds," occur with severe inflammation of the pleura, assuming that adhesion or effusion does not prevent the rubbing.

The absence of breath sounds may be simply because of obesity, as in some Nubians. Pleural effusion, pneumothorax, diaphragmatic hernia, and space occupying thoracic lesions (thymoma) are other possibilities.

Breath sounds may be decreased with shallow breathing from pain, weakness, or central nervous disorders (Curtis et al. 1986).

Percussion of the Lung Fields

In the past, the technique of finger-finger percussion or the use of a pleximeter has been more popular in Europe than in America. Thoracic percussion has been reviewed (Roudebush and Sweeney 1990). Veterinarians who expect to obtain useful diagnostic information from the procedure should routinely percuss many goats to become familiar with the normal sounds and lung boundaries. Percussion is usually done on the right side, although the presence of the spleen on the left makes it possible to identify the upper border between lung and rumen. The caudal lung border normally extends in an arc from the dorsal aspect of the eleventh intercostal space to the point of the elbow. A prescapular percussion field is present, and in thin animals the lungs can be percussed through the ventral portions of the scapula. Lifting a flexed forelimb to the side permits clearer percussion of axillary areas (Marek and Mocsy 1960). The full resonance of normal lung is to be contrasted with the more tympanic sound of gas-filled rumen or intestine, the relatively damped or dull sound of ventral abdominal organs, and the absolute dullness of the liver (on the right). A duller than normal sound over the lung fields can occur when large areas of the lung are consolidated by abscess, tumor, or interstitial pneumonia. The dull area is ventrally located and has a horizontal dorsal border if accumulation of fluid in the thorax is responsible. Processes causing increased intra-abdominal pressure (including late pregnancy) can displace the lung borders in a cranial direction.

Blood Gas Measurement

When laboratory testing is accessible, standard blood gas measurements give an indication of pulmonary function, as well as acid-base status of the animal. Venous blood is routinely collected in heparin, avoiding contamination of the sample with room air. Few studies specific to the goat have been published, and ideally each testing laboratory should determine the reference ranges for the apparatus being used, because some variability is to be expected (Kahrer et al. 2006). Time and temperature of blood storage before testing also influence test results. For instance, there is a slight decrease in concentration of HCO_3^- and a marked increase in pO_2 with storage for twenty-four hours at 4°C (39°F), while pH is stable (Piccione et al. 2007). Blood gases determined by Blood Gas Analyzer on twenty-nine adult goats, one each from twenty-nine farms, are presented in Table 9.2 (Stevens et al. 1994). Respiratory acidosis, with increased pCO_2 and HCO_3^-, is expected with impaired pulmonary function.

Table 9.2. Blood gases of adult goats determined on venous blood.

Parameter	Mean	2.5 percentile	97.5 percentile
pH	7.38	7.30	7.50
pCO_2 (mmHg)	40.6	34.6	48.8
HCO_3^- (mmol/L)	25.0	19.6	29.4
TCO_2 (mmol/L) calculated	26.2	20.7	30.7
pO_2 (mmHg)	48.8		

Transtracheal Aspiration

The small diameter of the trachea makes this a more difficult procedure in goats than in cattle.

Indications

Transtracheal aspiration is useful for obtaining samples for cytology and bacteriologic culture in the diagnosis of an etiologic agent. Microbial sensitivity testing aids the choice of antibiotics to be used in treating a particularly valuable goat or one that has failed to respond to previous rational therapy. The frequency of recovery of pathogens from the trachea of goats when pulmonary disease is absent is unknown. Cultures from nasal swabs are of no diagnostic value relative to bacterial pneumonia.

Technique

The hair is clipped midway over the cervical trachea and a small bleb of local anesthetic is injected beneath the disinfected skin. Sterile gloves should be worn. A 14-gauge needle is used to penetrate the trachea and a 3 French polypropylene catheter or a 3 1/2 French tomcat catheter is passed into the trachea. A 16- or 18-gauge intravenous catheter device may be used instead. The needle portion should be withdrawn after placement of the catheter into the trachea to avoid cutting off part of the catheter. Sterile, buffered saline (15 to 20 ml) is injected into the trachea. At once, as much as possible (often only a few milliliters) is aspirated into the syringe and submitted for microscopic examination and culture. The catheter is then removed. No special aftercare is needed.

Bronchoalveolar Lavage

In a hospital or research setting, better samples for cytology are obtained with the goat sedated (acepromazine at 0.3 mg/kg IV) or under general anesthesia and intubated. A tracheal wash catheter is passed through the endotracheal tube to the bronchial bifurcation. In an adult goat, approximately 50 ml of warm sterile saline is flushed into the lungs and then aspirated at once through the same catheter (Berrag et al. 1997). If available, recovery of fluid would probably be improved by use of a pediatric bronchoscope. The authors report that in normal goats the predominant cell type recovered is alveolar macrophage (80% to 95%) with fewer lymphocytes, eosinophils, neutrophils, and epithelial cells.

Radiography of the Lungs

Radiography can document the presence of cranioventral bronchopneumonia, interstitial pneumonia, pleural effusion (often marked in contagious caprine pleuropneumonia), a penetrating metallic foreign body, thymoma, tracheal compression by enlarged mediastinal lymph nodes, or underlying cardiac disease leading to respiratory signs (Ahuja et al. 1985). The value of pulmonary radiographs often comes from confirmation of advanced and extensive changes in the lung fields. Multiple abscesses or massive areas of interstitial pneumonia suggest a very grave prognosis. Sternal and mediastinal lymph nodes should be examined for evidence of enlargement. Sternal abscesses with penetration into the thorax are accompanied by visibly enlarged sternal nodes and often by osteomyelitis of the sternebrae. Both viral and bacterial pneumonias, if chronic, can result in enlargement of mediastinal nodes.

A large thymoma may displace the lungs caudally. Because many thymomas in goats are incidental findings at necropsy (Hadlow 1978), it is conceivable that an asymptomatic tumor might be identified during radiography of a goat with some other thoracic disease. If the lungs are displaced cranially, consideration should be given to a (very rare) diaphragmatic hernia (Tafti 1998).

The radiographic equipment and techniques used for dogs are also appropriate for goats. The forelimbs need to be pulled well forward to expose the cranioventral lung lobes. Light intravenous tranquilization with xylazine (0.05 mg/kg), combined with clever use of tape and sandbags, provides safe restraint.

Ultrasonography of the Thorax

The physical or chemical restraint needed to obtain diagnostic radiographs of the chest may be dangerous to a severely dyspneic animal. Ultrasound examination can be done in a standing animal, usually at less expense than radiography. Scott and Gessert (1998) have described the procedure for sheep, and their findings should be applicable to goats. A sector scanner transducer rather than a linear array transducer is preferred because of the narrow intercostal space, and examination may not be possible in small goats. Hair is clipped from a 7 cm wide strip of skin caudal to the scapula and elbow bilaterally. Starting in the sixth or seventh intercostal space, the thorax is examined in longitudinal and transverse planes. The front limb is adducted and the clipped skin slid forward several

spaces to allow access to the ventral aspect of the chest. Examination beginning from the ninth or tenth intercostal space assesses the dorsal lung field. Liberal wetting of the hair with alcohol can be substituted for clipping and application of an ultrasound gel.

Normally aerated lung does not permit penetration of the ultrasound beam, so a bright linear echo and reverberation artifacts are all that are seen during examination of a normal animal. Ultrasound is useful for demonstrating fluid accumulation in the pleural space, abscesses that reach the pleura, tumors, and consolidation by bacterial or interstitial viral pneumonia (Scott and Gessert 1998).

Lung Biopsy and Aspiration of Fluid from the Thorax

If a fluid line is percussed in the thorax or detected by radiography or ultrasonography, thoracocentesis may be indicated. Clipping of hair and thorough disinfection of the skin are mandatory. A site beneath the fluid level but not directly over the heart should be chosen, and the needle should be kept close to the anterior edge of a rib to avoid nerves and blood vessels.

Percutaneous lung biopsy (fine needle aspiration) is rarely performed but can be used to confirm the presence of an extensive interstitial pneumonia or tumor, as is associated with retroviral infections. The technique has been described in small animal medicine textbooks (Johnson 2005) and in sheep (Braun et al. 2000).

EFFECT OF ENVIRONMENT ON RESPIRATORY DISEASE

The veterinarian should not be content with examining only the goat with respiratory disease. The environment should also be analyzed to determine if it is contributing to the pathogenesis of disease. Table 9.3

Table 9.3. Optimal housing for goats in temperate climates.

Temperature	Minimal 43°F (6°C)
	Optimal 50°F to 64°F (10°C to 18°C)
	Maximal 81°F (27°C)
Relative humidity	Optimal 60% to 80%
Ventilation	Winter 30 m³/hour/goat
	Summer 120 to 150 m³/hour/goat
	Maximum air speed 0.5 m/s adults, 0.2 m/s kids
	Air intake at least twice surface area of air exit
Lighting	Window area equal to 1/20 of ground surface area

gives specifications for environmental conditions as recommended for milking goats in temperate climates (Toussaint 1984).

Temperature

At environmental temperatures above or below the optimal limits given in Table 9.3, the goat has to expend energy specifically to maintain its normal body temperature. As a consequence, production (milk or growth) is adversely affected. In a hot environment, the goat must decrease its heat production (eat less) while losing more heat through evaporation and radiation from lungs and skin. Under cold conditions, the goat must use more energy from feed or body reserves. It will also have increased levels of circulating glucocorticoids. Age and production level both affect the critical temperatures. For instance, the minimum temperature for kids is higher than for adults (Constantinou 1987). Indigenous breeds in many parts of the world are well adapted to more extreme conditions. Moderating the environment for these animals probably causes a loss of some degree of their genetic hardiness after a few generations.

Ventilation

Ventilation affects the purity of the air that the goats breathe. Heat, moisture, and carbon dioxide from the lungs need to be dissipated. Decomposition of feces and urine produces ammonia, hydrogen sulfide, methane gas, and other malodorous substances. A build-up of these chemicals can lead to irritation of the eyes and respiratory tract. Heaters and motorized equipment operating within the barn add to air pollution. Suspensions of dust from feeds and dirt carry with them numerous pathogens and saprophytic organisms. Coughing and sneezing serve to excrete many germs into the air in droplet nuclei (Ojo 1987), while dust helps to keep them airborne. Warm and humid conditions favor the survival of microorganisms in the air.

Animal Density

Overcrowding increases both the temperature and humidity in the barn because more goats generate heat and moisture into the atmosphere. Manure can also significantly increase the temperature. The surface area allotted per goat should be a minimum of 0.5 m² per stanchioned animal and 1.5 m² per adult in a free stall setting (Toussaint 1984). The minimum per unweaned kid is 0.3 m². The minimum feed trough length recommended per goat is 0.4 m. With the inclusion of feed alleys, the typical area per goat in the barn is 2 to 2.4 m². The height from the bedding to the ceiling then determines the volume per goat. If the ceiling is too low, temperature and humidity increase. If the air space is too great, the barn may be too cold in the winter.

Building Construction

The building where goats are housed should serve several functions. First, it should shelter the animals from intemperate weather while providing a suitable microclimate for the goats. The comfort of the goat rather than of the owner is paramount. Second, the building should be constructed so that the owner can group animals as necessary and efficiently perform all the tasks required for management of the herd. The building and its equipment must not be so expensive that the owner cannot pay the mortgage.

The barn should be situated where natural ventilation and drainage are good (top of a rise, not the bottom of a slope). In cold climates, exercise lots should have exposure to winter sun and a protective wall relative to prevailing winter winds. The barn should be situated away from wells and streams to avoid contamination of groundwater.

Proper construction of the barn is required to obtain the desired ventilation rate, whether natural or mechanical ventilation is used (Constantinou 1987; Collins 1990). In particular, the placement and size of air inlets and fans are very important. The assistance of an expert in this field should be sought when designing a barn or attempting to correct a preexisting problem (Bates and Anderson 1979). Fans and air intakes must also be cleaned regularly to ensure continuing function of the ventilation system. Plastic netting may be used to temper prevailing winds.

In cold climates, and in kid-raising facilities, insulation of the building avoids the stresses associated with large daily temperature fluctuations. While insulation prevents water condensation on the ceiling it requires more ventilation to remove moisture. A very serious error is the lining of the barn with plastic sheeting with the thought of keeping the goats comfortably warm. High humidity and dripping of condensed water onto the goats predisposes them to pneumonia. Leaky waterers also increase humidity, as does inadequate provision of new bedding.

A last way that building construction can help to limit respiratory disease is in the provision of appropriate isolation facilities. Sick animals should be removed from the main pen, and purchased or boarded animals should be kept isolated from the herd for a minimum of two weeks. If attendance at shows is part of the operation of the herd, the traveling goats should be kept isolated from the stay-at-home animals for an equal time period, though this may in effect mean running two herds during the show season.

UPPER RESPIRATORY TRACT DISEASES

As discussed earlier, clinical signs such as stertor, sneezing, nasal discharge, and cough suggest but are not limited to conditions with upper respiratory tract involvement.

Rhinitis

There are several possible etiologies for inflammation of the nasal passages. Irritation from foreign material or parasites should be ruled out before more esoteric explanations are sought. A single mature goat in Brazil developed *Prototheca*-induced pyogranulomatous lesions of the skin at the nares and extending onto the nasal mucosa, causing inspiratory stertor, dyspnea, and weight loss (Macedo et al. 2008). This report underscores the importance of obtaining a biopsy sample from perplexing cases.

Herpesvirus

Caprine herpesvirus infection (see Chapter 12) has caused severe generalized signs, including bloody diarrhea, fever, dyspnea, and purulent nasal discharge. Fibrinonecrotic ulceration of the nasal septum occurred in one kid experimentally infected (Berrios et al 1975). In other experimental infections, the virus has caused a catarrhal rhinitis and mild tracheitis (Buddle et al. 1990a).

Nasal Bots

Nasal bots (*Oestrus ovis*) cause a chronic catarrhal to purulent discharge (Prein 1938) that may contain many eosinophils. This parasite is less common (larval burdens are smaller) in goats than in sheep (Dorchies et al. 1998). The adult fly deposits larvae around the nostrils of animals on pasture. First instars enter the nasal cavity and develop into second instars, which invade the sinuses of the head. Mature larvae return to the nostrils (if they have not grown too large to escape from the sinuses) after two to ten months and are expelled by sneezing (Kimberling 1988). Pupation occurs in the ground. Adult flies emerge after four weeks or longer, or possibly the next spring. Occasionally larvae are deposited about the eyes of humans, causing painful conjunctival ophthalmomyiasis (Cameron et al. 1991).

Nose bots in goats can be suspected if nasal discharge is profuse and contains eosinophils. Frequent violent sneezing and avoidance behavior in late summer are typical. Caked-on dust leads to mouth breathing and interference with feeding, while inhaled bacteria and eosinophils may induce lung damage. Repeated infections induce a hypersensitivity and immunity in goats (Dorchies et al. 1998). Sometimes the bots are just an incidental finding in the sinus upon dehorning of adult goats.

The condition can usually be ignored if it does not interfere with feed consumption. Various questionable products have been sprayed into the nasal passages in late fall and winter to kill larvae, including ruelene

aerosol and concentrated lysol diluted 1:5 with water. Ivermectin (even at 0.2 mg/kg level) is highly effective against all stages of nose bots. A prolonged milk withdrawal of nine days is suggested if ivermectin is administered orally to goats producing milk for human consumption, and forty days if given subcutaneously (Baynes et al. 2000). Eprinomectin pour-on at 0.5 mg/kg has been shown to be effective against *Oestrus ovis* in sheep (Hoste et al. 2004) and does not contaminate milk.

Nasal Leech

The nasal leech (*Dinobdella ferox*) infests ruminants grazing at altitudes of 900 to 1,800 m in the foothills of the Himalayas. The leeches live in permanent pools and springs; young leeches attach themselves to the nostrils of animals that drink there during the dry season. Leeches migrate to the nasal passages to feed but drop back into the water at the onset of the monsoon season (mid-June). Clinical signs include sneezing, blood-tinged mucoid nasal exudate, intermittent epistaxis, and anemia (Mahato et al. 1993). When leeches become large enough to protrude through the nostrils (fifteen days after infection) and restrict breathing, goats become restless and anorectic. Treatment is achieved by wetting the goat's nostrils with water to encourage leeches to protrude, then permitting the leeches to dip their bodies in a (reusable) solution of 10 mcg/ml ivermectin. Leeches are expelled within a few hours after this therapy. Systemic ivermectin is not effective (Mahato 1989).

Nasal Schistosomosis

The blood fluke *Schistosoma nasale* has caused nasal obstruction in goats in India. This parasite is discussed in Chapter 8.

Foreign Matter

Foreign body rhinitis is often caused by powdery feeds. Regurgitation is a more serious possible cause. Assuming the absence of a cleft palate, nutritional muscular dystrophy (white muscle disease) should be considered whenever milk runs out a kid's nose. This is discussed under inhalation pneumonia. Vagal nerve irritation in the abdomen or thorax or poisoning by plants of the Ericaceae (rhododendron) family may cause regurgitation through the nose and mouth, but the distinctive smell and green color of rumen contents on the muzzle make the identification of the irritating substance simple.

Bacterial Rhinitis

Atrophic rhinitis associated with toxigenic strains of *Pasteurella multocida* has been recognized in goats in Norway (Baalsrud 1987). Signs observed in affected herds include purulent nasal discharge, nose bleeding, sneezing, and occasionally tender or distorted noses. Turbinate atrophy can be recognized when heads are sectioned at the level of the first premolar teeth. In tropical countries, purulent rhinitis with raised coalescing nodules on the nasal septum and turbinates has been observed in goats with melioidosis (Omar 1963).

Neoplasia

An enzootic nasal tumor of young adult goats has been reported from France and Spain and recognized in individual animals elsewhere in the world (Fontaine et al. 1983; Pringle et al. 1989; De las Heras et al. 1991a, 2003b). The lesion is unilateral or bilateral and papillary and results in lysis of the turbinates. Histologically, the tumor is benign. Retroviral-like particles have been demonstrated in the tumors of several goats that had negative agar gel immunodiffusion tests for maedivisna (and therefore CAE) virus (De las Heras et al. 1988, 1991a). Nasal secretions and the associated type D retroviral particles have transmitted the tumor experimentally (De las Heras et al. 1991b, 1995). Affected animals show profuse seromucous nasal exudate, coughing, dyspnea, and stertor. One or both eyes may protrude and pressure on softened cranial bones causes expulsion of mucous nasal exudate. The outcome is eventually fatal, the result of emaciation and asphyxiation (De las Heras et al. 1991a). Presumably, select cases might be amenable to surgical extirpation, as has been performed for nasal tumors of sheep (Rings and Rojko 1985, Trent et al. 1988). Lymphosarcoma can also invade the nasal sinuses of goats (Craig et al. 1986). A fungal granuloma caused by *Cryptococcus neoformans* has been reported to obstruct the nasal cavity of a goat in Australia (Chapman et al. 1990) and could be easily mistaken for a tumor.

Pharyngitis

Balling gun injuries can cause severe cellulitis in the region of the pharynx. Small plastic balling guns are particularly dangerous because the goats soon make them very rough by chewing on the plastic when bolus administration is attempted. Common clinical signs include cough, nasal discharge, and secondary inhalation pneumonia. The breath may have a foul odor, and the region of the pharynx is swollen and sensitive to palpation. Examination is simplified by tranquilization. Broad-spectrum antibiotics are given for treatment. Prevention typically involves using an alternative to anthelmintic or sulfonamide boluses.

Abscessation of Retropharyngeal Lymph Nodes

An enlarged retropharyngeal lymph node (Figure 9.3) may cause stertor, dyspnea, and coughing because of pressure on the pharynx or trachea. The mass can be detected by careful palpation and by radiography. The abscess is often caused by *Corynebacterium*

Figure 9.3. Abscessation of the retropharyngeal lymph node caused marked dyspnea in this goat. (Courtesy of Dr. J.M. King.)

pseudotuberculosis. A brave and careful surgeon is required to marsupialize the abscess without severing carotid artery, vagus nerve, or other important structures. Placement of a cuffed tracheostomy tube under local anesthesia has been recommended before induction of general anesthesia (Benson 1986). Caseous lymphadenitis is discussed in detail in Chapter 3.

Laryngitis or Tracheitis

These conditions are suspected when stridors are audible and can be localized to the corresponding portions of the upper respiratory tract. As discussed earlier, the trachea of a normal goat feels quite small.

Common Causes

Collars that press on the trachea may induce coughing in a tethered goat or one that is led by a collar. The cough is far less important than the danger of leg injury from the tether. Tracheitis because of irritants such as smoke, dust, whitewash, and ammonia in urine-soaked bedding has already been alluded to in the discussion of coughing. The diagnostician should get down to goat level and inhale deeply. If hay is dusty, the owner should try shaking it out while the goats are out of stall. If a goat is eating well and maintaining normal production and body condition, occasional coughing when fed or aroused is of no real concern.

The possible role of *Mycoplasma ovipneumoniae* (see below) in chronic cough of otherwise healthy kids on certain farms remains to be studied. This cough is usually outgrown by about eight months of age.

A single case of laryngeal hemiplegia has been reported in an adult Alpine goat (Tschuor et al. 2007). No etiology was determined, even with full necropsy and evaluation of the (normal) laryngeal nerve and musculature.

Necrotic Laryngitis

Fusobacterium necrophorum is a sporadic cause of laryngitis and of necrotic stomatitis in goats. The condition is discussed in Chapter 10.

Cilia-associated Respiratory Bacillus

Recently, a Gram-negative filamentous bacterium called cilia-associated respiratory bacillus, or CAR, has been associated with respiratory tract disease in laboratory rodents and cattle. This organism has also been found by histological examination (Warthin Starry stain and immunohistochemistry) and electron microscopy in the trachea of kids and adult goats with chronic tracheitis (Fernández et al. 1996; Orós et al.1997a) and in the lungs of slaughtered goats with enzootic pneumonia (Orós et al. 1997b). The bacteria are interspersed with cilia and oriented perpendicular to the surface of the tracheal and bronchial epithelium. The significance of CAR in goats remains to be determined.

Infectious Bovine Rhinotracheitis

Infectious bovine rhinotracheitis (IBR) virus (bovine herpesvirus type I) is rarely isolated from goats, but experimentally causes pyrexia and mild clinical signs. Cough and nasal discharge would be expected if any signs at all occurred, although there is one report of severe respiratory disease (Mohanty 1972). The use of IBR vaccination is not recommended for goats. In fact, several caprine isolates have been indistinguishable from bovine vaccine strains (Whetstone and Evermann 1988). Goats may be latent carriers of the virulent bovine virus, potentially interfering with eradication attempts in cattle herds (Six et al. 2001).

LOWER RESPIRATORY TRACT DISEASES

A clinician can only rarely be sure of the etiology of lung disease in a particular live goat. To make a more specific diagnosis than "pneumonia," it is necessary to rely on the history of this or nearby herds or to await the proclamations of a microbiologist or pathologist (Ojo 1977). The etiology of pneumonia is usually multifactorial, and treatment often precedes diagnosis. A general discussion of therapy and prophylaxis for pneumonia, then, can be found following the discussion of etiologic agents.

VIRAL CAUSES OF PNEUMONIA

Viral pneumonias in goats can be chronic or acute. Secondary bacterial infections are often superimposed.

Respiratory Syncytial Virus

A single caprine isolate of respiratory syncytial virus (RSV, a single stranded RNA pneumovirus of the family *Paramyxoviridae*, subfamily *Pneumovirinae*) has

been characterized in the United States (Lehmkuhl et al. 1980). This isolate is very closely related to strains of bovine respiratory syncytial virus (BRSV) (Trudel et al. 1989). An RSV similar to BRSV has been isolated from goat kids with respiratory disease in Spain (Redondo et al. 1994). Clinical signs reported in this outbreak included fever, loss of appetite, conjunctivitis, nasal discharge, cough, and tachypnea. Animals with a simultaneous fibrinous *Mannheimia haemolytica* bronchopneumonia had higher fevers and more labored breathing. Crackles were heard over the lungs of all affected animals.

Several surveys have documented antibodies against this virus or the closely related bovine RSV in healthy goats. This includes 36% of 112 adult goats from forty herds studied in Quebec (Lamontagne et al., 1985), 31% of 318 goats in twenty-two herds in another Quebec study (Elazhary et al. 1984), 50% of 332 goats in Louisiana (Fulton et al. 1982) and eleven of forty goats from farms in the Netherlands that also harbored cattle (Van der Pool et al. 1995). Goats in England were found to have antibodies against BRSV without ever having shown respiratory signs (Morgan et al. 1985), whereas goats seroconverted during a pneumonia outbreak in Zaire (Jetteur et al. 1989). The importance of RSV as a respiratory pathogen in goats remains unclear. There are no publications available concerning possible benefits of vaccination, although some veterinarians have used BRSV vaccines to prevent respiratory disease in show goats.

Progressive Interstitial Retroviral Pneumonia

Retroviruses (lentiviruses) are believed to cause both subclinical and fatal pneumonia in goats.

Etiology

The caprine arthritis encephalitis virus (CAEV, viral leukoencephalomyelitis) has been reported to cause subclinical interstitial pneumonia (Cork et al. 1974). Occasional kids with neurologic lesions also have diffuse involvement of one or more lung lobes.

A clinical syndrome indistinguishable from ovine progressive pneumonia and maedi-visna has been identified in CAEV-infected adult goats (Robinson 1981; Oliver et al. 1982). The sheep and goat viruses are still considered to be distinct by most researchers, but serologic tests cross react and both viruses are spread through milk, as discussed in Chapter 4.

To date it has not been possible to reproduce this condition experimentally. Therefore there is a suspicion that an additional agent, such as a helper virus, may be involved. There is currently no evidence that the production of interstitial pneumonia depends on the strain of CAEV with which the goat is infected (Ellis et al. 1988b). Inoculation of CAEV into Merino lambs has failed to produce clinical disease in the

sheep (Dickson and Ellis 1989). Natural transmission of small ruminant lentiviruses between sheep and goats has been documented in mixed herds (Shah et al. 2004).

Clinical Signs

The first signs of dyspnea usually occur after a stress such as kidding or mastitis. The clinical course may be several weeks in advanced pregnancy or many months in the doe first affected after kidding. Exercise intolerance, dyspnea, and wasting often accompanied by a cough are prominent. Some but not all affected goats have enlarged carpi. Secondary bacterial pneumonias may be superimposed, and antibiotics often appear to give temporary relief. The pulmonary form of caseous lymphadenitis has a similar clinical appearance.

Diagnosis

Radiographs show small patches of interstitial pneumonia early in the course. A more advanced case is depicted in Figure 9.4 and elsewhere (Koenig et al. 1990). As debilitation progresses, large areas of lung are consolidated and bullous emphysema may damage the remaining lung parenchyma. Either caudal lung lobes or cranioventral lung lobes may be involved (Ellis at al. 1988a). At necropsy, the affected areas are swollen, grey-pink, and firm (Figure 9.5); numerous 1- to 2-mm whitish gray foci are visible on cut section as shown in Figure 9.6 (Robinson and Ellis 1984). Mediastinal lymph nodes are enlarged. Lung biopsies might confirm the diagnosis before death. Serologic testing is of no diagnostic value, but should identify an infected herd.

Figure 9.6. Cross section of an affected lung lobe, showing infiltration of the pulmonary parenchyma. (Courtesy of Dr. M.C. Smith.)

Histological study of caprine progressive pneumonia reveals interstitial (peribronchiolar) accumulation of mononuclear cells and proliferation of type II pneumocytes. Alveoli are filled with an eosinophilic material that resembles surfactant when examined with the electron microscope (Robinson and Ellis 1984; Robinson and Ellis 1986).

Discussions of the other CAEV-associated syndromes (i.e., arthritis, neurologic disease, mastitis) can be found elsewhere in this text. Control procedures are discussed in detail in Chapter 4.

Ovine Pulmonary Adenocarcinoma, Sheep Pulmonary Adenomatosis, Jaagsiekte

This contagious lung tumor of sheep has been reported infrequently in goats (Rajya and Singh 1964;

Stefanou et al. 1975). The disease has been reported in sheep on all continents except Australia. The cause is an oncogenic beta-retrovirus (De las Heras et al. 2003a). Transmission appears to be via respiratory secretions. Experimental infection is much more difficult to produce in goats than in sheep (Sharp et al. 1986; Tustin et al. 1988).

Clinically affected animals are mature and afebrile (in the absence of secondary bacterial infections) and show prolonged weight loss and dyspnea. Fluid accumulates in the lungs, which results in auscultable crackles or rales. A simple test used to differentiate the condition from chronic progressive pneumonia is to elevate the animal's hindquarters. Fluid is expected to run out the nose if the animal is severely affected with adenomatosis. The disease is considered to be invariably progressive and fatal. There is no known treatment and no serologic test. Control is usually limited to culling goats that are wasting, although recently a PCR test for proviral DNA in leukocytes has permitted identification of subclinically infected sheep (Gonzalez et al. 2001). Removal at birth and artificial rearing on colostrum substitutes and milk replacer (essentially a CAE eradication program) has also been successful in creating a disease-free sheep flock (Voigt et al. 2007).

At necropsy, many grayish nodules or extensive solid tumors are found in the lungs. The respiratory passages are filled with white froth. Histologically, there are alveolar and intrabronchiolar growths composed of masses of cuboidal and columnar cells. Metastases to regional lymph nodes have not been reported in goats (Sharma et al. 1975).

Peste des Petits Ruminants

This important infectious disease of sheep and goats is also called PPR, stomatitis pneumoenteritis complex, and Kata (Hamdy et al. 1976).

Etiology and Pathogenesis

The etiologic agent is a paramyxovirus of the *Morbillivirus* genus that is not pathogenic for cattle. The closely related rinderpest virus of cattle causes similar signs in goats. The two viruses seriously limit goat production in West Africa, the Middle East, India, and Southeast Asia.

The virus is shed in secretions to infect other animals by direct contact. It can persist in the environment for as long as thirty-six hours, and thus holding pens can be a source of infection. The disease is discussed in detail in Chapter 10.

Clinical Signs

The disease is characterized by fever persisting five to seven days and a profuse, even bloody diarrhea. Necrotic stomatitis, foaming at the mouth, and an

ocular discharge are also noted. Pregnant animals may abort (Abu Elzein et al. 1990). Respiratory signs occur during the acute stages; these include malodorous, mucopurulent nasal discharge, frequent sneezing, increased respiratory rate, extended head, and mouth breathing. Severe leukopenia persists for ten days in animals that recover (Scott 1990). Some goats die two to three weeks later of a secondary bronchopneumonia (Whitney et al. 1967). The highest incidence of disease occurs during the rainy season, and goats most commonly affected are six to twelve months of age. Kids younger than three months of age usually have colostral immunity.

Diagnosis

Fluorescent antibody testing is useful for identifying the virus in nasal discharges and intestinal scrapings. Ocular or nasal discharges collected after two to three drops of phosphate buffered saline are placed in the eye or nostril can be used as the antigen in a hemagglutination test using 0.6% piglet red blood cell suspension (Wosu 1991). This test permits differentiation of peste des petits ruminants from simple bacterial pneumonia in live goats in situations where sophisticated laboratory facilities are not available. When available, a reverse transcriptase polymerase chain reaction test can be used to identify the virus in oculonasal swabs, oral lesions, or blood (Çam et al. 2005). Serological testing using a competitive ELISA also permits monitoring of the infection in endemic regions (Singh et al. 2004, 2006).

The necropsy findings relative to the gastrointestinal tract are described in Chapter 10. There may be consolidation of cranioventral lung lobes. Histologic lesions reported in the lung include a giant cell pneumonia with eosinophilic intracytoplasmic inclusions in epithelial cells in perhaps half of the goats dying because of peste des petits ruminants. Less commonly there is necrosis of the tracheal epithelium. Diagnosis is complicated by secondary *Pasteurella, Mannheimia,* or *Mycoplasma* pneumonia.

Prophylaxis

Vaccination against this disease in endemic areas is both feasible (Gibbs et al. 1979) and economically sound (Opasina and Putt 1985). Prophylaxis is covered in Chapter 10.

Hyperimmune serum (5 ml intravenously) reverses the signs of peste des petits ruminants if given during the febrile stage of the disease, when the temperature is 104.9°F (40.5°C) or higher. However, reinfection or relapse occurs after ten days and even those goats that develop labial scabs and appear to recover are susceptible to later challenge (Ihemelandu et al. 1985). Thus, goats treated with hyperimmune serum should still be vaccinated.

Goat Pox

The capripox virus, discussed in detail in Chapter 2, causes systemic signs that include pyrexia, anorexia, and an arched back. Case fatality rates are increased when the respiratory tract is involved. At necropsy, multiple foci of consolidation (0.5 to 2 cm diameter) are commonly found beneath the pleura. These lesions may be hemorrhagic (Kitching 2004). Similar lesions may be seen in other organs such as liver, kidney, and abomasum. Secondary bacterial pneumonia is commonly the cause of death (Davies 1981).

MYCOPLASMA, CHLAMYDIA, AND RICKETTSIA PNEUMONIAS

Of these organisms, mycoplasma are most frequently isolated and of the greatest economic importance.

Several species of mycoplasma have been shown to cause pneumonia in goats (Hudson et al. 1967; Ojo 1987; Nicholas 2002). Some of these (belonging to the *Mycoplasma mycoides* cluster) cause specific syndromes known as contagious caprine pleuropneumonia and pleuropneumonia and are discussed separately. Because of changes in classification schemes, it is very difficult to interpret the older literature and to know exactly which organism was involved in a given report (Moulton 1980).

Mycoplasma are generally fragile outside the host animal. They are easily inactivated by heat, sunlight, and disinfectants. Mycoplasma have been isolated from the external ear canal of goats (Ribeiro et al. 1997). Ear mites have been proposed as possibly disseminating the infection (Cottew and Yeats 1982; DaMassa 1983; DaMassa and Brooks 1991).

Nonspecific Mycoplasma Pneumonia

Several species are isolated sporadically from goats, either alone or in conjunction with other causes of pneumonia.

Etiology and Pathogenesis

Mycoplasma ovipneumoniae can be isolated from the trachea and lungs of healthy goats. When found in pneumonic lungs, the numbers of organisms present do not correlate with the severity of the lesion (Bolske et al. 1989). Fever and subacute fibrinous pleuritis have been produced experimentally with *M. ovipneumoniae* (Goltz et al. 1986), and natural cases also have been reported in goats (Livingston and Gauer 1979; Jones and Wood 1988). Production of a capsule may contribute to this organism's pathogenicity (Niang et al. 1998). It lacks the "fried egg" colony appearance typical of other mycoplasmas when grown on solid medium (DaMassa et al. 1992). Note that *M. ovipneumoniae* may accompany other mycoplasma species that are more pathogenic but also more difficult to isolate.

Oral administration of *M. capricolum* (*M. capricolum* subsp. *capricolum*) causes acute pneumonia and polyarthritis in kids via the septicemic route (DaMassa et al. 1983b, 1992; Bölske et al. 1988; Taoudi et al. 1988). The pneumonia is only rarely accompanied by pleurisy. The organism can then spread to contact kids, probably via respiratory secretions. *Mycoplasma agalactiae*, which typically causes mastitis in sheep and goats, has been shown capable of causing pneumonia in kids (Guha and Verma 1987). *Mycoplasma arginini* is isolated occasionally but is of doubtful pathogenicity (DaMassa et al. 1992). *Mycoplasma bovis* has been isolated from the lungs of goats, and could potentially have been acquired by consumption of milk from infected cows (DaMassa et al. 1992).

Associated Clinical Syndromes

In addition to respiratory disease, other conditions associated with mycoplasma include polyarthritis, mastitis, conjunctivitis, and keratitis (see Table 4.3). This combination of clinical signs has been termed the MAKePS syndrome, standing for mastitis, arthritis, keratitis, pneumonia, and septicemia (Thiaucourt and Bölske 1996). The differential diagnoses of these syndromes are considered elsewhere in this text.

Diagnosis

Thoracocentesis has been suggested for the diagnosis of mycoplasmal pneumonia in living goats. Pleomorphic coccoid, ring, and filamentous organisms can be seen with the dark field microscope or, alternatively, after staining with a 5% nigrosin solution (Ojo 1987). Although special media are required, the MAKePS mycoplasmas (including those that cause pleuropneumonia, see below) grow on modified Hayflick's mycoplasma medium (Rosendal 1994). It is relatively easy to isolate mycoplasma from acute cases, but difficult or impossible to culture the organism from chronically infected goats. Swabs should be shipped in transport media (without charcoal), refrigerated but not frozen. Tissue samples from the interface between consolidated and unconsolidated areas are chopped or pulverized in culture medium.

Peribronchiolar lymphocytic infiltrations and diffuse nonsuppurative pleuritis at necropsy are suggestive of mycoplasma, but secondary pasteurellosis complicates the diagnosis. Serologic tests are not available for many mycoplasmal species, and in fact few laboratories are capable of typing mycoplasma isolates to determine if a known pathogenic species is present.

Therapy

Penicillin and related drugs are ineffective because mycoplasma lack a cell wall. Tylosin (10 to 20 mg/kg once daily) and tiamulin (Ojo et al. 1984) (20 mg/kg once daily) are considered to be superior to tetracycline in the treatment of pulmonary mycoplasmosis. Adverse reactions associated with intramuscular injection of these drugs include lameness and collapse. Side effects may be reduced by diluting the drug with an equal quantity of sterile saline solution just before injection or administering the drug subcutaneously. The newer macrolide drug tulathromycin, which has a prolonged pulmonary half-life and activity against bovine mycoplasma, has not yet been evaluated in small ruminants. Isolation of infected animals is desirable, but very difficult in free-ranging systems, especially where communal water holes are used. Control measures used for pleuropneumonia are applicable if herd outbreaks occur.

Contagious Caprine Pleuropneumonia

Contagious caprine pleuropneumonia (CCPP) is a disease that naturally infects only goats, not sheep. Lesions are confined to the respiratory tract (Harbi et al. 1983). The disease is notifiable to the OIE (Office International des Epizooties).

Etiology and Pathogenesis

Mycoplasmologists have reclassified the etiologic agent several times (Martin 1983). In the 1980s the organism was specified as the highly fastidious F38 biotype *Mycoplasma* (McMartin et al. 1980), but currently it is named *Mycoplasma capricolum* subsp. *capripneumoniae* (Thiaucourt and Bölske 1996). Previously, *M. mycoides* subsp. *capri* was cited as the cause of CCPP, but now the disease associated with the latter organism is designated as pleuropneumonia, as discussed below. Although not identified in the Western Hemisphere, CCPP is prevalent in Africa, Turkey, the Middle East, and Asia (Thiaucourt and Bölske 1996). The organism is transmitted by aerosol during cohabitation and is highly contagious. The incubation period is typically six to ten days or longer. All ages are affected.

Clinical Signs and Diagnosis

In countries where this infection occurs, the signs are considered to be specific enough to permit an easy clinical diagnosis (Ojo 1987). These signs include fever, cough, and a painful respiration with grunting and the forelimbs held widely separated. The head is held low, there may be a frothy nasal discharge and salivation, and the goat is unwilling to move. Death occurs within two to ten days after onset of clinical signs. Typically there is a 100% morbidity rate and as much as 50% to 100% mortality rates in a susceptible flock (Ojo 1977).

Necropsy Findings and Diagnosis

Serofibrinous pleuritis results in accumulation of straw colored pleural fluid. Pneumonia usually causes hepatization of entire lobes and is often unilateral. The

lung appears granular or variegated, with red, yellow, white, and gray foci. Several reports include color photographs (Kaliner and MacOwan 1976; Thiaucourt et al. 1996; Nicholas 2002). There is extensive broncho-alveolar cellular exudate. In contrast to the findings in goats with pleuropneumonia caused by other organisms, there is no thickening of the interlobular septa (Thiaucourt et al. 1996; Nicholas 2002).

The isolation of the CCPP mycoplasma is difficult and requires special media. Techniques have been described elsewhere (Rosendal 1994; OIE 2004). The agent can be identified by immunofluorescence, growth inhibition, or metabolism inhibition tests (U.S. Animal Health Association 1998). Serologic cross-reactions and similarity in biochemical tests can cause confusion in distinguishing *M. capricolum*. subsp. *capripneumoniae* from *M. capricolum* subsp. *capricolum* (Jones 1989). Paired serology with samples taken three to eight weeks apart is useful for diagnosing the disease in animals that recover, but in acute cases death typically occurs before seroconversion (OIE 2004). A latex agglutination test for field detection of antibodies to *M. c.* subsp. *capripneumoniae* polysaccharide antigen has been reported to be specific for CCPP in goats (Rurangirwa et al. 1990). A PCR testing scheme, when available, is considered conclusive (Hotzel et al. 1996) unless the disease has not been diagnosed in the country before. A very important advantage of the PCR testing is that a sample of pleural fluid from an untreated sacrificed animal can be allowed to dry on filter paper and then transported to a reference laboratory without having to maintain a constant "cool chain."

In countries where CCPP exists, the disease must be differentiated from other or coexisting infections such as pleuropneumonia caused by other mycoplasma infections, peste des petits ruminants, pasteurellosis, heartwater, and goat pox.

Treatment and Control

As with other mycoplasma, treatment with tylosin, tetracycline (El Hassan et al. 1984), tiamulin, or streptomycin (30 mg/kg) (Rurangirwa et al. 1981) is recommended. When tylosin (11 mg/kg), oxytetracycline (15 mg/kg), chloramphenicol (22 mg/kg), and penicillin plus streptomycin (dose per kg not indicated) were compared experimentally, tylosin caused more rapid recovery than oxytetracycline, while fevers were more persistent and some deaths occurred with the other two treatments (Onoviran 1984). More recently, fluoroquinolones have also been found to be effective against caprine mycoplasmas (Al-Momani et al. 2006) but their veterinary use is discouraged or forbidden in food animals because of importance of the antibiotic class in human medicine.

Treatment should be continued for five days or provided with a long duration product (Thiaucourt et al.

1996). The prognosis for recovery with prompt treatment is approximately 87% (Rurangirwa et al. 1981; El Hassan et al. 1984). Animals recovered from clinical disease may remain carriers (El Hassan et al. 1984) and spread the disease to other herds. One study found dihydrostreptomycin-treated goats did not remain carriers (Rurangirwa et al. 1981) but use of this antibiotic is discouraged because of rapid development of resistance (Lefèvre and Thiaucourt 2004). Farmers usually retain animals that survive the infection.

An experimental vaccine has shown good protection for as long as one year after a single immunization (Rurangirwa et al. 1987). Vaccination of 10,000 goats in Kenya with an inactivated F38 vaccine was followed by cessation of reported losses to CCPP after three weeks. None of 400 closely monitored goats showed any evidence of clinical CCPP during the six-month period after vaccination (Litamoi et al. 1989). A commercial vaccine is currently available in Kenya (OIE 2004).

Pleuropneumonia

Etiology

Currently two different species of mycoplasma (*M. mycoides* subsp. *capri* and *M. mycoides* subsp. *mycoides* Large Colony [LC] or caprine type) are believed to cause very similar syndromes known as pleuropneumonia (Pearson et al. 1972). Earlier reports of *M. mycoides* subsp. *capri* from the United States probably reflect a misidentification of *M. mycoides* subsp. *mycoides* LC (DaMassa et al. 1984). *Mycoplasma mycoides* subsp. *capri* has been isolated from a high mortality respiratory outbreak in goats in Mexico (Hernandez 2006).

A closely related species, *Mycoplasma mycoides* subsp. *mycoides* Small Colony type (the cause of contagious bovine pleuropneumonia), has been isolated from pneumonic lungs of goats in Africa (Kusiluka et al. 2000).

Clinical Signs

Incubation is from two to twenty-eight days, depending on virulence. Clinical signs include high fever, cough, painful dyspnea, increased nasal secretion, ear droop, and anorexia. Morbidity rates are near 100%, but mortality rates vary with the organism, less than 40% for the large colony type and close to 100% for the *M. m. capri* subspecies. Since the discovery of *Mycoplasma capricolum* subsp. *capripneumoniae* (F38 biotype), mortality rates attributed to *M. m. capri* have been questioned (Jones 1989).

Diagnosis

In the pleuropneumonia caused by *M. mycoides* subsp. *mycoides* LC, which is common in California, the organism is easily isolated from many internal organs

and from joints and milk. The lungs of fatal cases are enlarged and firm. There is hepatization of cardiac and diaphragmatic lobes and marked pleural effusion and fibrinous pleuritis (Thigpen et al. 1981; DaMassa et al. 1986, 1992; Rodriguez et al. 1995). Both subspecies cause similar histopathologic changes; pulmonary edema is extensive and interlobular septa are distended and pale. Arterial and arteriolar vasculitis with necrosis of vessel walls and thrombi formation are seen (Jones 1989).

Mycoplasma mycoides subsp. *mycoides* LC is less fastidious in its growth requirements than many mycoplasma and can be isolated on blood agar. Growth is slow, beta hemolysis appears by day six or seven, and colonies have a "fried egg" appearance (DaMassa et al. 1983a). Biochemical characteristics and antisera can be used to differentiate the various mycoplasma causing pleuropneumonia and contagious caprine pleuropneumonia, but a polymerase chain reaction scheme has also been devised for differentiating these organisms (Hotzel et al. 1996).

Treatment and Prevention

Kids are often infected by ingestion of milk, and the entire kid crop may be infected by pooled colostrum or milk (DaMassa et al. 1983a). Pasteurization of milk is routinely suggested to control an outbreak. Kids should be raised isolated from adults. Burning or deep burial of placentas and stillborn kids is also important. Tylosin (11 mg/kg intramuscularly for five days to two weeks) has been reported to be more rapidly effective for treatment than oxytetracycline at 15 mg/kg.

Ear mites, which may spread mycoplasma to additional animals or herds, can be controlled with ivermectin (see Chapter 2).

Chlamydiosis

The role of chlamydia in caprine pneumonia is very unclear. A serious outbreak of pneumonia in goats in Japan seemed to originate with goats imported from the United States after World War 2 (Omori et al. 1953; Saito 1954). Elementary bodies of various sizes were seen in bronchial epithelial cells and stained by the Machiavello stain. An agent was isolated in embryonated eggs that caused mild chronic respiratory signs such as slight cough, nasal discharge, and fever after intratracheal inoculation, although secondary bacterial infections were often fatal. Experimentally infected goats were successfully treated with tetracycline (7 mg/kg intramuscularly for eleven days) (Ishii et al. 1954). A cough without dyspnea or nasal discharge developed in two of eleven goats experimentally inoculated with an abortion strain of *Chlamydophila abortus* (*C. psittaci*) and persisted one to two months in another study (Rodolakis et al. 1984).

Texas researchers have proposed that chlamydia are usually primary, with *Pasteurella* and mycoplasma causing a secondary pneumonia (Sharp et al. 1982). This theory does not seem to be commonly espoused, except perhaps in India. Fluorescent antibody tests, as have been used for diagnosis of abortion caused by chlamydiosis, would be a useful tool for additional study of the importance of the organism in pneumonia outbreaks. In a slaughterhouse study in India involving 3,799 apparently healthy goats, chlamydia were identified from fourteen of 218 (6.4%) pneumonic lungs by fluorescent antibody tests (Rahman and Singh 1990). Special stains identified elementary bodies in only eight of these cases. Gross lung lesions were mostly cranioventral. Histologically, there was an interstitial pneumonia and macrophages filled alveoli. Additional slaughterhouse studies have identified chlamydia in lung lesions of unknown clinical relevance by special stains or fluorescent antibody tests (Chauhan and Singh 1971; Patnaik and Nayak 1984; Kumar et al. 2004).

Too little is known about the condition to formulate control programs. Different chlamydia serotypes are incriminated from those included in anti-abortion vaccines. Long-lasting oxytetracycline would be appropriate for therapy if involvement of this agent were suspected in field cases of pneumonia.

Q Fever

Q fever, caused by *Coxiella burnetti*, is occasionally associated with abortion in sheep and goats but is otherwise considered to be nonpathogenic for livestock. Its importance is as a zoonosis. However, experimental intrapulmonary or intranasal inoculation has produced febrile bronchopneumonia in goats (Caminopetros 1948). Kids from an abortion outbreak have also shown nonsuppurative interstitial pneumonia (Moore et al. 1991).

BACTERIAL PNEUMONIA

Pasteurella and Mannheimia Pneumonia

Pneumonic pasteurellosis is a cranioventral fibrinous bronchopneumonia. The disease occurs in goats throughout the world.

Etiology

Both *Pasteurella multocida* and *Mannheimia* (previously *Pasteurella*) (Angen et al. 1999) *haemolytica* cause pneumonia in goats (Ojo 1977). Both species are Gram-negative, tiny, ovoid rods that do not form spores. They grow well on blood agar, where only *P. haemolytica* causes hemolysis. Colonies are 1 to 2 mm in diameter. *Pasteurella multocida* but not *M. haemolytica* produces indole.

Mannheimia (Pasteurella) haemolytica was previous divided into two biovars: biovar A, which ferments arabinose, and bivoar T, which ferments trehalose (Bingham et al. 1990). Subsequently, the T biovar was designated as *Pasteurella trehalosi*, and then the organism was assigned to a new genus, becoming *Bibersteinia trehalosi* (Blackall et al. 2007). How this might clarify the epidemiology of pasteurellosis in goats remains to be determined. The *trehalosi* organism has been cultured from the pharynx of healthy pack goats (Ward et al. 2002). A biotype T isolate obtained from an acute fatal case of caprine pneumonia has been used to experimentally produce a proliferative and exudative pneumonia (Ngatia et al. 1986). Biotype T *Mannheimia haemolytica* has also been cultured in association with an outbreak of contagious caprine pleuropneumonia in Ethiopia (Shiferaw et al. 2002). When typing has been performed of *Mannheimia* isolates from goats with pneumonia, *M. haemolytica* type A2 has been reported most frequently (Fodor et al. 1984; Midwinter et al. 1986; Hayashidani et al. 1988).

Epidemiology and Pathogenesis

Both of these organisms commonly reside in the upper respiratory tract of normal goats. While a previous viral infection would increase the probability of lung invasion by *Pasteurella* or *Mannheimia*, field conditions often provide enough stress for the organism to be a primary pathogen. Poor ventilation is a major factor permitting invasion of the lungs, but crowding, parasitism, and malnutrition all contribute to development of disease (Brogden et al. 1998). Some affected goats have been recently stressed by transport (Mugera and Kramer 1967), and steroid administration appears to increase the proliferation of *M. haemolytica* in the nasal passages of transport-stressed goats (Jasni et al. 1991).

The virulence of the *Pasteurella* organism is either very high or increases during an outbreak, so that the disease may spread to unstressed herd members (Pande 1943). In other instances, pneumonia is recognized only in animals exposed to newly introduced goats (Hayashidani 1988; Buddle et al. 1990).

A ruminant-specific leukotoxin produced by *M. haemolytica* is believed to be very important in the pathogenesis of pasteurellosis (Shewen and Wilkie 1985; Zecchinon et al. 2005). This toxin impairs and lyses alveolar macrophages and neutrophils that arrive in the lung to fight the infection. Enzymes released by the dying neutrophils cause additional injury to lung tissue. The deleterious effects of other toxins and cell-associated products of *M. haemolytica* have been reviewed (Brogden et al. 1998).

Clinical Signs

In the acute case, there is typically a fever of 104°F to 106°F (40°C to 41.1°C) and also mucopurulent nasal and ocular discharge. Lethargy, anorexia, dyspnea, and a moist, painful cough are noted. Auscultation may reveal crackles, areas of consolidation (increased bronchial tones), or pleuritis (friction rub early, muffled sounds later). Mortality rates may be 10% or more. Commonly, one goat is found suddenly dead before any are noticed to be ill (Borgman and Wilson 1955; Mugera and Kramer 1967).

Diagnosis and Post Mortem Lesions

Diagnostic cultures may be obtained from tracheal washes or from necropsy specimens. Cultures taken from the nasal passages are not acceptable substitutes. Kids with acute pasteurellosis often have a septicemia, and bipolar organisms may be visible in stained blood smears (Ojo 1987). A radiographic examination documents the cranioventral distribution and rules out the presence of a penetrating metallic foreign body from the reticulum, which rarely acts to introduce infection into the thoracic cavity (see Chapter 10).

At necropsy, the cranioventral lung lobes are usually affected bilaterally. There is a red to purple consolidation of these lobes, sometimes accompanied by a fibrinous pleuritis (Figure 9.7). Histologic changes are typical of pasteurellosis in other species and include hemorrhage, necrosis, and exudation of fibrin, edema fluid, and neutrophils or macrophages into airways.

A *Pasteurella* or *Mannheimia* infection may be secondary to an interstitial pneumonia or possibly may upregulate the CAE virus when macrophages are activated in the lung. If poor body condition suggests that a dead goat has been ill for weeks or months, the dorsal lung lobes should be palpated very carefully. If they seem firmer than normal, histological examination to detect concurrent interstitial pneumonia should be requested.

Figure 9.7. Cranial ventral localization of a *Mannheimia* pneumonia with marked fibrinous pleuritis. (Courtesy of Dr. M.C. Smith.)

Treatment and Prevention

Antibiotics commonly used for parenteral treatment include penicillin (20,000 to 40,000 IU/kg once daily), ampicillin (5 to 10 mg/kg twice daily), tetracycline (5 mg/kg once or twice daily), tylosin (10 to 20 mg/kg once or twice daily), ceftiofur (1.1 to 2.2 mg/kg daily), and florfenicol (40 mg/kg every one to two days SC). A sample for culture obtained by tracheal wash or at necropsy should be submitted for sensitivity testing when dealing with herd outbreaks, chronic cases, or very valuable goats. However, caprine isolates of *Mannheimia* and *Pasteurella* are not often resistant to antibiotics routinely used for respiratory disease, as determined by the disk diffusion assay method (Berge et al. 2006). Ventilation should be corrected to decrease humidity in the barn, so that there is no condensation on windows and walls. Nutrition, including vitamin E and selenium, should be optimized. Newly introduced goats should be kept isolated from the herd for at least two weeks.

In some outbreaks, young kids appear to be especially susceptible to pasteurellosis in a septicemic or pneumonic form. Colostral transfer of antibodies may be very important in preventing these infections of the neonate (Gourlay and Barber 1960).

No bacterin has been proven effective against pasteurellosis in goats. This is partly because of a multitude of serotypes possible (Ward et al. 2002) and partly because the antibodies produced in response to vaccination may contribute to damage of pulmonary tissue when infection occurs. A commercial vaccine containing multiple sheep isolates decreased lung lesions in goats in one small trial (Zamri-Saad et al. 1999). A toxoid vaccine directed against the leukotoxin produced by *M. haemolytica*, as developed for cattle (Bechtol et al. 1991), may prove more useful but needs further evaluation in goats (du Preez et al. 2000). Recently, *M. haemolytica* A1 organisms embedded in microagar beads and deposited in lung tissue by the transthoracic (Purdy et al. 1990, 1993) or subcutaneous (Purdy 1996) route have induced significant immunity to challenge exposure in goats. If goats become more popular models for bovine respiratory disease, an effective vaccine may eventually be developed.

Caseous Lymphadenitis Abscesses in the Lungs

Corynebacterium pseudotuberculosis abscesses are most commonly found in the head and neck lymph nodes (see Chapter 3), but abscesses may form in the lung parenchyma or mediastinal lymph nodes. In one slaughterhouse study of 25,467 goats in India, pseudotuberculosis lesions were seen primarily in the lungs of eighty-nine (0.349%) goats, and thirty of these animals had similar lesions in bronchial or mediastinal lymph nodes (Sharma and Dwivedi 1976b).

Clinical and Necropsy Signs and Diagnosis

Because the incubation period is long, this is a chronic pneumonia in adult goats and sheep. Clinical signs of dyspnea, exercise intolerance, and weight loss resemble the signs of progressive interstitial retroviral pneumonia. One to many abscesses may be present in any part of the lung. The abscesses are round, greenish-yellow, encapsulated, and caseo-purulent or caseo-calcified. Radiographic studies help distinguish the pneumonia from the cranioventral, lobar distribution of pasteurellosis. Pleuritis may occur when abscesses rupture into the pleural cavity, but crackles from exudate moving in airways are not routinely auscultated. Histologic examination reveals concentric zones of necrotic neutrophils, round cells (i.e., macrophages, lymphocytes, and occasional giant cells), and fibrosis. Presence of Gram-positive diphtheroid bacteria and absence of acid-fast bacteria help to rule out tuberculosis (Sharma and Dwivedi 1976b).

Diagnosis

In the absence of external abscesses, diagnosis is difficult without a tracheal wash or necropsy examination. If the goat is in a closed herd that has never experienced contagious abscesses, the probability of caseous lymphadenitis is minimal. Serological test results for the organism (see Chapter 3) in affected goats are usually positive, but this cannot be used to confirm a diagnosis of the pneumonic form of caseous lymphadenitis in a herd in which goats are frequently affected with external abscesses. Positive serologic test results also occur during the incubation period of an external abscess and after its resolution by drainage.

Treatment

Long-term antibiotic treatment has little effect on the abscesses. A possible exception might be the combination of penicillin or oxytetracycline and rifampin (Chapter 3). Because the condition is most readily confused with the equally untreatable retroviral pneumonia, euthanasia is warranted when other conditions amenable to therapy have been excluded from the differential diagnosis.

Prevention

The pulmonary form of caseous lymphadenitis is reportedly common in infected flocks of sheep that are driven through a dipping vat immediately after shearing. The dipping solution becomes contaminated with pus from open abscesses and is then swallowed or inhaled by other animals in the flock. Angora and Cashmere goats should be at similar risk. Dipping should be postponed until at least two weeks after

shearing if the disease is present in the flock. Another mode by which infection reaches the lungs is by drainage of the thoracic duct into the systemic circulation. Finally, aerosol transmission from another animal with pulmonary abscesses is possible, although intranasal inoculation failed to produce abscesses in experimental goats (Brown et al. 1985). Thus, culling all goats with external abscesses or chronic wasting is important to preventing pulmonic caseous lymphadenitis.

Tuberculosis

Contrary to the fervent belief of many hobbyists, goats are susceptible to tuberculosis (Ramirez et al. 2003). Goats may serve as a reservoir of infection for cattle or they may directly infect humans. On the other hand, humans with tuberculosis (especially if immunocompromised by concurrent human immunodeficiency virus infection) are a potential source of tuberculosis infection for goats.

Etiology

Mycobacterium bovis typically causes pulmonary lesions in goats, whereas *M. avium* is generally associated with intestinal involvement. Infection of goats seems to occur infrequently, even in regions where cattle and swine tuberculosis is prevalent (Nanda and Singh 1943; Thorel 1984). *Mycobacterium tuberculosis* (human type) is a rare cause of generalized caprine tuberculosis (Sharma et al. 1985). Recently, some strains of *M. tuberculosis* isolated from goats, cattle, wildlife, and humans in Europe and having multiple IS*6110* insertion sequences have been classified as a new species, *M. caprae* (Prodinger et al. 2005). These include strains previously identified as *M. bovis* subsp. *caprae* or *M. tuberculosis* subsp. *caprae*, calling into question the species identification in the earlier literature. *Mycobacterium kansasii* has been cultured from the mediastinal lymph nodes of one tuberculin positive goat during a tuberculosis eradication effort in the Canary Islands (Acosta et al. 1998).

Tubercle bacilli are Gram-positive, acid-fast, and aerobic. Culture is easily done in Dorset or Stonebrinks medium. Primary cultures require three to four weeks before colonies are visible. The organisms are killed by pasteurization but may survive for a long time in moist soil or organic matter.

Clinical Signs

In countries where tuberculosis still occurs in livestock, pulmonary tuberculosis caused by *Mycobacterium caprae* and possibly other species may cause severe respiratory signs in goats or remain in a subclinical stage. Weight loss, poor milk production, anemia, and moderate coughing are possible clinical signs (Bernabé et al. 1991) but are nonspecific. Some goats also have firm nodular lesions in the udder.

Diagnosis

Diagnosis in living goats is ordinarily made by an intradermal tuberculin test, performed as for cattle. In the United States, only federal, state, and accredited veterinarians may perform a tuberculin test. A 26-gauge, 1-cm needle is used to inject 0.1 ml of PPD Bovis tuberculin intradermally in one tail fold. The test result is determined by observation and palpation at seventy-two (±6) hours (USDA 2006). Other countries may require injection of the tuberculin in the cervical skin, and this site is used in the United States for a comparative cervical test where the reaction to *M. bovis* antigen is compared to the reaction to *M. avium* antigen. False-positive skin tests may be seen in herds infected with or practicing vaccination against paratuberculosis, because of a potential for mycobacterial cross reactions. Numerous dual infections with the two mycobacterial species have been observed, however, in goats in Spain (Bernabé et al. 1991).

An appropriate serologic test may be helpful in confirming a diagnosis of tuberculosis in animals from herds that are also infected with paratuberculosis (Acosta et al. 2000). A bovine gamma interferon test for cell mediated response using bovine PPD was positive in one tuberculin skin test positive goat from which *M. bovis* was isolated but was also positive in twelve other skin test negative goats which were negative on culture (Cousins et al. 1993). Thus, the gamma interferon test may have poor specificity in exposed but apparently uninfected goats.

Various authors report caseation, calcification, and encapsulation of lesions in lymph nodes; in the parenchyma of the lung, liver, and spleen; and in the peritoneal and pleural cavities (Murray et al. 1921; Carmichael 1938; Bernabé et al. 1991). When caseous granulomas are found in the lungs at slaughter or at necropsy, histology (including acid fast stains) and culture are necessary to confirm the diagnosis. Other agents that might cause a similar pneumonia include *Yersinia pseudotuberculosis* (Rajagopalan and Sankaranarayanan 1944), *Burkholderia* (*Pseudomonas*) *pseudomallei*, *Rhodococcus equi* (Carrigan et al. 1988), and *Corynebacterium pseudotuberculosis*. Granulomatous pneumonia caused by the opportunist *Cryptococcus neoformans* together with *M. bovis* has been reported in a goat that was negative on intradermal and serologic tests for tuberculosis, suggesting an underlying immunodeficiency (Gutiérrez and García Marin 1999).

Control

Government regulations concerning herd quarantine and removal of infected animals must be followed. Cleaning and disinfection with Virkon® (Antech International) or a cresol product such as 5% phenol solution should be stressed, with special attention to feed

troughs and water containers. Other livestock species on the premises and the human caretakers should be tested for tuberculosis. Milk fed to goats and humans should be pasteurized.

Melioidosis and Rhodococcal Pneumonia

Melioidosis is a disease in tropical regions caused by *Burkholderia* (*Pseudomonas*) *pseudomallei.* Infected goats may develop respiratory signs including coughing and dyspnea on exercise. Abscesses often form in external lymph nodes and lungs. Abscesses are frequently 2 to 5 mm in diameter (but may be larger) and may coalesce in the lungs. Abscess contents are white, cream colored, or greenish, and are viscous, caseous, or dry (Thomas et al. 1988). Affected animals are culled because of the danger of human infection. This condition is discussed in Chapter 3.

Disseminated *Rhodococcus equi* infection was identified in two goats, one of which had raised nodules in the lungs containing off-white caseous material arranged in concentric layers. An enteric route of entry was suspected because of extensive abscessation of the liver. The organism isolated appeared to lack virulence antigens normally present in strains pathogenic for foals (Davis et al. 1999). Similarly, rhodococcal pneumonia in a yearling Angora was confirmed by culture of *R. equi* from pulmonary abscesses that ranged from 0.5 to 4 cm in diameter and resembled the lesions of caseous lymphadenitis (Fitzgerald et al. 1994).

FUNGAL PNEUMONIA

Fungi rarely cause primary pneumonia in goats.

Cryptococcosis

Cryptococcus neoformans is a saprophytic fungus common in soil and in bird droppings. It is yeast-like when grown on Sabouraud's glucose agar. A halo-like capsule surrounds the single cell, which may be budding; this morphology is distinctive (Gillespie and Timoney 1988). Focal lesions have been found in the lungs of goats slaughtered in the West Indies (Sutmoller and Poelma 1957). The major loss seems to be associated with carcass condemnation. In Western Australia, cryptococcal pneumonia is reported to be associated with clinical signs that include nasal discharge, coughing, dyspnea and ill thrift (Baxendell 1988; Chapman et al. 1990). In Spain, affected goats had wasting and respiratory signs, but sometimes liver or brain was also involved (Baro et al. 1998). No effective, economical treatment has been developed.

Other Fungi

Although reports are few, other fungi can contribute to pneumonia in a goat that is immunosuppressed or that experiences inhalation of rumen contents. Animals

that receive corticosteroids simultaneously with antibiotics may be at special risk.

Mycotic organisms isolated from goat lungs in slaughterhouse or necropsy studies include *Aspergillus fumigatus*, *A. flavus*, *Nocardia* spp., *Penicillium* spp., and *Candida* spp. (Ikede 1977; Pal and Dahiya 1987; Chattopadhyay et al. 1992). Grayish nodules in the lungs may be seen and observation of organisms in histologic sections of lung and lymph node confirms the nature of the lesion, but clinical significance is unknown.

ENZOOTIC PNEUMONIA

Enzootic pneumonia is an ill-defined term that has been applied to both acute exudative bronchopneumonia and to chronic, nonprogressive, pneumonic lesions found at slaughter or necropsy. Cranioventral lobes are typically affected; they are a darker red than the rest of the lung and are consolidated. It is often assumed that viruses or mycoplasma initiated the pneumonia but that only secondary bacteria such as *Pasteurella* and *Mannheimia* spp. and *Arcanobacterium* (previously *Actinomyces) pyogenes* can still be isolated from the lungs.

Enzootic pneumonia is also a term used to encompass a variety of lung infections occurring in stressed animals. The stress may be provided by malnutrition, shearing, a change in the weather (cold or rain), or the presence of other diseases. Coccidiosis, because of the malnutrition produced by this very common intestinal disease, could be a major predisposing factor for enzootic pneumonia. Increased levels of glucocorticoids then lower the animal's resistance to infection by adversely affecting both cellular and humoral immunity.

In a scenario similar to the shipping fever complex of cattle, it has been proposed that viruses interfere with macrophage function and with the ability of cilia in the tracheal mucosa to transport inhaled bacteria away from the lungs (i.e., mucociliary clearance) (Brogden et al. 1998). A variety of viruses have been incriminated in the process (Daft and Weidenbach 1987); in general, documentation of pathogenicity to goats is scanty. Research conducted with lambs, however, is assumed to be applicable to both species. Parainfluenza virus 3 (Obi and Ibu 1990) and several serotypes of adenovirus (Woods et al. 1991; Lehmkuhl et al. 1997) may participate in multifactorial pneumonic processes.

Some sheep flocks in the United States have used a half dose of PI3 or IBR-PI3 vaccine intranasally because parainfluenza 3 predisposes the sheep to pneumonia. All adults are vaccinated, and then lambs are vaccinated as soon after birth as possible (Lehmkuhl and Cutlip 1985; Rodger 1989). There has been apparent efficacy in some flocks, but a practitioner should certainly not recommend such a program in goats without

first documenting the activity of the PI3 virus in the disease process to be combated, either by viral isolation or paired serology. It is also undesirable to inoculate goats or sheep with a live IBR vaccine because of the possibility that they will shed the virus later and thereby infect cattle or even become sick themselves with the bovine vaccine strain.

A respiratory syncytial virus distinct from bovine RSV also has been isolated from goats with severe coughing, oculonasal discharge, and fever (Lehmkuhl et al. 1980; Martin 1983), as discussed above.

Caprine herpesvirus (bovid herpesvirus type 6) has been isolated from the lungs and from nasal swabs of goats dying of *M. haemolytica* pneumonia (Buddle et al. 1990b). Experimental inoculation of the virus followed six days later by *M. haemolytica* resulted in pneumonia in five of six goats (Buddle et al. 1990a). *Mannheimia* alone also caused pneumonia (three of six), but the virus alone caused only catarrhal rhinitis and mild tracheitis. Thus, the role of this virus in producing pneumonia remains uncertain.

PARASITIC PNEUMONIA

Verminous pneumonia resulting from one or more species of lungworms occurs in most parts of the world. Liver flukes and tapeworm cysts have more restricted ranges.

Dictyocaulus Pneumonia

Etiology and Epidemiology

Although *Dictyocaulus filaria* is cosmopolitan, in many parts of the world this lungworm is not very common in goats. This may be caused in part by the tendency to keep young goats off pasture under intensive management systems. In India, sheep and goats graze the same infested pastures, and goats are believed to be more susceptible to the parasite (Dhar and Sharma 1978a).

Pathogenesis

Dictyocaulus filaria lungworms have a direct life cycle (Bowman et al. 2003; Panusaka 2006). Adults live in bronchi and are approximately 30 to 80 mm long. First-stage larvae approximately 550 µm long are coughed up and eliminated in the feces. Development to an infective stage takes one to two weeks. These third-stage larvae are long-lived in damp, cool surroundings. After ingestion, there is a one-month prepatent period and three months patency. Signs can occur as early as three weeks after the goats are put on pasture in the spring, but usually occur in autumn. Kids are most severely affected during their first season on pasture; age resistance is via prior exposure (Wilson 1970). The L4 can last the winter in lungs, but freezing kills larvae on pasture, as does a hot, dry summer.

Clinical Signs

The main sign during the prepatent period is polypnea; dyspnea develops later in the course of infection. The worms cause bronchial irritation, resulting in cough, moderate dyspnea, and loss of condition. Pathologic findings include bronchitis, bronchiolitis, atelectasis, and emphysema. Auscultable crackles and wheezes, fever, and toxemia occur if there is a secondary bacterial infection. Eosinophilia is marked in reexposed animals. An acute shock syndrome is seen when a significant reinfestation occurs after immunity has weakened.

Diagnosis

The diagnosis of verminous pneumonia is best done by the Baerman technique. Feces are collected fresh from the rectum to avoid confusion with *Strongyloides* larvae. Fecal pellets are put in a tea strainer or wrapped in gauze and half submerged in a funnel of warm 77.7°F (25°C) water; larvae fall to the neck of the funnel. A conical flask may provide a better yield than the traditional funnel system (McKenna 1999). The larvae are harvested after four to twenty hours and compared with photos in a parasitology text. The posterior is blunt in *Dictyocaulus*, whereas it is slender and pointed in *Protostrongylus* and has a definite dorsal spur in *Muellerius* (Bowman et al. 2003). Fecal exams for *Dictyocaulus* are positive during the patent period of the first infestation only.

Treatment and Control

Anthelmintics effective against *Dictyocaulus* are routinely used in goats, which probably decreases the prevalence of the disease. Treatments include tetramisole (15 mg/kg) (Kadhim et al. 1972) or levamisole (7.5 mg/kg) orally or subcutaneously. The drug is eliminated by the respiratory tract. Also reported to be effective are mebendazole (15 to 20 mg/kg), fenbendazole (5 to 10 mg/kg), febantel (5 mg/kg), and ivermectin (0.2 mg/kg). Owners should be advised not to sell milk or make it into cheese for at least four days after unapproved drugs are used. The milk withdrawal period for ivermectin should probably last at least nine days after oral use and forty days after subcutaneous injection (Baynes et al. 2000).

Treatment does not allow establishment of immunity, so goats should not be returned to infected pastures. Frequent pasture rotation is often an impractical means of control because moving the goats every four days would be required. Putting the goats out on pasture early in the season allows progressively increasing exposure and immunity. New goats should be separated from yearlings, and kids should not be placed on pastures inhabited by yearlings within the last year. The goats are treated after stabling in the fall

(a warm, humid barn allows the cycle to continue) to limit pasture contamination next spring. Other suggestions include avoiding overpopulation, draining wet pastures, and replacing ponds with watering devices on concrete slabs. An irradiated *Dictyocaulus* larvae vaccine has protected goats against experimental challenge (Dhar and Sharma 1978b; Sharma 1994).

Protostrongylids

Etiology

Protostrongylid lungworms include at least five genera. Two are well recognized in the United States; *Muellerius capillaris* is diagnosed more frequently than *Protostrongylus rufescens*. Two more (*Cystocaulus ocreatus* and *Neostrongylus linearis*) are recognized in Europe and northern Africa (Genchi et al. 1984; Perreau and Cabaret 1984; Berrag and Urquhart 1996), while *Varestrongylus pneumonicus* (*Bicaulus schulzi*) is found in eastern Europe and India.

Epidemiology and Pathogenesis

All types have an indirect life cycle and use a variety of snails and slugs as intermediate hosts. The mollusks remain infective for at least one year. Goats and sheep become infected by eating mollusks or third-stage larvae liberated on foliage by death of the intermediate host.

Protostrongylus rufescens adults live in bronchi and are approximately 16 to 35 mm long. The first stage larvae are 370 to 400 μm long and have a pointed tail (Gerichter 1951). Massive infections are unlikely, and only kids show any clinical involvement.

Muellerius lungworms usually cause clinically insignificant focal lesions in the lung parenchyma. Adults are present twenty-five to thirty-eight days after infection (Panuska 2006). They are 12 to 23 mm long and located in subpleural alveoli, never in the bronchi. First stage larvae approximately 300 to 320 μm long (Gerichter 1951) with a distinctive dorsal spur on the tail (Figure 9.8) are passed in the feces if both sexes are present in the same nodule. The infestation is carried over from one year to the next in the goat. Fewer adult worms are established following reinfection but the inflammatory response in the lungs is much more severe (Berrag et al. 1997). Goats do not develop a marked age resistance, and in fact older animals often have heavier infections than those on pasture for only one season. This is in contrast to sheep, which tend to clear the infection.

At least forty species of snails and slugs serve as intermediate hosts for *Muellerius*. A French study found abundant *Helix aspersa* in spring and *Deroceras reticulatum* in autumn to be associated with an increased risk of infection in grazing goats (Cabaret et al. 1986). Almost any goat that has been on pasture in temperate

Figure 9.8. Larva of *Muellerius capillaris*, showing dorsal spur on tail. (Courtesy of A. Lucia-Forster.)

regions of the United States has *Muellerius* larvae on Baerman examination (see above). In a Norwegian study, larvae were found in the feces of 447 out of 457 goats from seven flocks (Helle 1976).

Cystocaulus ocreatus has a very similar life cycle to *Muellerius*. It also forms nodules in the lung parenchyma, and uses many of the same mollusks as intermediate hosts. The first stage larvae are 390 to 420 μm long. The larvae are identified by a distinctive tail tip with two appendages (Gerichter 1951). The two species may be found simultaneously in the same goat.

Clinical Signs and Necropsy Findings

Muellerius infestations are usually subclinical. However, there are scattered reports of serious, even fatal pneumonia resulting from heavy *Muellerius* infestations. For instance, Lloyd and Soulsby (1978) found twenty of twenty-four herds infected with *Muellerius*. Eighty-three percent of 169 goats in these herds were passing larvae, including 100% of goats three years of age or older. Dyspnea and a persistent cough were noticed in four adult goats with higher than average larval counts, suggesting that the parasite may be pathogenic in heavily infested goats. In a Swiss herd of CAE-free Saanen goats, all nine adults displayed coughing that abated only temporarily with anthelmintic treatment. Many *Muellerius* larvae were present in the feces of all and in several goats first stage larvae and neutrophils were demonstrated in an increased amount of viscid bronchial secretion by endoscopy (Braun et al. 2000). Hematology and serum biochemistry test results were unremarkable in these goats. A possible association of *Muellerius* with decreased body weight has been reported in New Zealand (Valero et al. 1992).

Lesions (firm tan nodules) are most common in the caudal dorsal lung lobes and are less well localized in goats than in sheep. A frequently cited report (Nimmo 1979) ascribed a diffuse thickening of alveolar septa with mononuclear cell infiltrates to *Muellerius*. That paper suggested that diffuse (non-nodular) lesions occurred in cases of reduced host resistance, because eosinophils were more prominent in focal nodular lesions. Because L1 larvae, eggs, and adult worms in "brood nodules" are readily identified in histologic preparations of the lung (Gregory et al. 1985), it must be remembered that other conditions (such as progressive retroviral pneumonia) must be excluded before ascribing a clinically important pneumonia to these parasites. Also worth considering is the possibility that *Muellerius* lungworms contribute to clinical retroviral infection by attracting many macrophages to the lungs (Ellis et al. 1988a).

Treatment

Recommended treatments for *Protostrongylus* include levamisole and fenbendazole at dosages used for *Dictyocaulus*.

Levamisole is not effective against *Muellerius*. When considering drugs and dosages for *Muellerius* given in the literature, it is not always evident if efficacy was determined by death of the protostrongylids or a temporary infertility of the worms (Cremers 1983). Two treatments with fenbendazole at 15 mg/kg, three weeks apart, relieved clinical signs and completely eliminated shedding of larvae two weeks later (Kazacos et al. 1981). Extended studies revealed that larval shedding resumed in most goats by seven weeks after 30 mg/kg fenbendazole (Bliss and Greiner 1985). Another study found that shedding of larvae resumed many weeks after treatment with either fenbendazole or ivermectin; 25% of ivermectin-treated animals resumed shedding from four to more than nine weeks later. The authors assumed that immature *Muellerius* in the lungs resumed development after death of adult worms (McCraw and Menzies 1986, 1988). Treatment at approximately thirty-five-day intervals has been suggested. Topical eprinomectin at 0.5 mg/kg has been shown to prevent larval shedding for six weeks or maybe more (Geurden and Vercruysse 2007). Netobimin at 20 mg/kg (once orally or divided into two or three doses) failed to completely eliminate shedding or kill all adult *Muellerius* at day eighteen (Cabaret 1991). For other drugs such as mebendazole (20 to 40 mg/kg) and oxyfendazole (7.5 to 10 mg/kg) (Cabaret et al. 1984), the dose suggested is typically double that used for digestive strongyles.

Control

In Scandinavia, a protocol has been developed to specifically control *Muellerius* in goats. During the period when the goats are stabled and not lactating, fenbendazole is fed at 2 mg/kg/day for fourteen days. Prolonged low-level treatment reduces larval shedding for five to seven months (Helle 1986). This treatment is believed to decrease the prevalence of coughing and increase subsequent milk production and body-weight gains (Hammarberg 1992). The possible teratogenic effects of anthelmintics have not been well studied in goats, and it is prudent to avoid treatment during the first thirty-five days of pregnancy. Also, such a treatment program should not be undertaken when the goats are on pasture, because it might select for resistant gastrointestinal parasites.

Wet, undrained pastures should be avoided. It may be helpful to prevent grazing in early morning or evening when the herbage is damp and snails are up and about. It is best to treat before pasture season in the spring, to prevent contamination of mollusks. A second treatment in early fall is used in heavily contaminated environments.

Eimeria and Other Protozoa

A persistent cough is often associated with severe coccidial infection in young kids, though no adequate explanation has been advanced. The connection may be only that kids stressed by the poor nutritional state that accompanies coccidiosis are more prone to bacterial pneumonia. Prophylaxis includes keeping kids out of feeders, separate from adults, and in a dry environment. A systemically absorbed sulfonamide would be reasonable treatment for such kids.

There is a single case report of the presence of cysts and trophozoites of *Balantidium coli* in the lungs of a goat with interstitial pneumonia and *Dictyocaulus filaria* larvae (Parodi et al. 1985). Because this ciliated protozoon normally inhabits the large intestine, it might have been carried to the lungs by lungworm larvae.

Pneumocystis carinii was found filling the alveolar air spaces of a four-month-old Boer goat with severe diffuse interstitial pneumonia (McConnell et al. 1971). In other species, at least, this organism is usually associated with immunosuppressive conditions.

Besnoitia cysts (diameter 60 to 280 μ) were reported in the alveolar septa of the lungs of two adult goats from Kenya with purulent necrotizing bacterial pneumonia (Kaliner 1973). It has been proposed that the species of *Besnoitia* infecting goats, *B. caprae*, is distinct from that infecting cattle, at least in Kenya (Njenga et al. 1993).

Echinococcosis, Hydatidosis

Echinococcus granulosus hydatid cysts occur in goats in many parts of the world, especially Mediterranean countries, India (Upadhyaya 1983), and Africa. Dogs are the definitive host and herbivores or humans are

intermediate hosts. Goats appear to be less susceptible to infection than sheep in a given area, possibly because browsing causes less exposure to dog feces than does grazing (Rausch 1995). Cysts are most often observed in liver and lungs in goats (Pandey 1971; Perreau and Cabaret 1984), and the condition is discussed in greater detail in Chapter 11. Transplacental infection is possible. The cysts can be as large as a fist but are typically pea- to plum-size. The surface of the lung is distorted by focal collapse and emphysema. Older goats have more and larger cysts. They rarely cause specific clinical signs. No practical treatment has been found effective against the parasite in goats (Thompson and Allsopp 1988).

Prevention of zoonotic infection requires breaking the cycle between definitive and intermediate hosts (Gemmell 1979). All dogs should be treated (preferably with praziquantel) and feces passed after treatment should be destroyed. Eggs excreted in feces of dogs remain infective for at least one year. Wild dogs must be controlled. Access by dogs to carcasses of ruminants that die or are slaughtered on the farm or at the local slaughterhouse must be prevented. These measures are very difficult to enforce. More recently, vaccination of ruminants using a recombinant oncosphere peptide combined with twice-a-year dog dosing has shown promise (Craig and Larrieu 2006). Lambs and sheep are vaccinated twice at a one month interval, with a booster six to twelve months later. Reports of the use of this vaccine in goats are not yet available.

The dog tapeworm *Taenia multiceps* (*Multiceps gaigeri*) has also caused cysts within the thoracic and abdominal cavities and in muscles of goats in the Sudan (Hago and Abu-Samra 1980).

Liver Flukes

Both *Fasciola hepatica* and *Fascioloides magna* occasionally invade the lung. Their large size and the dark pigment that often accompanies them make the diagnosis at necropsy simple. Accompanying liver disease would be expected to overshadow any clinical signs originating from the lungs.

Schistosomosis

Pulmonary schistosomosis (*Schistosoma indicum*) has been reported in goats in India (Sharma and Dwivedi 1976a; Dadhich and Sharma 1996). Granulomas occur diffusely throughout the lung where adult parasites have laid eggs in pulmonary vessels. Emaciation and dyspnea may occur. The lesions grossly resemble retroviral interstitial pneumonia. Schistosomosis is discussed in Chapter 8.

INHALATION PNEUMONIA

Inhalation or aspiration of feed, saliva, or medication causes a cough and a nonspecific pneumonia from which a mixture of organisms can often be isolated. Unless foreign material such as a plant awn (King 1989), feed particles, or mineral oil is found in the affected lung at necropsy, the true etiology of the pneumonia may be overlooked.

Nutritional Muscular Dystrophy

Aspiration is a common sequela to nutritional muscular dystrophy (white muscle disease) in rapidly growing, well-fed kids. These kids cough after drinking and milk may appear at the nostrils because of weakness of the muscles of deglutition in the pharynx and tongue. Other animals in the herd may show stiffness, heart failure, dandruff, or off-flavored milk. A subcutaneous injection of vitamin E and selenium is reasonable adjunctive therapy for any kid with pneumonia. The diagnosis and prevention of nutritional muscular dystrophy are discussed in detail in Chapters 4 and 19.

Iatrogenic Inhalation Pneumonia

Although cleft palate and inadequate function of pharyngeal and laryngeal muscles due to nutritional muscular dystrophy can occur in very young kids, improper force feeding is a common cause of inhalation in this age group. It is far better for a kid to be tube-fed (see Chapter 19) than for milk to be dripped or squirted into the mouth of a kid that is unable to swallow.

Errors in administration of medication (e.g., anthelmintic drench, propylene glycol, mineral oil) can cause inhalation pneumonia. Dyspnea, cyanosis, mild fever or subnormal temperature, nasal discharge, mild coughing, crackles, and wheezes are often noted within a few hours after improper drenching. A radiograph reveals a ground glass appearance of involved areas of the lung (Ahuja et al. 1985).

When eliciting a complete history, it is prudent to ask if anything has been given orally before questioning the carefulness of administration. If surgery has been recently performed by another veterinarian, that veterinarian rather than the owner should be asked if a cuffed endotracheal tube was used. Proper positioning of the anesthetized goat so that the thorax is above the abdomen and the head hangs lower than the neck usually avoids inhalation problems when use of an endotracheal tube is not possible.

Neurologic Causes of Dysphagia

Any neurologic disease that interferes with the goat's ability to swallow can cause secondary pneumonia. The most common of these are listeriosis and caprine arthritis encephalitis, but pituitary abscess, cerebrospinal nematodiasis, and botulism are other possibilities.

Plant Poisoning

Plant poisoning with members of the heath family (*Ericaceae*), including rhododendrons, laurels, and Japanese pieris, produces a syndrome of abdominal discomfort that normally includes vomiting as a prominent sign (Knight and Walker 2001). Goats that have received a sublethal dose of the toxic principles, grayanotoxins, may develop inhalation pneumonia subsequent to vomiting. Therefore, prophylactic antibiotics are indicated when poisoning with these plants occurs. Consumption of sneezeweeds (*Helenium* and *Dugaldia* spp.), bitterweed (*Hymenoxys* spp.), and desert baileya *(Baileya multiradiata)* on ranges in the western United States has also produced inhalation pneumonia in sheep and goats (Knight and Walker 2001).

GENERAL CONSIDERATIONS REGARDING TREATMENT AND PROPHYLAXIS OF PNEUMONIA

Antibiotic therapy should be begun with a drug that is normally effective against the organisms suspected to be present in the pneumonic process. Anthelmintics should also be given if verminous pneumonia is suspected.

Choice of Antibiotic and Duration of Therapy

Initial treatment is usually determined by the practitioner's previous experiences. If a culture and sensitivity report is available from a tracheal aspirate or a necropsy, the choice of the antibiotic should be guided by that report. Commonly, however, additional or different organisms are involved in the pneumonia. The practitioner should re-evaluate the patient after forty-eight hours. If a definite response to therapy has not occurred (i.e., decreased fever, improved appetite and demeanor), another antibiotic should be chosen and administered for forty-eight hours. When a response is obtained, the effective drug should be continued until at least forty-eight hours after the goat is clinically normal. This means a minimum of four to five days of therapy for any goat with pneumonia. On the other hand, weeks of treatment are generally not possible because of the pain and mental anguish most goats suffer during a prolonged series of injections. Mycotic pneumonia is also a possible sequela to prolonged antibiotic use.

Ideally, any sick animal receiving treatment should be removed from the herd and kept in isolation facilities. This often is not possible, or the owner refuses to put forth the required effort. In such herds it is important to mark the sick animal so that it can be relocated after it is clinically healthy; otherwise, an adequate duration of therapy will rarely be achieved.

Drug Dosage and Extralabel Use

The dosage rate should be enough to achieve the tissue levels in the lungs that are necessary for the desired antimicrobial effect. When this dose is increased or is given more frequently than labeled dosage rates, or when the drug is not approved for goats, the practitioner must deal with government regulations regarding extralabel drug use. The animal to be treated must be carefully examined by the veterinarian, and provision must be made for prolonged withdrawal periods to prevent contamination of milk or meat for human consumption. In the United States, all goats of all breeds are defined by the Food and Drug Administration as food animals, which limits the choice of legal antibiotics (fluoroquinolones are forbidden). Routine milk and urine antibiotic residue tests after treatment are recommended because pharmacokinetic data for goats to establish withholding times is rarely available (Lofstedt 1987).

Routes of Administration

Except for sulfonamides and lesser doses of tetracyclines, oral use of antimicrobial drugs generally leads to severe systemic illness by interfering with rumen flora. In addition, sick animals usually do not eat or drink well enough to dependably consume medication in feed or water. It is the personal preference of the author to give most antibiotics by subcutaneous injection. Painful muscle necrosis is thereby avoided, as is paralysis from accidental injection into the sciatic nerve. There are several caveats with subcutaneous injections. First, sterile abscesses sometimes occur and can be confused with caseous lymphadenitis. Therefore, injection ahead of the shoulder should be avoided in show goats. Second, the pharmacokinetic disposition of most drugs in goats has not been studied after subcutaneous administration and residue persistence is apt to be erratic. Third, subcutaneous injection of a drug labeled only for intramuscular use is an extralabel use of that drug, even if the government-approved dosage is used.

Supportive Therapy

Many supportive drugs have been used to treat pneumonia. Naturally, a drug effective against lungworms should be administered if historical or laboratory findings suggest parasite involvement. In general, vitamins (including vitamin E and selenium) are part of the routine regimen. Bronchodilators and nonsteroidal anti-inflammatory drugs probably have a place in select cases, but proper dosages have not been determined scientifically. Corticosteroids are best avoided because they increase the frequency of relapse when treatment is discontinued. If an antipyretic agent has been administered (such as acetylsalicylic acid

100 mg/kg orally twice daily or flunixin intravenously, intramuscularly, or orally at 2.2 mg/kg, Königsson et al. 2003), body temperature cannot be used as an indicator of response to antimicrobial therapy. Exudates should not be allowed to obstruct the nares, and aromatic oils can be tried if rapid production of mucus is adding to the distress of the goat. The goat should be kept comfortable with a coat in cold weather, fan under very hot conditions, dry bedding, and good food and water within easy reach.

Pneumonia Prophylaxis

Prophylaxis of pneumonia, except of contagious mycoplasma pneumonia, is almost never through vaccination. Instead, careful attention must be paid to proper ventilation, housing, and nutrition. An increased colostrum intake should be encouraged and dry bedding provided for kids. In cold climates, supplying newborn kids with wool body socks prevents chilling without interfering with barn ventilation. Angora and Cashmere kids should not be shorn during inclement weather and supplemental feed may be required after shearing. When animals must be worked in a dry and dusty corral, wetting down the area with a 5% formalin solution has been proposed to decrease the quantities of both irritant dust and infectious microorganisms inhaled by the goats. Crowding must be avoided.

Strict isolation of purchased animals or those stressed by traveling and showing is also important. The etiology of the febrile illness accompanied by coughing that frequently sweeps through a goat herd after a show is rarely identified. Viruses, mycoplasmas, chlamydia, and pasteurellosis are possible suspects. One approach to handling the herd is to administer tetracycline or tylosin to goats that are off feed or febrile. Close observation, good feed, and good ventilation suffice if the animals are eating well.

In some instances, specific infectious diseases are controlled by separating kids from adults and feeding heat-treated colostrum and pasteurized milk. Pooled milk from other goats at a show should not be fed to members of one's own herd.

PULMONARY EDEMA AND PLEURITIS

The signs associated with pulmonary edema include dyspnea, increased bronchial sounds, crackles, and cough. Thus, it may be difficult to distinguish the condition from a pleuritis or pneumonia of infectious origin. In severe cases of edema, froth may appear at the mouth and nares. Various gastrointestinal diseases discussed in Chapter 10 can cause severe hypoproteinemia and subsequent hydrothorax and pulmonary edema.

Anaphylaxis and Fluid Therapy

Acute lung edema may be caused by an anaphylactic reaction to, for example, a serum or vaccine product. Emergency treatment measures for such an animal include epinephrine (1 ml of 1:1,000 strength per 50 kg), the diuretic furosemide (5 mg/kg), and possibly atropine (100 µg/kg) (Black 1986). If the edema occurs during the course of intravenous fluid therapy, the fluids should be temporarily discontinued and furosemide administered.

Cardiac Disease

Pulmonary edema may occur with severe exertion (as when chased by dogs), heart failure (i.e., because of white muscle disease, ionophore coccidiostats, or toxic plants), or a congenital heart defect. Vitamin E and selenium and symptomatic therapy such as diuretics are indicated.

Pulmonary Disease

Edema may occur in pneumonias caused by many of the infectious and parasitic agents already discussed. It is quite pronounced in certain other conditions affecting the lungs.

Toxic Gases and 3-methylindole

Toxic gases, particularly hydrogen sulfide, can cause pulmonary edema, but goats are rarely exposed to high levels of gases under normal housing conditions. Ruminal administration of 3-methylindole, a metabolite of L-tryptophan, causes severe pulmonary edema and respiratory distress and moderate emphysema in goats (Carlson et al 1972; Dickinson et al. 1976; Huang et al. 1977; Mesina et al. 1984). It is uncertain if this toxin causes naturally occurring disease in goats.

Cor Pulmonale

Chronic edema occasionally occurs along with cor pulmonale in severe long-term lung diseases such as progressive pneumonia and adenomatosis (Gay and Richards 1983). Goats thus affected also have ascites. Treatment is unrewarding.

Heartwater

In endemic areas (sub-Saharan Africa, Caribbean), infection with the tick-borne rickettsia *Ehrlichia* (*Cowdria*) *ruminantium* (heartwater) may cause hydrothorax and pulmonary edema because of increased capillary permeability. In addition to dyspnea, clinical signs may include fever, central nervous system dysfunction, and death (Brown and Skowronek 1990). Edema of other organs such as lymph nodes and brain also occurs (Mebus and Logan 1988). Organisms may be demonstrated in endothelial scrapings of the aorta and jugular vein or in capillaries in histologic sections or smears of the brain, as discussed in Chapter 8.

Pleuritis

Mannheimiosis, pasteurellosis, and mycoplasmosis are the most common causes of pleuritis in goats. Infections resulting in abscessation, such as caseous lymphadenitis, can also result in pleuritis if an abscess ruptures into the pleural cavity.

Of special note is the condition of sternal abscess or osteomyelitis. Goats that spend much time recumbent, as with arthritis, may develop a chronic draining tract over the sternum. Radiography is important in offering a prognosis, because if the infection extends between ribs or through sternebrae into the chest (Figure 4.8), neither antibiotic nor surgical treatment is likely to be effective. Such animals have enlargement of sternal lymph nodes and, commonly, pleuritis.

PULMONARY AND THYMIC NEOPLASIA

The most commonly reported neoplasm in the chest of the adult goat is the thymoma (Figure 9.9). Clinical signs of thymoma may include dyspnea and muffled lung sounds, often unilaterally. However, some animals develop congestive heart failure (Rostkowski et al. 1985; Hanselaer 1988) or rumen tympany and megaesophagus (Parish et al. 1996). Either radiographic or ultrasonographic findings of a mediastinal mass, which may be cystic, support the diagnosis, although an abscess could have a similar appearance (Hanselaer 1988). Some affected animals have copious thoracic fluid, which obscures the mass and contains normal lymphocytes. Either epithelial or lymphocytic cells may predominate in the tumor, but the neoplastic cell population is the epithelial cell. Asymptomatic thymomas have been reported in both female and castrated male Saanen goats (Hadlow 1978).
Figure 9.9. Large thymoma that displaced the heart and lungs caudally. (Courtesy Dr. M.C. Smith.)

Lymphosarcoma produced nodular lesions in the lung parenchyma of six of eleven goats in one necropsy study. Only two of these six animals had been reported to by dyspneic antemortem (Craig et al. 1986). Another goat with pulmonary lymphosarcoma detected radiographically was initially believed to have pulmonary nocardiosis originating from a chronic mastitis (Rozear et al. 1998). A viral-induced neoplasm of the lung has been discussed under the topic of jaagsiekte (see above). Although rarely reported, other primary or metastatic lung tumors might be found occasionally in older goats. In one eight-year-old Alpine wether, a thymoma metastasized to the lungs and spleen (Olchowy et al. 1996).

PLANT POISONINGS CAUSING ACUTE RESPIRATORY SIGNS

Perilla frutescens (perilla mint) and moldy sweet potatoes can be expected to produce severe pulmonary edema, emphysema, and adenomatosis in goats, as in other ruminants (Linnabary et al. 1978; Belknap 2002). There is no specific therapy, and exertion by affected animals may precipitate death. Dyspnea may be a prominent sign associated with cardiotoxic effects of avocado (*Persea*) (Sani et al. 1991) or other plants discussed in Chapter 8. *Acacia nilotica* subsp. *kraussiana* causes methemoglobinemia, hemolysis, anoxia, and dyspnea that may be severe enough to cause abortion or death (Terblance et al. 1967).

Even though cyanide and nitrate toxicities are conditions that interfere with cellular respiration rather than affecting the respiratory tract per se, the severe dyspnea associated with these poisonings suggests respiratory tract disease.

Cyanide Poisoning

Hydrocyanic acid (HCN), or prussic acid, is present as a glycoside in certain plants. Hydrolysis in the course of wilting, frosting, or digestion within the rumen releases free HCN. A plant enzyme, glycosidase, hydrolyzes the terminal glucose on a cyanogenic glycoside such as amygdalin, producing the aglycone compound hydroxynitrile. Another enzyme catalyzes a further breakdown into HCN and benzaldehyde (Conn 1978). The cyanide is absorbed directly from the rumen.

Etiology and Epidemiology

A variety of plants are potentially cyanogenic; the level of HCN can be affected by genetic selection. Immature or rapidly growing plants, and plants heavily fertilized with nitrogen, tend to have higher concentrations of cyanogenic glycosides. Damage to the plants by drought, wilting, frosting, or chewing increases toxicity because glycoside and enzyme combine more rapidly. Other ingesta in the rumen may react with cyanide and prevent absorption.

There are few reports of cyanide poisoning in goats (Webber et al. 1985; Shaw 1986; van der Westhuysen et al. 1988; Gough 1995; Tegzes et al. 2003; Radi et al. 2004), but toxicity levels should be comparable with those reported in other ruminants. The goat's propensity for browsing and for escaping from enclosures increases the potential hazard of cyanogenic shrubs and trees. A list of some potentially toxic plants follows.

- *Cynodon* spp. (quick grass, star grass)
- *Eucalyptus cladocalyx* (sugar gum)
- *Heteromeles arbutifolia* (toyon, California holly)
- *Linum* (flax)
- *Lotus corniculatus* (birdsfoot trefoil)
- *Manihot esculenta* (cassava)
- *Phaseolus lunatus* (lima bean [tropical varieties])
- *Prunus* spp. (cherries, apricots, peaches)
- *Pyrus malus* (apple)
- *Sambucus canadensis* (elderberry)
- *Sorghum* spp. (Sudan grass, Johnson grass)
- *Suckleya suckleyana* (poison suckleya)
- *Triglochin maritima* (arrow grass)
- *Trifolium repens* (white clover)
- *Zea mays* (corn)

Pathogenesis and Clinical Signs

The cyanide ion binds to the ferric ion in cytochrome oxidase, yielding a stable complex that cannot transport electrons in the process whereby O_2 is used in metabolic respiration. Oxygen is not released from hemoglobin in the blood and thus is not available within cells; cellular asphyxiation occurs. The oxygen-laden blood is bright red but the animal rapidly becomes severely dyspneic. Cerebral anoxia leads to the clinical signs; initial excitement and muscle tremors are followed by gasping and convulsions. Pupils are dilated. Signs are generally peracute, with death occurring within fifteen minutes to a few hours after plant consumption.

Diagnosis

Venous blood is bright red in peracute cases but cyanosis of mucous membranes supervenes if death is delayed. There may be an odor of "bitter almond" because of benzaldehyde in the rumen contents. Feed, blood, rumen contents, liver, or muscle tissue may be analyzed. Quick freezing or immersing in 1% to 3% mercuric chloride prevents additional release and loss of HCN from the sample. Levels in plants of 200 mg/kg HCN or more are considered potentially toxic, and with cyanide, toxic usually means lethal. A field test using picrate paper has been described (Kingsbury 1964; Radostits et al. 2007), but this detects cyanide at less than the toxic level. Other causes of sudden death (see Chapter 16) must be considered.

Treatment

Because death occurs so rapidly (often in two to three minutes), treatment is rarely possible. However, prompt intravenous injection of sodium nitrite (22 mg/kg) converts some hemoglobin to methemoglobin, which preferentially picks up CN ions from the cytochrome oxidase enzymes. Simultaneous sodium thiosulfate (67 mg/kg) converts cyanide to stable, less toxic thiocyanate. More recently, an increased intravenous dosage of sodium thiosulfate (660 mg/kg) has been proposed (Burrows and Way 1979). Oral or intraruminal sodium thiosulfate (perhaps 6 g to a large goat) at hourly intervals is recommended to fix free HCN in the rumen of affected or exposed animals.

Nitrate Poisoning

Ruminant digestion converts ingested nitrates to nitrites and then reduces the nitrites to ammonia. Nitrite is considered to be ten times more toxic than nitrate (Kingsbury 1964; El Bahri et al. 1997).

Etiology and Epidemiology

Atmospheric nitrogen is converted to nitrate (NO_3^-) by nitrogen fixing bacteria, including those associated with the roots of certain plants such as legumes. The plants can then reduce nitrates to nitrites and eventually convert the nitrogen into plant protein. Animal wastes (urea and ammonia) can also enter into the nitrogen cycle.

Animals most often consume excess nitrates by eating plants containing increased nitrate concentrations. Water contaminated with animal wastes or run-off from fertilized fields and direct consumption of fertilizers are other possible sources. Sources of nitrate are cumulative. Some plants that may accumulate toxic levels of nitrates are listed below.

- *Amaranthus* (pigweed [Agouroudis et al. 1985])
- *Avena sativa* (oats)
- *Beta vulgaris* (beet)
- *Chenopodium* spp. (lambsquarters, goosefoot)
- *Medicago sativa* (alfalfa)
- *Sorghum* spp. (Sudan grass, Johnson grass)
- *Zea mays* (corn)

Heavily fertilized soils make more nitrates available for plant uptake. Uptake is also favored by acid and moist soils, soils deficient in certain minerals (molybdenum, phosphorus, or sulfur), and low temperatures. Rapidly growing plants after drought or hormonal herbicide application accumulate increased nitrates. Finally, decreased light results in accumulation of nitrates within plants because nitrate reductase enzyme requires light for normal activity. Nitrates accumulate in vegetative tissue rather than fruits or grains, and

nitrate levels in the whole plant decrease rapidly after flowering and setting of fruit. Corn, for instance, is not dangerous after tasseling out.

Pathogenesis and Clinical Signs

Nitrate toxicity is caused by nitrite formation within the rumen or, occasionally, in ensiled forages. Starved animals are at greatest risk because they are less selective grazers. Also, active rumen microorganisms supplied with rapidly digestible carbohydrates (the well-fed animal) can convert nitrates to microbial protein and thereby escape toxicity.

Nitrite is absorbed from the rumen. The nitrite causes oxidation of ferrous hemoglobin to ferric hemoglobin (methemoglobin) that cannot transport oxygen. The blood turns a dark, chocolate brown color. In addition to cyanosis, clinical signs include weakness, trembling, severe dyspnea, and frothing at the mouth.

Clinical signs are visible when 30% to 40% of the hemoglobin is converted to methemoglobin. Death occurs at 80% to 90% conversion, although this is influenced by stress and exertion. Death usually occurs within twelve to twenty-four hours after ingestion.

Plants containing more than 1% nitrates (as KNO_3) on a dry weight basis and water with more than 1,500 ppm nitrates may cause acute toxicity (Osweiler et al. 1985). Toxicity to goats caused by low-level nitrate exposure has not been described (Mondal et al. 1999).

Diagnosis

Unless there is a history of direct nitrate consumption (e.g., with fertilizer), diagnosis usually requires laboratory confirmation. Dark brown blood and cyanotic membranes indicate the need for methemoglobin determination. Use of a phosphate buffer as a preservative is recommended if testing of heparinized blood will be delayed longer than a few hours (Osweiler et al. 1985). Nitrate levels may be determined in feed, water, rumen contents, or body fluids (including aqueous humor). Nitrite is converted to nitrate very rapidly after death and is often undetectable in field specimens (Boermans 1990). Samples should be preserved by freezing.

Treatment

If nitrate toxicity is likely and respiratory signs are present, the clinician should not delay therapy while awaiting laboratory confirmation. Affected animals are treated intravenously with 4 to 15 mg/kg of methylene blue as a 1% solution in distilled water (Burrows 1984; Mondal and Pandey 2000); this is repeated if necessary. The methylene blue is reduced in blood and body tissues to leucomethylene blue, which in turn rapidly reduces methemoglobin to hemoglobin. When methylene blue is given intravenously to goats, it passes readily into the milk (Ziv and Heavner 1984). Another injectable dye, tolonium chloride, has also been used successfully to treat goats with experimental nitrate toxicity (Mondal and Pandey 2000).

Ruminal lavage with cold water or administration of oral antibiotics or a laxative may decrease additional ruminal reduction of nitrate to nitrite.

DEVOCALIZATION

Certain goats bleat almost continuously when separated from something they want, such as human companionship, or during estrus. Providing the goat with a pen mate (another goat or sheep, a cat, or even a pony) may alleviate the problem. Ovariectomy (see Chapter 13) may solve the problem of vocalization during estrus. In other cases the goat persists in its vocalizations, and the family, the neighbors, or the research group threatens mayhem. Displeased neighbors are especially dangerous to suburban goats because most zoning laws classify the pet wether as livestock. Under these circumstances, surgical removal of the vocal cords is justified.

Two techniques of devocalization are described in the literature and summarized here. Anesthetic agents that might be used include xylazine/ketamine and barbiturates. These are discussed in detail in Chapter 17. Atropine (0.08 mg/kg) administered intramuscularly twenty minutes before induction of anesthesia is recommended to decrease salivation (Tillman and Brooks 1983).

Traditional Surgical Technique

For the older surgical approach (Durant 1974), the goat is positioned in dorsal recumbency with the head lower than the neck. This is achieved by placing a sand bag beneath the neck. Food should be withheld for twenty-four hours and water for six hours before surgery; it is not possible to use a cuffed endotracheal tube to prevent regurgitation and aspiration during the surgery. Skin over the larynx is prepared as for an equine roarer operation. A midline skin incision 35 to 40 mm long is made, with careful attention to hemostasis. The first tracheal ring is incised and that incision is carried forward on the midline through the cricoid cartilage and crico-thyroid ligament to but not through the anterior border of the larynx (see Figure 9.10a). A small divider is used to spread the larynx and expose the vocal cords. Each cord (about 6 mm long) is clamped and removed down to the surface of the cartilage with curved scissors. After hemostasis is achieved the divider is removed and the skin incision closed.

Electrosurgical Technique

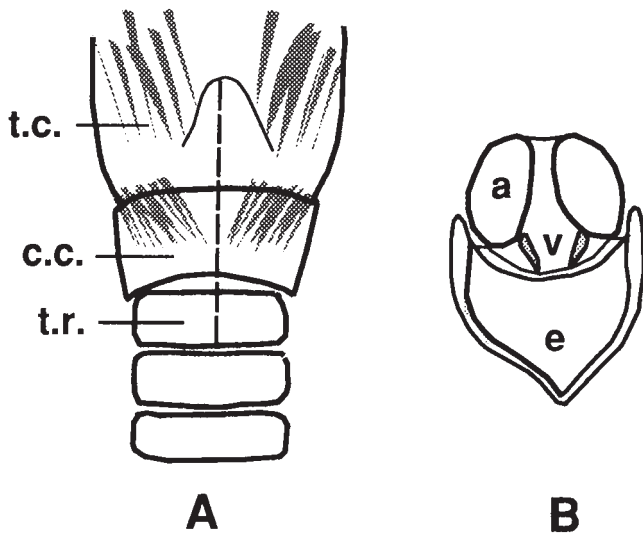
The second technique involves electrosurgical destruction of the vocal cords via the oral cavity (Tillman and Brooks 1983). The anesthetized


Figure 9.10. Removal of the vocal folds for devocalization. (a) Ventral view of larynx showing initial incision through cartilages of larynx. (b) Larynx as viewed from oral cavity.
a = arytenoid cartilage, v = vocal folds, e = epiglottis, t.r. = first tracheal ring, c.c. = cricoid cartilage, t.c. = thyroid cartilage.

(ketamine/xylazine) goat is placed in sternal recumbency with its chest on the ground plate of an electrocautery unit. A 38-cm tonsil snare arm (without the snare wires) is allowed to protrude 2 to 3 mm from its insulating sheath and is used as a long electrode. A long laryngoscope blade for ruminants (Soper laryngoscope blade 257 or 385 mm, Penlon Ltd., Abingdon, England) is also needed. The goat's head and neck are fully extended by an assistant and the tip of the laryngoscope blade is used to depress the epiglottis. The vocal cords are positioned just posterior to the arytenoid cartilage. They are much smaller than the arytenoids and almost meet ventrally, forming a "V" (Figure 9.10b). Using a coagulation setting, each vocal fold is pressed against the wall of the larynx (5 o'clock and 7 o'clock positions). The energized cautery tip is drawn forward over the vocal fold for a distance of about 1 cm, although closure of the larynx usually prevents visualization while this is being done. The aim is to create scar tissue to prevent elevation of the vocal fold; cautery is repeated if the first attempt has not cauterized an adequate area to ensure this result. Recovery from the adverse effects of surgery takes only a few days, and voice loss is permanent. Devocalization by carbon dioxide laser surgery, as done in dogs, has apparently not been described in goats.

The structure and function of the caprine digestive system are typical of the basic ruminant design and closely resemble that of sheep. The goat does exhibit some known anatomic and physiologic characteristics, however, that distinguish it from the sheep and reflect both its specialized feeding behavior and adaptability to environments hostile to other domesticated ruminants.

The spectrum of diseases that affect the caprine digestive system is similar to that seen in sheep and cattle. Infectious and metabolic conditions predominate, and many of the same diseases occur. However the frequency of occurrence may differ significantly in goats for certain conditions. For example, abomasal displacement and traumatic reticulitis are commonly encountered in dairy cattle, but rarely diagnosed in the goat.

A discussion of differential diagnosis of caprine digestive diseases is provided in this chapter, organized on the basis of presenting clinical signs. The major diseases that affect primarily the digestive system are discussed in detail in the last section of the chapter.

BASIC CAPRINE GASTROENTEROLOGY

Several atlases of topographic anatomy and dissection guides of the goat are available (Chatelain 1987; Constantinescu 2001; Popesko 2008), but most anatomic texts focus on cattle or sheep with goats mentioned comparatively, if at all. The situation is very similar for caprine digestive physiology. The following discussion serves to identify known differences in the structure and function of the caprine digestive system that are anatomically distinctive, functionally adaptive, or clinically relevant. Readers requiring a more general review of ruminant anatomy and physiology are referred to comprehensive texts in these areas (Habel 1975; Church 1993; Cronje 2000; Reece 2004).

Clinical Anatomy

Oral Cavity

The upper lip of the goat is complete and muscular and lacks the dividing philtrum of the sheep. This favors the grasping and tearing of browse while the philtrum in the sheep favors consumption of grasses close to the ground. The tongue of the goat is not used

for prehension of feed, as it is in cattle. It is shorter and smoother and not as easily extracted or displaced from the oral cavity during oral examination. Taste buds on the tongue can discriminate bitter, sweet, salty, and sour tastes and the tolerance for bitter taste exceeds that of cattle and sheep. This favors the browsing of a wider range of plant species.

There are four main pairs of salivary glands: the parotids, mandibulars, sublinguals, and buccals. The latter are divided into dorsal, middle, and ventral portions. The histology of these glands has been described (Nawar 1980). The parotid and ventral buccal glands are serous, the dorsal and middle buccal glands are mucous, and the mandibular and sublingual glands are mixed. In addition, numerous mucus-secreting labial glands occur in the lips, particularly near the commissures of the mouth. Lingual and palatine glands are minor. Parotid salivary glands must be distinguished from adjacent lymph nodes, especially when diseases such as caseous lymphadenitis cause lymph node enlargement.

The dental formula of the goat is 0033/4033. The upper incisors are replaced by a dental pad that facilitates the tearing of forage. The lower incisors must properly appose the dental pad for efficient acquisition of feed during grazing or browsing. Brachygnathism and prognathism both occur in goats and adversely affect feeding behavior under range conditions. Deciduous lower incisors, or milk teeth, occur in young goats. The central pair may be present at birth or appear within the first week of life. The second pair generally appears at one to two weeks, the third pair at two to three weeks, and the lateral pair at three to four weeks of age.

Permanent incisors generally appear according to the following schedule: central incisors usually are present by one year of age but appear as late as one and a half years of age; second pair, one and a half to two years of age; third pair, two and a half to three years of age; and lateral or fourth pair, three and a half to four years of age. Occasionally, there is a failure of eruption of the permanent incisors. Aged goats with persistent deciduous central incisors have been observed. Aging of older goats using teeth is difficult. Incisors continue to wear over time and the teeth become rounded rather than rectangular. The speed of this process varies considerably with type of feed and management.

Anodontia, or absence of the mandibular incisor teeth, has been reported in a West African Dwarf goat (Emele-Nwaubani and Ihemelandu 1984). Congenital absence of the first cheek tooth (P2) has been noted in feral goats (Rudge 1970).

Molars are present at birth and elongate throughout life, but are continuously worn down by the grinding action of mastication. Shortened molars may be expelled altogether in older goats, leading to accumulation of feed in empty sockets and excessive growth of the unopposed molar.

The lower dental arcades are closer together than the upper arcades. Because the goat chews with a strong lateral grinding motion, extremely sharp dental points may develop on the lateral aspect of the upper molars and the medial aspect of the lower molars, and care must be taken in carrying out an oral examination so that fingers are not injured.

Cleft palate occurs in goats as a congenital malformation. Usually the cause is unknown. However, plants containing piperidine alkaloids, notably *Lupinus formosus*, can produce teratogenic effects, including cleft palate and multiple tendon contractures, when consumed by dams between thirty and sixty days of gestation (Panter et al. 1990, 1994). Cleft palate has also been reported in fetal monsters, associated with duplication of the pelvis and hind limbs (monocephalus dipygus) in one case (Corbera et al. 2005), and with two faces (diprosopus) in another (Mukaratirwa and Sayi 2006).

Esophagus

The embryonic development of the caprine esophagus has been described (Jung et al. 1994). In adult dairy goats of the European breeds, the esophagus is approximately 1 m in length, so at least that length of tube should be used to reach the rumen for relief of bloat or administration of medications. A speculum should be used to avoid the goat chewing the tube. The movement of swallowed boluses, eructated gas and cud, and correctly placed stomach tubes may be seen in the esophagus along the left jugular furrow.

An esophageal or reticular groove is present in the goat and reflexively closes in response to suckling in the neonate, allowing milk to bypass the rumenoreticulum and directly enter the abomasum via the omasal groove. This reflex wanes after weaning and is vestigial in adults, although it can be stimulated by drinking after severe, prolonged water deprivation. There are practical advantages to inducing the reflex in adult animals, particularly for the purpose of administering oral medications directly into the abomasum that otherwise would be deactivated or diluted if introduced into the rumen. The esophageal groove in the goat can be closed reliably by the intravenous administration of lysine-vasopressin at a dose of 0.25 IU/kg. Administration of vasopressin (antidiuretic hormone) is presumed to mimic the natural physiologic response occasioned by prolonged water deprivation (Mikhail et al. 1988). Copper sulfate solution (1 tablespoon $CuSO_4$ in a liter of water) is also thought to reliably close the groove when 5 cc is given orally.

The surgical establishment and maintenance of esophageal fistulae for collection of dietary samples in

goats have been described (Pfister et al. 1990). An apparatus for the remote control collection of esophageal fistulae samples and its long-term performance have also been reported (Raats and Clarke 1992; Raats et al. 1996)

Forestomachs and Abomasum

The structure of the forestomachs is quite similar in goats and sheep (Gueltekin 1953; Horowitz and Venzke 1966; Bhattacharya 1980; Chungath et al. 1985). The reticulorumen occupies most of the left half of the abdomen, and extends cranially to the eighth intercostal space and caudally to the tuber coxae, in contact with the left body wall. The cardia occurs at the eighth intercostal space.

The omasum of the goat is much smaller than the reticulum. In small ruminants, the omasum is proportionately smaller and lighter than in the cow. Internally, the longitudinal folds, or leaves of the omasum, produce *laminae omasi* of four different lengths in sheep, but only three in goats; the fourth or shortest lamina is absent. The average number of laminae in the goat is around thirty-five, compared with 169 in cattle (McSweeney 1988). The omasum is situated deep to the eighth and ninth intercostal spaces on the right-hand side of the abdomen, and does not contact the body wall. It sits on the dorsal aspect of the abomasum. In the cow, the heavier larger omasum drops to the abdominal floor and displaces the abomasum more to the left in the abdominal cavity. This anatomic difference may be a factor in explaining why cattle are more likely to develop clinical disorders associated with abomasal displacement than are goats.

The abomasum in small ruminants is proportionately larger and longer than in the cow. The abomasum of the goat is situated on the abdominal floor in the right anterior abdomen and runs caudally along the costal arch.

A wide variety of stomach volumes have been reported for mature goats. Much of the variation is probably caused by breed differences, rations fed, and the method of measurement. The range for rumen volume is 12 to 28 liters, although in most cases, the upper limit is around 20 liters. For the reticulum, the range is 1.6 to 2.3 liters; for the omasum, 0.75 to 1.2 liters; and the abomasum, 2.1 to 4 liters.

The goat is born with an undeveloped rumen and a proportionately larger abomasum (Tamate 1956; Benzie and Phillipson 1957). During the first three weeks of life, the body of the abomasum is located mainly on the left side of the abdomen, adjacent to the diaphragm with the pyloric antrum to the right of the midline. It gradually moves to its adult position in the right abdomen as the forestomachs enlarge on the left. At birth, the ratio of reticulorumen capacity to abomasal capacity is 1:4, with a reticulorumen volume of 70 ml

and an abomasal volume of 290 ml. Omasal volume is negligible. In kids given access to roughage, the ratio at six weeks has become 5.7:1. Full rumen capacity is usually reached by twelve weeks of age. Acceleration of rumen development can be achieved by early introduction of roughage and concentrate into the diet of the suckling kid (Tamate 1957).

Small Intestine and Cecum

The small intestine accounts for approximately 77% of the length of the alimentary tract distal to the forestomachs, and the cecum an additional 2%. The measured mean length of the small intestine is 18 meters (and the cecum 0.3 meters) in Barbari goats, a relatively small breed (Rai and Pandey 1978), and up to 25 meters in larger breeds. The common bile duct enters the duodenum approximately 25 to 40 cm distal to the pylorus in the goat. The small intestines and cecum are located for the most part on the right side of the abdomen due to dislocation by the large reticulorumen on the left. Except for the duodenum, the remainder of the small intestine is enclosed within the supraomental recess or omental sling. The blind end of the cecum usually points caudally, but the orientation is variable.

Colon and Rectum

The structure of the caprine colon is typical of the ruminants in that there is a proportionately elongated ascending colon that is spirally coiled, followed by shorter transverse and descending colon segments leading to the rectum and anus. In the goat and sheep, there are usually three centripetal and three centrifugal turns in the spiral segment. The colon and rectum account for approximately 21% of the length of the alimentary canal distal to the forestomachs, and the mean length is 5 meters in most breeds. The diameter is approximately 8 cm at the cecum and 2 cm at the rectum. The colon also is largely displaced to the right abdomen by the reticulorumen. The spiral colon lies medial to the small intestine and cecum.

Omentum and Mesentery

The goat shows a marked predilection for the deposition of fat in omentum and mesentery compared with cattle and sheep. This undoubtedly has adaptive value when goats inhabit environments with scarce feed supplies. It also may be significant in the pathogenesis of pregnancy toxemia because overfeeding in early pregnancy can result in considerable deposition of intra-abdominal fat. This space-occupying fat can reduce feed capacity throughout the digestive tract, leading to decreased feed intake, negative energy balance, and ketosis. Intra-abdominal fat can also be misleading when assessing body condition. Goats that appear underconditioned, with little palpable

subcutaneous fat, may have considerable intra-abdominal fat stores. Goats with little mesenteric fat at necropsy have been severely malnourished for an extended period of time.

Digestive Physiology

Feeding Behavior

With regard to diet selection, the goat has been characterized as intermediate between the true grazers, such as the domesticated cow and buffalo, and the true browsers or concentrate selectors, exemplified by wild ruminants such as the moose and whitetail deer (Demment and Longhurst 1987; Hofmann 1988). This means that the goat can exploit a range of plant materials to meet nutrient requirements. This diversity accounts in large part for the growing interest in goats as a desirable livestock species where intensive cropping or maintenance of abundant grassland is not possible. The goat is also being exploited in mixed farming systems, where stocking of goats along with sheep and cattle reduces weeds and shrubs. This improves grass quality and availability for the grazing species, and increases overall yields of animal products per acre.

The typical feeding behavior of goats also has a negative side. They are so successful at exploiting limited feed resources that when overstocking occurs in environments with marginal plant growth, permanent destruction of the flora with desertification of the environment can occur. Traditionally, the goat has been blamed for instances of desertification that are as much a result of failure of livestock population management by stock owners as the goat's superior foraging ability (Dunbar 1984; El Aich and Waterhouse 1999). The ecology of feeding behavior and its impact on animal productivity and environmental quality have been reviewed (Merrill and Taylor 1981; Owen-Smith and Cooper 1987; Van Soest 1987; Devendra 1987).

Nutrient Use

It has long been suggested that the goat has more digestive efficiency than cattle or sheep. Many studies have been carried out regarding comparative digestive efficiency and the results have not been consistent in identifying a distinct advantage for the goat. In general, goats and sheep show equal efficiency on high-quality, low-fiber diets. When fed low-quality, high-fiber diets, however, the two species show different compensatory advantages. Sheep digest fiber more completely than goats, but have a decreased rate of intake, while goats have a greater rate of intake and a faster rate of removal of nondigested fiber from the rumen (i.e., shorter rumen retention time) (Brown and Johnson 1984). The subject of comparative digestive efficiency in domestic ruminants with emphasis on the goat has been reviewed (Morand-Fehr 1981; Devendra 1983; Brown and Johnson 1984).

Digestive Activities

Goats eat more frequently and rapidly than sheep (Geoffroy 1974). In the process, they produce more abundant saliva. Goats produced parotid saliva at the rate of 110 ml/hour compared with 40 ml/hour in sheep when eating the same diet of fresh cut Egyptian clover (Seth et al. 1976). In addition to the known functions of bolus lubrication, urea recycling, and rumen buffering, copious saliva may have adaptive significance for goats regarding diversity of diet. Goat saliva may contain proportionately higher levels of mucin or proline than that of grazing ruminants, enabling binding of potentially toxic tannins found in many of the tree and shrub species browsed by goats (Van Soest 1987, 1994). The rumen flora of feral goats may also contain streptococcal bacteria that can degrade tannins (Brooker et al. 1994; Sly et al. 1997).

The rumination cycle of goats averages sixty-three seconds, or once per minute. The cycle is fairly constant, but may be slightly shorter on silage rather than hay diets. The motility pattern of rumenoreticular contraction of the goat is similar to that of sheep and differs in similar ways from the bovine pattern (Dziuk and McCauley 1965). Involuntary rumen contraction in goats is under vagal control (Iggo 1956). In confinement, on a hay and concentrate ration, goats were observed to actively ruminate approximately 7.75 hours per day, with 75% of cud chewing activity occurring at night (Bell and Lawn 1957).

Descriptions of normal caprine rumen fluid composition are limited, but it is known that certain properties of rumen fluid can vary markedly with changes in water intake. In desert breeds that may have access to drinking water only every three to four days, the rumen plays a vital role as a fluid reservoir. Desert goats are able to maintain a constant serum osmolarity in the face of severe dehydration and subsequent overhydration by pooling fluid in the rumen. After four days without water, the average rumen osmotic concentration in black Bedouin goats is 360 mOsm/kg, but only 82 mOsm/kg immediately after drinking as much as 32% of their original bodyweight. The sudden hypo-osmotic effect reduces rumen protozoa numbers presumably by rupture, but causes no decrease in bacterial numbers or fermentation activity (Brosh et al. 1983).

An interesting aspect of the caprine rumen microflora has to do with the ability to detoxify the feedstuff *Leucaena leucocephala.* This leguminous shrub or low tree is widely distributed throughout the tropics and subtropics. It can contribute considerably to improved animal nutrition and productivity when used as a

protein-rich feed for ruminants (Jones 1979). However, when the plant comprises more than 30% of the diet, cattle, sheep, and goats in certain countries develop a variety of clinical abnormalities including alopecia, wool loss, excessive salivation, poor appetite, hypothyroidism, cataracts, poor reproductive performance, weight loss, and death. Goats are reported to show hypothyroidism and erosions of the esophageal mucosa and rumen papillae (Jones and Megarrity 1983).

Some of these toxic effects are directly caused by the amino acid mimosine, which is present in the leaves of *Leucaena leucocephala*, at levels of 2% to 5%. The thyroid effects are caused by a breakdown product of mimosine, 3,4-dihydroxypyridine (DHP), a potent goitrogen. The DHP is produced during mastication and subsequent rumen bacterial degradation. In animals not suffering ill effects from *Leucaena* consumption, DHP is additionally degraded in the rumen to harmless breakdown products by specific anaerobic rumen bacteria (Allison et al. 1990). It has been demonstrated that cultures of rumen bacteria from goats in Hawaii, where clinical *Leucaena* toxicity is not observed, can prevent clinical signs when inoculated into the rumens of goats and cattle in Australia, where *Leucaena* toxicity is widespread (Jones and Megarrity 1986).

Studies on the rate of passage of foodstuffs through the gastrointestinal tract of goats have been carried out using stained markers (Castle 1956, 1956a, 1956b). Stained particles first appear in goat feces from eleven to fifteen hours after ingestion, and have disappeared by six to seven days. The maximum appearance of stained particles is at approximately thirty hours after ingestion. The majority of the time spent by ingesta traversing the alimentary canal occurs in the forestomachs. Passage of ingesta through the entire small intestine takes an average of three hours.

Approximately 58% of the total dry matter digested by the goat is digested in the forestomachs, as is 93% of the crude fiber, 11% of the crude protein, and 80% of the soluble carbohydrate (Ridges and Singleton 1962). Most of the soluble carbohydrate digested in the forestomachs is absorbed from the rumen after fermentation as volatile fatty acids. Some carbohydrate absorption and most protein absorption occurs in the intestine.

Extensive removal of water from intestinal contents occurs in the large intestine of goats and sheep. This serves as an adaptation for water conservation. The average time for passage of ingesta through the large intestine is eighteen hours, compared with three hours in the small intestine, despite the fact that the small intestine is at least three times as long. This delayed transit accounts for the dry consistency of goat and sheep feces. The dry matter content of normal goat feces is usually between 50% and 60%, compared with 15% to 30% for cattle.

Clinical Pathology and Diagnostic Aids

Clinical Chemistry

Normal values for clinical chemistry parameters associated with the organs of digestion are given in Table 10.1

Serum electrolyte levels may change dramatically in digestive disease. Hypokalemia and especially hypochloremia are associated with gastrointestinal stasis. In obstructive diseases such as intussusception and blockage by phytobezoars or foreign bodies, hypochloremia and hypokalemia may be marked (Sherman 1981). Metabolic alkalosis may also occur in these conditions, but if surgical obstructions are severe enough to cause shock, acidosis may prevail. Displacements of the abomasum, the most common cause of hypochloremic, hypokalemic, metabolic alkalosis in dairy cattle, rarely occur in goats. Experimental goats with surgically induced right abomasal displacement, left abomasal displacement, or abomasal torsion were hypochloremic, hyponatremic, and hypokalemic following induction of these abnormalities and also had increased chloride ion levels in rumen fluid (Kwon et al. 1997).

The major chemical abnormalities associated with diarrhea are metabolic acidosis, with decreased serum bicarbonate, and hyponatremia, caused by sodium and bicarbonate loss in the diarrheic feces. Marked acidosis is also commonly seen in d-lactic acidosis due to grain overload or engorgement toxemia. In this condition, serum lactate levels are also markedly increased.

Abdominocentesis

The examination of peritoneal fluid may help in the diagnosis of digestive disease, particularly when lack of forestomach motility and abdominal distension are prominent clinical signs. The most common use of abdominocentesis in goats is to differentiate gastrointestinal causes of abdominal distension from nonalimentary causes. In male goats, ruptured bladder secondary to obstructive urolithiasis is common and leads to accumulation of urine in the abdomen. Hydrops conditions associated with abnormal pregnancy in the female must also be ruled out.

In cattle, abdominocentesis is most often performed immediately behind the xiphoid cartilage to confirm the presence of localized peritonitis in the anterior abdomen from traumatic reticulitis or perforated abomasal ulcers. Because goats rarely experience these conditions, and the main intent is generally to rule out genito-urinary conditions, abdominocentesis is better performed at the lowest point of the ventral abdomen, 2 to 4 cm to the right of the midline to avoid penetrating the rumen. Care must be taken to avoid mammary

Table 10.1. Normal values for blood constituents used in the assessment of diarrheal and other gastrointestinal diseases.

Parameter	Sample Type	Units	Range	Mean	Reference
Anion gap	S	mmol/l	8–20		Sherman and Robinson 1983
Bicarbonate	VB	mmol/l		24.2 ± 1.52	Cao et al. 1987
Chloride	S, HP	mmol/l	99–110.3	105.1 ± 2.85	Kaneko 1980

Sodium	S, HP	mmol/l	142–155	150.4 ± 3.14	Kaneko 1980

CO_2 = carbon dioxide, mmol/l = millimoles per liter, S = serum, VB = venous blood, P = plasma, HP = heparinized plasma, VLDL = very-low-density lipoproteins, LDL = low-density lipoproteins, HDL = high-density lipoproteins, LPDF = lipoprotein deficient fraction.

veins in does or the penis and prepuce in males. The sampling site should be aseptically prepared and a local anesthetic administered. If the animal is nervous, tranquilization should be considered before proceeding, but the animal should remain standing. Penetration of the ventral abdominal wall and peritoneum usually can be accomplished with a standard disposable 18- or 20-gauge needle. If fluid does not flow freely when the peritoneum is traversed, the needle should be rotated gently and a mild suction applied with an attached syringe.

Rumen Fluid Evaluation

Rumen fluid evaluation has not received much attention in goats as a diagnostic aid, but it may be helpful in the diagnosis of intoxications, high intestinal obstruction, indigestion, and grain overload. Rumen fluid analysis has been reported several times in control animals before the experimental induction of d-lactic acidosis (Tanwar and Mathur 1983; Cao et al. 1987) or water loading (Brosh et al. 1983). These reported values are summarized in Table 10.2. Changes observed in rumen fluid during experimental grain overload included decreased pH, decreased protozoal counts, increased lactic acid concentration, and increased bacterial counts. In experimental rumen acidosis, the normal olive green color of rumen fluid changed first to milky gray at twelve hours post induction and then to cream colored from twenty-four hours onward (Shihabudheen et al. 2006).

At necropsy, examination of rumen content is essential for the detection of toxic plants and their subsequent identification. In lead poisoning, lead levels in rumen fluid may be diagnostic because most cases of lead intoxication involve ingestion.

Obtaining a usable sample of rumen fluid by stomach tube can be difficult in goats. Passage of the tube orally with a speculum can cause excessive saliva contamination of the fluid sample, which can erroneously elevate the sample pH. A smaller diameter tube can be passed nasally into the esophagus and rumen, but aspiration of viscous rumen fluid can be difficult with a small diameter tube. A specially designed device for obtaining rumen fluid is illustrated in Figure 19.7. Alternatively, a transabdominal sample can be collected. The fluid/gas interface of the rumen content can be estimated by ballotment or percussion of the left flank and a point selected below the fluid line. After aseptic preparation, a 3-inch (7.6-cm) 18-gauge needle can be passed through the abdominal and adjacent rumen wall and a fluid sample aspirated by syringe. This procedure presents no more risk of inducing peritonitis than routine abdominocentesis. In outbreaks of accidental grain overload involving numerous animals, this method allows for rapid determinations of rumen pH in affected goats to establish treatment priorities.

Table 10.2. Normal values reported for rumen fluid constituents.

Constituent	Unit	Reported range	Reported mean	Comments/reference
pH			7.35 ± 0.3	Re-domesticated feral goats with rumen fistulae. Lucerne chaff and water diet fed free choice (Cao et al. 1987).
Osmolarity	mOsmol/kg		248 ± 14.2	"
Lactate	mmol/l		0.0	"
Sodium	mmol/l		115 ± 27	"
Potassium	mmol/l		40 ± 18.2	"
Chloride	mmol/l		21 ± 2.2	"
pH		6.9 (pre-drinking)— 6 (post-drinking)		Black Bedouin goats with rumen fistulae. Lucerne hay free choice. Water once a day (Brosh et al. 1983).
Osmolarity	mOsmol/kg	330 (pre-drinking)— 178 (post-drinking)		"
Bacterial count	×10^9/ml	24–26 (no change with drinking)		"
Protozoal count	×10^4/ml	43–60 (no change with drinking)		"
pH			7.40	Marwari goats with rumen cannulae. No feed for 24 hours before sampling. Water free choice (Tanwar and Mathur 1983).
Lactate	mg/dl		0.0	"
Bacterial count	×10^9/ml	100–160		"
Protozoal count	×10^4/ml	20–30		"
Protozoal count	×10^6/ml	0.25–2.83	0.96	150 Black Bengal goats at slaughter (Mukherjee and Sinha 1990).

mOsmol/kg = milliosmoles per kilogram, mmol/L = millimoles per liter.

Fecal Examination

The gross and microscopic examinations of feces are indispensable aids to the diagnosis of diseases of the digestive system. Normal goat feces is usually voided in piles of individual pellets 0.5 to 1.5 cm in diameter, although it is not necessarily abnormal if the pellets are sometimes caked together. Feces less well formed may be seen from animals grazing lush pasture. Feces similar to that normally produced by the dog, with poorly discernible pellets, should be considered abnormal. It is most often seen associated with gastrointestinal parasitism and sometimes paratuberculosis.

Whole kernels or identifiable portions of grain are rarely observed in goat feces unless the goat is on a very high level of grain feeding because the goat normally produces a consistently fine particle size of ingesta during mastication and regurgitation. Grain in the feces on a low-grain diet suggests dental disease or rumen disease.

Small, stony, darker pellets suggest constipation, most commonly caused by dehydration, and the cause should be pursued. Mucus coating the feces suggests prolonged transit through the alimentary tract and possible dehydration.

Fresh blood is uncommon in normal-appearing goat feces, but may be seen mixed in diarrheic feces in a number of conditions, including Nairobi sheep disease, rinderpest, enterotoxemia, coccidiosis, nodular worm infection, chabertiosis, and Japanese pieris toxicity. Dark, tarry stools (melena) can be seen in coccidiosis. Diarrhea is discussed in detail below.

Microscopic examination of goat feces, using direct smear or fecal flotation techniques, is valuable in the diagnosis and monitoring of most gastrointestinal parasitic infections. Samples for analysis should be fresh because ova will hatch rapidly and larvae will be undetectable using fecal flotation methods. Interpretation of results is discussed under the various specific parasitic diseases.

Imaging Techniques

Because of the goat's small size, radiographic studies can be readily performed and can be helpful in diagnosing intestinal obstruction, congenital atresia, foreign body penetrations, and mass lesions. The radiographic anatomy of the caprine digestive tract and contrast studies have been described (Cegarra and Lewis 1977; Chhadha and Gahlot 2006). Adult goats are fasted for forty-eight hours and given 600 ml of barium sulfate via stomach tube. The first film should be taken within one hour because in some cases the media may rapidly leave the rumen and already be in the abomasum. If the media is still in the rumen, the next film can be taken six to eight hours later and then at four-hour intervals until twenty-four hours, when most of the gastrointestinal tract will have been visualized.

DIAGNOSIS OF GASTROINTESTINAL DISEASE BY PRESENTING SIGN

The purpose of this section is to assist in the differential diagnosis of gastrointestinal diseases on the basis of common presenting signs. The possibilities offered are not geographically restricted, so some of the diseases listed for a given presenting sign may not apply to the sick goat at hand.

The major infectious, parasitic, and metabolic diseases of the digestive system are mentioned when appropriate for a given presenting sign, but are discussed in detail later in the chapter. Other diseases that occur infrequently or sporadically, that are very localized geographically, or that are not well described in goats are discussed fully in this section and are not addressed again later in the chapter. For conditions discussed elsewhere in the text outside of this chapter, the reader is referred to the appropriate chapter number.

Inappetence

A history of inappetence often tempts the clinician into presuming a primary digestive disorder. However, many multisystemic diseases, particularly if they produce fever, reduce appetite. The likelihood that inappetence reflects a digestive dysfunction increases if it is accompanied by changes in rumen motility, vomiting, the development of abnormal feces, tenesmus, or distortions of the abdominal contour.

Frothing at the Mouth

Frothing at the mouth may be seen independently of excessive salivation, slobbering, and drooling as discussed below. In all species, frothing is commonly associated with uncontrolled chewing or lip smacking during convulsive activity. In goats, frothing is probably seen most commonly as a mild adverse reaction to administration of the anthelmintic levamisole. Froth-ing or excessive salivation, depression, and hyperesthesia may occur in some goats shortly after administration of the drug, even at the suboptimal dose of 8 mg/kg orally or parenterally. Frothing, along with dyspnea, frequent urination and defecation, and clonic convulsions may occur when levamisole is overdosed, particularly by parenteral administration.

Idiopathic frothing at the commissures of the lips associated with cud chewing has been observed by the author in several individual French Alpine and Nubian does in different herds. The animals were normal in all other respects and were not receiving medications of any kind. Owners reported the condition occurred intermittently in individuals over periods of months to years.

Frothing at the mouth in conjunction with dyspnea, diarrhea, and ataxia was reported in goats from the Sudan poisoned by the plant *Cadaba rotundifolia* (El Dirdiri et al. 1987). In Kenya, frothing at the mouth in conjunction with bloat, incoordination, and death was caused by ingestion of *Cestrum aurantiacum*, a shrub used for hedges and windbreaks (Mugera and Nderito 1968). At necropsy, there was severe hemorrhagic gastroenteritis.

Excessive Salivation, Slobbering, or Drooling

Stomatitis, or inflammation of the mucosa of the oral cavity, is most often responsible for excess salivation, slobbering, or drooling in the goat. A foul odor to the breath may accompany salivation if necrosis of the oral mucosa has occurred. If pain is severe, dysphagia may also occur.

Infectious causes of stomatitis include contagious ecthyma, goat pox, unclassified viral dermatitis, foot and mouth disease, bluetongue, vesicular stomatitis, rinderpest, peste des petits ruminants, caprine herpesvirus, necrotic or ulcerative stomatitis caused by *Fusobacterium necrophorum* infection, and alveolar periostitis.

Contagious ecthyma (soremouth, orf) is the most common cause of stomatitis in goats worldwide. The virus produces papular eruptions mainly at the commissures of the lips that may become secondarily infected with bacteria. The lesions heal spontaneously within six weeks, but excess salivation, reluctance to eat, and mild dysphagia leading to weight loss can precede resolution.

Goat pox may produce ulcerative lesions on the lips and in the mouth in addition to the characteristic skin nodules, pyrexia, and conjunctivitis. The disease is absent from the Americas and Australia and has been largely eliminated from Europe. A highly fatal, unclassified viral dermatitis has been observed in India since 1946 (Haddow and Idnani 1948). The condition is distinct from goat pox clinically and pathologically, although a pox virus has been isolated from clinical

cases (Patnaik 1986). Widespread cutaneous eruptions may include the lips, gums, and tongue. Rubbery, non-exudative nodules and papules develop on the oral surfaces and lead to necrotic ulcers in seven to ten days.

Foot and mouth disease may have drooling or lip smacking as presenting signs resulting from vesicles in the oral cavity. In goats and sheep, as compared with cattle, however, foot lesions are more common than oral lesions. The disease is endemic in much of Asia, Africa, and South America.

Bluetongue rarely causes clinical disease in goats, although serologic evidence of exposure occurs extensively. When clinical signs do occur, they include stomatitis associated with edema and congestion of the oral mucosa and ulceration of the lips and dental pad. These signs are accompanied by high fever, nasal discharge, diarrhea, and lameness caused by coronitis.

Vesicular stomatitis, caused by a rhabdovirus, occurs only in the Americas. Goats are less susceptible than cattle, horses, and swine. In goats, the only sign may be salivation with vesicles at the commissure of the lips, and the condition should be differentiated from contagious ecthyma by virus isolation.

Rinderpest produces a necrotic stomatitis involving the gums, cheeks, and tongue. However, salivation is not a dominant sign; it can be overshadowed by profuse, mucopurulent, oculonasal discharge, and later, diarrhea. Until recently, rinderpest was endemic in Africa, the Middle East, and south Asia, but the disease is close to being eradicated worldwide as a result of internationally coordinated control efforts. Goats are less severely affected than cattle.

Peste des petits ruminants is similar to rinderpest in clinical presentation, causing necrotic stomatitis, diarrhea, and bronchopneumonia. It affects goats severely. It occurs in much of Africa the Middle East and South Asia.

Caprine herpesvirus has been reported as a cause of severe illness and fatality in kids in Switzerland. Marked oral erosions were observed in conjunction with nasal discharge and conjunctivitis, and at necropsy, erosions of the cecum, colon, and urinary bladder (Mettler et al. 1979).

Necrotic stomatitis, caused by *Fusobacterium necrophorum* and other secondarily invasive bacteria, has been reported in four- to six-week-old Boer goat kids in South Africa (van Tonder et al. 1976). Clinical signs included fever, salivation, frothing, lip smacking and chewing movements, mucopurulent nasal discharge, anorexia, weight loss, and a mortality rate of 21%. Lesions were confined to the mouth, tongue, and throat and consisted of well circumscribed necrotic ulcers up to 4 cm in length. Treatment with parenteral chloramphenicol twice daily for five days was effective. Sodium sulfadimidine, penicillin, streptomycin, and tetracycline are all effective treatments for this condition in calves. A similar outbreak in India involved adult goats and kids. Pregnant does aborted and there was evidence of *F. necrophorum* septicemia (Nayak and Bhowmik 1988).

Dental disease, particularly alveolar periostitis, can produce pain in the mouth and inflammation of the gums leading to dysphagia and salivation. Oral examination should include careful inspection of the molars. Radiographs of the dental arcades may be helpful, because thorough visual examination of the teeth is awkward.

Noninfectious causes of stomatitis include chemical irritants, traumatic injuries, plant and chemical poisonings, and possibly neoplasia. If caustic dehorning pastes are used to remove horn buds on young kids, their licking the paste from each other's polls leads to chemical stomatitis. Caustic soda used to clear drains on farms may also cause stomatitis if the drains are backed up and goats drink the standing water. Battery acid from automotive storage batteries carelessly discarded can taste salty and has been consumed by curious goats, leading to chemical stomatitis (King 1980).

Giant hogweed *(Heracleum mantegazzianum)* has caused ulcerative stomatitis with anorexia and profuse salivation in a goat in Britain (Andrews et al. 1985). Other specific references to plant or chemically induced stomatitis in goats are rare. Agents known to cause stomatitis in other species can presumably affect the goat. These include mercurial and arsenical compounds and plants containing ranunculin, such as buttercup and crocuses.

Traumatic stomatitis with salivation can result from sharp dental points on the buccal aspect of the upper molars and lingual aspect of the lower molars. Abrasion and ulceration of the mucosa can lead to secondary bacterial infections and abscesses, particularly in the cheek. Certain plant awns, such as barley, foxtail, and thistle, can also traumatize the oral mucosa.

Rough or careless administration of medications using dose syringes and balling guns is a common cause of traumatic stomatitis of the hard palate and pharynx. Resulting injuries can produce salivation, dysphagia, regurgitation of feed, and possibly aspiration pneumonia.

Neoplasia of the oral cavity is rare in goats but three cases of lymphosarcoma or adenocarcinoma have been reported to involve oral structures, leading to loosening and displacement of molar teeth (Baker and Sherman 1982; Lane and Anderson 1983; Craig et al. 1986). A rare, primary parotid salivary gland tumor of mixed epithelial and mesenchymal elements has been reported in a two-month-old Jamnapuri crossbred female goat (Omar and Fatimah 1981).

Salivation may occur independent of stomatitis, usually caused by neurologic disease, systemic poisonings, or obstructions of the digestive tract distal to the oral cavity. Neurologic diseases associated with salivation or drooling in the goat are listeriosis, caprine arthritis encephalitis virus infection, migrations of the nematode parasite *Parelaphostrongylus tenuis*, and trauma to the facial nerve. Rabies and polioencephalomalacia may also produce excessive salivation, but usually in conjunction with other neurologic signs that are more general or progressive than those seen with the focal conditions just mentioned. Botulism produces a general weakness of the muscles including the tongue and muscles of mastication. Therefore, dysphagia and drooling can be seen along with recumbency. Neurologic diseases are discussed in detail in Chapter 5. Nutritional muscular dystrophy, or white muscle disease, can produce necrosis of the muscles of the tongue and pharynx, leading to dysphagia and drooling. The condition is discussed in detail in Chapter 4.

Profuse salivation may be one of the first recognized signs of organophosphate and carbamate poisoning. Additional signs include muscle stiffness and fasciculation, frequent urination and diarrhea, pupillary constriction, colic, dyspnea, nervousness, and sudden death. Some of these same signs, including salivation, may be seen in urea toxicity as discussed in Chapter 19. Acute chlorinated hydrocarbon poisoning also produces an abundant flow of ropy saliva in conjunction with signs suggesting neurologic dysfunction, such as belligerence, muscle twitching, clonic and tonic convulsions, and death. Xylazine produces excessive salivation at doses used for tranquilization.

Some plant poisonings produce salivation without stomatitis in goats. Plants of the family Ericaceae produce salivation and vomiting as discussed later in the section on regurgitation. *Cotyledon orbiculata* is common in South Africa. The plant is cardiotoxic, but excessive salivation is an important presenting sign after ingestion (Tustin et al. 1984).

Consumption of *Prosopis juliflora* (mesquite) and *Prosopis glandulosa* (honey mesquite) can be toxic to goats. When ingested in sufficient quantities, the unknown plant toxin can produce signs of salivation, dysphagia, protrusion of the tongue, and tremors of the mandible (Washburn et al. 2002; Misri et al. 2003). Vacuolation of neurons in the trigeminal motor nucleus and neuronal necrosis and loss in the trigeminal ganglia are associated with these clinical signs (Washburn et al. 2002).

"Slobbers" is caused by the fungus *Rhizoctonia leguminicola*, or "black patch," that grows on legume forages, particularly red clover, during wet weather and high humidity. It can persist on stored forages. The fungus produces an alkaloid, slaframine, which produces copious salivation within one hour of ingestion and may last for twenty-four hours after a single exposure. The condition is seen primarily in the United States and Japan and is reported in goats (Isawa et al. 1971). Slobbering may be the only clinical sign, but lacrimation, frequent urination, diarrhea, dyspnea, abortion, and even death may be seen with prolonged exposure. There is no specific treatment except for rapid diagnosis of the problem and removal of goats from the offending feed.

Cyanide poisoning, associated with ingestion of numerous plant species, can have salivation as the initial sign. The disease is discussed in Chapter 9.

Physical obstruction of the esophagus or pharynx can prevent the normal swallowing of saliva and lead to excess salivation. Bloat accompanies salivation when obstruction of the pharynx or esophagus is complete. Foreign bodies likely to produce obstruction are fruits, tubers, and roots.

No specific treatment for excessive salivation is recommended. Atropine may reduce saliva flow, but the additional effects of reduced gastric motility argue against its use. The major goal is to identify and treat the underlying cause of salivation. It should be remembered, however, that saliva is produced in very large amounts and contains many electrolytes, including bicarbonate. Prolonged loss of saliva may lead to dehydration, electrolyte imbalance, and acidosis. These sequelae should be managed with fluid and electrolyte therapy.

Dysphagia

Dysphagia may be manifested by prolonged chewing, retaining feed in the mouth, dropping feed from the mouth (quidding), and as just discussed, drooling or slobbering. Many of the causes of stomatitis also can produce dysphagia depending on the extent and severity of the oral lesions present.

Focal neurologic diseases such as listeriosis, brain abscess, parasitic larval migration, and CAE can produce dysphagia when damage to the cranial nerve roots VII, IX, X, or XII occurs. Nutritional muscular dystrophy affecting the tongue and pharyngeal muscles can mimic these neurologic deficits. Accumulation of feed in the buccal space can be associated with the loss of one or more molars secondary to aging or alveolar periostitis. This can also occur with facial nerve paralysis resulting in flaccidity of the cheek muscles. Holding feed for prolonged periods in the mouth without chewing may be observed in rabies, tetanus, botulism, and polioencephalomalacia.

Developing teeth are subject to structural modification by chronic exposure to fluoride. Fluorosis can produce pitting, a rough, chalky enamel, discoloration, and accelerated wearing of teeth (Milhaud et al. 1980). The excessive tooth wear and associated pain can produce signs of dysphagia. The third and fourth pairs

of incisors are most often affected. Exostoses of the mandible and maxilla may also occur. Fluorosis is discussed in detail in Chapter 4. Excessive tooth wear is also associated with grazing of sandy soils by goats.

Additional dental problems that may lead to dysphagia include over-eruption of teeth; broken teeth; vestigial teeth; and displaced, rotated, or migrated teeth (Rudge 1970). Fibrous osteodystrophy, discussed in Chapter 4, can lead to severe inward rotation of the dental arcades.

In recent years, there have been unsubstantiated reports from Kenya that goats grazing on the seed pods of *Prosopis juliflora* (mesquite) are losing their teeth as a result of the seeds sticking between the teeth and gums, leading to gingivitis, alveolitis, disfigured jaws, impaired ability to eat, and inanition (Mwangi and Swallow 2005). While tooth loss is unsubstantiated, *Prosopis* spp. can produce salivation and dysphagia without a direct effect on teeth, as discussed above in the section on salivation.

Presence of milk or chewed feed at the nares and coughing in kids may result from cleft palate. Retropharyngeal abscess caused by *Corynebacterium pseudotuberculosis* in older goats may block normal swallowing by compression of the soft palate leading to coughing and nasal expulsion of feed. Balling gun or dose syringe injuries may initiate these abscesses. Attempts at surgical drainage carry a guarded prognosis. There is a reported case of a goat whose tongue was encircled by the neck of a broken bottle, leading to trauma to the tongue and dysphagia. To correct the condition, the glass ring was snapped with a bone forceps and with supportive treatment the goat recovered (Alhendi et al. 1999).

Treatment of animals with dysphagia should include broad-spectrum parenteral antibiotics until normal swallowing resumes because the risk of aspiration pneumonia in association with dysphagia is high. Correction of dehydration and nutritional supplementation through a stomach tube must also be considered during prolonged disease.

Regurgitation, Retching, or Projectile Vomiting

Partial or complete obstructions of the pharynx or esophagus can lead to regurgitation of feed in goats (Fleming et al. 1989). Acute copper toxicity in a herd of goats given an overdose of oral copper sulfate resulted in repeated attempts to vomit, as well as abdominal pain, muscle fasciculations, labored breathing, tachycardia, and frothing at the mouth before death (Shlosberg 1978).

In other species, notably dogs, megaesophagus is associated with vomiting. However, in the one reported case of megaesophagus in a four-year old Nubian doe there was no history of vomiting. The only clinical signs were an obvious swelling of the dilated esopha-gus in the ventral portion of the neck and gurgling sounds audible from a few meters. Contrast radiography indicated that the esophageal dilation extended through the thorax to the cardia (Ramadan 1993).

The toxic plants most often associated with vomiting in goats are members of the heath family (Ericaceae) and include rhododendrons, laurels, azaleas, lily of the valley tree (*Clethra arborea*), and Japanese pieris. They contain the toxic principle grayanotoxin (also referred to as andromedotoxin), which acts primarily on the autonomic nervous system, stimulating the vomiting center via the vagus nerve and producing hypotension (Smith 1978; Knight 1987; Gibb 1987). Clinical signs can occur when as little as 0.1% of the animal's bodyweight is ingested as fresh leaves.

Within six hours of ingestion of Ericaceae, goats may show signs of depression, weakness, anorexia, salivation, abdominal pain, vomiting, and possibly bloat and diarrhea. Tenesmus and blood in the feces were reported in a goat consuming *Pieris formosanum* (Hollands and Hughes 1986). While the condition may be self-limiting within days if only small amounts of the plants are eaten, ingestion of large quantities may cause death (Visser et al. 1988). Exposure of eighteen goats to clippings of *Rhododendron macrophyllum* resulted in convulsions and death in two, weight loss in all, and agalactia in seven (Casteel and Wagstaff 1989). Sublethal ingestion of Japanese pieris has been associated with fetal mummification in a goat (Smith 1979).

If known exposure has occurred, rumenotomy before the onset of signs is recommended. After onset of signs, treatment should include intravenous fluid therapy to counter hypotension, relief of bloat by stomach tube if necessary, oral magnesium hydroxide and activated charcoal, and parenteral calcium gluconate, as well as parenteral antibiotic to minimize the risk of aspiration pneumonia associated with vomiting. The antispasmodic hyoscine-*n*-butylbromide has also been used to control vomiting.

Prevention involves educating goat owners regarding the potential danger of these plants to livestock. Members of the heath family are widely used as ornamental plantings, and goats should be kept away from plantings and not fed prunings because these will be readily eaten.

Other plants may cause vomiting in goats. A spontaneous case of vomiting in conjunction with constant bellowing, rumen atony, and depression was reported in a goat ingesting *Raphanus sativus*, a member of the Cruciferae, or mustard, family (Drahn 1951). Vomiting, depression, and a staggering gait were observed in a goat in England after ingestion of *Solanum nigrum*, or black nightshade (Gunning 1949). Gladiolus corms eaten by goats produced bleating or moaning, vomiting, staggering, and depression within hours.

Exposure was fatal in some cases. The prominent finding at necropsy was watery-brown rumen content (Anonymous 1988).

Rumen Atony

Normal rumen mixing contractions may be reduced in frequency when goats are fed rations low in coarse roughage and high in finely ground concentrate. Contractions may disappear when goats are excited or fearful, when parasympathomimetic drugs such as atropine are administered, or when central nervous system anesthetics and depressants such as barbiturates have been given.

Pathologic processes occurring outside the digestive system can inhibit rumen motility. These include pain from any source, severe dehydration, electrolyte or acid-base imbalances, hypocalcemia, high fever, and toxemias. Peritonitis as a cause of rumen atony is uncommon in goats as compared with cattle, mainly because of the infrequent occurrence of traumatic reticuloperitonitis in goats. There are few references to this condition in the goat (Maddy 1954; Sharma and Ranka 1978; Tanwar and Saxena 1984). It is presumed that the more selective, discriminating food prehension behavior of goats limits the ingestion of foreign bodies capable of penetrating the reticulum. When traumatic reticulitis does occur in goats, signs are similar to those in cattle. There is a report of experimentally induced traumatic reticuloperitonitis in seventeen goats fed wires, nails, and/or needles (Roztocil et al. 1968). The clinical presentation reflected what is seen in naturally occurring bovine cases, namely fever, anorexia, depression, cessation of rumen motility, elicitation of pain with application of pressure in the region of the xiphoid cartilage, and neutrophilia with a left shift. Some individuals also developed traumatic pericarditis, pneumonia, and/or hepatitis, depending on the ultimate locations of the metal foreign bodies.

Pathologic processes within the digestive system leading to rumen atony include simple indigestion, bloat, rumen acidosis caused by acute carbohydrate engorgement, and rumen alkalosis associated with urea poisoning. In general, plant and chemical poisonings frequently include rumen atony as one of the presenting signs.

Abdominal Distension

There is considerable variation in the normal abdominal silhouette. Pygmy goats are achondroplastic dwarfs, and as such, their abdominal girth is proportionately greater for their height and weight compared with other breeds. As young pygmy goats develop full rumen capacity, they sometimes appear to inexperienced owners to be abnormally distended in the abdomen. An inherited condition identified as "dropped stomach" has been reported in Toggenburg

does. It involved permanent stretching of the ventral abdominal musculature in late pregnancy. After parturition, the ventral abdomen remains pendulous but affected animals are otherwise normal (Wirth 1980). The condition has also been observed in other breeds (Figure 10.1).

Ruminal tympany, or bloat, is not uncommon in goats, and both the frothy (nutritional) and free gas forms can occur. In all types, abdominal distension is initially most prominent in the left paralumbar fossa, and may also involve the entire left side of the abdomen and the right ventral abdomen if severe.

The single case of left displaced abomasum reported in the goat was associated with intermittent bloat (West et al. 1983). Acute carbohydrate engorgement can also produce a similar pattern of abdominal distension due both to gas accumulation and fluid pooling in the rumen. The presence of fluid can be established by ballotment of the ventral rumen and by reflux through a stomach tube.

Rumen impaction produces a distended rumen palpable as a firm mass low on the left side of the abdomen behind the ribs. The causes and management of rumen impaction are discussed later in this chapter. Abdominal distension predominantly in the lower right quadrant is most commonly associated with late pregnancy as the rumen displaces the expanding uterus to the
Figure 10.1. Dropped stomach in a mother and daughter pair of Saanen goats. Note prominent abdominal distension. Neither goat is pregnant. (Courtesy of Dr. David M. Sherman.)

right. Herniation of the gravid uterus through the right abdominal floor causing prominent right ventral abdominal distension occasionally occurs (Horenstein and Elias 1987).

Abnormal distension of the right ventral abdomen also can be associated with abomasal disorders. Abomasal impaction with metal shavings has been reported in an adult goat from India (Purohit et al. 1986). Numerous abomasal impactions with phytobezoars have been reported from South Africa. The concretions are composed of the pappus hairs of the seeds of Karoo bushes. Goats are more often affected than sheep and Boer goats more often than Angora goats (Bath 1978). The clinical syndrome is one of progressive abdominal distension and weight loss. Occasionally animals are found dead due to rupture of the stomach. The phytobezoars, which are multiple and round, may be felt in the abomasum by deep palpation behind the xiphoid cartilage. Early recognition and quick slaughter for salvage are recommended because no satisfactory treatment has been identified (Bath and Bergh 1979).

The feeding of high-fiber roughages of low digestibility mentioned as a cause of rumen impaction can also produce abomasal impaction, particularly in pregnant does. In these cases, the lower right abdomen is distended, or a doughy abomasal content can be palpated. Animals are thin and feces are soft, fibrous, and malodorous. Treatment includes dietary improvement and the use of laxatives such as mineral oil. The value of abomasotomy has not been reported. Pregnancy toxemia is a possible sequela, and the prognosis is guarded.

Abrupt changes in feeding, from milk to milk replacer or milk pellets, are associated with abomasal bloat. The pathogenesis of abomasal bloat may involve the rapid fermentation of sugars by gas-producing, anaerobic bacteria present in the abomasum, such as *Sarcina* spp., which were identified during an epidemic of abomasal bloat in kids six to ten weeks of age that occurred in a large goat dairy in California (DeBey et al. 1996). Abomasal bloat is also seen predictably in young kids in artificial rearing systems, particularly when milk is fed directly from a trough or bucket without a nipple (Thompson 1987). This is presumed to be caused by too rapid ingestion followed by excessive fermentation of milk. Because the abomasum in the suckling goat is the largest stomach, gas distension may occur on the left and right sides of the abdomen. The condition can be fatal. Alternative methods of feeding using nipple feeders or feeding *ad libitum* should be considered (Morand-Fehr et al. 1982; Thompson 1987). Successful treatment of a series of abomasal bloat cases in kids one to two weeks of age has been reported using a single intramuscular injection of hyoscine at 0.3 mg/kg bw plus metaclopramide at 0.5 mg/

kg bw and a vitamin E/selenium compound at 0.1 mg/kg bw (Kojouri 2004).

Overfeeding of milk can also lead to ruminal bloat when excessive volumes of milk reflux into the developing rumen (Chennells 1981). Overfeeding may also predispose to acute enterotoxemia with signs of hemorrhagic enteritis, nervous dysfunction, or death.

Bilateral ventral distension of the abdomen due to chronic indigestion secondary to abomasal impaction, as described above, may be seen in goats. It also has been observed in a goat with acute duodenal obstruction caused by a phytobezoar (Sherman 1981). Accumulation of ascites fluid secondary to conditions causing hypoproteinemia or cardiac insufficiency also may produce such bilateral distension. There is a report of marked fluid distension of the abdomen of an eleven-year-old pygmy goat secondary to extensive abdominal fat necrosis attributed to tall fescue toxicity in North Carolina (Smith et al. 2004). In young goats, gastrointestinal nematodiasis and tapeworm infestations can lead to a marked "pot-bellied" appearance.

In female goats of breeding age, pseudopregnancy or hydrometra is a common cause of bilateral ventral abdominal distension. In male goats, the most common cause is urine accumulation in the abdomen after ruptured bladder caused by obstructive urolithiasis. This condition is discussed in detail in Chapter 12.

Intestinal and ovarian adenocarcinomas have been associated with accumulations of as much as 30 liters of intra-abdominal fluid in aged, female goats with progressive abdominal distension and discomfort (Haibel 1990; Memon et al. 1995). There is also a single case report of abdominal mesothelioma involving the peritoneum in an eight-year-old female Toggenburg goat in Austria that presented with marked ascites and a distended, pear-shaped abdomen (Krametter et al. 2004). Peritoneal mesothelioma was also diagnosed in a goat in South Africa (Bastianello 1983).

Generalized distension of the abdomen may occur secondary to conditions causing generalized ileus such as severe peritonitis and sporadic intestinal accidents. General abdominal distension in young kids may occur before the onset of diarrhea in the early stages of infectious bacterial enteritis, when the causative organisms are potent gas producers. Congenital atresia ani and atresia coli or recti occur in newborn kids. Atresia can usually be diagnosed by a history of progressive abdominal distension, straining to defecate with no fecal output, depression, and waning appetite in kids from one to four days old. However, kids as old as fourteen days of age have been presented for veterinary attention with a history of no defecation. Atresia ani has been successfully corrected surgically in goats by creation of anal patency (Ali et al. 1976). Atresia coli or recti may require a colostomy to salvage

the affected animal (Philip 1973). In the goat, atresia ani also can occur associated with rectovaginal fistula, which allows for fecal voiding and may not be recognized until doelings approach breeding age or vaginitis occurs (Johnson et al. 1980). Animals with congenital anomalies of the anus, rectum, and colon should not be used for breeding if salvaged by surgical repair. A high incidence of atresia ani has been reported in the Shami breed of goat in Jordan (Al-Ani et al. 1998).

Focal distortions of the abdominal silhouette can be seen. Causes include umbilical hernia and spontaneous or traumatic ruptures of the abdominal wall, sometimes associated with fighting between horned goats (Figure 10.2). Ventral abdominal herniation in the doe has been associated with stretching of the ventral musculature during pregnancy and the subsequent increased weight of the enlarging udder (Misk et al. 1986). In Saudi Arabia, 193 goats with hernial swellings were presented to a veterinary teaching hospital over a five-year period. Umbilical, ventral abdominal, inguinal, scrotal, and perineal hernias were all diagnosed, some with the assistance of contrast radiography (Abdin-Bey and Ramadan 2001).

Abdominal Pain or Colic

Abdominal pain in goats may be manifested by depression, restlessness, bleating, teeth grinding, reluctance to move, increased shallow respiration, increased heart rate, tenesmus, or an abnormal posture with an arched back and tucked-up abdomen. Overt colic signs such as kicking at the belly or rolling are less common.

Mechanical Causes

In young kids, abdominal pain may be caused by feeding very cold milk or too much milk. Cecal torsion, intussusception (Mitchell 1983), and torsion of the root of the mesentery are sporadically occurring intestinal accidents more common in young goats than mature goats and are associated with pain. Torsion of the root of the mesentery is most common in unweaned kids fed by bottle or in *ad libitum* systems (Thompson 1985). In pregnant does, uterine torsion can produce abdominal pain. There is a report of rumen impaction in a goat in which extension and stretching of the fore and hind limbs and muscular rigidity, typical of a colicky horse, were presenting signs (Otesile and Akpokodje 1991).

Infectious Causes

Signs of severe abdominal pain may occur in conjunction with diarrhea, screaming, and convulsions before death from acute *Clostridium perfringens* type D enterotoxemia. Episodes of abdominal discomfort or pain may be observed during or immediately after eating in young goats with acute coccidiosis, before the onset of diarrhea. In young kids, enterotoxemia and coccidiosis must be differentiated from intestinal accidents such as torsion of the root of the mesentery at necropsy.

Peritonitis

Peritonitis can produce abdominal pain in addition to ileus, abdominal distension, and fever. Causes of infectious peritonitis in goats include rumen trocharization, uterine tears associated with dystocia, and extension of metritis from the uterus to the abdominal cavity. It can also occur as a sequela to rumenitis after acute carbohydrate engorgement. Organisms commonly associated with infectious peritonitis are *E. coli*, streptococci, staphylococci, *Fusobacterium necrophorum*, and *Clostridium* spp. Systemic mycoplasmosis in goats can produce a serositis-arthritis disease complex that includes peritonitis (DaMassa et al. 1983). Filarial worms of the genus *Setaria* may be found in the peritoneal cavity of goats, but are considered nonpathogenic (Subramanian and Srivastava 1973).

Noninfectious causes of peritonitis in goats include chemical irritation caused by intraperitoneal injections

of sulfa drugs or calcium solutions, talc from surgical gloves (Hall 1983), and bile.

Toxicities

Several ingested plants and chemical toxins can produce abdominal pain. The Ericaceae can produce signs of colic, as can acute oral copper poisoning, acute carbohydrate engorgement, and organophosphate insecticide toxicity.

Urolithiasis

Perhaps the most common cause of abdominal pain in goats is obstructive urolithiasis seen in male goats. The appearance of pain is characterized by frequent and strained attempts to urinate. This is often misinterpreted by owners as straining to defecate caused by constipation.

Absence of Feces or Constipation

A history of no fecal output in association with tenesmus, abdominal pain, or abdominal distension strongly suggests an intestinal blockage caused by volvulus, intussusception, incarceration, or luminal obstruction by foreign body. Digital palpation of the rectum may reveal feces that arrived at the rectum before the obstruction occurred. The fecal matter should be removed and the animal rechecked later. If the rectum contains mucus only or mucus mixed with blood, this is strong evidence of intestinal obstruction. In neonates, atresia ani and atresia coli must be considered when there is no feces.

Constipation may be observed as a side effect of normal pregnancy or as a sign of pregnancy toxemia during late gestation (Pinsent and Cottom 1987). It may also be seen when access to water is limited or when diets are fibrous and of poor quality.

Extraluminal compression of the intestine by intra-abdominal abscesses due to *Corynebacterium pseudotuberculosis* may impede fecal output in goats. While clinical coccidiosis is noted for producing diarrhea, subclinical coccidiosis, which is common in young goats, produces constipation in conjunction with anorexia and reduced growth rate (Aumont et al. 1984).

Diarrhea

There are numerous known infectious and parasitic causes of diarrhea and their frequency of occurrence varies to a large extent with the age of goats affected, as presented in Table 10.3. Diarrhea in young goats results from a complex interaction of etiologic, immunologic, and husbandry factors. The topic is discussed separately at the end of this chapter under the heading Neonatal Diarrhea Complex.

Noninfectious causes of diarrhea include overfeeding in kids, simple indigestion, acute carbohydrate engorgement (lactic acidosis), copper deficiency, and

intoxications. Though not as well documented, it is reasonable to assume that toxic agents known to produce diarrhea in other species, such as arsenic and organophosphates, would also do so in goats.

A number of plant intoxications have been documented as causing diarrhea in goats. These include *Parthenium hysterophorus, Nerium* spp. (oleanders), *Euphorbium* spp. (spurge), members of the Ericaceae family, *Aristolochia bracteata, Ipomoea sericophylla, Citrullus colocynthis, Lagneria siceraria, Jatropha* spp., *Sesbania vesicaria, Tephrosia apollinea, Malus sylvestris* (crab apple), *Abrus precatorius, Brachiaria mutica* (para grass), *Cassia senna* (coffee senna), and *C. italica* (Prasad et al. 1981; El Sayed et al. 1983; Galal et al. 1985; Shaw 1986; Dobereiner et al. 1987; Barri et al. 1990).

Goats are considered resistant to the toxic effects of oak ingestion and are often used to clear oak from pastures to allow grazing by cattle and sheep. Nevertheless, hemorrhagic gastroenteritis with bloody diarrhea caused by oak ingestion *(Quercus floribunda)* has been reported in goats in India and resistance of goats to oak toxicity cannot be considered absolute (Katiyar 1981).

Selenium toxicosis related to the ingestion of selenium-concentrating plants can also produce diarrhea. Experimental daily dosing of goats with sodium selenite at 6 mg/kg produced constipation followed by diarrhea with blood and mucus, as well as polydipsia, polyuria, lacrimation, coughing, and nasal discharge (Pathak and Datta 1984).

Oral ochratoxin administration produced diarrhea and death in a doe fed 3 mg/kg for five days (Ribelin et al. 1978). This is less than one-fourth the lethal dose rate in cattle.

Weight Loss

The major causes of weight loss associated with the alimentary tract are inadequate nutrition, gastrointestinal nematodiasis, and paratuberculosis. In addition, numerous diarrheal diseases such as enterotoxemia, salmonellosis, rinderpest, and peste des petits ruminants have chronic forms that lead to weight loss. However, there are numerous causes not associated with the alimentary tract. Progressive weight loss is a clinical presentation so common in goats that the differential diagnosis of this condition is discussed in detail in Chapter 15.

SPECIFIC DISEASES OF THE DIGESTIVE SYSTEM

VIRAL DISEASES

Peste des Petits Ruminants

This virus disease of goats and sheep in Africa and Asia is clinically similar to rinderpest in cattle in that animals are affected by fever, stomatitis, and diarrhea, but in contrast to cattle, respiratory signs and pneumonia are prominent features. The comparative aspects of the two diseases in small ruminants have been reviewed (Lefèvre 1982; Roeder and Obi, 1999).

Etiology

Peste des petits ruminants (PPR) is caused by a morbillivirus in the family Paramyxoviridae. The morbillivirus genus also includes the canine distemper, measles, and rinderpest viruses and the related viruses of cetacean and phocine marine mammals. These RNA viruses are enveloped, contain RNA in tightly coiled, helical nucleocapsids, and are structurally, physicochemically, and antigenically similar.

Serologic cross-reactions between PPR and rinderpest virus are observed in immunodiffusion and complement fixation reactions. The shared antigens occur in the nucleocapsid and envelope. Cross-reactive serum neutralizing antibodies also occur, but the reaction to the two viruses can be distinguished based on quantitative antibody assays. There is no evidence of antigenic differences among various field isolates of PPR virus; all belong to one serotype. However, phylogenetic analysis based on amplification and sequencing of a fragment of the viral fusion (F) protein indicates that there are four distinct lineages for the PPR virus (Shaila et al. 1996). Lineages 1 and 2 are found exclusively in West Africa. Lineage 3 has been found in eastern Africa, the Arabian peninsula and southern India, while lineage 4 is found from Turkey eastward through the Middle East and the Indian sub-continent (Dhar et al. 2002).

Peste des petits ruminants virus can be cultivated in sheep or goat kidney cell, Vero cell, and embryonal or neonatal testicular cell cultures. A cytopathic effect with formation of syncytia and clock-faced giant cells is observed. Intracytoplasmic and intranuclear inclusions occur.

Epidemiology

Peste des petits ruminants was first described as a disease mimicking rinderpest in sheep and goats in the Ivory Coast in 1942 (Gargadennec and Lalanne 1942). Serologic cross-reactions with rinderpest virus confused early recognition of the disease as a distinct entity of separate etiology. By the late 1970s, experimental infections, virological studies, and serologic studies established that PPR was a disease distinct from rinderpest and that the small ruminant disease syndromes of West Africa known as Kata and stomatitis pneumoenteritis complex were in fact PPR (Rowland et al. 1971; Hamdy et al. 1976; Gibbs et al. 1979).

From the 1970s PPR has been identified progressively further eastward in sub-Saharan Africa (Roeder et al. 1994), in the Middle East and South Asia. It is

now becoming apparent that PPR is in fact caused by an Asian virus which was introduced to West Africa in the early part of the twentieth century (Taylor and Barrett 2007). Much of what was earlier reported to be rinderpest in small ruminants in South Asia is now considered to have been PPR.

An epizootic of highly virulent PPR appears to have developed in South Asia in the early 1990s and to have spread widely between Bangladesh, Turkey, and the Middle East. It is still gaining ground as evidenced by widespread infection in the Central Asian countries in recent years (Roeder, personal communication 2007). The People's Republic of China reported PPR to the World Organization for Animal Health (OIE) for the first time in July 2007. The outbreak occurred in Tibet.

The principal hosts of PPR are sheep and goats, with goats more susceptible to development of disease. Breed variation in susceptibility among goats has been suggested. However, some studies suggest that management and climatic factors may be confounders in this analysis (Ezeokoli et al. 1986). For example, different rates of breeding may affect population susceptibility, as the more prolific breeds may have a higher proportion of younger, more susceptible animals in the population. The disease is considered to be a major constraint in the development of small ruminant productivity among small-holders, mainly by causing high mortality in young stock (Sumberg and Mack 1985).

Virus replication occurs in cattle and pigs, and serum neutralizing antibodies may occur. Neither species, however, is considered to play an active role in disease transmission. Rats can be subclinically infected but do not appear to transmit the virus to other rats or goats (Komolafe et al. 1987).

There is evidence that some wild ruminants can be infected with PPR and experience clinical disease, but the role of wild ruminant populations in the epidemiology of the disease remains unclear. The white tail deer of North America is readily infected experimentally (Hamdy and Dardiri 1976). An outbreak of PPR in a zoological park in the United Arab Emirates resulted in peracute deaths in gazelles, ibex, and gemsbok. Goats grazing on the zoo perimeter were believed to be the source of infection (Furley et al. 1987). In 2002, a PPR outbreak was confirmed in semi-free ranging Dorcas gazelles and Thomson's gazelles in Saudi Arabia with case fatality rates of 100% (Abu Elzein et al. 2004). The source of the infection was not confirmed.

When populations of naive, susceptible goats are suddenly exposed to infected animals, morbidity and mortality from PPR can approach 100%. In outbreaks of PPR in endemic areas, it is young goats between three and twelve months of age that are most often and most seriously affected. Concurrent diseases, such as parasitism or goat pox, can increase mortality. Older animals are protected by antibody derived from previous natural exposure or by vaccination, while newborn animals up to three or four months of age have maternally derived immunity from colostrum. In places where kidding occurs year-round, the continuous supply of susceptible young kids with waning maternal antibody facilitates maintenance of endemic PPR infection.

Seasonal peaks of disease may be observed during the heavy rains of summer or the dry cold winds of winter in some endemic countries. These increases may simply reflect peaks in susceptible young kid populations, but the pattern of disease may also be conditioned by variations in climate, geography, and differences in livestock management practices (Obi et al. 1983; Ezeokoli et al. 1986). Pastoralism and/or transhumance which leads to high densities of susceptible animals on seasonal pastures is often associated with increases in disease.

Goats and sheep that recover from infection do not shed the virus, and no carrier state has been identified for PPR. Recovered animals develop a strong immunity of at least several years' duration. Slaughterhouse surveys of apparently healthy goats in northern Nigeria indicated a seroprevalence of PPR antibody in 44% of goats tested, with goats older than three years of age having the highest rates of prevalence (Taylor 1979).

Pathogenesis

Infected animals shed the virus in oculonasal discharges, saliva, and feces during the clinical stages of disease. The disease is transmitted by direct contact or by aerosol via the coughing and sneezing that occur. After entry into the respiratory tract, virus localizes in the tonsils and in mandibular and pharyngeal lymph nodes during an incubation period of four to six days. Viremia follows with subsequent localization of virus in the visceral lymph nodes, spleen, bone marrow, and mucosae of the respiratory and digestive systems. Virus replication in the mucosal epithelium of the digestive tract produces mucosal erosions resulting in stomatitis and diarrhea. Diarrhea can be severe, with many deaths resulting from dehydration and electrolyte imbalances. Virus replication in the lymphoid tissue produces a marked loss of lymphocytes. Immunity is impaired and secondary infections contribute to the severity of clinical disease and increased mortality, most notably in association with bacterial pneumonias.

Clinical Findings

Exposure to newly introduced goats or sheep during the preceding few days to weeks is a common history in explosive outbreaks of PPR. After an incubation period of four to six days, a fever of 104°F to 106°F

(40°C to 41.1°C) or higher develops, and the animals become depressed, with a rough hair coat and dry muzzle. Within a few hours of the onset of fever, a serous nasal or oculonasal discharge is observed. Superficial necrosis of the lips may also be seen at this time.

The next day, affected animals become anorexic and the nasal and ocular discharges become mucopurulent. Ocular discharges are sometimes accompanied by conjunctivitis but keratitis is not seen. Erosive lesions may be found inside the mouth on the cheeks, lips, gums, and tongue (Figure 10.3). These lesions may be covered with necrotic tissue and inflammatory debris and there is a fetid odor to the breath. Similar erosive lesions sometimes occur on the vaginal mucosa or within the prepuce. A profuse, watery, brown diarrhea may begin one or two days after the onset of fever. Coughing and sneezing are prominent signs at this time.

Fever usually persists for five to eight days; during that time, the animals grow progressively weaker and lose weight. Pregnant does may abort. The eyes, muzzle, and lips are increasingly crusted and matted and animals sneeze in attempts to clear the nares. Diarrhea persists, and marked dehydration ensues. Signs of secondary bacterial pneumonia may also develop. Although fever eventually subsides and erosive lesions in the oral cavity may heal, many animals grow steadily worse due to the persistent anorexia, severe dehydration, and complications of pneumonia. Prostration and death usually occur seven to twelve days after the onset of fever.

Subclinical infections are common, especially in arid regions. In these cases, PPR may go unrecognized, but affected animals are likely to develop fevers and respiratory signs caused by secondary bacterial pneumonia.

Clinical Pathology and Necropsy

The hemogram demonstrates leukocytosis during the incubation period, and leukopenia during the acute phase of clinical disease. The leukopenia is predominantly a lymphopenia. Neutrophil responses are variable depending on the development of secondary bacterial infections.

During the early febrile stage of the disease, which coincides with viremia, the virus can be isolated from the buffy coat of whole blood. Circulating antibody is not detectable during the febrile stage of the disease, but an increase in convalescent titer can be observed in recovering animals. The virus neutralization test (VNT) and the competitive ELISA are the tests of choice for identifying antibody to PPR. The VNT is the prescribed test for international trade. In areas where rinderpest and PPR both occur, the quantitative serum cross-neutralization test is useful because it does not only quantify the increase in titer, but it discriminates between PPR and rinderpest by demonstrating higher neutralizing antibody titers to PPR (OIE 2004). Convalescent antibody is detectable for at least one year after recovery.

At necropsy, the carcass is emaciated, dehydrated, and soiled around the hindquarters. The eyes, muzzle, and mouth are heavily crusted. Red, raw, shallow mucosal erosions are most common on the lips, tongue, and cheeks near the commissures, and in severe cases, on the soft and hard palate. The pharynx, esophagus, ruminal pillars, and abomasal leaves may also demonstrate mucosal erosions. Intestinal erosions are less common, but congestion is a consistent finding, with a streaky "zebra stripe" pattern of congestion or hemorrhage common in the large bowel near the ileocecal valve, cecocolic junction, and rectum. Peyer's patches may slough from the intestinal wall. Catarrhal inflammation of the upper respiratory tract with occasional petechiation and a necrotic tracheitis may be observed. The lungs may be dark red, congested, and firm. Lobular lung consolidation and airway exudate caused by secondary bacterial pneumonia are common. Lymph nodes and spleen are enlarged, congested, edematous, and possibly hemorrhagic.

Histologically, the mucosal lesions show marked epithelial necrosis with hydropic degeneration of epithelial cells at the edge of erosions. Intranuclear and intracytoplasmic inclusion bodies are common in areas of alimentary and respiratory epithelial necrosis. Syncytial cells in the oral epithelium and giant cells in lung alveoli may be observed. In the small intestine, villous atrophy and cellular casts in the crypts are seen. Lymph nodes and Peyer's patches show a dramatic depletion of lymphocytes and collapse of germinal centers. Lymphocyte necrosis is evident and macrophage numbers are increased. Multinucleated giant cells with eosinophilic intracytoplasmic inclusions are seen. Hemorrhagic necrosis occurs in the spleen.

Virus isolation should be attempted in cell culture from nasal, conjunctival, or buccal mucosal swabs in live animals or from tissues derived at post mortem, especially lymph nodes, spleen, tonsils, and lung. For detection of viral antigen in samples, the agar gel immunodiffusion test is the preferred assay. The immunocapture ELISA can be used when it is necessary to differentiate the PPR and RP viruses. Other assays which can be used to identify the PPR virus or its antigens include counter immunoelectrophoresis, polymerase chain reaction, immunofluorescence, and immunoperoxidase (OIE 2004).

Diagnosis

Peste des petits ruminants is easily confused with rinderpest, which produces a very similar spectrum of clinical signs. However, rinderpest is currently uncommon in places where PPR is endemic as a result of effective international control efforts. If characteristic clinical signs are seen in cattle, buffalo, or yaks, as well as in goats and/or sheep, then rinderpest becomes the more likely diagnosis. Goats and sheep are less severely affected by rinderpest and have morbidity and mortality rates that are lower than those usually seen with PPR. During the early febrile stage, heartwater (cowdriosis) should be considered in the differential diagnosis. In heartwater, however, neurologic signs develop as the disease progresses.

When oral lesions without diarrhea are observed, contagious ecthyma, bluetongue, and goat pox must be considered. While goats are more severely affected by PPR than sheep, the opposite is true in bluetongue, and goats rarely show clinical disease in endemic regions. Goat pox may present as fever followed by oculonasal discharges, but subsequent skin changes are widespread over the body. When diarrhea predominates, salmonellosis, Nairobi sheep disease, and coccidiosis must be ruled out. In recent years, there has been an increasing overlap in the endemic ranges of PPR and Nairobi sheep disease. Coccidiosis is particularly common in the age group most often affected with PPR but can be readily identified by examination of intestinal smears or feces. When pneumonic signs predominate, pasteurellosis and contagious caprine pleuropneumonia need to be considered. In areas where PPR has not occurred previously, the disease is commonly misdiagnosed as pneumonic pasteurellosis. A thorough physical examination that includes inspection of the oral cavity for erosive or ulcerative lesions should help to avoid such misdiagnosis.

Treatment

There is no specific treatment for PPR, although hyperimmune serum temporarily reverses clinical

signs if given early, as discussed in Chapter 9. Affected animals should be placed on parenteral broad-spectrum antibiotics early in the disease to reduce the risk of likely secondary bacterial infections. Long-acting oxytetracycline, requiring an injection only every third day, is useful when repeated daily injections are impractical. The dose is 20 mg/kg given intramuscularly. Oral or parenteral fluid and electrolyte therapy may reduce mortality associated with diarrhea and dehydration.

Control

Because control of livestock movement through markets and between villages is so difficult, the main thrust of PPR control in endemic regions currently is vaccination using homologous tissue culture vaccines. The most common of these is derived from a West African strain, Nigeria 75/1, but there are other attenuated vaccines produced with strains from India, Bangladesh, and Kazakhstan. In the past, rinderpest vaccine was used to control PPR. While it offered good cross protection, its use is now contraindicated because it prevents countries from entering on the OIE pathway for accreditation of rinderpest freedom. PPR vaccine produced according to OIE guidelines provides protection against PPR for at least three years (OIE 2004).

In endemic areas, vaccination efficiency can be increased by targeting young animals in the first year of life after the loss of colostral immunity at three to four months of age. This is the group most at risk of infection. In the face of outbreaks, the spread of PPR is limited by ring vaccination of herds surrounding the index herd. When PPR occurs in nonendemic areas, total eradication is advised by slaughter and proper disposal of all sick and exposed sheep and goats.

Efforts are currently being made to develop effective PPR marker vaccines to enable differentiation between infected and vaccinated animals which would allow countries to implement both vaccination and disease surveillance programs at the same time (Diallo et al. 2007). A heat stable PPR vaccine has also been developed that would obviate the need for maintenance of cold chain in the field and thereby facilitate vaccination in remote areas to improve PPR control efforts (Worrall et al. 2001).

Rinderpest

Rinderpest, or cattle plague, is best known as a devastating disease of cattle. At the time of this writing, there is growing confidence that rinderpest has now been eradicated from the world. Formerly a disease widespread in Africa and Asia, the disease and its causative virus were last seen in eastern Africa in Cape buffaloes in 2001 (Roeder et al. 2005). Global accreditation of freedom from rinderpest is expected to be achieved by 2010 by following guidelines in a process overseen by OIE.

Goats are a mildly susceptible host. Frank clinical disease in goats is rarely observed and is associated with spill-over of infection from cattle or buffaloes. Neither goats nor sheep display any ability to maintain virus transmission in the absence of large ruminant infection. Diagnosis of rinderpest in goats can be complicated by the more common occurrence of peste des petits ruminants (PPR), a disease of similar geographic distribution, clinical presentation, and related etiology.

Etiology

Rinderpest virus, like PPR virus, is a morbillivirus in the family Paramyxoviridae. The virus does not survive well away from its mammalian hosts, which include all domestic and wild ruminants and swine. It has been identified in insects feeding on infected cattle, but it does not replicate in insects. In the field, it is readily killed by desiccation, heat, and common disinfectants. In the laboratory, it can remain infective for as long as one year or more in the frozen or lyophilized state. Numerous strains of the virus exist. They are all antigenically similar and immunologically cross-reactive. However, there is a great variation in their infectivity and virulence for different ruminant hosts, including goats (Lefèvre 1982).

Epidemiology

Waves of panzootic rinderpest spread around Africa and Asia throughout history. These epizootics almost always have been associated with the introduction of infected domestic or wild ruminants, frequently following in the wake of military campaigns as last observed in Iraq, Turkey, and Iran in the early 1990s. The introduction of infected goats has been documented as the cause of several major epidemics: in the Himalayas in 1900, Malaya in 1935, and Ceylon in 1943 (Scott 1957).

Reports of clinical caprine rinderpest are uncommon compared with the body of documented work in cattle. The disease has never been reported as a major cause of illness of sheep and goats in Africa, even during the massive rinderpest epizootics that swept the continent in the 1890s; from then until 1955, only two more epizootics involving small ruminants were reported (Scott 1955). Over the next thirty years, reports of caprine rinderpest were limited to the isolation of the virus from a kid in Uganda in 1958 (Libeau and Scott 1960) and to a putative epidemic in the eastern Sudan in 1971 that may actually have been PPR (Ali 1973; Scott 1985). A laboratory confirmed case of rinderpest was identified in a goat in northern Pakistan in association with a severe epizootic in cattle and yaks during 1994 to 1995 in which more than 40,000 large ruminants died (Rossiter et al. 1998).

In contrast with the lack of clinical reports, serologic surveys indicate that exposure of goats to rinderpest was previously common in endemic areas of Africa (Rossiter et al. 1982; Obi et al. 1984). Antibodies were also found in a number of wild ruminant species (Rossiter et al. 1983, 1983a). Wildlife play a minimal role as a disease reservoir for perpetuation of the disease in cattle and are more appropriately considered as victims of epizootics involving domestic ruminants (Karstad et al. 1981). The maximum period for independent maintenance of rinderpest in wildlife appears to be three years (Kock et al. 2006).

Unlike in Africa, outbreaks of clinical rinderpest in goats and sheep in India have been reported more commonly. In the southern states of Karnataka, Andhra Pradesh, and Tamil Nadu, between 1981 and 1986 there were 984 documented outbreaks of rinderpest and 374 (38%) occurred in sheep and goats only, with mortality rates between 44.5% and 67.8% (Ramesh Babu and Rajesekhar 1988). Mortality rates as high as 80% have been reported in Indian goat flocks (Mohan Kumar and Christopher 1985). Subclinical infections are also common and the maintenance of virus in small ruminant populations is considered to encumber control of the disease in cattle. Until recently it was unclear why clinical disease is more common in small ruminants in India compared with Africa. Current understanding indicates that most, but not all, of what was described as rinderpest in small ruminants was in fact PPR (Taylor et al. 2001). Rinderpest in small ruminants is now essentially seen as being acquired from infected cattle with which they are in contact and they do not sustain infection independently (Taylor and Barrett 2007).

Transmission of rinderpest is by direct contact with infected animals shedding virus in nasal, oral, ocular, or other secretions and excretions. The virus can be shed during the early, subclinical, febrile stage of the disease, making it difficult to detect inapparent shedders at markets or during livestock drives. In addition, cross-species transmission occurs among domestic ruminants and between domestic and wild ruminants and these animals may commonly share watering holes and grazing grounds in endemic regions. Contact transmission from cattle to goats and goats to cattle has been confirmed under experimental conditions (Zwart and Macadam 1967, 1967a; Macadam 1968) but appears not to be of major significance in the maintenance of rinderpest transmission chains. Prolonged carrier states are not known to exist in any susceptible species. Infected animals either die or eventually recover with a lifelong immunity.

The endemic nature of rinderpest may be sustained by year-round calving. Newborn cattle are protected from infection by maternal antibody while adults are protected by antibody from past exposure or vaccination. Young stock with waning maternal antibody act as the bridge for maintaining infection in livestock populations throughout the year.

Pathogenesis

There are few studies or reports on the pathogenesis of rinderpest specifically in goats (Wafula and Wamwayi 1988; Brown et al. 1991; Bidjeh et al. 1997). In cattle, animals are exposed by inhalation of infective aerosols. The virus penetrates the epithelium of the upper respiratory tract and primary growth occurs in the tonsils and lymph nodes of the nasopharynx. From there, the virus enters the blood in mononuclear cells and is disseminated to other lymphoid organs, lungs, and epithelial cells of mucous membranes, with a high affinity for alimentary tract mucosa. The lesions which develop are a direct result of the replication of virus in the mucosal cells with cytopathic effect. Stomatitis and diarrhea result from inflammation and disruption of normal mucosal integrity and function. The virus also has a predilection for lymphocytes and the destruction of lymphocytes underlies the leukopenia which develops. The virus induces a strong host antibody response and in cases that are not fatal, the affected animal clears the virus and develops a strong immunity (Radostits et al. 2007).

Clinical Findings

Goats exposed to rinderpest virus may experience either subclinical or clinical infections. The clinical course of acute rinderpest is very similar to PPR, although the progression may be slower. The early phase of disease after incubation is one of fever (104°F to 105.8°F; 40°C to 41°C), rough hair coat, anorexia, and depression. This is accompanied by, or followed within one to two days by, oculonasal discharge that is initially serous but soon becomes mucopurulent. By the second or third day of fever, small epithelial erosions may be seen in the oral cavity, particularly on the inside of the lower lip and on the gums around the incisors. During the next few days, these can spread to the cheeks, commissures, tongue, soft and hard palate, and pharynx. The necrotic epithelium produces a cheesy looking cover to the erosions, which are shallow and red underneath. Around day four or five after the onset of fever, affected animals can develop a profuse watery diarrhea that may be bloody.

Animals with severe diarrhea may die of dehydration, electrolyte imbalance, and general weakness. In animals that survive, a convalescence phase begins around day nine after the onset of fever. Diarrhea may begin to slow and oculonasal discharges abate, and there may be evidence of healing of oral erosions. Animals may still die, however, because of extensive debilitation or the development of severe secondary

infections. Bacterial pneumonia, often a fatal sequel of PPR in goats, is less common in goats with rinderpest; this may help to discriminate the two conditions clinically.

Clinical Pathology and Necropsy

Leukocytosis occurs during the incubation period and a leukopenia characterized by lymphopenia develops concurrently with the onset of fever. Dehydration can cause increases in packed cell volume and total protein, and persistent diarrhea may cause electrolyte and acid-base imbalances.

With regard to serologic diagnosis, detectable serum-neutralizing antibodies may take longer to develop in goats than cattle, perhaps as long as twenty-eight days after infection (Afshar and Myers 1986; Wafula and Wamwayi 1988). In general, serum neutralization titers less than $0.3 \log 10 \, VN_{50}$ are considered negative for rinderpest, 0.3 to 0.6 are trace-positive, and more than 0.6 are considered positive. However, evidence of rising titers in convalescent goats should be evaluated.

The virus neutralization test (VNT) and the competitive ELISA are the tests of choice for identifying antibody to rinderpest. The VNT is the prescribed test for international trade (OIE 2004). Antibodies to rinderpest can be discriminated from antibodies to PPR by the quantitative serum cross-neutralization test.

Tests for the detection of rinderpest virus or viral antigen include virus isolation in cell culture; the agar gel immunodiffusion test; immunohistochemistry; and reverse transcription polymerase chain reaction. The differential immunocapture ELISA test can be used to discriminate between PPR and rinderpest viral antigens in tissue samples (OIE 2004).

Studies in goats indicate that, unlike cattle, ocular and nasal secretions are less reliable sources of antigen than prescapular lymph node aspirates for performing these tests in live animals (Wafula and Wamwayi 1988). Samples should be maintained at 39°F (4°C).

Goats dying of clinical rinderpest are emaciated, dehydrated, soiled on the hind end from diarrhea, and have prominent crusting of exudate on the face. Extensive mucosal erosions are present in the oral cavity and possibly also in the pharynx. The abomasum will also demonstrate mucosal erosion, but forestomach lesions are minimal. Ulcerations and hemorrhage of the colonic and cecal mucosa are common. Small intestinal lesions are less prominent and may be limited to congestion and swollen or necrotic Peyer's patches. Lung involvement is less common in rinderpest than in PPR. Histologically, lesions are similar to those described earlier for PPR.

Tissues to be submitted for virus isolation and virus neutralization studies include noncoagulated whole blood, lymph nodes, spleen, and gut lesions. They should be shipped on ice at 39°F (4°C) but not frozen. Where maintenance of cold chain for samples is not possible, formalin fixed third eyelid or mucosal tissue can be submitted for immunohistochemical confirmation of rinderpest viral antigen.

Diagnosis

In countries where both diseases occur, the primary differential for rinderpest in goats is PPR. Definitive diagnosis depends on performance of serum neutralization tests specific for one virus or the other, or on the post mortem isolation of virus from tissues. In the field, concurrent disease in large ruminants points toward rinderpest. There are a number of other diseases that could be mistaken for rinderpest or PPR at different times during the disease. These are presented earlier in the chapter in the diagnosis of PPR.

The differential diagnosis of rinderpest in cattle must include bovine virus diarrhea-mucosal disease, infectious bovine rhinotracheitis, and malignant catarrhal fever. These diseases have never been reported in goats.

Treatment

There is no specific treatment for caprine rinderpest. As rinderpest is now a highly regulated disease on the verge of eradication, suspect cases are likely to be destroyed for diagnostic and control purposes rather than treated.

Control

Rinderpest control is usually carried out by national and international authorities and the approach is two-pronged: control of animal movements and vaccination. Rinderpest-free countries distant from endemic regions simply do not allow the importation of stock from endemic regions. When rinderpest does enter a disease-free country, rapid destruction of all sick and exposed livestock with appropriate disposal by burial or burning can bring the epidemic under control and eliminate the disease (Scott 1981). Countries bordering rinderpest-endemic areas may be obliged to permit livestock movements because of local political and social considerations, but three-week segregation periods are required. In practice, these segregation periods are difficult to monitor and enforce.

In endemic areas, vaccination is the most important means of rinderpest control. This is particularly true in Africa, where migrating herds of wild ungulates exist. Internationally orchestrated rinderpest control campaigns, including Joint Project 15, the Pan-African Rinderpest Campaign, and most recently the Pan-African Control of Epizootics program, were mounted under African Union coordination over the last fifty years. These contributed to the Global Rinderpest Eradica-

tion Program (GREP), hosted by FAO, which has the goal of eliminating rinderpest from the world by 2010 (Food and Agriculture Organization 1985; Roeder et al. 2005). The last time rinderpest virus was encountered in the field was in 2001 when African buffaloes were found infected in Kenya. There is now growing confidence that rinderpest has been eradicated and the focus of GREP attention is now on proving freedom from rinderpest by an OIE country accreditation process (Roeder 2005).

The Plowright tissue culture-derived vaccine was used widely in vaccination programs (Plowright and Ferris 1962; Plowright 1984) but is now rarely used, even for protection of small ruminants against PPR, because it can interfere with rinderpest serosurveillance programs and because attenuated homologous PPR vaccines are now widely available. The most common is based on the Nigeria 75/1 isolate.

Modified lyophilization techniques have been applied to enhance and prolong the thermostability of the rinderpest tissue culture vaccine while maintaining antigenicity (Mariner et al. 1990, 1990a). This has allowed the vaccine to be carried into more remote endemic regions without the need for a costly, supportive cold chain to maintain vaccine viability. This innovation has been an important factor in achieving control of rinderpest through vaccination. As global rinderpest eradication efforts have advanced, emphasis has moved from control by vaccination to surveillance for confirmation of rinderpest free status.

Bluetongue

Bluetongue is an infectious, non-contagious, arthropod-borne, viral disease of ruminants. While goats are frequently infected, clinical disease is uncommon or mild in this species, even during epizootics severely affecting sheep. Direct economic losses caused by bluetongue disease in goats are minimal, although historically, importation restrictions existed in bluetongue-free countries resulting in limitations on trade of live goats, semen, and embryos. These restrictions are now becoming less stringent as scientific understanding of the disease ecology of bluetongue has improved (MacLachlan and Osburn 2006).

Etiology

Bluetongue is caused by a non-enveloped, RNA orbivirus in the Reoviridae family. It has a genome of ten segments of double-stranded RNA that produce seven structural and four non-structural proteins. There are currently twenty-four different known serotypes of the bluetongue virus that are distinguished by epitopes on the outer capsid protein VP2 which is encoded by the L2 gene. Individual serotypes are identified in the laboratory by serum neutralization tests. Various serotypes may share common complement fixing and precipitating antigens but cross-protective immunity against heterologous serotypes is poor. Virulence between serotypes varies.

Bluetongue virus (BTV) can be grown in embryonating chicken eggs as well as mouse L, baby hamster kidney-21, African green monkey kidney (Vero), or *Aedes albopictus* cells in culture (OIE 2004a). The virus is very resistant to environmental degradation. It remains infective in citrated blood held at 39°F (4°C) or room temperature for years. Three percent sodium hydroxide (lye) is an effective disinfectant (Kohler 1989).

Epizootic Hemorrhagic Disease (EHD) virus is a closely related Orbivirus infecting primarily wild ruminants. It has caused disease outbreaks in whitetail deer (*Odocoileus virginianus*) in North America. Goats challenged intravenously with EHD virus produce low levels of neutralizing antibodies but show no evidence of viremia or clinical disease (Gibbs and Lawman 1977). Another mosquito-transmitted Orbivirus, Orungo virus, causes febrile disease in humans in Africa. There is serologic evidence of infection in goats, but clinical disease is not reported (Ezeifeka et al. 1984).

The principal insect vectors responsible for transmission of BTV are members of the genus *Culicoides*, variously referred to as biting midges, sandflies, noseeums, or gnats.

Epidemiology

Bluetongue disease was first recognized in European sheep imported into South Africa in 1870 and the disease was originally thought to be restricted to Africa. The first major epizootic confirmed outside of Africa occurred in Cyprus in 1943. The disease was identified in sheep in Texas in 1948 and the BTV-10 serotype isolated from sheep in California in 1952.

Bluetongue was first confirmed in the laboratory in Israel in 1950, but it is suspected that the disease was occurring in the Middle East since the 1920s (Shimshony 2004). Major epizootics occurred in Spain and Portugal in 1956 and 1957 and over the past fifty years there have been several incursions of bluetongue into the Mediterranean region. There have been large, notable outbreaks in Europe in recent years and the epidemiology of these European outbreaks has recently been reviewed (Saegerman et al. 2008). The first was in southern Europe beginning in 1998 (Gomez-Tejedor 2004), involving the Greek mainland and islands, Bulgaria, Turkey, Serbia and Montenegro, Macedonia, Croatia, and Italy. BTV-9 was mainly reported but also serotypes 1, 4, and 16. A second wave of outbreaks occurred in 1999 in Tunisia, Algeria, and various island groups in the Mediterranean. This outbreak involved BTV-2 but serotypes 4 and 9 were also reported. Successive Mediterranean outbreaks occurred through 2004.

The most recent outbreak began in northern and western Europe in 2006 due to BTV-8 (Elliott 2007). It continued well into 2007. The most recent information at the time of this writing is that vector activity persisted over the winter of 2007–2008 with new cases occurring in 2008. The main countries involved include Belgium, Luxembourg, the Netherlands, Germany, France, and the UK, with Denmark, Switzerland, and the Czech Republic also reporting small numbers of cases in 2007. These European epizootics may be facilitated by climate change as discussed further below.

The global distribution of BTV reflects the distribution of competent *Culicoides* spp. vectors. The virus is found on all continents except Antarctica. Within those continents, it is found mainly in tropical and subtropical regions. Historically the global distribution of bluetongue virus was considered to be between 40°N latitude and 34°S latitude, except in western North America and eastern Asia where the northern demarcation may extend as far as 50°N. The recent European outbreaks are noteworthy because the 1998 outbreak extended northward to 44°N latitude in Serbia and the current 2006–2008 outbreak extends above 51°N latitude in the U.K. In light of these new realities, OIE puts the global distribution of BTV between 53°N and 34°S latitudes (OIE 2007).

From an epidemiological standpoint, the geographic distribution of BTV can be categorized into three ecological zones: enzootic, epizootic, and incursive. Enzootic zones are mainly tropical regions where BTV transmission occurs throughout the year and subclinical infection is common. Clinical disease usually occurs only when immunologically naïve ruminants are introduced to the zone. Epizootic zones include temperate areas where outbreaks occur seasonally, generally in late summer when vector populations are at their highest. Incursive zones are areas that experience sporadic outbreaks when climatic conditions favor disease transmission by vectors (Gibbs and Greiner 1994).

In any given country there may be areas where infection is enzootic and areas free of infection. This is because local climate and geography, host populations, patterns of animal movements, and presence of competent vector species can all influence the presence of infection. For example, BTV was first isolated from a pool of trapped *Culicoides* in northern Australia in 1975, but to date, except for one case in a sentinel flock maintained in the north, there are no reports of disease in sheep, which are raised mainly in the southern portion of the country (Kirkland 2004). Similarly, in the United States, the northeast remains free of bluetongue, while it is enzootic in much of the west and south, with seasonal outbreaks occurring in the northwest.

More than 1,400 *Culicoides* spp. exist worldwide but only seventeen to twenty of these species have been identified as capable of BTV transmission, and the competent *Culicoides* spp. vectors vary regionally. Vector competency appears to be linked to BTV serotype so that distinct regional disease ecologies or episystems exist involving particular *Culicoides* spp. and particular BTV serotypes (Tabachnick 2004). The current, regional distribution of these vectors and serotypes is given in Table 10.4. In addition to *Culicoides*, the sheep ked, *Melophagus ovinus*, certain ticks, and biting flies have been implicated as mechanical vectors for transmission of BTV, but these are of minor importance in the dissemination of BTV. Because the virus is associated with blood cells, iatrogenic transmission by repeated use of needles when administering injections is possible.

All domestic ruminants are susceptible to BTV infection. Among sheep, European fine wool and mutton breeds, are more susceptible to bluetongue than tropical and subtropical breeds. Goats and cattle most often have subclinical infections and are generally considered as reservoir hosts. However, in the recent outbreaks of bluetongue in Europe, disease in cattle and to a lesser extent in goats has occurred. Even when goats are present with severely affected sheep during major epizootics, they usually have lower morbidity and mortality, exhibit milder clinical signs, or most likely, remain clinically normal. The reasons for these differences in ruminant species susceptibility are not well understood.

In tropical and subtropical regions, where *Culicoides* are active year-round, there may be a continuous cycle of new infection in animals and the infection becomes enzootic. In temperate regions, disease is more likely to be seasonal, occurring in the summer and fall when populations of infected *Culicoides* have rebounded from die-offs in winter associated with cold or freezing temperatures. Vector, host, and environmental factors can influence overwintering of BTV. *Culicoides* do not pass BTV virus transovarially so immature stages of the insect are not infective. Therefore, overwintering of the virus in the vector depends on the survival of at least some adult *Culicoides*, which can have life spans as long as three months. The other major factor is the presence of virus in host animals on which *Culicoides* feed. The viremic period in sheep and goats is shorter than that of cattle. Most small ruminants are no longer viremic thirty to forty days post infection and cattle after fifty to sixty days.

In recent years, global warming appears to be altering arthropod-borne disease ecology in Europe. Increases in nighttime temperature and winter temperature along with increases in precipitation in summer and autumn have led to an increased geographical and seasonal incidence of BTV transmission by increasing the range, abundance, and seasonal activity of vectors, by increasing the proportion of the vector species that are competent, and by increasing

Table 10.4. Global distribution of bluetongue virus serotypes and the associated *Culicoides* vector species.

Region	Bluetongue virus serotypes	Major Culicoides vector(s)	Other secondary or possible Culicoides vectors	Comments	Reference
North America	2, 10, 11, 13, 17	*C. sonorensis, C. insignis* (serotype 2 only)	*C. variipennis*	Serotype 2 restricted to Florida	Walton 2004
Central America and the Caribbean	1, 3, 4, 6, 8, 12, 14, 17	*C. insignis*	*C. pusillus, C. furens, C. filarifer, C. trilineatus*		Walton 2004
South America	4, 6, 12, 14, 17, 19, 20	*C. insignis*	*C. pusillus*		Lager 2004
Europe	1, 2, 4, 8, 9, 16	*C. imicola*	*C. obsoletus, C. pulicaris*		Saegerman et al. 2008
Africa	1–15, 18–20, 22, 24, 25	*C. imicola*	*C. bolitinos* and possibly others		Walton 2004
South Asia	1–9, 11–20, 23	?	*C. imicola, C. oxystoma,*	Details on competent vector species lacking	Sreenivasulu, et al. 2004
Southeast Asia	1–3, 9, 12, 14–21, 23	*C. brevitarsis*	*C wadai, C. actoni, C. fulvus,* and possibly others.		Walton 2004
Australia and Oceania	1, 3, 9, 15, 16, 20, 21, 23	*C. brevitarsis, C. wadai*	*C. actoni, C. fulvus, C. oxystoma, C. peregrinus*		Australian Veterinary Emergency Plan (1996)

the development rates of the virus within vectors, thereby extending transmission ability to other *Culicoides* species. For example, *C. imicola*, the widely distributed midge of Africa and Asia, has been the primary vector in outbreaks of bluetongue in southern Europe. The vector competence of the more temperate palearctic groups of midges, *C. pulicaris* and *C. obseletus*, were known from laboratory studies but only suspected in the absence of *C. imicola* in outbreaks of bluetongue in Greece and southern Bulgaria in 1999 and in the Balkans in 2000–2001 (Purse et al. 2005). However, in 2006 in northwest Europe, these midges clearly established themselves as competent vectors for BTV (Elliott 2007; Saegerman et al. 2008).

Historically, it was considered that the movement of infected livestock was a key element in the global dissemination of bluetongue and this had a significant impact on international trade in live animals, semen, and embryos, with disease-free countries prohibiting the importation of these products from countries where the disease was present. However, it is now understood that trade plays a comparatively minor role in the dissemination of bluetongue. There are two main reasons for this. First, is the recognition that viremia in ruminants has a limited duration and that persistent carriers do not occur. Some early studies, on which trade regulations were based, suggested that bovine

fetuses exposed to BTV *in utero* become immunotolerant, persistent carriers (Luedke et al. 1977, 1977a). The existence of persistent carriers has since been disproven (Roeder et al. 1991; MacLachlan et al. 1994; Bonneau et al. 2002).

Second is the recognition that the regional occurrence of bluetongue depends on the particular disease ecology of that region with regard to the specific *Culicoides* vectors and associated BTV serotypes that occur there. There is little evidence that alien serotypes become established or persist if accidentally introduced into a region. The introduction of a new serotype to a region, such as the recent finding of BTV-8 in northern Europe, had more to do with the dissemination of competent *Culicoides* vectors than the movement of animals. Issues of trade policy relative to bluetongue have been reviewed (MacLachlan and Osburn 2006).

Recognition of goats as a host species for bluetongue virus was established experimentally in 1905 (Spruell 1905). The susceptibility of goats to clinical bluetongue, however, remained obscure for years as sick goats were not observed in mixed flocks with sick sheep during outbreaks (Hardy and Price 1952).

Reports of clinical bluetongue in goats are infrequent, as the infection in goats is generally subclinical. The first reported epidemic involving goats occurred

in Israel in 1950. Cattle and sheep were the principal species affected. Prevalence was less in goats and signs less severe (Komarov and Goldsmit 1951). The second reported epidemic of bluetongue affecting goats occurred in southern Spain in 1956. While losses in sheep were extreme, with more than 100,000 animals dead, cases in goats were infrequent and mild, with limited mortality (Lopez and Botija 1958). A more severe involvement of goats in a bluetongue epidemic occurred in India in 1961 (Sapre 1964). The clinical disease appeared with equal severity in sheep and goats, though variation in breed susceptibility was noted. Clinical bluetongue associated with BTV-4 occurred in goats in Portugal in December of 2004 with twenty-three cases and two deaths reported to the OIE. In the epizootic in Northern Europe which began in 2006, clinical cases in goats due to BTV-8 were seen in the Netherlands (Dercksen et al. 2007; Backx et al. 2007).

The epidemiology of caprine bluetongue has been studied in the northwestern United States (Osburn 1981; Stott 1985). As in sheep and cattle, there is a seasonal variation in both virus isolation and serologic evidence of infection. The season of maximal infection, June through December, correlates with increases in insect vector populations. Goats are an unlikely reservoir of bluetongue infection, as no virus isolations from goats were made in California from January and June, indicating that the virus does not persist. The prevalence of infection in goats was half that recorded in cattle and sheep. All four of the major American serotypes were found in goats and multiple serotype infections occurred. However, no clinical disease was associated with infection in goats during a three-and-a-half-year period of study.

The epidemiology of caprine bluetongue has received considerable attention in Africa. In Zimbabwe, bluetongue antibody was present in 71% of goats tested, but no evidence of clinical disease has been observed (Jorgensen et al. 1989). Serologic surveys in goats in North African countries in the intertropical zone show a range of seroprevalence from 5% to 54%, with distinct differences in seroprevalence rates between different climatic regions. Low-lying and humid regions tend toward a greater prevalence rate than drier and higher regions (Lefèvre and Calvez 1986). Seroprevalence in goats increases with advancing age (Obi et al. 1983a).

Pathogenesis

There are few if any studies on the pathogenesis of bluetongue specifically in the goat. Therefore, most available information is extrapolated from sheep or cattle. Infection results from cutaneous inoculation of the host with virus during feeding by infected insects. Initial viral replication takes place in the lymph nodes draining the feeding site and dissemination in mononuclear cells to secondary sites of replication. Viremia is usually detectable by day three and peak viremia along with fever and leukopenia usually occurs six to seven days post infection. With viremia, there is localization of the virus in vascular endothelium leading to cell damage and necrosis, with thrombosis, hemorrhage, and edema in affected organs, most notably in the tongue, mouth, esophagus, rumen, and skin, causing hyperemia, erosions, or ulcers. The virus may cross the placenta. It can also be found in semen. The clinical signs of stomatitis, glossitis, rhinitis, enteritis, and coronitis are attributable to the primary endothelial necrosis and loss of capillary integrity. In sheep, disseminated intravascular coagulation may occur, exacerbating the severity of clinical signs. In cattle, endothelial cell damage is minimal and the cell-associated viremia involves mainly erythrocytes and platelets (Radostits et al. 2007).

Recent research on the *in vitro* response of ovine and bovine endothelial cells to BTV suggests that inherent species-specific differences in the production and activities of endothelial cell-derived inflammatory and vasoactive mediators contribute to the greater sensitivity of sheep to BTV-induced microvascular injury. No such comparison has been carried out yet with goat cells (DeMaula et al. 2002).

Experimental challenge studies indicate that viremia in goats can last as long as twenty-one days after challenge and that measurable antibody responses occur during viremia (Barzilai and Tadmor, 1971; Luedke and Anakwenze 1972).

Clinical Findings

In the majority of cases, bluetongue infection in goats is subclinical. When clinical illness does occur, it is often limited to mild depression, temporary loss of appetite, fever, and hyperemia of the oral and nasal mucosa.

Occasionally, more severe cases are seen. The initial signs are fever and anorexia lasting for three to four days. This is followed by hyperemia of the oral mucosa with excoriations of the tongue, lips, and gums that become ulcerative and necrotic. Affected goats salivate excessively. Edema of the face ensues (Figure 10.4) and a watery to mucoid nasal discharge develops.

This is sometimes followed by diarrhea. Coronitis also develops, with hyperemia and swelling around the coronet leading to obvious lameness in one or more legs. In affected goats in India, walnut-sized skin eruptions appeared and were distributed all over the body (Sapre 1964). This presentation appears unique to goats and perhaps to the outbreak in India because it has not been reported again elsewhere. The clinical course is eight to twelve days.

Figure 10.4. Edema of the face in goats affected with bluetongue, as reported from India. Most caprine bluetongue infections are subclinical. (From Sapre 1964.)

Clinical cases were seen in goats in the Netherlands in August, 2006, during the BTV-8 outbreak in northern Europe (Dercksen et al. 2007). The most obvious clinical signs were an acute drop in milk production and a high fever, up to 107.6°F (42°C). Other clinical signs were less obvious than usually seen in sheep, but a few goats had edema of the lips and head, some nasal discharge, scabs on the nose and lips, erythema on the skin of the udder, and some small subcutaneous hemorrhages. When the field strain of BTV-8 was administered intravenously to two experimental goats, both developed viremia and antibody responses, but one remained clinically normal while the second developed fever and became depressed, standing apart with head hanging down. It also showed dysphagia, diarrhea, and lameness. Sheep inoculated in the same experiment showed more severe clinical signs (Backx et al. 2007).

In sheep, the convalescent phase is prolonged and is characterized by emaciation and weakness secondary to active myositis. This has not yet been described in goats. Abortions have been ascribed to bluetongue virus infection in goats, but the causal role is poorly documented (East 1983).

Clinical Pathology and Necropsy

Clinicopathologic changes have not been reported in field cases of caprine bluetongue. In experimental infections, leukopenia occurs and is most pronounced five to ten days after inoculation (Luedke and Anakwenze 1972).

Several serologic tests are available for identifying antibody to bluetongue virus. These include complement fixation, agar gel precipitation, and more recently, the competitive enzyme-linked immunosorbent assay (ELISA). The latter two are considered prescribed tests for international trade (OIE 2004a). In experimentally infected goats, antibody was first detectable at day thirteen post inoculation using a blocking ELISA (Backx et al. 2007).

Virus isolation from blood and tissues is best carried out in embryonated eggs or in cell culture. However, where bluetongue is enzootic, the presence of the virus in individual animals does not establish causality when clinical signs are nonspecific (Inverso et al. 1980).

The development and application of the reverse transcriptase polymerase chain reaction has allowed for the detection of bluetongue viral nucleic acids in blood. This has revolutionized the laboratory diagnosis of bluetongue. Using this tool, antibody positive animals can be confirmed negative for the presence of virus, allowing them to enter international trade when, in earlier times, without PCR this would not have been possible (OIE 2004a).

Identification of bluetongue serogroup can be done using a number of techniques, including immunofluorescence, antigen capture ELISA, and the immunospot test using serogroup-specific reagents. For serotyping of BTV, virus neutralization tests are conducted in tissue culture systems using BTV serotype-specific antisera. Techniques employed include plaque

reduction, plaque inhibition, microtiter neutralization, and fluorescence inhibition (OIE 2004a)

Gross necropsy lesions in goats with full-blown clinical bluetongue are similar to those observed in sheep (Sapre 1964). There is hyperemia and edema of the buccal mucosa and ulceration of the palate. Lung congestion and secondary pneumonia may be present. Severe hemorrhagic gastroenteritis may be seen in the abomasum, small and large intestines, and rectum. Pinpoint hemorrhages and congestion occur in the spleen and on the epicardium. Hydropericardium is variable. The mesenteric lymph nodes are enlarged and edematous. Hyperemia and hemorrhage may be noted on the skin of the limbs above the coronets.

Diagnosis

Definitive diagnosis of clinical bluetongue depends on isolation of the virus from animals showing typical clinical signs during seasons of insect activity. Historically, bluetongue has been recognized in goats only when clinical disease occurs simultaneously in sheep or cattle. Subclinical bluetongue in goats may be identified by changes in antibody titers in paired serum samples.

The differential diagnosis for caprine bluetongue includes foot and mouth disease, contagious ecthyma, goat pox, and photosensitization. Stomatitis and enteritis can occur in rinderpest and peste des petits ruminants, but coronitis, lameness, and edema are not prominent findings.

Treatment

There are no specific treatments for bluetongue. In sheep, prophylactic antibiotics are used to prevent secondary bacterial infections. Clinically ill animals should be kept out of direct sunlight, because sunlight appears to aggravate skin lesions. Affected animals should be fed separately so they do not need to compete for food.

Control

Control methods are not routinely directed toward goats because the infection is generally subclinical. In general, recommendations for sheep apply. Animals should not graze in low-lying, wet areas during seasons of insect activity so as to avoid spread of infection, and paddocks and flooring of animal houses should be kept dry. *Culicoides* feed mostly at dusk and early evening so animals should be removed from pastures at these times. Use of chemical insect repellants can be considered if approved for use in food animals.

In areas where seasonal occurrence of bluetongue is a known problem, vaccination is the major means of control, and vaccine should be administered prior to the onset of *Culicoides* feeding. Because the various serotypes offer little cross-immunity, to be effective,

vaccines must contain the serotypes known to be problematic in the area. In the United States, only a monovalent vaccine employing serotype 10 is commercially available. Multivalent vaccines against twenty-one serotypes are produced in South Africa. Vaccination against the full complement of serotypes requires three separate injections at three-week intervals.

In 2007, the UK tendered for the development of a serotype 8 vaccine for use in controlling the newly emergent BTV-8 serotype in northern Europe. The vaccine became available in May of 2008 and vaccination began in Protected Zones in the UK in the same month. The vaccine is approved only for use in sheep and cattle, but under the European cascade system, it can be administered to goats by veterinarians, with no withdrawal times necessary.

There are some problems with modified-live, tissue culture virus vaccines. Passively acquired maternal antibody can impair the vaccinal response, so kids and lambs younger than three months of age may not be effectively vaccinated. Vaccination of ewes in the first five to ten weeks of pregnancy can lead to fetal malformations or early embryonic death. This has not been reported in goats, but vaccination before breeding or after kidding is recommended. Vaccination should be timed to precede the insect season to promote maximum protection during high-risk periods.

In the past, bluetongue-free countries had strict prohibitions on the importation of livestock, embryos, and semen, but as of 2005, OIE revised and adopted new, less stringent international trade provisions to reflect improved understanding of the transmission of bluetongue infection as described above. The new regulations set the infective period for bluetongue in animals at sixty days and establish protocols by which livestock, semen, and embryos can be imported into bluetongue free countries from known positive bluetongue countries and zones through the use of quarantines and testing for antibody and virus. The availability of highly sensitive PCR tests to detect the presence or absence of virus in animals independent of their antibody status has helped to facilitate these new protocols. The current OIE provisions for bluetongue are available at http://www.oie.int/eng/normes/mcode/en_chapitre_1.8.3.htm.

Nairobi Sheep Disease

Nairobi sheep disease is an infectious, noncontagious, zoonotic, viral disease transmitted by ticks. Goats, sheep, and humans are affected. The disease occurs in Africa and is characterized by fever and gastroenteritis.

Etiology

The causative virus, Nairobi sheep disease virus (NSDV), is a single-stranded RNA virus in the genus

Nairovirus of the family *Bunyaviridae*. There are thirty-four tick-borne viruses in the Nairovirus genus, classified into seven serogroups. NSDV is the prototype virus of the Nairobi sheep disease serogroup. This serogroup also includes the Dugbe virus and the Ganjam virus. Earlier serologic analysis suggested that NSDV and Ganjam virus were closely related. More recently, sequence analysis of the S RNA genome segment and encoded proteins of both viruses indicate that they are in fact the same virus (Marczinke and Nichol 2002).

Cultivation of NSDV can be accomplished in lamb kidney, baby hamster kidney, or Vero cell culture. Intracerebral inoculation of infant mice is also used. The virus is moderately resistant to environmental degradation and can persist in blood at room temperature for as long as forty-five days (Liebermann 1989).

Epidemiology

Nairobi sheep disease was first described in Africa in 1910. A major epizootic occurred when large numbers of sheep and goats were brought into Kenya in 1915 to feed troops in World War I. The close relationship of Ganjam virus in India to NSDV has led to speculation that NSDV is a variant of Ganjam virus introduced by livestock trading between India and East Africa. Nairobi sheep disease now occurs in Kenya, Uganda, Tanzania, Somalia, Ethiopia, Rwanda, Burundi, Botswana, Mozambique, and the Democratic Republic of Congo. In 1996, it was reported that NSDV was isolated from *Haemaphysalis intermedia* ticks collected on goats in the North Western Province of Sri Lanka (Perera et al. 1996). This same tick is responsible for transmission of Ganjam virus in India, where clinical disease has been reported in sheep and serologic evidence of infection documented in sheep and goats. The full extent of Ganjam virus as a cause of disease in small ruminants in South Asia remains largely undetermined.

Transmission of NSDV is principally by the brown ear tick, *Rhipicephalus appendiculatus*, in which it can be transmitted transovarially and transtadially. The distribution of the disease closely follows the geographic range of this tick and the disease is unlikely to occur in parts of Africa where *R. appendiculatus* has a seasonal rather than a continuous breeding cycle (Davies 1997). In Somalia, it is reported that the main vector is *R. pulchellus*, a tick that can transovarially transmit the virus (Groocock 1998). *Amblyomma variegatum* also transmits NSDV but plays a minor role. *A. variegatum* is a less effective vector because transovarial transmission of the virus does not occur in this tick.

Infected ticks are rendered non-infectious by feeding on immune or resistant hosts. Ticks and subclinically infected sheep and goats are considered the agent reservoir. Wild ruminants and cattle are not implicated.

A seasonal occurrence of clinical disease is observed during rainy periods when tick activity increases. Sheep and goats born in enzootic regions generally are subclinically infected. Clinical disease is seen in imported stock or stock transported from non-enzootic areas. Goats in general are less severely affected than sheep. Goat mortality may be high, but is usually less than the 50% to 90% mortality that occurs in sheep. Experimental inoculation of goats and sheep with blood from infected sheep resulted in lower morbidity, milder clinical signs, and lower mortality in goats (Montgomery 1917).

Human infection is acquired by tick bites. Though seroprevalence in endemic human populations is high, clinical disease is rare. In the case of Ganjam virus in India, human disease was reported in seven laboratory personnel in association with laboratory exposure (Banerjee et al. 1979).

Pathogenesis

The pathogenesis is not completely known. The virus is introduced into goats and sheep by feeding ticks. The incubation period is four to fifteen days under natural conditions and one to three days with experimental inoculation (Groocock 1998). Incubation is followed by viremia and localization of virus in tissues. There is an apparent predilection for epithelial cells of the gut. Bone marrow suppression also occurs. Necrosis of the mucosal epithelium of the intestines and rupture of capillaries leads to a hemorrhagic enteritis. Fluid and electrolyte loss in diarrhea is considerable and may result in death (Kimberling 1988). Recovered animals develop lifelong immunity. Kids and lambs of immune dams are probably protected by maternal antibody during the first few months of life.

Clinical Findings

The disease begins with a fever of 104°F to 106.7°F (40°C to 41.5°C) accompanied by anorexia, pronounced depression, and a variable mucous nasal discharge that may become blood-tinged. This is followed by profuse, watery, diarrhea that may progress to a bloody dysentery with straining or even some colicky signs. Fever usually subsides at the time of onset of diarrhea. Depending on the severity of the disease, affected animals may die during the febrile stage before the onset of diarrhea or after one to six days of diarrhea, or they may gradually recover. Pregnant animals may abort. Swelling of the external genitalia is reported in ewes, but not in goats. Animals that recover maintain a lifelong immunity against reinfection.

Clinical Pathology and Necropsy

Affected sheep and goats have a marked leukopenia during the febrile period. Serum antibody is detectable

using the hemagglutination inhibition test, enzyme-linked immunoabsorbent assay, complement fixation, or indirect immunofluorescent antibody test. Paired acute and convalescent serum samples should be evaluated for changes in titer. The virus may be isolated from plasma of the live animal during the febrile stage of disease. Cytopathic effect (CPE) in cell culture may vary with strain of NSDV and cell type used. When CPE is absent, direct immunofluorescence staining or the indirect fluoroscein antibody test confirms presence of virus. At necropsy, virus is best isolated from spleen and mesenteric lymph nodes. In the absence of cell culture, agar gel immunodiffusion, complement fixation, or ELISA can be used to detect NSDV antigen in tissues (OIE 2004b).

Animals that die in the acute, febrile phase of the disease before onset of diarrhea may not have obvious or specific gross lesions at necropsy and this may mistakenly lead the investigator away from a diagnosis of Nairobi sheep disease. In more advanced cases, lesions are found mainly in the gastrointestinal tract, lymph nodes, and spleen. The abomasal mucosa is hyperemic and may contain petechial hemorrhage. The gut lumen content may be bloodstained and there are numerous hemorrhages in the gut mucosa, especially in the cecum and anterior portion of the colon. These hemorrhages may have a linear or streaked appearance along the crest of mucosal folds. The spleen is considerably enlarged and blood-engorged. The mesenteric lymph nodes are also enlarged and edematous. Petechial hemorrhage may also be seen in the epicardium and endocardium and other serosal surfaces. Hyperemia of the genital tract may be noted and when fetuses are present, their tissues may show focal hemorrhages. Histologically, there is a characteristic nephritis with hyaline, epithelial casts, myocardial necrosis, and hemorrhagic gastroenteritis.

Diagnosis

Nairobi sheep disease occurs only in areas where the known tick vectors occur. Disease is most likely to affect recently introduced sheep and goats. The disease should be suspected when high mortality occurs in sheep and goats with vector tick infestations, especially if the animals have been recently moved into an enzootic area or when tick populations have increased due to heavy rainfall. The definitive diagnosis is based on isolation of the virus or detection of viral antigen from clinically affected animals or documentation of seroconversion after clinical disease.

The differential diagnosis includes rinderpest, peste des petits ruminants, Rift Valley fever, heartwater, salmonellosis, anthrax, and bluetongue. Because fever may have subsided when diarrhea begins, coccidiosis and helminthiasis must also be considered.

Treatment

There is no specific treatment for this viral disease. Therapy should be directed at managing the effects of diarrhea and should include fluid and electrolyte therapy and adequate nutrition. Affected animals become leukopenic, so broad-spectrum antibiotics are indicated to reduce the risk of secondary bacterial infections.

Control

Use of acaricides may reduce the risk of exposure for sheep and goats moving into enzootic areas, particularly following rainy seasons when tick numbers and activity increase. Vaccination of susceptible sheep and goats prior to moving them into enzootic areas has been recommended but no vaccines are commercially available. Both an attenuated live vaccine and a killed vaccine have been developed, but there has been little demand for their use from the field (OIE 2004b).

BACTERIAL DISEASES

Enterotoxemia

Enterotoxemia, caused by *Clostridium perfringens*, is recognized worldwide as a common, frequently fatal disease of goats. The disease also occurs in sheep and cattle, but species differences occur in the epidemiology, pathogenesis, clinical presentation, and management of enterotoxemia. Distinctive characteristics of enterotoxemia in goats include the clinical prominence of diarrhea, the presence of severe enterocolitis at necropsy, and the frequent failure of vaccination to protect from clinical disease.

Etiology

Clostridium perfringens causes enteric disease in a wide range of species including domesticated mammals, poultry, and humans. There are five main types of *C. perfringens* based on the lethal exotoxins that they produce, as presented in Table 10.5. This discussion focuses on the disease in goats. Broader discussions of *C. perfringens* and the enteric diseases it produces in other species are available elsewhere (Songer 1996, Radostits et al. 2007).

The principal cause of caprine enterotoxemia worldwide is *C. perfringens* type D. This Gram-positive, non-motile, spore-forming, toxin-producing, anaerobic, rod-shaped bacterium is resident in the ruminant digestive tract, generally in low numbers. It is passed in feces and may persist in soil, though it dies out more quickly in soil than other *Clostridium* spp. The organism has a quick generation time, as short as eight minutes, allowing for rapid proliferation in the intestine under favorable conditions. It is the rapid proliferation of this resident organism and the associated release of toxins that causes disease in the host.

Table 10.5. *Clostridium perfringens* types and the toxins produced.

C. perfringens type	*Toxins produced (Gene expressing the toxin)*						*Occurrence in goats*
	Alpha *(cpa)*	*Beta* *(cpb)*	*Beta-2* *(cpb-2)*	*Epsilon* *(etx)*	*Iota* *(iA)*	*Enterotoxin*** *(cpe)*	
A	+		+*			±	Infrequently reported
B	+	+		+		±	Rarely reported
C	+	+	+**			?	Infrequently reported
D	+			+		±	Most common cause
E	+				+	±	Not reported

*There is one reported case of caprine enterotoxemia involving a *C. perfringens* expressing alpha toxin and beta-2 toxin (Dray 2004). Similar findings were reported from cases of enterocolitis in horses (Herholz et al. 1999).

**The original identification of beta 2 toxin involved a *C. perfringens* type C associated with necrotic enterocolitis in a pig. The organism expressed alpha, beta, and beta-2 toxins.

***Expression of enterotoxin is not consistent within types. It is most often associated with type A isolates but may be associated with other *C. perfringens* types as well.

C. perfringens type D produces two main toxins: alpha and epsilon. While both toxins are important for typing the organism, epsilon toxin is considered to be the principal virulence factor as discussed later under pathogenesis.

C. perfringens type C has also been cited as a cause of caprine enterotoxemia in the United States and Britain, though definitive confirmation of its role is scarce (Barron 1942; Guss 1977). There is also a report of type C enterotoxemia in goats and sheep in Greece (Tarlatzis et al. 1963). The major toxins of type C are alpha and beta. Because beta toxin is degraded by trypsin, type C enterotoxemia is most common in very young animals with low concentrations of intestinal trypsin, usually under ten days of age.

Enterotoxemia due to *C. perfringens* type B, which causes lamb dysentery, is also uncommon in goats. Type B contains alpha, beta, and epsilon toxins. In Iran, anomalous *C. perfringens* type B strains (lacking hyaluronidase) were isolated from goats in two different but nearby outbreaks of clinical enterotoxemia (Brooks and Entessar 1957). In Germany, type B enterotoxemia was confirmed in a dairy goat herd and a herd of dwarf goats. Mortality of kids up to twelve days of age was reported following bouts of watery, yellow, blood-stained diarrhea (Scharfe and Elze 1995).

In Greece, *C. perfringens* type A was cited as the most common cause of enterotoxemia in sheep and goats (Deligaris 1978). However, ascribing pathogenicity in goats to type A remains controversial because it is considered to be the *C. perfringens* type most widespread in the intestines of warm-blooded animals and the environment and can rapidly overgrow in organs following death (Songer 1996). Another early report of type A enterotoxemia involved captive Siberian ibex (*Capra sibirica*) at a zoo (Russell 1970). Experimental challenge of domestic goats by intraduodenal administration of type A in broth culture produced only a transient diarrhea at twelve hours post inoculation which resolved twelve hours later with no other clinical signs or deaths. In contrast, a second group of goats given type D in the same manner all developed diarrhea and convulsions and died within thirty-six hours (Phukan et al. 1997.)

More recently, a fatal case of enterotoxemia in a five-week-old Boer goat kid in Canada was reported as due to type A (Dray 2004). This was an unusual case in that the *C. perfringens* isolated from the gut at necropsy was found to have genes which expressed alpha toxin and beta-2 toxin, making it an atypical type A isolate. Pathogenicity of type A is usually associated with alpha toxin alone. Beta-2 toxin has been characterized only relatively recently, originally in association with a *C. perfringens* type C organism (Gilbert et al. 1997). *C. perfringens* organisms that produce beta-2 toxin have now been associated with necrotic enterocolitis in piglets (Waters et al. 2003) and horses (Herholz et al. 1999) as well as this single reported case of caprine enterotoxemia (Dray 2004).

C. perfringens can also produce an enterotoxin (Songer 1996). Though most commonly associated with *C. perfringens* type A, it has been found in some isolates of types B and D as well. The gene for enterotoxin expression has been identified in type E isolates but the toxin is not produced (Billington et al. 1998). The role of enterotoxin in the pathogenesis of enterotoxemia in goats has not been studied and its importance, if any, remains unknown.

Epidemiology

Enterotoxemia is frequently cited by producers, veterinarians, and extension personnel around the world

as a common and important disease of goats. Paradoxically, there is little documentation of caprine enterotoxemia in the veterinary literature and comparatively little research that relates specifically to the disease in goats.

Descriptions of caprine enterotoxemia have come from Australia (Oxer 1956), Britain (Shanks 1949), Canada (Blackwell and Butler 1992), France (Delahaye 1975), South Africa (van Tonder 1975), Sri Lanka (Wanasinghe 1973), Switzerland (von Rotz et al. 1984) and the United States (Boughton and Hardy 1941; Guss 1977). Most outbreaks of caprine enterotoxemia involve dairy goats raised under intensive or semi-intensive management conditions. When fiber goats have been affected, as in South African or Texas Angoras, the disease is far more likely to occur during periods of corralling or restricted grazing in grain fields than during normal free-range grazing and browsing (van Tonder 1975; Ross 1981). The greatest losses caused by enterotoxemia in sheep occur in growing lambs on concentrate rations in feedlots, but this management situation is rarely encountered in goat practice.
